Em seguida, os dados de M_c são manipulados buscando montar vários vetores A_i. Cada um desses vetores irá conter os espectros de frequência de cada ciclo do sinal a ser reconstruído, sendo que as componentes reais e imaginárias são armazenadas separadamente, ou seja, uma componente espectral ocupa duas posições de A_i, como feito em FFT_{ARRAY}. Para tal manipulação, são utilizados os valores das posições l, os CNT e valores médios (SUM/CNT). Como mencionado anteriormente, estes valores correspondem a primeira, segunda e terceira linhas de M_c, respectivamente.

Para facilitar o entendimento do processo de reconstrução do sinal a partir da matriz M_c na prática, considere o exemplo didático de uma matriz M_c contendo apenas $J = 4$ colunas, conforme apresentado em (2). O índice das colunas de M_c será denotado por j, que varia de 1 até $J = 4$. Além disso, o comprimento dos vetores A_i é 3.

$$M_c = \begin{array}{r} \\ l \\ \text{CNT} \\ \text{SUM/CNT} \end{array} \begin{array}{c} \begin{array}{cccc} j=1 & j=2 & j=3 & j=4 \end{array} \\ \begin{bmatrix} 1 & 2 & 3 & 2 \\ 2 & 1 & 2 & 1 \\ 5 & 4 & 9 & 7 \end{bmatrix} \end{array} \tag{2}$$

De posse dos valores médios e CNT, a reconstrução é feita, inicialmente, analisando o valor da posição l, o valor médio e o CNT da primeira coluna ($j = 1$). Se o valor de CNT for maior que zero, copia-se o valor médio na posição l do vetor A_i. Após isso, um valor unitário é decrementado de CNT da mesma coluna da posição l em análise. Quando o vetor A_i estiver totalmente preenchido, o processo é reiniciado para a criação de um próximo A_i.

Por exemplo, se para a posição $l = 1$ de M_c, o valor médio foi 5 e CNT foi 2, copia-se então o valor médio para a posição $l = 1$ do primeiro vetor ($A_1[1] = 5$) e o valor de CNT é decrementado para 1. O mesmo procedimento é feito de forma subsequente para as próximas colunas $j = 2$ e $j = 3$ de M_c, correspondentes às posições $l = 2$ e $l = 3$, uma vez que o valor de CNT é maior que zero nessas colunas, a fim de completarmos A_1. Após isso, como todas as posições de A_1 foram preenchidas, A_1 está concluído e inicia-se a criação do segundo vetor (A_2). O vetor A_1 completo e a atualização de M_c, podem ser vistos em (3) e (4), respectivamente.

$$A_1 = \begin{array}{c} \begin{array}{ccc} l=1 & l=2 & l=3 \end{array} \\ \begin{bmatrix} 5 & 4 & 9 \end{bmatrix} \end{array} \tag{3}$$

$$M_c = \begin{array}{r} \\ l \\ \text{CNT} \\ \text{SUM/CNT} \end{array} \begin{array}{c} \begin{array}{cccc} j=1 & j=2 & j=3 & j=4 \end{array} \\ \begin{bmatrix} 1 & 2 & 3 & 2 \\ 1 & 0 & 1 & 1 \\ 5 & 4 & 9 & 7 \end{bmatrix} \end{array} \tag{4}$$

Realiza-se o mesmo procedimento para a construção do vetor A_2. Porém, neste caso, nota-se que o CNT referente à coluna

$j = 2$ da versão atualizada da matriz M_c é zero. Isso significa que todas as cópias relacionadas ao valor médio daquela coluna já foram feitas. Sendo assim, o algoritmo busca outra coluna que contém a posição $l = 2$ com CNT diferente de zero para utilizar na criação de A_2. Nesse caso, a coluna $j = 4$ de M_c atende a essa condição e o seu valor médio 7 será usado para preencher a posição $l = 2$ de ($A_2[2] = 7$). Os resultados da criação do segundo vetor e a nova atualização de M_c podem ser vistos em (5) e (6), respectivamente.

$$A_2 = \begin{bmatrix} \overset{l=1}{5} & \overset{l=2}{7} & \overset{l=3}{9} \end{bmatrix} \tag{5}$$

$$M_c = \begin{array}{r} \\ l \\ \text{CNT} \\ \text{SUM/CNT} \end{array} \begin{array}{c} \begin{array}{cccc} \overset{j=1}{} & \overset{j=2}{} & \overset{j=3}{} & \overset{j=4}{} \end{array} \\ \begin{bmatrix} 1 & 2 & 3 & 2 \\ 0 & 0 & 0 & 0 \\ 5 & 4 & 9 & 7 \end{bmatrix} \end{array} \tag{6}$$

Como nesse exemplo não há mais colunas em M_c para serem processadas, verifica-se se todos os valores de CNT são nulos (segunda linha de M_c composta apenas de zeros), significando que não há mais vetores A_i a serem criados.

Os últimos estágios do processo de reconstrução consistem na realização da recomposição dos espectros de cada ciclo a partir da propriedade de simetria, aplicação da transformada de Fourier inversa em cada vetor recomposto e concatenação horizontal para obter o sinal reconstruído no domínio do tempo.

C. Custo computacional e requisitos de memória do método

O custo computacional foi avaliado analiticamente pelo número de operações aritméticas reais por ciclo cardíaco, sendo M o número de amostras brutas do ciclo e $N = 128$ o número de amostras após a reamostragem. Todos os estágios apresentam custo linear, exceto a FFT, de custo $O(N \log_2 N)$, resultando em complexidade total $O(M + N \log_2 N)$ por ciclo. A Tabela I detalha a contagem por estágio. Cabe destacar que os 65 valores de $\gamma[m]$ são calculados uma única vez a partir de T e β e armazenados em uma tabela, de modo que o limiar adaptativo não acrescenta custo em tempo de execução. A memória de trabalho totaliza cerca de 22 kB e é constante, independente da duração do registro, pois apenas o arquivo comprimido de saída cresce ao longo da aquisição, o que viabiliza o processamento contínuo de exames de longa duração em dispositivos com memória limitada.

TABELA I
CONTAGEM DE OPERAÇÕES REAIS POR CICLO CARDÍACO (FREQUÊNCIA CARDÍACA DE 75 BPM, $M = 288$, $N = 128$, $L = 130$).

D. Avaliação da qualidade de compressão dos sinais

Para demonstrar o desempenho do método proposto, foram utilizados sinais de ECG do banco de dados de arritmia MIT-BIH, devido à sua ampla utilização em trabalhos na literatura [15, 16] e a presença de diversas arritmias, desde as mais comuns até as mais raras. Além disso, os sinais do banco são contaminados por interferências e outros distúrbios que proporcionam o caráter realístico de aquisição dos ECGs. Foram utilizados 27 registros ambulatoriais, com duração de 30 minutos cada, amostrados a 360 Hz e com resolução de 11 bits [26].

Os registros selecionados contêm as seguintes arritmias: fibrilação atrial (FA), extrassístole ventricular (EV), extrassístole supraventricular (ESV), taquicardia ventricular (TV), taquicardia supraventricular (TSV), síndrome de Wolff-Parkinson-White (WPW) e flutter atrial (FLA), definidas segundo a diretriz da Sociedade Brasileira de Cardiologia [27].

Além disso, eles também apresentam, em sua maioria, um elevado número de eventos com variações rítmicas e morfológicas, artefatos de movimento e presença de ruído intenso em partes dos traçados.

Para avaliar o desempenho de compressão do sistema proposto, foi usada a taxa de compressão (CR) como métrica. Ela é caracterizada pela razão entre o tamanho do sinal original descomprimido e o mesmo sinal, porém na sua forma comprimida. Tal métrica foi calculada individualmente para cada um dos registros utilizados. Além dessas, a média das taxas de compressão de todos os registros utilizados (CR_μ) e o seu respectivo desvio padrão (CR_σ) também foram calculados. Tais métricas podem ser averiguadas em (7) e (8), respectivamente.

$$CR_\mu = \frac{1}{N} \sum_{i=1}^{N} CR_i \tag{7}$$

$$CR_\sigma = \sqrt{\frac{1}{N-1} \sum_{i=1}^{N} \left(CR_i - CR_\mu\right)^2} \tag{8}$$

As métricas de qualidade de reconstrução usadas neste trabalho são: a diferença percentual da raiz quadrada média (*percentage root-mean-square difference* (PRD)), a média dos valores de PRD (PRD_μ) e o seu desvio padrão (PRD_σ), definidas por (9), (10) e (11), respectivamente.

$$PRD = \sqrt{\frac{\sum_{n=1}^{N_a} [x[n] - x'[n]]^2}{\sum_{n=1}^{N_a} [x[n]]^2}} \times 100\% \tag{9}$$

$$PRD_\mu = \frac{1}{N_r} \sum_{i=1}^{N_r} PRD_i \tag{10}$$

$$PRD_\sigma = \sqrt{\frac{1}{N-1} \sum_{i=1}^{N} \left(PRD_i - PRD_\mu\right)^2} \tag{11}$$

Sendo CR_i e PRD_i as notações que correspondem aos valores de CR e PRD, respectivamente, para cada sinal, N_r, o número de registros avaliados, N_a, o número de amostras de um sinal, $x[n]$, a n-ésima amostra do sinal original e $x'[n]$, a amostra correspondente do sinal reconstruído.

E. Análise da qualidade de reconstrução dos sinais

Para aumentar a credibilidade do método proposto, foi feita, por um cardiologista com experiência na interpretação de eletrocardiogramas, a inspeção visual dos sinais reconstruídos após o processo de compressão. Os sinais da base de dados foram comprimidos, utilizando $T = 0,03$ e $\beta = 0,1$. Tanto os sinais originais quanto suas versões reconstruídas foram analisados pelo especialista. Os valores de T e β foram obtidos previamente no estudo reportado em [28].

A participação do cardiologista teve caráter complementar à avaliação quantitativa apresentada neste trabalho e não foi considerada, isoladamente, como uma validação clínica do algoritmo. Dessa forma, os resultados obtidos pelo especialista foram analisados em conjunto com as métricas objetivas de desempenho empregadas para avaliar a qualidade dos sinais reconstruídos.

Os critérios para diagnóstico eletrocardiográfico de aspectos morfológicos, intervalos e laudo conclusivo foram baseados na diretriz da Sociedade Brasileira de Cardiologia sobre análise e emissão de laudos eletrocardiográficos [27]. Nesta análise, foram avaliados os parâmetros de regularidade do intervalo RR, batimento a batimento, amplitude e duração do QRS, morfologia das ondas P e T, focando em identificar corretamente todas as arritmias, caso houvesse.

Vale ressaltar que o médico não sabia de nenhuma informação prévia sobre os eventos de anormalidades cardíacas contidos nos sinais. Os diversos parâmetros e registros obtidos da avaliação do cardiologista foram utilizados para identificar os eventos em que o médico relatou a ausência de arritmias no sinal reconstruído, mas que havia no original (Falsos negativos (Fn)), os eventos em que o médico indicou a presença de arritmias no sinal reconstruído, mas que não havia no original (Falsos positivos (Fp)), os eventos em que o cardiologista registrou corretamente a ausência de arritmias em ambos os sinais (Verdadeiros negativos (Vn)) e os eventos em que o cardiologista indicou corretamente a presença de arritmias em ambos os sinais (Verdadeiros positivos (Vp)). Utilizando esses registros, foram feitos os cálculos e análises da sensibilidade (SE) e especificidade (EP) de cada arritmia cardíaca encontrada nos bancos de dados, baseado nas equações (12) e (13).

$$SE = \frac{Vp}{Vp + Fn} \tag{12}$$

$$EP = \frac{Vn}{Vn + Fp} \tag{13}$$

É importante observar que a sensibilidade, neste caso, ilustra a probabilidade do médico identificar no sinal reconstruído a arritmia alvo corretamente. Já a especificidade apresenta a probabilidade do médico identificar, em concordância com o laudo do sinal original, as regiões do sinal reconstruído onde não há a arritmia alvo.

III. Resultados e Discussões

Baseado nas informações da Tabela II e da Tabela III, considerando que existem interferências e artefatos nos sinais originais que podem prejudicar a detecção, pode-se dizer que o método de compressão proposto apresentou boas taxas de compressão e resultados de qualidade de reconstrução satisfatórios. Em relação aos valores de CR, de acordo com a Tabela II, o método alcançou altas taxas de compressão para a maioria dos sinais.

TABELA II
Valores de CR e PRD para cada sinal avaliado. Os valores máximos de cada métrica estão destacados em negrito.

Sinais	CR	PRD (%)
1	115	16,28
2	360	14,54
3	69	17,15
4	**525**	13,13

27	424	11,10
Média $\mu \rightarrow$	CR_μ = 154,2	PRD_μ = 15,13
Desvio $\sigma \rightarrow$	CR_σ = 120,8	PRD_σ = 3,38

TABELA III
Sensibilidade e especificidade obtida por cada classe de arritmia.

Arritmias	**Sensibilidade (%)**	**Especificidade (%)**
EV	93,54	99,96
ESV	84,54	99,94
TV	100,00	99,81
TSV	81,82	99,70
WPW	100,00	99,91
FA	100,00	97,86
FLA	66,67	100,00
Arritmias Gerais	91,71	99,97

Percebe-se também que o método apresenta, para alguns sinais, valores elevados de PRD. A razão disso é que o sistema de compressão armazena somente as informações relevantes do sinal, logo, involuntariamente, ele filtra boa parte de suas componentes espectrais de alta frequência, resultando em um sinal reconstruído menos ruidoso que o original. Um exemplo desse acontecimento pode ser observado na Figura 3.

Nota-se também que, com exceção da arritmia flutter atrial, o valor do parâmetro sensibilidade foi superior a 80%, atingindo 100% em alguns casos. Esse resultado demonstra que, na maioriados casos, o algoritmo preserva as informações relevantes (manifestações rítmicas e morfológicas das arritmias) dos sinais de ECG originais, nos seus respectivos registros reconstruídos e evidencia que a métrica PRD não foi eficaz, neste caso, para avaliar a qualidade da compressão, devido à

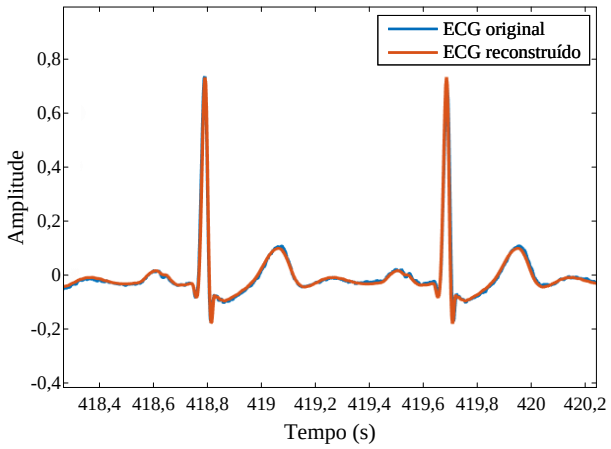

Fig. 3. Um exemplo de um sinal ECG original e reconstruído.

filtragem involuntária realizada pelo sistema, como mencionado anteriormente.

Já o valor da especificidade, por sua vez, foi superior a 97% para todas as arritmias avaliadas, evidenciando que o sistema não introduz alterações significativas nas regiões de normalidade dos sinais originais. Esse comportamento indica que os trechos sem arritmia foram preservados de forma a não gerar discordância relevante entre os laudos emitidos sobre o traçado original e sobre o reconstruído.

Para o caso da FLA, sabe-se que ela possui aspecto serrilhado em seu traçado, sendo usualmente conhecido como "Dente de serrote". No entanto, algumas derivações eletrocardiográficas podem não evidenciar essa morfologia típica. Portanto, existe a possibilidade de alguns sinais enviados para a análise do especialista serem as derivações que não apresentam tal característica dessa arritmia. Esse fato justifica o valor de SE ser um pouco menor e evidencia que o problema, neste caso, não está relacionado com o método de compressão e sim com a derivação em análise.

Considerando-se o grupo genérico de arritmias (Arritmias Gerais) estruturado neste artigo, é possível comparar o presente trabalho com os que são apresentados na literatura em [15] e [16]. A Tabela IV apresenta os resultados de todos os projetos para os seguintes parâmetros: valores de CR e PRD médios (CR_μ, PRD_μ) e máximos (CR_{MAX}, PRD_{MAX}), bem como os de SE e EP. Em relação ao trabalho de [16], as métricas SE e EP não estão presentes na avaliação e os valores de CR_{MAX} e CR_μ obtidos foram inferiores aos do trabalho proposto, com destaque no CR_{MAX} registrado, pelo menos 4 vezes menor que o do presente projeto.

Já em relação ao trabalho de [15], o valor de SE do método proposto foi discretamente inferior, com uma diferença de aproximadamente 4%, enquanto os valores de EP foram similares. Contudo, se também levarmos em consideração os valores de CR_{MAX} e CR_μ obtidos, o método proposto se sobressaiu em ambos, uma vez que o CR_{MAX} registrado neste projeto é mais de 6 vezes maior que o de [15] e o médio é aproximadamente 5 vezes maior. Já em relação aos valores de PRD máximo (PRD_{MAX}) e médio (PRD_μ), é possível notar que o PRD_{MAX} do método proposto é o maior de todos e o PRD_μ é o segundo maior. Isso novamente pode ser justificado pela filtragem involuntária que o método de compressão proposto aplica no sinal ao comprimi-lo. O trabalho de [16] apresenta o menor erro, mas, como não aborda métricas de análise qualitativas, não é possível garantir que os dados reconstruídos preservam as características de interesse. Assim, o ganho expressivo na eficiência de compactação justifica a sutil redução na sensibilidade, dado que o sistema proposto alcança CR_{MAX} e CR_μ maiores que os outros trabalhos abordados.

TABELA IV
COMPARAÇÃO DE DESEMPENHO.

Abordagem	CR_μ	CR_{MAX}	PRD_μ	PRD_{MAX}	SE	EP
Método Proposto	154,2	525	15,13%	26,28%	91,71%	99,97%
Ref. [15]	31,68	76,4	11,15%	31,08%	95,77%	99,18%
Ref. [16]	117,33	117,5	7,76%	22,86%	-	-

Baseando-se nos valores dos parâmetros de sensibilidade e especificidade, pode-se dizer que os resultados das análises dos sinais reconstruídos foram, na maioria das vezes, iguais/semelhantes aos dos sinais originais. Sendo assim, é possível questionar se o uso da métrica PRD na análise de qualidade de reconstrução de ECGs, reflete ou mascara a real situação.

Para verificar o funcionamento do método, uma implementação de referência desenvolvida em MATLAB foi executada em um computador com processador AMD Ryzen 7 7735HS de 3,20 GHz e 16 GB de memória DDR5-4800. O processamento de um registro de 30 minutos demandou aproximadamente 5 s, o que corresponde a 360 vezes o tempo real de aquisição, com consumo de 300 MB de memória de processo. Ambos os valores refletem o ambiente de prototipagem adotado, que carrega o registro integralmente em memória e não foi otimizado, e não a demanda intrínseca do algoritmo, de cerca de 22 kB. Para uma frequência cardíaca de 75 bpm, as $2{,}5 \times 10^4$ operações reais por segundo de sinal estimadas na Seção II-C representam margem superior a três ordens de grandeza sobre microcontroladores de baixo consumo da classe ARM Cortex-M4, corroborando a viabilidade de implementação embarcada.

IV. Conclusão

Este trabalho apresentou um método adaptativo baseado na variação do conteúdo espectral via FFT, associado a limiares de tolerância exponenciais e à codificação LZW, voltado para a compressão eficiente de sinais de ECG de longa duração. A metodologia proposta visa mitigar as restrições de armazenamento e transmissão sem fio em sistemas de monitoramento contínuo de sinais de ECG, como o Holter.

A validação experimental utilizando a base de dados MIT-BIH, complementada por uma avaliação clínica cega conduzida por um cardiologista, indicou o potencial do algoritmo. O método alcançou uma taxa de compressão média ($CR_\mu = 154{,}2$) elevada, preservando os atributos morfológicos e temporais dos traçados nos registros avaliados. Esse desempenho refletiu-se nos elevados índices de sensibilidade (91,71%) e especificidade (99,97%) gerais obtidos na avaliação médica. Embora limitações tenham sido observadas na reconstrução da patologia de flutter

atrial (sensibilidade de 66,67%), não se observou discordância entre os laudos (100% de sensibilidade) para arritmias críticas de caráter intermitente, como a taquicardia ventricular e a Síndrome de Wolff-Parkinson-White (WPW).

Ademais, o estudo levanta uma discussão relevante acerca da métrica PRD, sugerindo que valores elevados de erro quadrático nem sempre se traduzem em perda de qualidade clínica, visto que o processo atua como um filtro atenuador de ruídos de alta frequência.

Como trabalhos futuros, pretende-se investigar a adaptação dinâmica dos parâmetros de ganho (T) e decaimento (β) para otimizar a compressão de espectros complexos como o do flutter atrial, bem como avaliar a viabilidade de implementação do algoritmo em sistemas embarcados de ultra-baixo consumo e processamento em tempo real para dispositivos de monitoramento de próxima geração. Além disso, uma avaliação futura dos sinais envolvendo múltiplos especialistas e protocolos de avaliação clínica padronizados é considerada uma importante extensão deste trabalho.

Agradecimentos

Os autores deste trabalho gostariam de agradecer à Universidade Federal de Juiz de Fora (UFJF), à Universidade Estadual de Campinas (UNICAMP) e à Universidade Federal do Piauí (UFPI) pelo apoio institucional a este estudo. O presente trabalho foi realizado com apoio da Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brasil (CAPES) - Código de Financiamento 001.

***Abstract*—Multimodal deep learning has been increasingly applied to cognitive decline detection, yet fusion strategies across different acquisition settings remain incompletely characterized. This scoping review maps deep learning-based multimodal fusion approaches for the detection and classification of mild cognitive impairment and dementia in studies published between 2021 and 2026. Evidence was identified through bibliographic database searches, retrospective citation searching, and generative artificial intelligence-assisted searches. Post hoc supplementary searches in PubMed and Web of Science were subsequently conducted to assess coverage and selection sensitivity. After screening and categorization, 310 records were organized by primary data source, from which 20 studies were purposively selected for in-depth qualitative synthesis using a reporting-completeness criterion and stratified acquisition-category quotas. The broader bibliographic corpus was strongly dominated by neuroimaging, whereas continuous sensing and eye tracking remained sparsely represented. Among the four of eight neuroimaging studies reporting unimodal baselines, multimodal fusion improved performance in all cases, whereas the two sensor studies allowing direct fusion-gain assessment reported negligible or negative differences. Speech studies were concentrated on related benchmark corpora despite employing diverse fusion mechanisms. Overall, fusion benefits varied across acquisition settings, suggesting that source complementarity may contribute to performance, although the available evidence does not allow its effect to be isolated from other methodological factors.**

***Index Terms*—Alzheimer's disease, cognitive decline, deep learning, multimodal fusion, scoping review**

I. Introduction

Early detection of *Alzheimer's Disease* (AD) and cognitive decline has become an important research direction in artificial intelligence applied to healthcare. Since no single data source captures the full complexity of cognitive decline [1], multimodal deep learning approaches have been increasingly explored to combine complementary information from speech, neuroimaging, and real-world sensors, particularly through attention mechanisms and *Transformer*-based architectures [1], [2].

Despite this progress, the landscape of multimodal fusion for cognitive decline remains incompletely characterized. Existing reviews either provide a broad overview of fusion mechanisms without a clinical focus [2] or are dominated by neuroimaging studies [1], leaving the contribution of speech, continuous sensing, and other acquisition categories unclear. Furthermore, the use of generative AI-assisted search tools for literature identification has not been sufficiently evaluated regarding coverage and reproducibility.

This study maps deep learning-based multimodal fusion approaches for the detection and classification of cognitive decline in studies involving control participants and individuals with *Mild Cognitive Impairment* (MCI) or dementia. Its contributions are threefold: (i) a **quantitative mapping** of modality distributions across recent literature; (ii) a **qualitative synthesis** of fusion strategies, architectures, and methodological limitations; and (iii) an **empirical comparison** between the three original identification routes regarding yield, overlap, and reproducibility, complemented by post hoc analyses of bibliographic database coverage and sensitivity to category-based prioritization.

The findings are interpreted in relation to the meta-analysis by Guo et al. [1], which reported a pooled AUC of 0.924 (95% CI: 0.912–0.936) for *Transformer*-based multimodal models. Whether these conclusions extend beyond the neuroimaging-dominated literature, particularly to speech and continuous sensing, remains an open question addressed by this review.

II. Methodology

This review followed the **PRISMA-ScR** (*Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews*) guidelines [3]. No protocol was registered for this review. The research question, "What is the current state of the art of deep learning-based multimodal fusion approaches for the detection and classification of cognitive decline?", was formulated using the **PCC** (*Population, Concept, Context*) framework recommended by the *Joanna Briggs Institute* for scoping reviews. The PCC elements were defined as follows: *Population*, adults with MCI, dementia, or Alzheimer's disease, together with cognitively healthy

controls; *Concept*, deep learning based fusion of two or more data modalities for detection, prediction, diagnosis, or classification; and *Context*, any acquisition setting, including clinical, laboratory, and real world environments, in studies published between 2021 and 2026.

A. Information sources and search strategy

Three complementary approaches were used to identify relevant studies, considering publications from **2021 to 2026**.

- **Approach 1: Bibliographic databases.** Searches were performed in the Scopus and IEEE Xplore databases. In Scopus, the query was executed using the `TITLE ABS KEY` field. In IEEE Xplore, the *Command Search* interface was used to search the *Document Title* and *Abstract* fields. In both databases, Boolean queries were developed based on the PCC framework.
- **Approach 2: Retrospective citation searching.** Reference lists of key studies related to the review scope were manually examined using backward citation searching.
- **Approach 3: Generative AI assisted search.** The Elicit and Consensus platforms were queried in natural language using *prompts* derived from the same research question.

The complete Boolean search strings used in Scopus and IEEE Xplore and the natural-language prompts used in Elicit and Consensus are available in the supplementary repository [4].

B. Eligibility criteria

The eligibility criteria were defined before screening. Eligible studies were peer-reviewed primary research articles published in English between 2021 and 2026, with full text available, that employed deep learning to fuse two or more data modalities for the detection, prediction, diagnosis, or classification of cognitive decline, MCI, Alzheimer's disease, or dementia. Reviews, surveys, meta-analyses, editorials, letters, book chapters, conference abstracts without a full paper, posters, extended abstracts, animal-only studies, studies outside the cognitive-decline domain, and studies without multimodal fusion or deep learning were excluded.

C. Operational definition of fusion

The identified modalities were grouped into families according to the nature of the signal: neuroimaging, speech and language, clinical and neuropsychological, omics, neurophysiology, sensors, and behavioral. Based on this taxonomy, two configurations were defined, both of which were considered eligible.

- **Heterogeneous fusion:** the combination of modalities from *two or more* different families, for example neuroimaging and clinical variables, or electroencephalography and magnetic resonance imaging.
- **Homogeneous fusion:** the combination of two or more modalities belonging to the *same* family, for example *sMRI* and *FDG PET*, both from the neuroimaging family, or acoustic signal and transcript, both from the speech and language family.

D. Paper Selection Process

Duplicate records were removed, and title and abstract screening was performed manually according to the predefined eligibility criteria.

Records passing the initial screening were classified according to their primary data source into three acquisition categories: neuroimaging, speech and language, and sensors, with the latter subdivided into physiological sensors, face and gaze, and environment and daily living. Primary data sources were assigned by weighted term occurrence, with matches in the title weighted 3 and matches in the abstract or keywords weighted 1.

Within each category, studies were ranked using an author-defined reporting completeness score calculated from the information available in the title and abstract. The reporting completeness score was calculated according to Equation 1.

$$S = 2M + \min(V, 6) + 3\min(X, 3) + 2L + \min(F, 5) \quad (1)$$

where M represents explicitly named performance metrics, V the number of numerical performance values reported, X the number of interpretability approaches described, L the number of validation strategies reported, and F the number of distinct modalities identified. The score was used exclusively as a prioritization criterion for qualitative synthesis and was not interpreted as a measure of methodological quality or used to determine study eligibility.

Because the categorized corpus was strongly dominated by neuroimaging studies, a purposive stratified quota was applied to preserve coverage of the three acquisition categories in the qualitative synthesis. Twenty studies were therefore selected for in-depth qualitative synthesis: eight neuroimaging-primary, seven speech-primary, and five sensor-primary studies. The quotas were intended to ensure analytical coverage of underrepresented acquisition categories rather than to reproduce the proportional distribution of the retrieved literature. Within each category, studies with higher reporting completeness scores were prioritized for selection.

During full-text charting of the 20 studies selected for qualitative synthesis, methodological characteristics relevant to the review objectives were extracted, including modalities and fusion configuration, validation strategy, participant-level data splitting when reported, external validation, unimodal baselines, quantified fusion gain, performance and agreement metrics, and the use of cognitive scores as model inputs or components of the diagnostic reference standard. These characteristics were used descriptively in the qualitative synthesis and were not used to determine eligibility or derive a methodological quality score.

A formal methodological quality or risk-of-bias assessment was not performed. Consistent with the scope of this review, the objective was to map the available evidence and methodological characteristics rather than to estimate pooled effects or establish clinical recommendations. Critical appraisal is not routinely recommended for scoping reviews and may be

undertaken when required by the specific review purpose [3], [5].

E. Supplementary coverage and sensitivity analysis

After completion of the initial review, supplementary searches were conducted in PubMed and the Web of Science Core Collection to assess whether the use of Scopus and IEEE Xplore as the original bibliographic databases materially affected the coverage and modality distribution observed in the review. These searches were treated as a post hoc coverage and sensitivity analysis rather than as part of the original identification strategy. The same publication window (2021–2026) and conceptual scope of multimodal deep learning for cognitive decline detection and classification were retained.

Records retrieved from the supplementary databases were deduplicated against the original bibliographic corpus and across the two supplementary sources. Records without abstracts and secondary publications were removed before further analysis. An automated rule-based screening procedure was then applied to prioritize records potentially consistent with the review scope. The procedure used predefined search strings and Boolean rules applied to titles and abstracts to identify records mentioning cognitive decline as the predominant clinical domain, at least two distinct modalities, multimodal fusion, deep learning, and a detection or classification objective. This automated step was used only for prioritization within the sensitivity analysis and was not interpreted as a formal eligibility assessment. The reporting completeness framework described above was subsequently reimplemented for the supplementary records using automated metadata detectors. The supplementary analysis was used to examine the robustness of the modality distribution and the effect of the category-based prioritization strategy; it did not retrospectively redefine the original set of 20 studies used for the qualitative synthesis.

The complete PubMed and Web of Science search strings, export details, and sensitivity-analysis worksheet are available in the same supplementary repository.

III. Results

A. Identification results

The bibliographic database search identified **525** records, with 255 retrieved from IEEE Xplore and 270 from Scopus. After removing 33 duplicates, **492** unique records remained for title and abstract screening. Retrospective citation searching identified an additional **14** records, while the generative AI assisted search identified **19** records (15 from Consensus and 4 from Elicit), resulting in a total of **558** identified records.

Records identified through Approach 3 were screened under the same eligibility criteria applied to the other routes. The retrieval strategy and the ranking criteria of these platforms, however, could not be fully replicated, which limits the reproducibility of this identification route.

The supplementary searches retrieved 1,060 records from the Web of Science Core Collection and 580 from PubMed. After restricting the results to the 2021–2026 publication window, removing records already present in the original corpus or duplicated across the supplementary databases, and excluding records without abstracts and secondary publications, 810 records remained available for analysis. A predefined rule-based metadata filter, implemented using search strings and Boolean conditions applied to titles and abstracts, prioritized 287 records as potentially consistent with the review scope. The reporting completeness framework was then applied to the supplementary records, and 98 records reached or exceeded the cutoff defined for their respective acquisition categories. These automated procedures were used only to prioritize records for the sensitivity analysis and did not constitute a formal eligibility decision. Consequently, the supplementary analysis did not redefine or modify the 20 studies selected for the original qualitative synthesis.

B. Distribution of modalities in the corpus

Table I summarizes the frequency of the modality families identified in the 492 consolidated records retrieved through Approach 1. The results reveal a marked imbalance across modalities. Magnetic resonance imaging was identified in 287 records, representing approximately 58% of the corpus, whereas continuous sensing in real world environments, including wearable devices, environmental sensors, and digital biomarkers, was identified in 42 records, representing just over 8%. Behavioral modalities were even less frequent, with face and video appearing in 20 records and eye tracking in only 6.

TABLE I
FREQUENCY OF MODALITY FAMILIES IN THE 492 CONSOLIDATED RECORDS RETRIEVED THROUGH APPROACH 1

Modality	n	**Modality**	n
MRI	287	Sensors / wearables	42
Clinical data	113	Text / language	22
PET	108	CSF biomarkers	20
Speech / audio	75	Face / video	20
Neuropsychological tests	64	Handwriting / drawing	16
EEG / MEG	46	Eye tracking	6
Genetics / omics	44		

A record may mention more than one family, so the counts do not sum to 492.

C. Supplementary coverage analysis

The supplementary Web of Science search reproduced the overall modality distribution observed in the original bibliographic corpus. The rank order of the 13 modality families reported in Table I showed a strong positive correlation with their frequencies in Web of Science (Spearman's $\rho = 0.902$, $p < 0.001$). Neuroimaging modalities remained predominant, whereas sensor-based, behavioral, and eye-tracking modalities remained comparatively less represented. This agreement does not establish exhaustive coverage of the literature, but indicates that the marked imbalance across modality families was robust to the inclusion of an additional bibliographic database.

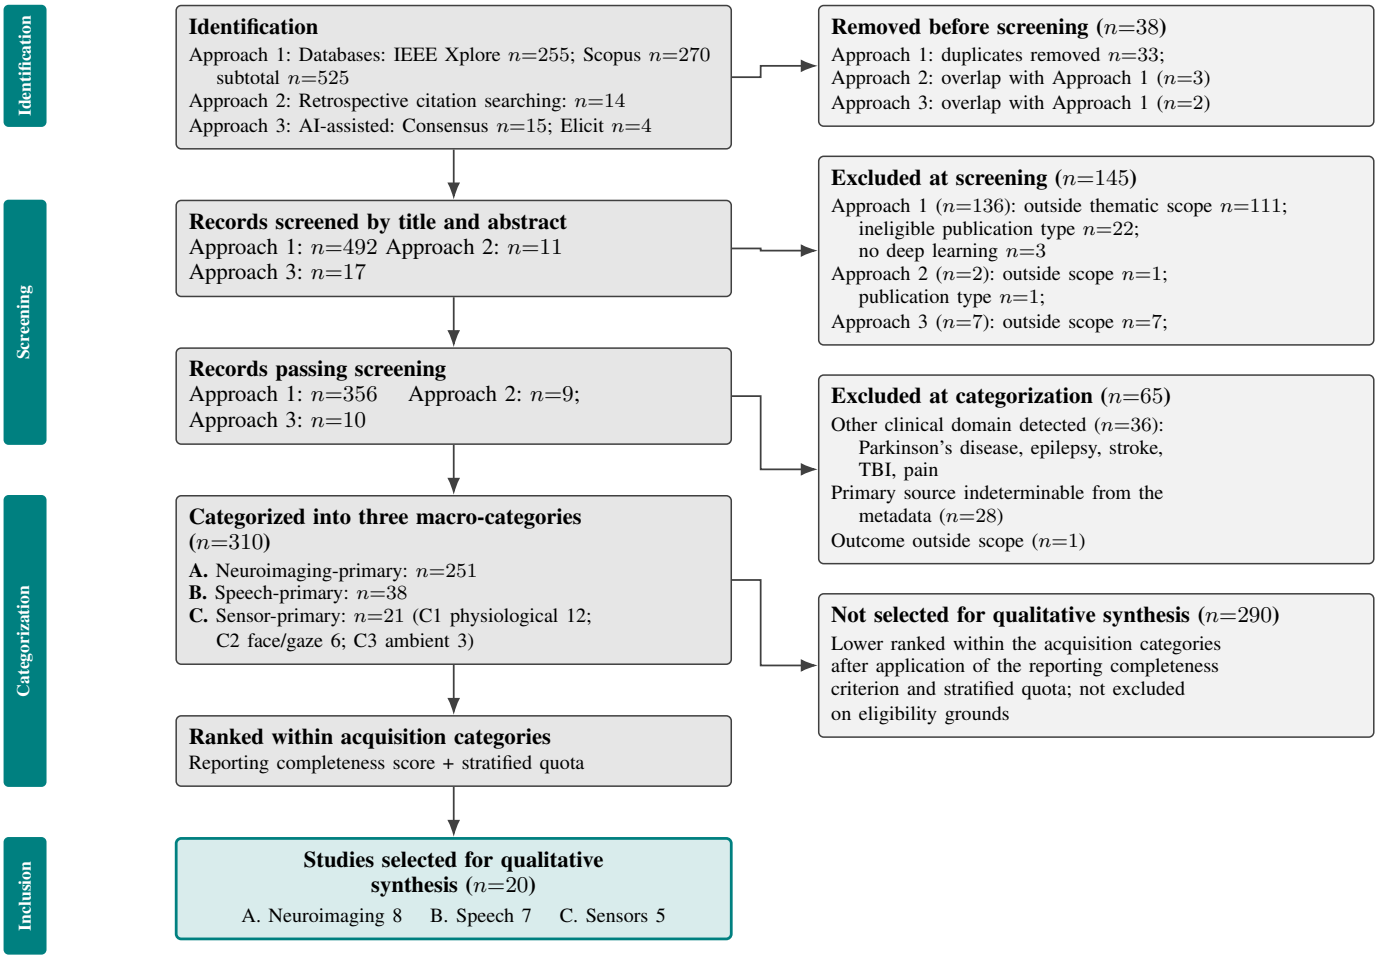

Fig. 1. PRISMA-ScR flow diagram with three original identification pathways. Approach 1 corresponds to the Boolean search of bibliographic databases; Approach 2, to retrospective citation searching; and Approach 3, to AI-assisted search tools. Post hoc PubMed and Web of Science searches were conducted separately for coverage and sensitivity analyses and are therefore not included in the original identification flow.

D. Sensitivity to category-based prioritization

To examine how study composition might differ without category-specific quotas, the supplementary records were ranked globally using the same reporting completeness score. Seventeen records scored above the global selection boundary: 14 neuroimaging-primary and 3 sensor-primary. Seven additional records were tied at the boundary score of 17: 5 neuroimaging-primary and 2 speech-primary. Thus, a 20-study selection based only on reporting completeness would include 15–17 neuroimaging, 0–2 speech, and 3 sensor studies, depending on tie resolution.

This result indicates that the stratified quota substantially changes the composition of the qualitative synthesis. Its purpose was therefore not to reproduce the prevalence of acquisition categories in the literature, but to preserve sufficient representation of speech and sensor studies for qualitative examination. Conclusions regarding the relative frequency of acquisition modalities were consequently based on the broader bibliographic corpus rather than on the quota-selected set of 20 studies.

E. Studies selected for the qualitative synthesis

Table II presents the 20 studies selected for the qualitative synthesis, organized according to their primary data source, together with the fusion configuration and the modalities effectively integrated, as determined through full text extraction.

IV. QUALITATIVE SYNTHESIS

Results across neuroimaging, speech and language, and sensor-based studies should not be interpreted as directly comparable because datasets, diagnostic tasks, sample sizes, performance metrics, and validation strategies differ substantially across studies. Accordingly, fusion benefit was interpreted primarily through within-study comparisons with unimodal baselines when available, rather than through absolute performance comparisons across acquisition categories.

A. Neuroimaging

Neuroimaging was the predominant acquisition category in the broader categorized corpus. The reviewed studies show a clear evolution of fusion strategies, ranging from integration at the image level to the fusion of learned representations and,

TABLE II
STUDIES SELECTED FOR THE QUALITATIVE SYNTHESIS ($n = 20$), ORGANIZED BY PRIMARY DATA SOURCE

#	Study	Year	Config.	Modalities
A. Neuroimaging-primary				
1	Odusami et al. [6]	2023	Homogeneous	MRI + PET (pixel-level)

20	Syed [23]	2026	Homogeneous	Ambient sensors (gait + sleep)

[a]Treated as a primary study on the grounds that the paper introduces the ADReSS-M dataset and reports an original fusion baseline, rather than synthesizing prior findings. Modalities determined through full text extraction and may differ from those suggested by the abstracts.

more recently, to the integration of information beyond the image itself.

From the pixel-level to the feature *level:* Odusami et al. [6] investigate pixel-level fusion of MRI and PET images using wavelet-based image integration followed by Vision Transformer classification. Evaluated on ADNI, the approach illustrates an early fusion strategy in which multimodal information is combined before feature learning, contrasting with the feature-level methods developed in subsequent studies.

Moving fusion to the *feature level*, Tang et al. [7] extract deep representations from *sMRI* and *PET* images using a 3D CNN and integrate them through an enhanced *Transformer* capable of learning global correlations across the different representations. The architecture performs *cross modal* fusion and incorporates visualization mechanisms to improve interpretability. Evaluated on the ADNI dataset using paired Fluorodeoxyglucose Positron Emission Tomography (FDG PET) and *sMRI* images from the same participant and ten fold cross validation, the model achieved an accuracy of 98.1%, outperforming the unimodal versions by 6.19 percentage points for sMRI and 10.96 percentage points for PET. The left parahippocampal region consistently emerged as one of the most relevant regions for classification.

Khan et al. [8] extend feature-level fusion to early multiclass diagnosis with the *Dual-3DM^{3}AD* model, combining Transformer-based semantic segmentation, multiscale feature extraction, dense feature aggregation, and attention mechanisms over MRI and PET data. The study illustrates the use of increasingly structured representation learning for multimodal multiclass diagnosis, a setting that is inherently more challenging than binary classification.

Leng et al. [9] propose a cross-enhanced feature-level fusion strategy for sMRI and FDG PET, explicitly modeling correlations and complementarity between the two modalities through attention-based interactions. Applied to the joint diagnosis of Alzheimer's disease and subjective memory complaints on ADNI, the study illustrates the transition from simple feature combination toward explicit cross-modal interaction.

A different practical challenge is the presence of incomplete data. Gravina et al. [10] propose a *Multi Input Multi Output* (MI MO) architecture based on a 3D CNN that adapts the training process to the available modalities, allowing inference even when *MRI* or amyloid *PET* images are unavailable. Evaluated on the OASIS 3 dataset for dementia severity estimation, the method outperformed both unimodal models and other fusion approaches. Its main contribution is the ability to handle missing data, a common situation in clinical practice that has received limited attention in previous studies.

Beyond imaging: incorporating clinical variables: Chen et al. [11] extend multimodal fusion beyond imaging by integrating MRI with clinical records in the MMDF model. The architecture combines image and clinical representations through cross-modal feature learning and adaptive feature recalibration, achieving 97.35% accuracy on ADNI.

Vega-Guzman et al. [12] quantify the benefit of fusion using one of the few experimental designs in the corpus that explicitly reported participant-level data splitting. Combining structural magnetic resonance imaging with positron emission tomography produced an improvement of 9.7 percentage points over the best-performing unimodal approach, achieving an accuracy of 0.90 with a standard deviation of 0.03 under ten-fold cross-validation. The data split was explicitly performed at the participant level, a precaution that was rarely reported in the remaining studies and is essential to prevent data leakage when multiple slices or examinations belong to the same individual.

Abarnaswara et al. [13] integrate MRI, FDG PET, and clinical-cognitive variables, achieving 0.921 accuracy, a 6.7 percentage-point gain over the best unimodal model and a 3.4-point gain over image-only fusion. The study also reports Cohen's kappa of 0.902 and quadratic weighted kappa of 0.935. However, the data were curated from unnamed repositories, limiting reproducibility, and the model includes MMSE, MoCA, and CDR scores that also contribute to the diagnostic reference standard, raising a potential circularity concern; Vega-Guzman et al. [12] explicitly excluded such cognitive instruments from model inputs.

B. Speech and language

The speech category is strongly concentrated on the ADReSS corpus and its successors, ADReSSo and ADReSS-M, which share provenance in the Cookie Theft sessions of the Pitt Corpus distributed through DementiaBank; ADReSS-M additionally evaluates cross-lingual generalization using a Greek test set. Although participant sets differ across editions, this shared provenance provides greater internal comparability than in the other acquisition categories while potentially limiting generalizability because of the repeated use of closely related source corpora.

From attention based fusion to pretrained representations: Ilias and Askounis [14] combine speech spectrograms processed by a Vision Transformer with BERT-based transcript representations using attention and gating mechanisms. On ADReSS, their best configuration achieved 90.00% accuracy, an F1 score of 89.94%, and an RMSE of 3.61 for MMSE regression. The study illustrates early end-to-end multimodal fusion of acoustic and linguistic representations, while also highlighting the limitations imposed by small datasets.

Lin and Washington [15] compare textual and acoustic contributions on the Pitt Cookie Theft corpus using text- and audio-based representations under five-fold cross-validation. Textual models dominated performance, particularly after data augmentation, while adding Wav2vec-based audio features produced only marginal improvements. This finding shows that adding a modality does not necessarily provide substantial benefit when the added representation contributes limited complementary information.

Rohanian et al. [16] investigate adaptive gating for combining acoustic features with noisy ASR-derived linguistic information, including disfluencies and pauses. On ADReSSo, the model achieved 84% accuracy and an RMSE of 4.26 for MMSE regression. The results suggest that gating can regulate modality contributions under recognition noise, supporting adaptive rather than fixed fusion strategies.

Luz et al. [17] address cross-lingual generalization in ADReSS-M, evaluating whether models trained in English generalize to Greek. Their multimodal baseline combining acoustic and linguistic information achieved 73.91% accuracy and an RMSE of 4.995 for MMSE regression, with hard fusion outperforming the isolated feature sets. The study extends multimodal speech analysis beyond monolingual evaluation settings.

Gao et al. [18] combine interpretable linguistic features with pretrained audio embeddings for three-class classification of healthy controls, MCI, and dementia, as well as MMSE regression. In the PROCESS Grand Challenge, the approach achieved an F1 score of 0.649 and an RMSE of 2.628, obtaining the highest overall ranking in the competition.

Divergent fusion mechanisms over related corpora: Sahu et al. [19] use late fusion to combine acoustic, linguistic, disfluency, and cognitive information, whereas Kumari et al. [20] apply feature-level fusion of BERT-based text representations and acoustic features. These contrasting integration strategies over closely related speech corpora reinforce that performance differences cannot be attributed to the fusion mechanism alone.

C. Sensors, continuous monitoring, and digital biomarkers

Sensor studies ranged from clinically supervised EEG experiments [21], [22] to wearable and ambient sensing in everyday environments [23]–[25], making this the most heterogeneous acquisition category in the review. Reported sample sizes ranged from 56 to 125 participants, none of the studies included external validation, and only the free-living studies by Seo et al. [24] and Ouyang et al. [25] used prospectively collected data.

Home based acquisition under federated learning: Ouyang et al. [25] propose *ADMarker*, a federated multimodal sensing system for home-based monitoring of Alzheimer's disease that preserves privacy by keeping raw data local. In a four-week study with 91 older adults, the system identified digital biomarkers with up to 93.8% accuracy and detected early-stage Alzheimer's disease with an average accuracy of 88.9%, illustrating the feasibility of multimodal analysis in real-world environments.

Two additional studies illustrate the breadth of the category without introducing new fusion mechanisms. Wu et al. [21] combine electroencephalography with clinical variables into a continuous health score for mild cognitive impairment, whereas Syed [23] applies a *Transformer* to smart home sensors using gait and sleep patterns as behavioral markers.

Protocol realism and evaluation design: Sensor studies differed substantially in acquisition and evaluation design. Seo et al. [24] used 30 days of passive free-living data with a subject-independent split, whereas Anand and Kumar [22] used controlled acquisition with window-level analysis and did not report participant-based grouping. These differences limit direct comparison of performance estimates across studies.

Fusion gain and redundancy between sources: Only two sensor studies reported unimodal baselines allowing fusion gain to be quantified. Anand and Kumar [22] reported a 3.77 percentage-point decrease after combining EEG and MRI, using representations randomly paired across databases without subject-level correspondence. Seo et al. [24] reported an AUC of 0.700 for the best multimodal configuration versus 0.699 for the wrist gyroscope alone. Because the evaluated inertial streams measured the same physical phenomenon at different body locations, the negligible gain is consistent with the possibility of substantial source redundancy.

V. Discussion and Conclusion

This scoping review mapped multimodal deep learning approaches across neuroimaging, speech, and sensor-based settings. Neuroimaging strongly dominated the broader corpus, while the stratified quota intentionally increased the representation of speech and sensor studies in the qualitative synthesis. Accordingly, modality-frequency conclusions were based on the broader corpus, whereas category-specific observations reflect purposive qualitative sampling.

Fusion benefit varies across acquisition contexts

Neuroimaging studies show a progressive evolution from pixel-level fusion [6] to attention-based *cross-modal* fusion [7]–[9], incomplete-data strategies [10], and integration of non-imaging variables [11], [13]. Of the eight neuroimaging studies, only four reported a unimodal baseline. Fusion improved performance in all four. In the three studies reporting directly quantifiable gains over the best-performing unimodal baseline, improvements ranged from 6.2 to 9.7 percentage points [7], [12], [13], while Gravina et al. [10] reported a qualitative improvement over the unimodal models.

Among the sensor studies, only two provided unimodal baselines that allowed the contribution of fusion to be directly assessed. In these studies, fusion produced either a negative or negligible within-study gain: Anand and Kumar [22] reported lower performance after combining EEG and MRI representations, whereas Seo et al. [24] reported an AUC of 0.700 for the best multimodal configuration compared with 0.699 for the best unimodal configuration. Because the studies differ substantially in acquisition protocols, evaluation metrics, and validation procedures, their absolute performance values should not be compared directly. These results therefore provide limited evidence regarding the benefit of fusion in sensor-based settings rather than evidence of systematically lower performance for this acquisition category.

Speech studies point in a similar direction. Despite being the most homogeneous category regarding data provenance, they are highly heterogeneous regarding fusion mechanisms, preventing direct attribution of performance differences to the integration strategy. Moreover, adding audio to textual representations produced only marginal improvements [15].

Returning to the meta-analysis by Guo et al. [1], the pooled AUC of 0.924 (95% CI: 0.912–0.936) is broadly consistent with the strong performance reported in the neuroimaging literature mapped in this review. However, this estimate should be interpreted within the acquisition and evaluation context from which it was derived rather than as a general estimate of the benefit of multimodal fusion across all modality families. The modality distribution reported in Table I further illustrates the predominance of neuroimaging in the broader mapped corpus. Evidence from speech and sensor-based studies remains more heterogeneous in terms of datasets, outcome definitions, metrics, and validation strategies, preventing direct quantitative comparison with pooled neuroimaging estimates.

Source complementarity as a potential factor in fusion benefit

The reviewed studies suggest that the complementarity of the combined sources may influence the benefit obtained from multimodal fusion. For example, the sensor configurations examined by Seo et al. [24] combined signals related to the same underlying physical phenomenon and showed only a negligible gain over the best unimodal configuration, whereas several neuroimaging studies combined structural and metabolic information and reported improvements over unimodal baselines. However, source complementarity or physical independence was not directly manipulated or experimentally compared across the reviewed studies. Differences in datasets, fusion architectures, validation strategies, and acquisition protocols also prevent attribution of the observed fusion gains to this factor alone. Therefore, the pattern identified in this review should be interpreted as a hypothesis-generating observation rather than evidence that source independence is more important than the number of modalities.

Methodological limitations across categories

Three limitations recur throughout the literature. External validation is almost absent, as studies generally evaluate models within partitions of the same cohort. Agreement metrics such as Cohen's kappa are rarely reported, with only one study providing them [13]. Additionally, unimodal baselines are frequently missing, limiting the verification of claimed fusion benefits.

A further concern is the circularity introduced when cognitive screening scores are used as predictors while also contributing to the diagnostic reference standard. Studies addressing this issue reached opposite decisions [12], [13], but the implications remain insufficiently discussed. The field also lacks shared reporting standards, particularly for sensor studies, where metrics, units of analysis, and label definitions vary substantially.

Search strategy as a methodological finding

The identification routes differed in yield and reproducibility. Retrospective citation searching yielded 9 additional records passing screening from 14 tracked references, compared with 10 from 19 AI-assisted records. Although generative AI tools contributed eligible studies, their retrieval and ranking procedures could not be fully reproduced and should therefore be considered complementary to reproducible database searches. The post hoc PubMed and Web of Science analyses further supported the robustness of the observed modality-distribution pattern without establishing exhaustive literature coverage.

Limitations of this review

The categorization of records by primary data source relied on titles, abstracts, and keywords, which does not allow reliable determination of the modalities actually employed. The prioritization of studies for synthesis was based on reporting completeness rather than methodological quality, potentially penalizing studies with limited abstract descriptions. The stratified quota also intentionally altered the category composition of the 20-study qualitative synthesis; therefore, category-specific observations should not be interpreted as proportionally representative of the broader literature. Although the original identification strategy was based on Scopus and IEEE Xplore, supplementary searches in PubMed and Web of Science were subsequently conducted as a post hoc coverage and sensitivity analysis. These additional searches reduced concerns regarding database-specific coverage, but they do not establish exhaustive retrieval of all potentially relevant studies.

Directions for future work

Future priorities differ across categories. Speech studies require stronger unimodal baselines and standardized evaluation protocols before new fusion mechanisms can be meaningfully compared. Sensor research requires public benchmark datasets comparable to those available for neuroimaging, as the only prospective study using realistic protocols and heterogeneous instrumentation [25] is not publicly reproducible. Neuroimaging, in turn, requires external validation across independent cohorts and routine reporting of agreement metrics.

Across all categories, future studies should characterize the complementarity and redundancy of combined sources, report strong unimodal baselines and validation procedures, and clearly distinguish whether cognitive instruments are used as predictors, targets, or components of the diagnostic reference standard. Overall, adding modalities alone does not guarantee improved performance.

ACKNOWLEDGMENT

This article, developed as part of Dementia project, was made possible by Samsung Electronica da Amazonia LTDA, with support from SUFRAMA and implementation by the Federal University of Amazonas, a beneficiary of funds originating from the Federal Law No. (8,387/1991), with its dissemination and publicity in accordance with the provisions of Article 39 of Decree No. 10,521/2020.

***Abstract*—Neurological prognostication in comatose survivors of cardiac arrest remains a critical challenge in intensive care, where clinical uncertainty often hinders therapeutic decision-making. Although continuous electroencephalography (EEG) is the gold-standard monitoring modality, its visual interpretation is subjective, labor-intensive, and dependent on specialized expertise. This work presents a pilot, hypothesis-generating study of an automated prognostic support pipeline built upon the multicenter I-CARE database, integrating advanced signal processing with hybrid machine learning. The pipeline comprises (i) FIR filtering (0.5–45 Hz), (ii) 1-second temporal segmentation with 25% overlap to preserve slow-wave Delta activity, (iii) time–frequency representation via the Continuous Wavelet Transform (CWT) with a Complex Morlet mother wavelet, and (iv) a hybrid classifier combining ResNet50-based feature extraction with a Random Forest. To prevent data leakage, the dataset was split at the patient level (12 patients for training, 4 for testing). On the independent test set, the model achieved an accuracy of 95.27% (95% Wilson CI: 91.7–97.3%), a Cohen's Kappa of 0.9054, and an Area Under the ROC Curve (AUC) of 0.991. Per-class analysis revealed balanced sensitivity (94.8% for good outcome, 95.7% for poor outcome), with no evidence of class bias. Given that the test partition comprises only four patients, these estimates should be interpreted as a preliminary signal rather than a definitive performance ceiling; nevertheless, the results suggest that latent spectral texture patterns, rather than overt morphological graphoelements, may carry prognostic information, motivating validation on larger, independent multicenter cohorts before any claim of clinical readiness.**

***Index Terms*—Electroencephalography, cardiac arrest, continuous wavelet transform, neurological prognosis, hybrid machine learning.**

I. Introduction

Cardiac arrest (CA) is a high-severity medical emergency that frequently leads to Hypoxic-Ischemic Encephalopathy (HIE) in survivors. The extent of neuronal damage resulting from oxygen deprivation is the primary determinant of functional recovery or progression to permanent vegetative states, making early prognostic evaluation essential for guiding ethical and therapeutic decisions [1], [2]. Current clinical guidelines emphasize the integration of multimodal prognostic markers, including neurological examination, somatosensory evoked potentials, neuroimaging, and continuous electroencephalography (cEEG) [3], [4].

Among these modalities, cEEG is considered the most sensitive for monitoring cortical function in real time. Specific patterns such as background reactivity, burst-suppression, and status epilepticus carry high predictive value [5], [6]. However, continuous interpretation of these records in Intensive Care Units (ICUs) faces significant logistical barriers: visual analysis is intrinsically subjective, susceptible to inter-observer variability (with kappa values as low as 0.40–0.60 in some studies [7]), and impractical for the large data volumes generated 24 hours a day [8].

The need to overcome these limitations has driven the development of quantitative EEG (qEEG). Digital Signal Processing (DSP) techniques allow the decomposition of cerebral signal complexity into objective markers [9]. Traditional Fourier-based approaches (FFT), however, assume signal stationarity and fail to capture transient events that are critical in post-arrest encephalopathy [10]. Wavelet-based time–frequency analysis overcomes this limitation by providing multi-resolution decomposition, simultaneously capturing temporal and spectral dynamics [11], [12].

Recent advances in deep learning have further expanded the diagnostic potential of EEG. Convolutional Neural Networks (CNNs) can automatically extract high-level features from time–frequency representations, eliminating the need for manual feature engineering [13], [14]. However, the application of CNNs to small clinical datasets (typical in neurophysiol-

ogy) poses significant challenges, including overfitting and poor generalization [15]. Transfer learning from pre-trained architectures (e.g., ResNet, EfficientNet) offers a promising solution, leveraging representations learned from large-scale datasets (e.g., ImageNet) and adapting them to the specific domain of biomedical signals [16], [17].

Despite these advances, several gaps remain in the literature: (i) most studies rely on the Discrete Wavelet Transform (DWT), which introduces geometric artifacts that impair feature learning; (ii) the impact of temporal resolution (window size) on prognostic accuracy is underexplored; and (iii) the interpretation of deep learning models in clinical contexts remains opaque, hindering adoption.

This work presents a pilot, hypothesis-generating study of an automated prognostic classification pipeline that addresses these gaps by combining the Continuous Wavelet Transform (CWT) for dense spectral texture extraction with a hybrid machine learning architecture. Given the small cohort size (16 patients), the results are framed as preliminary evidence to be confirmed on larger, independent cohorts, rather than as a claim of clinical-grade performance. The main contributions are:

1) A hybrid pipeline coupling CWT-based scalograms, ResNet50 feature extraction, and Random Forest classification, designed for small-sample clinical datasets and reported with explicit uncertainty quantification;
2) Empirical, exploratory evidence that 1-second windows, rather than the conventional 500 ms, are associated with improved capture of slow Delta-band biomarkers, with a 7.3 percentage-point accuracy gain observed in this cohort;
3) Preliminary evidence that prognostic information may reside in latent spectral textures rather than in visually overt graphoelements, a hypothesis that warrants confirmation with interpretability analysis (e.g., Grad-CAM, SHAP);
4) A patient-level splitting protocol to prevent data leakage, a common methodological flaw in EEG-based prognostic studies, together with an explicit discussion of the residual statistical limitations that patient-level splitting imposes on small cohorts.

II. Background

A. EEG and Post-Cardiac Arrest Prognosis

Neurological prognostication after CA is determinant for clinical management. The EEG consolidates as an essential tool to identify functional patterns associated with recovery or irreversible ischemic injury, such as burst-suppression and status epilepticus [1], [5]. Nevertheless, traditional visual EEG interpretation faces severe limitations due to inter-observer subjectivity and the exhaustion inherent to manual processing of long recordings [7]. Quantitative methods based on DSP, particularly time–frequency wavelet analysis, have become indispensable for extracting latent objective markers, enabling automated decision-support systems that increase diagnostic precision and agility [9], [18].

B. From DWT to CWT

Biomedical signals such as EEG are non-stationary, with spectral content varying dynamically over time. The Continuous Wavelet Transform (CWT) decomposes a signal $x(t)$ by convolving it with a scaled and translated mother wavelet $\psi(t)$:

$$X_{CWT}(a,b) = \frac{1}{\sqrt{|a|}} \int_{-\infty}^{\infty} x(t)\, \psi^* \left(\frac{t-b}{a} \right) dt \qquad (1)$$

where a is the scale parameter (inversely proportional to frequency) and b is the translation parameter. The Complex Morlet wavelet, a sinusoid modulated by a Gaussian, is widely adopted in neurophysiology due to its morphological resemblance to cortical oscillations and its ability to extract both magnitude and phase [19].

During preliminary experiments, the Discrete Wavelet Transform (DWT) produced scalograms with geometric "pyramid" artifacts and artificially filled discontinuities, which impaired neural network feature learning. Migration to the CWT yielded dense, continuous power spectral representations, revealing microstructures essential for class discrimination (Fig. 1).

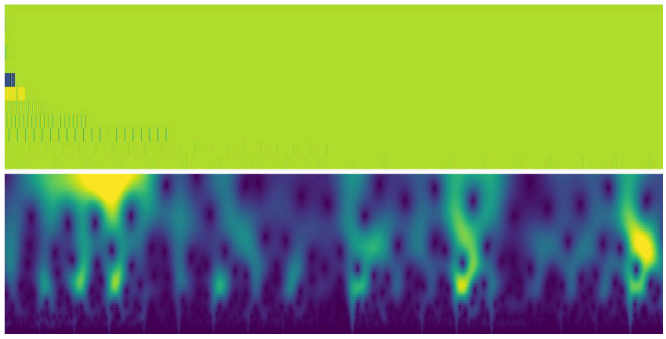

Fig. 1: Visual comparison of wavelet transforms. (A) Artifacts generated by the DWT, discarded from the study. (B) Scalogram generated by the CWT, evidencing the high spectral resolution used in training.

C. Machine Learning for Clinical Decision Support

The high dimensionality of biomedical data frequently exceeds the analytical capacity of traditional statistical methods. Ensemble learners such as Random Forest, proposed by Breiman, aggregate multiple decision trees built on random subsets of data, reducing variance and mitigating overfitting—a common issue when handling extensive feature vectors extracted from images [20]. In imbalanced clinical datasets, the Synthetic Minority Over-sampling Technique (SMOTE) generates synthetic instances of the minority class through linear interpolation between k-nearest neighbors, enriching the decision space and improving classifier sensitivity [21].

III. Methodology

A. Proposed Method: Overview

Fig. 2 summarizes the end-to-end pipeline proposed in this work. Raw multi-channel EEG recordings are first standardized and filtered (Section III-C), then segmented into 1-second

windows with 25% overlap (Section III-D). Each window is converted into a spectral-texture image via the Continuous Wavelet Transform (Section III-E) and passed through a frozen ResNet50 to obtain a 2048-dimensional feature vector (Section III-F.1). SMOTE is applied exclusively to the training partition to balance classes (Section III-F.2), and a Random Forest classifier produces the final good/poor outcome prediction (Section III-F.3). The following subsections detail each stage.

B. Dataset and Patient Selection

Data were obtained from the I-CARE (International Cardiac Arrest REsearch consortium) database, available on PhysioNet, comprising clinical records and continuous EEG from comatose post-CA patients with return of spontaneous circulation (ROSC) [9]. Sixteen patients were selected from five distinct hospital centers, prioritizing diversity of clinical scenarios and temporal homogeneity. The inclusion criteria required recordings performed within the first 24 hours post-ROSC. Table I details the demographic and clinical characteristics of the selected cohort. The rightmost column reports the number of discrete EEG recording files available for each patient within the first 24 hours post-ROSC (not their duration); recording counts vary across patients because the I-CARE acquisition protocol stores continuous monitoring as sequential files whose number depends on hospital-specific acquisition settings and clinical events, rather than on a fixed per-patient schedule. As described below, for every patient the analysis is restricted to 2-minute segments drawn from the first 10 available recordings, so this heterogeneity in file count does not translate into heterogeneity in the amount of data analyzed per patient.

The cohort was intentionally balanced to ensure statistical robustness: 50% male and 50% female; 8 patients with good neurological outcome (Cerebral Performance Category, CPC 1–2) and 8 with poor outcome (CPC 3–5). To prevent data leakage, the dataset was split at the *patient level* rather than the window level: 12 patients (75%) for training and 4 patients (25%) for testing. The split preserved balanced gender distribution and balanced outcomes across both subsets. For each patient, 2-minute segments corresponding to the first 10 available EEG recordings were selected, ensuring temporal standardization within the first 24 hours post-ROSC; because every patient contributes the same number and duration of segments regardless of how many recording files were originally stored, the varying file counts in Table I do not bias the amount of data used per patient.

C. Signal Preprocessing

Given the heterogeneity of data from multiple hospital centers, a rigorous standardization protocol was established:

1) Spatial Standardization and Scale Normalization: Channels were mapped according to the International 10–20 System. To mitigate unit heterogeneity (μV vs. V) across recording devices, a Median Absolute Deviation (MAD) normalization was applied. The median, rather than the mean, was

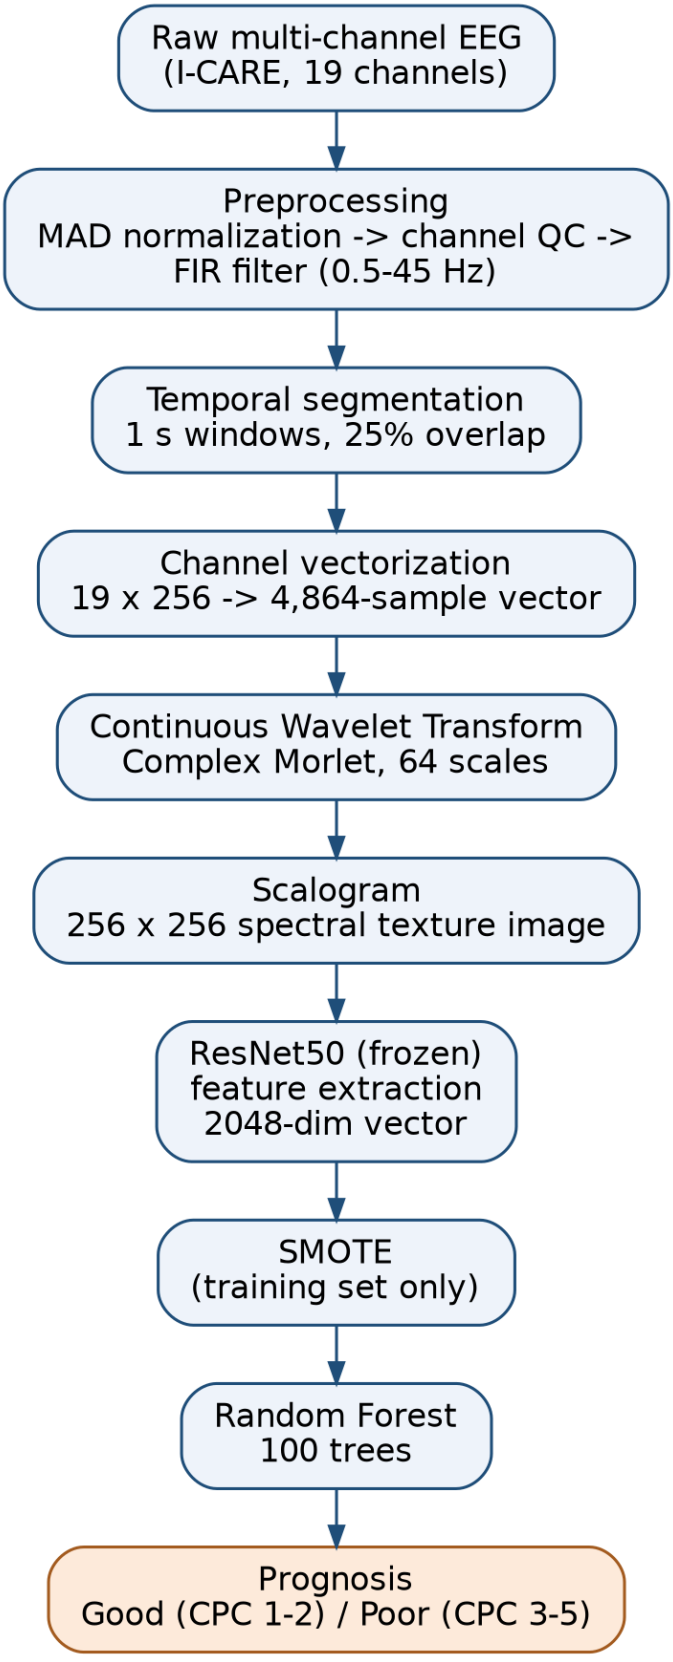

Fig. 2: Overview of the proposed prognostic pipeline, from raw EEG acquisition to the good/poor outcome prediction.

TABLE I: Demographic and Clinical Characteristics of the Selected Cohort (n = 16)

Patient ID	Sex	Outcome	Hospital	Number of EEG recording files (first 24 h)
563	Male	Good	e	16
470	Male	Good	b	19
948	Male	Good	d	20
422	Male	Good	f	39
958	Male	Poor	e	11
702	Male	Poor	b	12
541	Male	Poor	a	11
623	Male	Poor	f	23
913	Female	Good	e	42
487	Female	Good	b	22
543	Female	Good	d	40
843	Female	Good	a	23
588	Female	Poor	b	11
935	Female	Poor	d	20
944	Female	Poor	e	40
577	Female	Poor	f	12

Outcome: Good = CPC 1–2; Poor = CPC 3–5. Hospitals: a, b, d, e, f (multi-center).
The last column is the count of discrete EEG files stored for the patient in the first 24 h post-ROSC, not recording duration.

chosen for its statistical robustness against extreme outliers common in ICU recordings.

2) Channel Quality Validation: Channels with inadequate impedance or connection failure were automatically detected. Channels exhibiting zero standard deviation (flatlines) were discarded to prevent propagation of null coefficients into the wavelet stage.

3) Digital Filtering: A high-order linear-phase FIR filter with passband 0.5–45 Hz was applied. The 0.5 Hz lower cutoff removes baseline wander and low-frequency artifacts (sweat, respiration) while preserving Delta integrity; the 45 Hz upper cutoff attenuates power-line interference (50/60 Hz) and myogenic artifacts without compromising the lower Gamma band.

D. Temporal Segmentation Strategy

Continuous recordings were segmented into 1000 ms (1 s) epochs at $F_s = 256$ Hz, yielding 256 samples per window. The enlargement from the initially tested 500 ms to 1 s was decisive: a 500 ms window imposes a physical limit on the representation of complete slow-wave cycles (< 4 Hz), resulting in spectral information loss and temporal aliasing. The 1 s window ensures faithful representation of Delta oscillations—critical biomarkers in coma and HIE evaluation. A 25% overlap between consecutive segments was applied to maximize data utilization and mitigate boundary information loss, yielding approximately 1,590–1,600 segments per patient.

E. Time–Frequency Transformation

Each 1 s multi-channel window (19 channels $\times$ 256 samples) was transformed into a spectral texture image through three steps:

1) Channel Vectorization: The 19 temporal series were concatenated serially (channel flattening), producing a unified 4,864-sample vector. This choice preserves intra-channel temporal continuity while exposing inter-channel spatial variation in the linear time domain, and avoids the need for a montage-specific multi-channel image encoding, which would require a larger training set to be learned reliably. We acknowledge that concatenation introduces artificial discontinuities at channel boundaries, analogous in principle to the boundary artifacts discussed for the DWT in Section II-B; however, because the CWT is applied to the already-concatenated vector as a single continuous signal, these boundary transitions are smoothed by the wavelet's finite support rather than producing the sharp block artifacts characteristic of DWT decomposition. A systematic comparison against alternative multi-channel encodings (e.g., per-channel scalogram stacking) was not performed in this pilot study and is identified as a direction for future work.

2) CWT Application: The Complex Morlet wavelet (`cmor1.5-1.0`) was applied across 64 scales, covering the entire physiologically relevant frequency range (Delta to Gamma).

3) Scalogram Generation: The magnitude of the complex coefficient matrix was computed (phase discarded) and interpolated to a 256×256 pixel square image. Each EEG segment thus became a spectral texture image serving as high-dimensional input to the deep learning model.

F. Feature Extraction and Classification

The classification pipeline adopted a hybrid Deep Learning / classical machine learning architecture:

1) Feature Extraction with ResNet50: Scalograms were processed by a ResNet50 pre-trained on ImageNet, used in *feature extraction mode*. All convolutional layers were frozen, and the final fully-connected layer (1000 ImageNet classes) was removed. The output of the global average pooling layer—a 2048-dimensional feature vector—served as a compact, high-level representation of each scalogram's spectral texture. This approach was chosen over fine-tuning due to the limited

sample size, as unfreezing convolutional weights on small datasets would inevitably lead to overfitting.

2) Class Balancing (SMOTE): The training set (12 patients) exhibited class imbalance at the window level. SMOTE was applied *exclusively to the training set* to generate synthetic instances of the minority class, preventing classifier bias without introducing leakage into the test set.

3) Random Forest Classifier: The 2048-dimensional feature vectors were classified by a Random Forest configured with 100 decision trees. This ensemble method was selected for its robustness to high dimensionality and its inherent resistance to overfitting through bagging. Model validation followed a stratified 10-fold cross-validation protocol on the training set, with final performance reported on the held-out patient-level test set. This held-out evaluation corresponds to a single train/test split (one round): the 12/4-patient partition was fixed once, and the Random Forest was trained and evaluated on it a single time, rather than being repeated across multiple random splits or resampling runs. Consequently, the point estimates in Table II reflect one realization of the patient-level split; the Wilson confidence interval in Section IV-B quantifies window-level sampling uncertainty within this single split, but does not capture the additional variability that would arise from repeating the split with different patients. Repeating the evaluation across multiple leave-patients-out folds is identified as a priority for future work (Section IV-B and Section V).

IV. Results and Discussion

A. Classifier Performance

The model was evaluated on the independent test set of 4 patients, ensuring that validation data were entirely unseen during training. Table II summarizes the performance metrics.

TABLE II: Random Forest Performance Metrics on Training and Test Sets

Metric	Train	Test	Δ
Accuracy	0.9354	0.9527	+0.0173
Cohen's Kappa	0.8708	0.9054	+0.0346
ROC AUC	0.9850	0.9910	+0.0060

The proximity between training and test metrics indicates a stable operating point rather than gross overfitting, and is consistent with SMOTE mitigating class bias during training. The Cohen's Kappa of 0.9054 on the test set falls in the range conventionally described as almost perfect agreement between automatic prediction and clinical outcome. However, because the test set comprises only four patients, these point estimates carry substantial uncertainty, which we quantify explicitly in Section IV-B. Fig. 3 illustrates the comparison between training and test performance.

B. Statistical Robustness and Effective Sample Size

A window-level accuracy of 95.27% was obtained from 221 correct predictions out of 232 test-set windows (Table III).

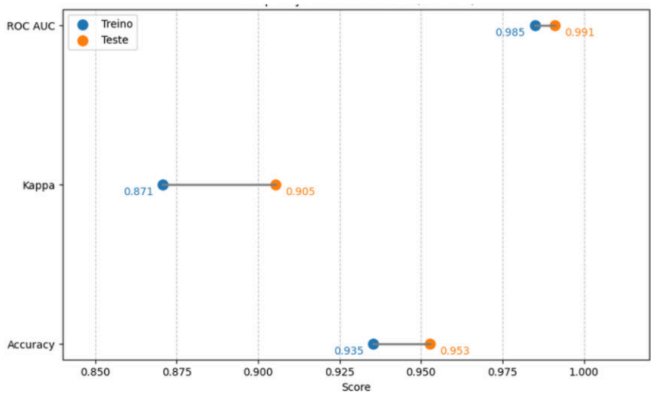

Fig. 3: Comparison of classifier performance metrics (Accuracy, Cohen's Kappa, and ROC AUC) between training and test sets.

Treating these 232 windows as independent Bernoulli trials, a 95% Wilson score confidence interval for accuracy is $[91.7\%, 97.3\%]$. This interval, however, is optimistic: the 232 windows are drawn from only four patients, so predictions within the same patient are statistically dependent (clustered), and the true effective sample size for generalization is closer to four independent units than to 232. Consequently, the reported metrics should be read as a within-cohort estimate of discriminative capacity rather than as a population-level performance guarantee. A leave-one-patient-out evaluation on an expanded cohort, together with patient-level (rather than window-level) confidence intervals – e.g., via a cluster bootstrap resampling patients rather than windows – is identified as a necessary next step before the reported metrics can be interpreted as clinically generalizable, and is planned as immediate future work.

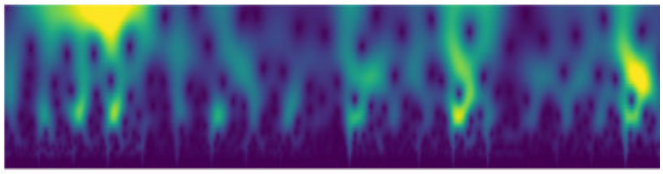
C. Per-Class Analysis

To assess class-specific discrimination capacity, we analyzed the confusion matrix for the test set (Table III). The model demonstrated balanced sensitivity across both classes: 94.8% for good outcome (CPC 1–2) and 95.7% for poor outcome (CPC 3–5). This symmetry is clinically significant, as it indicates that the model does not exhibit bias toward either class—a common pitfall in imbalanced clinical datasets.

TABLE III: Confusion Matrix for the Test Set (4 Patients)

		Predicted Good	Predicted Poor
Actual	Good	110	6
	Poor	5	111

The low number of misclassifications (11 out of 232 total predictions) suggests that the spectral texture features extracted by the CWT + ResNet50 pipeline may capture prognostically relevant markers, though this observation is drawn from a small, four-patient test set and should be treated as preliminary.



Notably, the model correctly identified 111 out of 116 poor-outcome windows, indicating a favorable sensitivity profile for detecting unfavorable prognoses within this cohort—a property that would be clinically desirable if confirmed on larger samples, since false negatives (misclassifying a poor outcome as good) carry severe ethical implications.

D. Impact of Window Size

A notable finding concerns the influence of temporal resolution on feature extraction quality. Preliminary tests with 500 ms windows yielded an accuracy of 87.9%, compared to 95.3% with 1 s windows—a 7.3 percentage-point difference observed in this cohort. This pattern is consistent with the physiological hypothesis that prognostic markers in critical states reside predominantly in low frequencies (Delta band, 0.5–4 Hz), although, given the small sample, it should be regarded as a motivating observation for a dedicated ablation study on a larger cohort rather than a settled result. A 500 ms window physically constrains the representation of complete slow-wave cycles, which may explain part of the observed gap. By extending the window, the CWT scalogram (Fig. 4) captured greater energy density in these bands, which appears to have helped the ResNet50 identify diffuse slowness patterns associated with unfavorable outcomes in this dataset.

(A)

(B)

Fig. 4: CWT scalograms for (A) favorable outcome and (B) unfavorable outcome. Although the images may present macroscopic similarities to visual inspection, the computational model extracts latent features in the spectral energy distribution that enable correct classification.

E. Spectral Texture vs. Visual Morphology

A common barrier to AI adoption in clinical practice is the expectation of "explicit visual biomarkers" analogous to radiological findings (e.g., a tumor mass). However, qualitative analysis of the generated images reveals that the distinction between "good" and "poor" prognoses does not always manifest through macroscopic morphological events visible to the human specialist.

While traditional EEG visual inspection searches for specific graphoelements (e.g., spikes, sharp waves), the Convolutional Neural Network appears to operate by identifying spectral texture patterns and non-linear correlations distributed throughout the time–frequency image. The observation that the algorithm correctly classifies segments lacking obvious visual abnormalities is consistent with the hypothesis that the model detects micro-alterations in cerebral dynamics—candidate "spectral signatures" that may precede the manifestation of coarse graphic patterns. We emphasize, however, that this interpretation is qualitative and has not yet been verified with a formal interpretability method; it should therefore be read as a hypothesis motivating future work rather than as an established mechanism.

This hypothesis is broadly consistent with recent studies suggesting that deep learning models can identify subtle electrophysiological patterns that escape visual detection [13], [22]. Confirming it, however, requires interpretability methods (e.g., Grad-CAM, SHAP) to bridge the gap between model predictions and clinical understanding—a direction we identify as a priority for future work rather than a claim made by the present study.

F. Comparison with Literature

The performance of the proposed system compares favorably, in point-estimate terms, with recent studies on EEG-based prognostication after cardiac arrest. Tjepkema-Cloostermans et al. [13] achieved an AUC of 0.89 using quantitative EEG features and logistic regression, while Westhall et al. [6] reported a sensitivity of 91% for standardized EEG interpretation. Our model's AUC of 0.991 and balanced sensitivity (94.8% / 95.7%) nominally exceed these benchmarks; however, this comparison must be qualified: the present pilot cohort (16 patients, 4 in the test set) is substantially smaller than those typically used in the cited studies, and metrics obtained from small, single-pipeline cohorts are known to be optimistically biased relative to multi-cohort or externally validated estimates. We therefore present these figures as an encouraging exploratory signal rather than as evidence of outperforming the cited methods in a rigorous head-to-head sense.

However, direct comparison is further limited by differences in datasets, preprocessing pipelines, and evaluation metrics. The I-CARE database used in this study is multi-center and temporally standardized, which enhances generalizability but may differ from other cohorts in terms of patient demographics and recording protocols.

V. Limitations and Future Work

Despite the promising results, this study presents limitations that must be acknowledged. First, the sample size (16 patients) restricts the absolute generalization of findings to heterogeneous clinical scenarios. Multi-center validation on larger cohorts is essential before clinical deployment. Second, the patient-level split, while methodologically rigorous to prevent

data leakage, yields a small test set (4 patients); because test-set windows are clustered within these four patients rather than statistically independent, the effective sample size underlying the reported metrics is much smaller than the raw window count of 232, and the associated uncertainty is larger than a naive window-level confidence interval would suggest (Section IV-B). Moreover, the reported metrics stem from a single train/test split rather than from repeated or leave-patients-out evaluation (Section III-F.3), so they do not yet capture the variability that could arise from a different choice of held-out patients. Third, the current pipeline relies on handcrafted preprocessing choices (filter cutoffs, wavelet parameters, window size) that were tuned empirically on this same small cohort, which raises the possibility of implicit overfitting to cohort-specific characteristics even though the final classifier was not directly tuned on the test patients. Fourth, while the model captures latent spectral textures, a formal interpretability analysis has not been performed—this limits direct association between extracted features and specific electrophysiological patterns, and the discussion in Section IV-D should accordingly be read as hypothesis-generating rather than confirmatory.

Finally, it is crucial to contextualize the scope of this work as a proof-of-concept study. Although the patient-level split prevents data leakage, the small cohort size may limit the statistical robustness and generalizability of the reported benchmarks. Moreover, although the model successfully captures spectral textures, this pilot study does not incorporate formal Explainable AI (XAI) techniques—such as Grad-CAM or SHAP—to interpret its internal decision process. These boundaries were deliberately established to validate the feasibility and low computational cost of the pipeline prior to resource-intensive clinical deployment. Consequently, the current results should be interpreted as a hypothesis-generating signal, rather than as a definitive clinical benchmark.

Future work will focus on: (i) validation on expanded multi-center cohorts; (ii) end-to-end Convolutional Neural Networks that jointly learn preprocessing and classification; (iii) investigation of attention mechanisms and interpretability methods (e.g., Grad-CAM, SHAP) to improve model transparency and highlight the time–frequency regions most influential for prognosis; and (iv) development of a bedside real-time prototype for continuous prognostic monitoring in the ICU.

VI. Conclusion

This pilot study evaluated the feasibility of a clinical decision-support pipeline based on automated EEG signal analysis for post-cardiac arrest prognosis. The proposed approach, combining the time–frequency resolution of the Continuous Wavelet Transform with a Random Forest classifier fed by ResNet50-extracted features, achieved encouraging performance metrics on a small, independent test set (accuracy 95.27%, 95% CI $[91.7\%, 97.3\%]$; AUC 0.991; Kappa 0.9054), offering preliminary support for the hypothesis that reliable prognostic markers can be extracted mathematically even in the absence of overt visual graphoelements. Given the small cohort (16 patients, 4 in the test partition) and the resulting clustering of predictions within few patients, these results should be treated as hypothesis-generating rather than as a validated clinical tool.

A central technical contribution was the preprocessing strategy, specifically the exploratory finding that 1-second segmentation windows outperformed shorter windows in this cohort, consistent with the physiological role of slow-wave (Delta) activity as a candidate biomarker of functional recovery versus irreversible damage. The channel vectorization and concatenation strategy allowed synthesizing the brain's global topography into a single attribute representation, simplifying modeling, though at the acknowledged cost of introducing channel-boundary discontinuities whose impact was not directly quantified.

The hybrid architecture—CWT for dense spectral representation, frozen ResNet50 for high-level feature extraction, and Random Forest for classification—appears well suited to the small-sample regime typical of clinical neurophysiology pilot studies. Before this pipeline can be considered a candidate decision-support tool for intensive care, however, it requires validation on a substantially larger, multi-center, externally held-out cohort, patient-level (rather than window-level) uncertainty quantification, and formal interpretability analysis, all of which we identify as immediate next steps.

Acknowledgment

The authors thank the Universidade Federal de Pernambuco (UFPE) and the Department of Biomedical Engineering for the infrastructure provided. We also extend our gratitude to our classmates for the daily partnership and mutual support throughout this project.

Response to Reviewers

Dear Reviewers,

First, we thank you for your suggestions and time dedicated to reviewing the manuscript "Objective Characterisation of Pronation-Supination Movements in Individuals with Parkinson's Disease Undergoing Pharmacological Treatment" (Paper ID: 285), as well as for the opportunity to submit a revised version of this manuscript to the "Brazilian Congress on Biomedical Engineering".

We have carefully considered all suggestions and revised the manuscript accordingly. Below, we provide a point-by-point response to each comment. For clarity, the reviewers' comments are presented in bold, followed by our responses. Changes made to the manuscript are indicated in red in the annotated version of the article.

Responses to the comments from Reviewer 1

Comment: Gyroscope-based characterization of pronation-supination may complement visual bradykinesia ratings, but nine medicated participants support only a pilot description.

Response: We thank the reviewer for this observation. We agree that the small number of participants limits the generalizability of the results derived from the statistical comparisons. However, the aim of all the proposed analyses was not to provide a clinical validation of gyroscope-based measurements, but rather to present a quantitative characterisation of movement patterns, primarily on an individual basis without relying on measurements from other participants. Rather than focusing exclusively on the average response across participants, this study provides insight into individual response patterns, highlighting the heterogeneity that may be masked by group-level analyses, particularly in small or more homogeneous samples. To clarify this point, we have revised the study objective to more explicitly reflect its focus on characterizing individual response patterns and inter-individual variability.

Comment: Report age, sex, disease stage, affected side, medication dose and timing, MDS-UPDRS scores, sensor placement, sampling, calibration, task instructions, repetitions and signal processing.

Response: We thank the reviewer for this suggestion. We would like to clarify that most of these points had already been addressed in the original version of the manuscript. To provide further detail on the description already provided, we added information regarding the time elapsed between medication administration and assessment, as well as the anatomical region in which the sensors were positioned and the device used to acquire signals, with its settings. Although MDS-UPDRS scores are not reported, scores on the Hoehn and Yahr scale are provided, which reflect the patient's overall clinical status; this scale is not as sensitive to motor fluctuations as the MDS-UPDRS, but it is statistically correlated with it (M. Skorvanek, P. Martinez-Martin, N. Kovacs et al., "Differences in MDS-UPDRS scores based on Hoehn and Yahr stage and disease duration," Movement Disorders Clinical Practice, vol. 4, no. 4, pp. 536-544, 2017). The modifications made to the text are highlighted in red.

Comment: Clarify whether both limbs and repeated cycles were analyzed as independent observations.

Response: For statistical comparisons, the measurements extracted from the cycles (i.e., the peak-to-peak values) were obtained from the same participant for each limb, and these values were averaged within each limb for each participant prior to statistical analysis; this was not necessary for the period, given that this measurement is already an aggregate of the cycles. The aggregated values for the two limbs were then compared using a paired-samples t-test, with each participant serving as the pairing unit. To help readers better understand this in the text, we explain this point in more detail in the "Statistical Analysis" subsection. All modifications made to the text are highlighted in red.

Comment: Use participant-level summaries or mixed models, provide individual trajectories and uncertainty, and relate features to blinded clinical ratings.

Response: We thank the reviewer for these suggestions. As explained in more detail in the response to the previous comment, the statistical analyses already took participant-level summaries into account. In the revised manuscript, we have included effect size estimates for the statistical comparisons, as described in the Methods section, to provide a more informative assessment of the magnitude and uncertainty of the observed effects.

Regarding a correlation between the proposed features and the blinded clinical scores, as the study proposes to characterise the pronation and supination movements in order to better understand the profile of these movements in Parkinson's disease and, when present, to quantify bradykinesia, considering that these movements are typical to evaluate this motor signal, an evaluation of the convergence of the measurements obtained with the inertial sensors and the clinical scores goes beyond the scope of the study, because the results obtained by the different methods would have to be combined in some way and translated to describe only bradykinesia, an aspect that is now discussed in the manuscript.

<u>Comment:</u> Without an OFF-medication or control comparison, observed profiles cannot be attributed to treatment response or disease-specific impairment.

Response: We thank the reviewer for this comment. We acknowledge that assessing these conditions would be beneficial in allowing a comparison of different profiles, and in this regard, we recognize this as one of the limitations of the present study. However, we also acknowledge that, even if these comparisons were included, the findings could not be interpreted as evidence of a response to treatment or as a disease-specific impairment. This is because the effect of medication on each individual's voluntary motor response will also depend on whether the voluntary activity was learned under the influence of the medication or not; and, since this type of movement is routine in the evaluation of these patients, those with a longer duration of diagnosis are likely to be more influenced by the medication in their motor learning as well. Therefore, we hypothesize that medication may contribute to both voluntary and involuntary responses in some cases but not in others, given that even when a person is under the influence of the medication, they exhibit a sustained decline in speed – a very distinct sign of bradykinesia in PD. Thus, the manuscript has been revised, and we now discuss these aspects in more detail.

<u>Comment:</u> The prose smoothly connects sensor features with precise monitoring and individualized therapy, a pattern that may be machine-polished but does not prove AI authorship. Human revision should keep conclusions descriptive, discuss tremor, fatigue and learning effects and identify which metric is genuinely new. The contribution is a compact feature set from one standardized task. Correct statistical units, feature definitions, figures, ethics reporting and the distinction between characterization and validation.

Response: Thank you for all suggestions. We have revised the manuscript to ensure that the interpretation remains descriptive and appropriately distinguishes feature characterization from clinical validation. In addition, the suggested points are best discussed in the manuscript and aligned with the pertinent literature. All changes have been incorporated into the revised manuscript and are highlighted in red.

<u>Responses to the comments from Reviewer 2</u>

Comment: The discussion appropriately relates the observed movement patterns to clinical manifestations such as bradykinesia, motor adaptation, and medication effects, while acknowledging the limitations associated with sample size, kinematic-only assessment, and the absence of physiological measurements. Nevertheless, the manuscript would benefit from a more quantitative interpretation of the results, including a clearer justification of the practical implications of the detected change

points and a deeper comparison with existing movement analysis approaches for Parkinson's disease.

Response: We thank the reviewer for this suggestion. To address these issues, the results pertaining to the points of change were rewritten to provide a more quantitative description of the results. All modifications made to the text are highlighted in red.

In addition, the authors are encouraged to carefully review the manuscript formatting to ensure full compliance with the CBEB template.

Response: We thank the reviewer for this suggestion. The manuscript has been carefully reviewed and reformatted to ensure compliance with the event template.

Observational Analysis of the Performance of Image Reconstruction Algorithm Techniques in Head CT Protocol

***Abstract*—CT exams are widely utilized for diagnosing pathologies due to their rapid acquisition and high image quality. To optimize radiation dose, manufacturers have developed advanced computational image reconstruction algorithms to mitigate the noise inherent in low-dose acquisitions. Following an institutional CT scanner upgrade, this study presents an observational evaluation of FBP, IR, and DLIR reconstruction algorithm techniques using Quality Assurance (QA) phantom. For low-contrast resolution, the FBP - UA kernel - resolved more holes across the three acrylic disks, whereas UB and UC kernels resolved an average of six holes in disk C. The IR resolved an average of six holes in disk C at iDose levels 1 to 6, and iDose level 7 resolved five holes in disk C. Conversely, the DLIR technique (Precise Image) yielded lowest low-contrast detectability, resolving only an average of five holes in disk C. In high-contrast analysis, FBP and DLIR resolved similar results, an average of 6.6 lp/cm, while IR resolving an average of 5.0 lp/cm. DLIR demonstrated superior SNR improvement. The CNR analysis revealed that DLIR induces a substantial loss in image contrast when compared to FBP kernels. No significant CNR variations were observed across IR levels. In conclusion, while DLIR provides unprecedented noise reduction, it may compromise low-contrast detectability in soft-tissue in clinical applications. IR demonstrated an essential digital resource to CT protocols optimization.**

Keywords—computed tomography, image reconstruction, algorithm, low contrast, CNR, SNR

I. INTRODUCTION

Computed tomography (CT) exams are widely utilized for diagnosing pathologies due to their rapid acquisition time and high image quality [1], [2]. Consequently, CT has become the primary contributor to increased population exposure to artificial ionizing radiation worldwide [3]. To optimize radiation doses, manufacturers have invested in advanced computational image reconstruction techniques to mitigate the noise inherent in low-dose acquisitions [4], [5].

While Filtered Back-Projection (FBP) remains the benchmark reconstruction method in CT, it requires higher radiation doses to maintain acceptable image quality [6]. Computational advancements in processing large data volumes have enabled the adoption of innovative reconstruction algorithms [7]. These techniques suppress noise in low-dose images through hybrid approaches, incorporating both Iterative Reconstruction (IR) and Deep Learning Image Reconstruction (DLIR) algorithms [8].

However, depending on the aggressive manipulation of the noise reduction, these algorithms can introduce a "plastic" texture to the images and potentially obscure low-contrast pathologies [5], [9], [10]. Because certain noise-reduction strength levels are operator-dependent, imaging professionals must consider alternative strategies to minimize noise in low-dose protocols [11]. For instance, simply reconstructing the image with a greater slice thickness can reduce noise without compromising critical diagnostic details.

This study presents an observational evaluation of the performance of advanced CT image reconstruction algorithm techniques regarding noise suppression, following institutional head CT protocol, after the upgrade of the CT scanner system.

II. METHODOLOGY

A. Comparative Study Using a QA Phantom

This study was conducted in the Radiology Department of Escola Paulista de Medicina, Universidade Federal de São Paulo. CT images were acquired using a Philips Incisive CT scanner (Philips Medical Systems, Netherlands). Table I presents the reconstruction algorithm techniques available on the Incisive CT system and their main characteristics.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

TABLE I. Characteristics of Incisive CT reconstruction algorithms used in this study

Reconstruction	Characteristics *
Filtered Back-Projection (FBP)	Standard FBP kernel acquisitions: UA smooth on the brain; UB standard preset for head scans; UC brain enhancement, all kernels improve the bone/brain interface, for head scans only [12].
iDose (IR)	Reconstruction techniques are used to reduce noise by implementing levels to determine the amount of noise that is removed from the images (IR). Level 1 (20%) is the least aggressive noise reduction, level 7 (80%) is the most aggressive noise reduction [12].
Precise Image (DLIR)	Precise Image is a reconstruction mode where the system uses a trained deep learning neural network to generate noise reduction images (DLIR) and improve low contrast detectability with reduced dose compared with standard FBP recon mode [12].

* From Philips Incisive CT User Guide [12].

A Philips Quality Assurance (QA) Phantom, model C for AV E1, was used for image acquisition. This methodology, i.e., the use of QA phantoms in clinical settings, is widely described in the literature [13], [14], [15], [16], [17], [18]. These results obtained can be used as image quality baselines and in optimization processes.

The institutional adult routine head CT protocol was selected for this study; Table II lists the acquisition parameters. Three acquisitions were performed, and the reconstruction algorithms applied to the same raw data to allow an unbiased comparison of the results.

TABLE II. Incisive CT parameters for the institutional adult head CT protocol acquisitions.

Exposure Parameters	
Voltage (kV)	120
Current x Time (mAs)	399
FOV*	190
Slice Thickness (mm)	1.00
Pitch	0,5
Collimation	64 x 0.625
Matrix	512 x 512
CTDIvol (mGy)	56.27

* Field of View

The low-contrast and high-contrast resolution, Signal-to-Noise Ratio (SNR) and Contrast-to-Noise Ratio (CNR) parameters were selected because they represent the primary targets for optimization by the reconstruction algorithms.

In this study, the impact of varying radiation doses, for example computed tomography dose index volume (CTDIvol) was not evaluated; only the baseline settings of the institutional adult head CT protocol were considered without dose optimization.

B. Data Analyses

For the qualitative assessments, three independent readers, each with over 10 years of experience, performed unblinded evaluations across all reconstructed images, using a 5-megapixel Barco© medical display, model MDNG-6121.

A qualitative assessment of low-contrast resolution was performed visually. Images were acquired in accordance with the institutional adult routine head CT protocol, using the QA phantom. The low-contrast resolution section of the phantom comprises three disks of varying materials and thicknesses, each containing eight holes of different diameters. Fig. 1 and Table III show the low-contrast test tool region of the phantom, with the disks identified according to their respective materials and thicknesses.

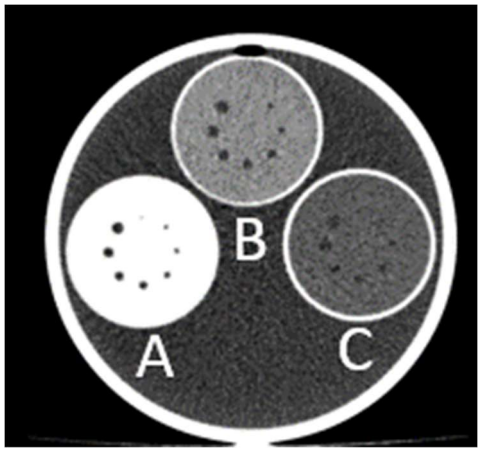

Fig.1. CT image of the QA phantom low-contrast resolution region, categorized by disk thickness.

TABLE III. QA phantom low-contrast test tool groups specifications.

Disk Identification	Material	Thickness
A	Acrylic	1.65
B	Acrylic	0.4
C	Polyester	0.075

A qualitative assessment of high-contrast resolution was performed visually, with the same methodology described for the low-contrast resolution. Images were acquired in the line pairs per centimeter (lp/cm) test tool section of the QA phantom. This assessment identified the last group in which the individual bars remained distinguishable. Fig. 2 presents the group of line pairs on the QA phantom, while Table IV lists the representative resolution values in centimeters.

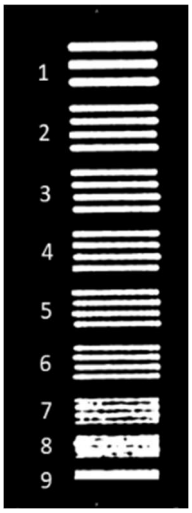

Fig. 2. CT image of the QA phantom high-contrast resolution region, exhibiting the line pairs per centimeters test tool.

TABLE IV. Representative resolution in lp/cm test tool groups

Group	Resolution (lp/cm)
1	5.0
2	6.6
3	7.1
4	7.7
5	8.3
6	9.1
7	11.1
8	12.5
9	14.3

Additionally, a quantitative analysis was conducted by calculating the SNR and CNR, in accordance with the recommendations outlined in the American Association of Physicists in Medicine (AAPM) Task Group 233 (TG-233) report and the American College of Radiology (ACR) CT Quality Control Manual.

The SNR is a measure of the signal level in the presence of noise given by the equation (1):

$$SNR = \frac{MeanValue(ROI)}{SD(ROI)} \quad (1)$$

Where Mean Value and Standard Deviation (SD) are the value of the Hounsfield Unit (HU) in a Region Of Interest (ROI) in the image.

The CNR was calculated as the ratio of Mean Value to SD in the ROI given by the equation (2):

$$CNR = \frac{Mean(Low_Contrast) - Mean(Water)}{SD(Water)} \quad (2)$$

Fig. 3 illustrates the ROI positioned for the quantitative analysis. The disk B of the low-contrast resolution section was selected for this assessment, as its HU values closely approximate those of brain tissue. The ROI had an area of 2.346 cm^2 and comprised approximately 2005 pixels.

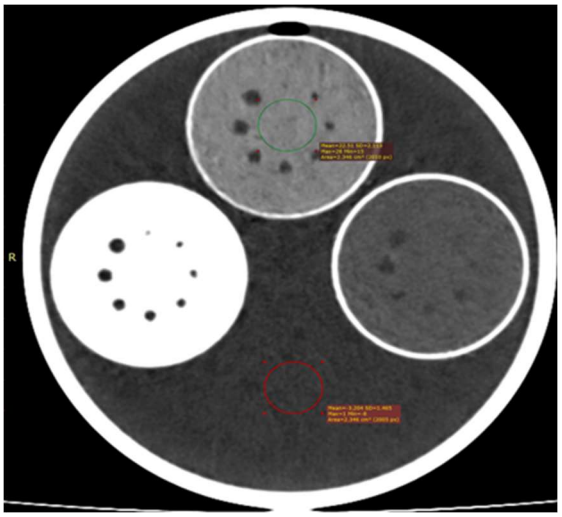

Fig. 3. ROIs location and size for SNR and CNR analysis.

III. Results and Discussion

Following CT image acquisition and the application of the respective image reconstruction algorithm techniques, a noticeable change in the visual perception of the phantom's low-contrast test tools was observed, primarily driven by excessive image noise reduction. However, the opposite occurs with high-contrast visual perception. Fig. 4 and 5 shows the visual appearance of the phantom's low-contrast and high-contrast region after the application of reconstruction algorithm techniques, respectively.

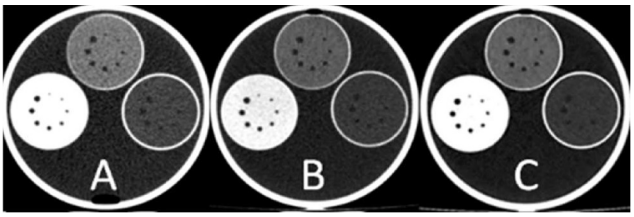

Fig. 4. Low-contrast QA phantom image. In ***A*** UA kernel (FBP), in ***B*** iDose level 7 (IR) and ***C*** Precise Image (DLIR).

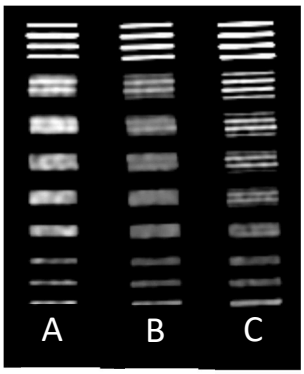

Fig. 5. High-contrast QA Phantom image. In ***A*** UA kernel (FBP), in ***B*** iDose level 7 (IR) and ***C*** Precise Image (DLIR).

A. Low-Contrast analysis

In the visual analysis, all reconstruction algorithms techniques enabled the visualization of all holes across the acrylic disks A and B by the readers. Conversely, the reconstruction algorithms techniques demonstrated random performance to resolve the holes images in the polyester disk C (Table V).

TABLE V. Results of low-contrast visual analysis in polyester disk C, presented as mean ± standard deviation based on the evaluation of three images by three independent readers.

Algorithms	Reader 1	Reader 2	Reader 3
Precise Image	5.33 ± 0.58	5.0 ± 0.0	5.33 ± 0.58
iDose 1	6.0 ± 0.0	5.33 ± 0.58	5.67 ± 0.58
iDose 2	5.67 ± 0.58	6.33 ± 0.58	6.0 ± 0.0
iDose 3	6.33 ± 0.58	5.33 ± 0.58	5.33 ± 0.58
iDose 4	6.67 ± 0.58	6.0 ± 0.0	5.33 ± 0.58
iDose 5	6.0 ± 1.0	5.33 ± 0.58	5.67 ± 0.58
iDose 6	6.33 ± 0.58	6.0 ± 0.0	5.67 ± 0.58
iDose 7	5.33 ± 0.58	5.33 ± 0.58	5.33 ± 0.58
UA Kernel	7.0 ± 0.0	6.0 ± 0.0	5.67 ± 1.15
UB Kernel	6.33 ± 0.58	5.67 ± 0.58	5.67 ± 1.15
UC Kernel	5.67 ± 0.58	6.0 ± 1.0	5.67 ± 1.15

Regarding the IR technique, five to six holes were discernible in disk C at iDose levels 1 to 6. However, at the

most aggressive level (iDose 7), an average of five holes was discernible in the disk C. Also, the DLIR technique (Precise Image) yielded inferior results regarding low-contrast feature detectability in the disk C, an average visualization of five holes.

B. High-Contrast analysis

In the high-contrast resolution analysis, the FBP, IR and DLIR techniques showed similar results (Table VI). The FBP and DLIR technique resolved an average of 6.6 lp/cm, whereas the IR technique resolved 5.0 lp/cm across all iDose levels.

The FBP technique exhibited a gradual, kernel-dependent improvement in high-contrast resolution. The UA kernel resolved an average of 5.0 lp/cm, the UB kernel resolved up to the second group (6.6 lp/cm), and the UC kernel achieved the highest spatial resolution, 7.1 lp/cm.

TABLE VI. Results of visual analysis of high-contrast, presented as mean ± standard deviation based on the evaluation of three images by three independent readers.

Algorithms	Reader 1	Reader 2	Reader 3
Precise Image	6.6 ± 0.0	6.6 ± 0.0	6.6 ± 0.0
iDose 1	5.53 ± 0.92	5.53 ± 0.92	5.53 ± 0.92
iDose 2	5.53 ± 0.92	5.0 ± 0.0	5.0 ± 0.0

iDose 7	5.53 ±0.92	5.5 ± 0.87	5.0 ± 0.0
UA Kernel	5.53 ± 0.92	5.0 ± 0.0	5.0 ± 0.0
UB Kernel	6.6 ± 0.0	6.07 ± 0.92	6.07 ± 0.92
UC Kernel	6.77 ± 0.29	6.93 0.29	6.77 ± 0.29

This performance is critical since CT imaging inherently requires a certain level of noise to preserve the boundary differentiation between distinct soft-tissue densities, particularly within the brain parenchyma where structures share highly similar attenuation values.

C. SNR and CNR analysis

In a direct comparison between the reconstruction algorithm techniques, the SNR was determined in the region where the HU was similar to the brain tissue.

In the SNR analysis, the DLIR (Precise Image) demonstrated superior signal improvement (Fig.6), a direct result of the algorithm's noise correction capabilities.

Reconstructions using IR exhibited the expected trend, showing progressive signal enhancement as the iDose level increased.

FBP reconstructions also followed expected patterns: the UA kernel yielded a smoother image; the UC kernel produced the highest noise levels, and the UB kernel, standard for brain imaging, delivered intermediate noise levels between UA and UC.

Regarding CNR analysis, it is noteworthy that although the DLIR method significantly improves the SNR, it induces a substantial loss in image contrast, particularly when compared to the FBP kernels (UA and UC, Fig. 6). While the latter exhibit higher absolute image noise, they preserve greater contrast between structures of similar density, which is often preferable for the clinical evaluation of brain images. This contrast degradation manifests as the characteristic "plastic" artifact that DLIR algorithms can introduce in certain brain scans.

For the IR reconstruction algorithm, no significant variations in image contrast were observed across the different iDose levels.

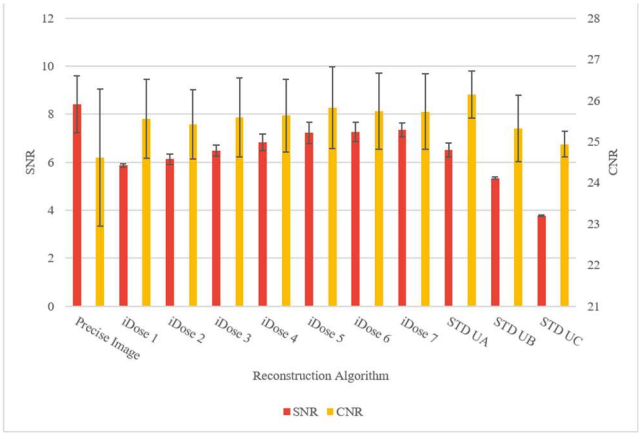

Fig. 6. SNR and CNR through reconstruction algorithm techniques analyzed.

Fig. 6 shows that, for FBP reconstructions, as the CNR is optimized (using sharper kernels), the SNR decreases due to higher noise levels. Conversely, DLIR reconstructions exhibit the opposite performance, enhancing the SNR at the expense of CNR. On the other hand, IR reconstruction techniques attempt to maintain a balance, stabilizing both SNR and CNR across different iterations.

In Fig. 7, the plot demonstrated the influence of the reconstruction algorithm technique in high-contrast resolution, SNR and CNR parameters analyzed in this study.

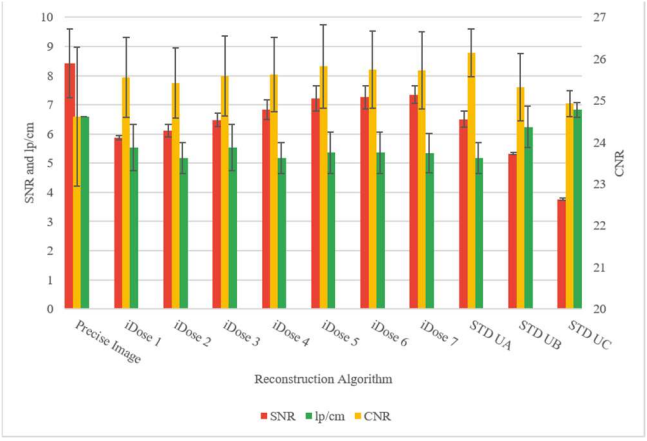

Fig. 7. Results of high-contrast, SNR and CNR through reconstruction techniques analyzed.

The findings of this study highlight the variations that modern reconstruction algorithms can cause in CT images. When significant density differences exist between adjacent objects, the DLIR algorithm (Precise Image) effectively suppresses noise and degrades high and low-contrast

resolution in the image. This phenomenon clinically manifests as a "plastic" artifact. Fig. 8 summarizes the results from qualitative image analysis for high and low-contrast resolution.

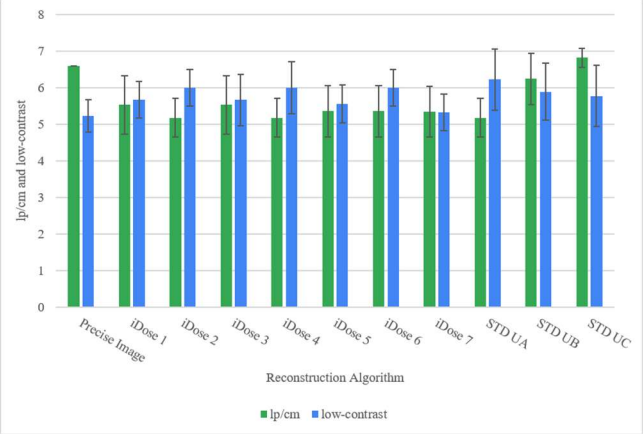

Fig.8. Results from qualitative image analysis for high and low-contrast.

The observed degradation in CNR correlates directly with high-contrast performance. The superior visualization of lp/cm achieved with the UC FBP kernel can be attributed to its better preservation of CNR, despite the higher background noise.

However, modern reconstruction algorithms, such as those based on IR and DLIR, can contribute to the optimization of clinical examinations as they compensate for image noise generated by low doses.

These results suggest that while deep-learning-based reconstructions offer unprecedented noise suppression, traditional FBP kernels remain highly valuable for preserving boundary definitions in low-contrast diagnostic tasks.

IV. Conclusions

This study shows that although DLIR algorithms (e.g., Precise Image) offer superior noise reduction and SNR enhancement, careful consideration is required due to potential low-contrast degradation in structures with similar attenuation.

Iterative reconstruction algorithms like iDose remain essential components for institutional CT protocol optimization.

Further optimization studies are currently underway to establish dose reduction strategies, that balance the noise suppression of IR and DLIR techniques with clinical image quality requirements.

***Abstract*—This article addresses the challenge of accessibility for people with motor disabilities and highlights the importance of assistive technologies, focusing on human-machine interfaces based on biosignals. It presents the development of an open-source platform for electrooculography (EOG) signal acquisition using the ADS1299-4 chip, aimed at detecting double blinks and converting them into assistive commands. The work fills a gap in the literature by providing detailed hardware schematics, PCB layout, and signal acquisition methodology, supporting scientific reproducibility. A pilot study validated the system, with double-blink events classified by a Support Vector Machine (SVM) model achieving 78% precision, demonstrating feasibility for real-time and embedded applications even in the presence of signal noise. The main contributions are: (1) the creation of an open-source, reproducible EOG acquisition platform; (2) validation for double-blink detection in assistive interfaces; and (3) public release of all materials to foster further research and adaptations, advancing independent interaction for individuals with limited mobility.**

***Index Terms*—Assistive technology, electrooculography (EOG), biosignal acquisition, open-source hardware, double blink detection, human-machine interface, support vector machine (SVM).**

I. Introduction

In a study involving adults from 59 countries, 7.2% of the surveyed population reported having severe or extreme difficulty in moving around [1]. This figure indicates that a considerable portion of society has some type of motor limitation. Furthermore, for many of these individuals, assistance and support are necessary for participation in society [1]. This makes this population highly dependent on family members, preventing both individuals with disabilities and their caregivers from becoming economically active and socially included.

In this regard, assistive technologies are extremely important for reducing this dependence and, consequently, promoting greater autonomy and integration for these individuals. Assistive technology aims precisely to promote autonomy and social interaction through resources, devices, technologies, and services.

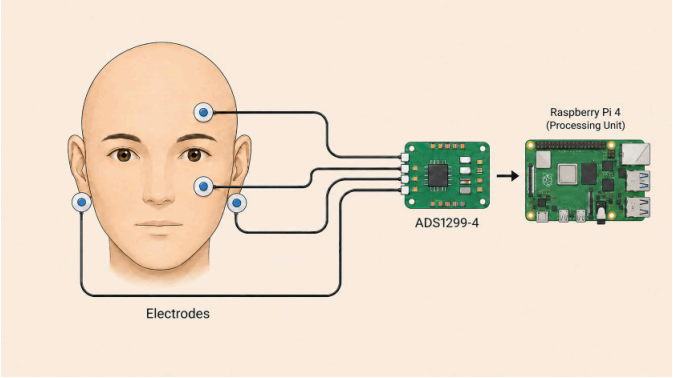

Fig. 1. System overview - Blink acquisition and processing

In this context, assistive human-machine interfaces emerge as solutions that promote interaction with systems and device control for people with physical disabilities. In [2], several studies that use biosignals for conversion into digital commands are presented. In addition, in [3], a similar application is presented, in which double blinks, acquired from EOG signals, and head movements are used to control a robot. In [4], a wearable headband with dry electrodes is presented, and the detection of events such as eye movements and single blinks is investigated.

Regarding the acquisition of EOG signals, [2] shows that most approaches use commercial solutions, while a few are implemented on custom acquisition boards. However, even

in cases where such customization is proposed, few studies presented details of the developed hardware, such as electrical schematics, system layouts, and development guidance, thereby hindering project reproducibility and limiting scientific contributions through improvements, adaptations, and further research based on these circuits.

Considering this aspect, the objective of this work was to develop an open-source, customized acquisition platform using the ADS1299-4 chip to acquire double blinks via electrooculography (EOG) signals. The detected blinks were classified using the Support Vector Machine (SVM) algorithm to be used as commands, expanding the possibilities of interaction for people with physical disabilities and contributing to the reduction of accessibility barriers.

The main contribution of this work is the development and validation of an open-source, EOG-customized acquisition platform, including PCB design, electrical schematics, and signal acquisition methodology, enabling reproducible research in assistive human-machine interfaces, which is available at [5]. The project overview is shown in Fig. 1

The remainder of this paper is organized as follows. The Theoretical Background section presents key concepts and information necessary for a better understanding of the work. The Materials and Methods section describes the entire process carried out to develop the project. In the Results and Discussion section, the results are presented and discussed, including the metrics used to evaluate the proposed solution's performance. Finally, the Conclusion section presents the final considerations based on the results achieved.

II. Theoretical Background

To contextualize the development of this work, this section presents the theoretical background related to the acquisition and use of EOG signals in human-machine interface applications. It addresses biological signals, with emphasis on electrooculography (EOG), the use of double blinks as interaction commands, the main characteristics of the ADS1299-4, and referential and bipolar electrode montages.

A. Electrooculography Signals

Signals originating from physiological activities of the human body are referred to as biosignals and can be measured, processed, and analyzed. Among these signals, bioelectric signals stand out, as they are characterized by voltage or electric current variations generated by biological processes. In this context, the EOG consists of the recording of electrical variations associated with the ocular region, mainly resulting from the potential difference generated by eye movements and blinks.

B. Blinks as Interaction Command

The EOG signal enables the detection of ocular events, such as blinks. These events can then be processed and analyzed to be assigned to specific commands or used as command confirmation mechanisms, thereby increasing safety in human-machine interaction. In a work, for example, blink frequency was associated with specific commands, demonstrating the broad applicability of this type of signal [6].

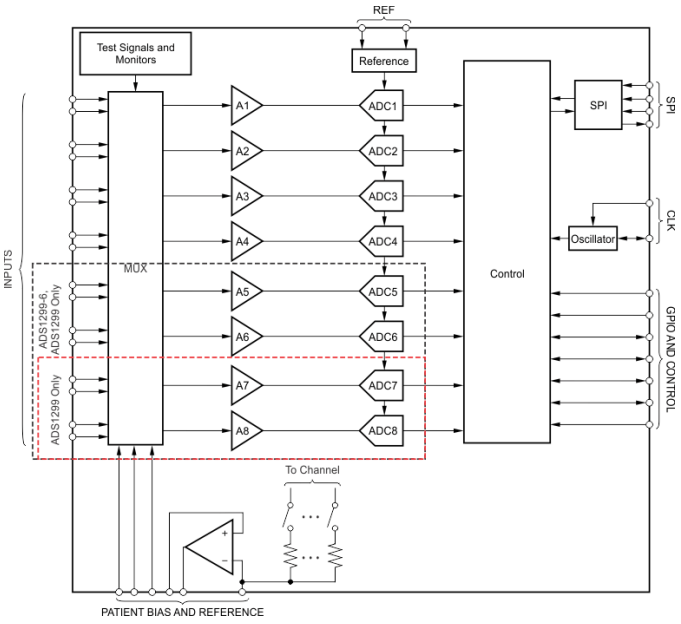

Fig. 2. Block diagram of ADS1299-4 [8]

A blink is an event that can be easily identified in the EOG signal, generally characterized by the presence of a peak or valley in the signal. In the case of a double blink, its main characteristic is the occurrence of two consecutive peaks or two consecutive valleys within a short time interval [7].

C. ADS1299-4

The ADS1299-4 chip is a low-noise, 24-bit analog-to-digital converter with a programmable gain amplifier and SPI communication, designed especially for biosignal acquisition. This chip is available on the market in different versions, which differ only in the number of channels.

Its high resolution, programmable gain amplifier, and low-noise architecture make it suitable for acquiring ECG, EEG, and EOG signals. The Figure 2 shows how the chip operates internally. It includes amplifier circuits, analog-to-digital converters, an internal control module, and a BIAS circuit, which is used to help reduce noise. The signals from the electrodes pass through the analog inputs, are routed by the multiplexers, amplified, and then converted from analog to digital. After this conversion, the data are managed by the internal control block and made available to the external system through SPI communication.

Through this chip, it is possible to develop robust and compact devices, in addition to providing an affordable solution when compared to ready-made systems.

D. Referential and Bipolar Electrode Montages

For biosignal acquisition, two electrode montages stand out for enabling better event detection: the referential montage and the bipolar montage. In the referential montage, the reference electrode is common to all active electrodes, whereas in the

bipolar montage, the potential difference is measured between two electrodes placed in adjacent regions. The referential montage is suitable for analyzing signals with respect to the same reference, while the bipolar montage is suitable for comparing electrical potentials from nearby regions.

III. Materials and Methods

A. Hardware Architecture

First, the system for acquiring and providing EOG signals was developed using the ADS1299-4 chip.

The circuit is composed of two main sections: the analog section, responsible for extracting and amplifying the biosignals; and the digital section, which provides the measurements through the SPI communication protocol. In this sense, the printed circuit board design can be seen in Figure 3.

Part "A" of the figure represents the analog side of the circuit. In this section, it can be observed that each electrode has an associated capacitive low-pass filter, whose purpose is to allow only frequencies below 6.9 kHz to be acquired. Furthermore, an active BIAS reference electrode is also present, whose function is to attenuate noise, such as interference from the power line, for example.

Part "B" of the figure shows the digital region of the system. This section can be connected to a computational device so that the chip can be configured, including parameters such as gain, sampling frequency, among others, and then provide the data according to the defined settings.

It is also worth noting that the two regions have their GND planes interconnected through connector J3. This ensures equipotentiality while maintaining the separation between the digital and analog regions. ***In addition, a current-limited power supply was used, with a maximum current of 4 mA for the analog section and 1 mA for the digital section. All these factors contribute to reducing interference and enhancing user safety.***

Moreover, a symmetrical power supply was adopted for the circuit, and the referential electrode montage was used.

The developed electrical schematic is shown in Figure 4. The electrical schematic was divided into two parts, A and B. Part A corresponds to the electrode connections, initially organized in a referential montage, and also includes analog filters responsible for attenuating noise and limiting the frequency range of the acquired signal. Part B corresponds to the SPI communication between the ADS1299-4 and the control system. In this section, some pins are connected to resistors in order to help stabilize the logic levels, reduce possible interference, and avoid undefined states in certain digital inputs. Unused pins should be kept at a known logic level, when necessary, through pull-up or pull-down resistors, preventing incorrect readings or undesired circuit behavior.

B. Signal Acquisition

Data acquisition was performed using the developed hardware together with a Raspberry Pi 4. Communication between the embedded system and the hardware was carried out through the SPI interface. For this stage, a Python code developed by [9] was used as a basis.

Next, the data collection stage was carried out in order to subsequently evaluate the quality of the signal provided by the circuit.

The selected electrode placement is shown in Figure 5, consisting of two active electrodes, one below and one above the eye, a reference electrode placed on the right earlobe, and a BIAS electrode placed on the left earlobe.

Additionally, the protocol used for this process was as follows: recording of 20 double blinks over 2 minutes; 1 minute in a resting state, with the participant blinking naturally and maintaining a fixed gaze; 10 facial contractions distributed over 1 minute; and, finally, 10 vertical eye movements, upward and downward, also performed over 1 minute. The data were saved in a CSV file.

C. Signal processing

It was necessary to process the stored data in order to make them more suitable for the tests that would be performed subsequently. Therefore, the following steps were carried out: outlier removal; digital filtering using a 0.5 Hz high-pass filter and a 15.0 Hz low-pass filter; windowing with 1-second windows and manual labeling of the windows that contained double blinks. After this process, a new CSV file was generated containing the columns *t_s*, *filtered_signal*, *window* (window with its respective ID) and *classification*.

D. Tests and Validation

A pilot study was conducted with two healthy volunteers to validate the hardware and signal acquisition process. Then, to check the performance of all system, the mean square power of a noise sample and a filtered signal sample was calculated using Equation 1. Subsequently, the average signal-to-noise ratio (SNR) was determined using Equation 2.

$$P = \frac{1}{N}\sum_{n=1}^{N} x^2[n] \tag{1}$$

$$\mathrm{SNR}_{dB} = 10\log_{10}\left(\frac{P_{\text{signal}}}{P_{\text{noise}}}\right) \tag{2}$$

In addition, a SVM model was trained and tested for double-blink identification, and its performance was evaluated using the metrics of accuracy, recall, and precision, calculated respectively by Equations 3, 4, and 5.

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{3}$$

$$\text{Recall} = \frac{TP}{TP + FN} \tag{4}$$

$$\text{Precision} = \frac{TP}{TP + FP} \tag{5}$$

- True Positive (TP): When the model predicts the positive class and the actual class is positive.

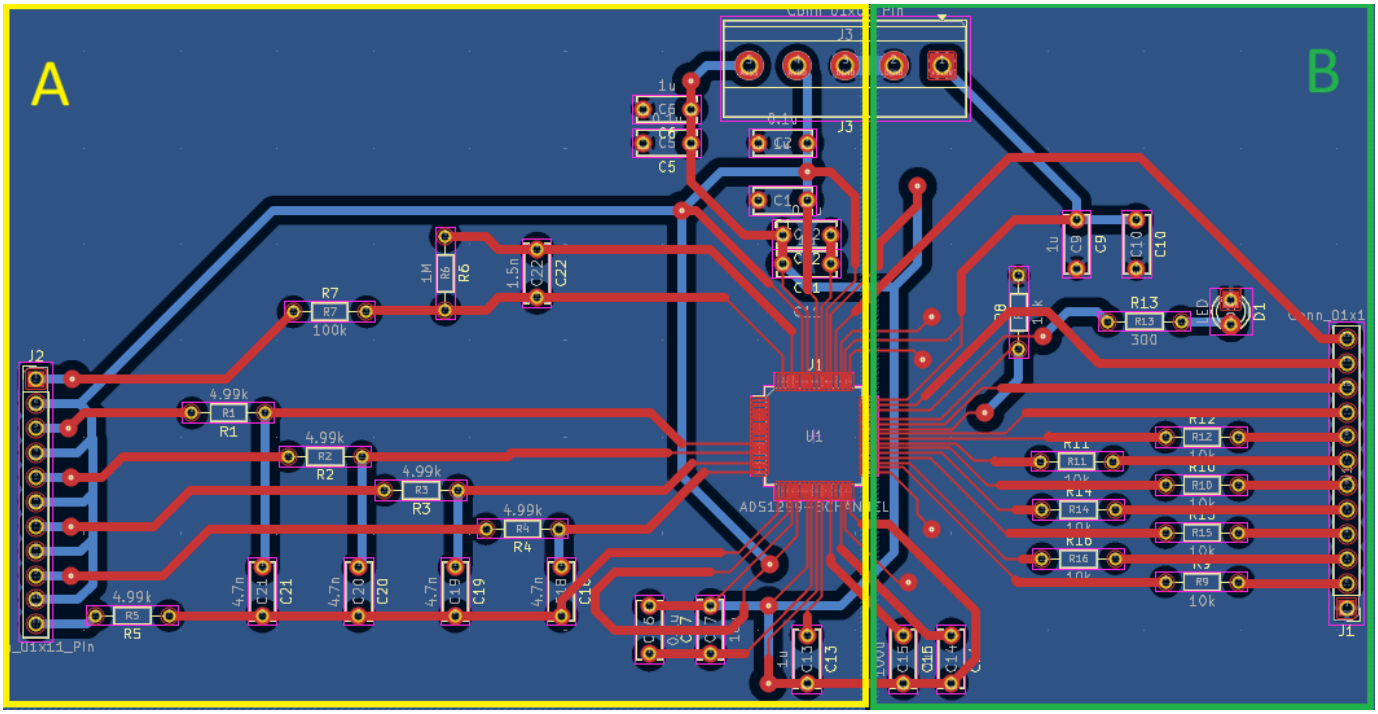

Fig. 3. Layout of the printed circuit board

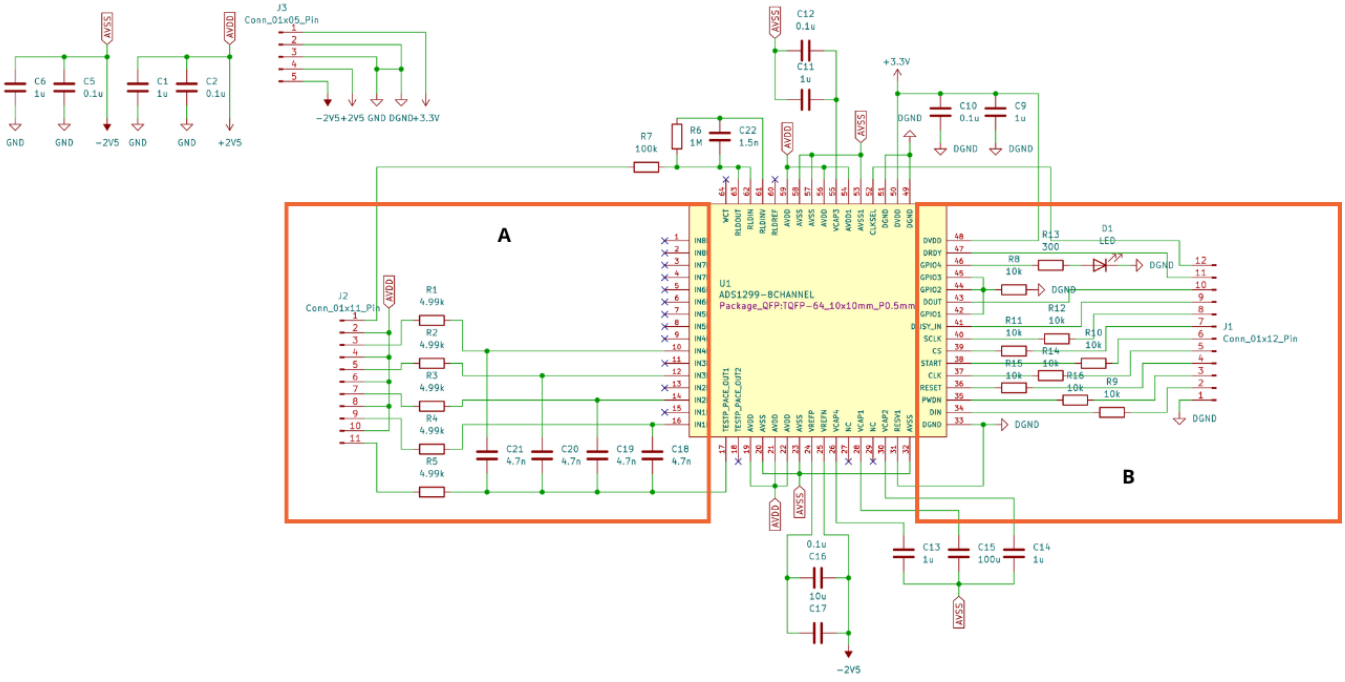

Fig. 4. System circuit schematic.

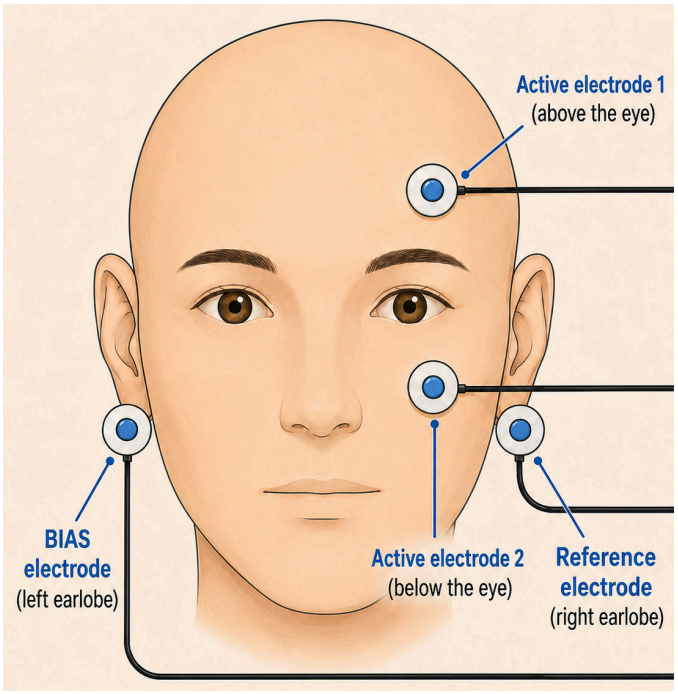

Fig. 5. Positioning of the electrodes.

- True Negative (TN): When the model predicts the negative class and the actual class is negative.
- False Positive (FP): When the model predicts a positive class but the actual class is negative.
- False Negative (FN): When the model predicts the negative class and the actual class is positive.

The SVM was selected because it has demonstrated good performance in EOG classification tasks even with relatively small datasets. In addition, it has parameters that allow control over the balance between the separation margin and classification errors. This test was essential to verify whether the developed solution is capable of extracting relevant information from the acquired signals.

Before training the model, the data were normalized using the StandardScaler function in Python. And after that, for the SVM model, the following settings were used: RBF kernel, a C value of 20, gamma set to 'scale', class_weight set to 'balanced', and random_state set to 42. The RBF kernel enables the separation of data that is not linearly separable. The C value was chosen to strike a balance between the width of the separation margin and the tolerance for misclassifications, while setting gamma to 'scale' allows this parameter to be calculated automatically. Additionally, 'balanced' class_weight was used to balance the classes. The training was conducted using 25% for testing and 75% for training.

It is also important to highlight that, for SVM training, the following metrics had to be extracted from each signal window: mean, minimum value, peak-to-peak amplitude, skewness, kurtosis, maximum absolute difference, and median crossing rate. **All the implemented code can be accessed at [5]**

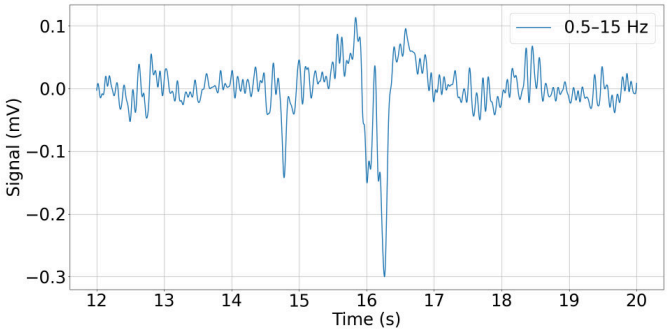

Fig. 6. EOG signal containing a double blink.

IV. Results and Discussion

Based on the developed hardware, it was possible to acquire EOG signals. However, it was necessary to adapt the electrode montage, since the referential configuration did not prove suitable for the application. Therefore, to overcome this issue, a bipolar montage was used by subtracting the signals from active electrodes 1 and 2 using software, rather than performing the subtraction analogically through the circuit.

To evaluate the developed hardware, the SNR was calculated. The system presented an SNR of -4.54 dB, indicating the presence of considerable noise levels in the acquired signal, possibly due to the prototype nature of the project. This value indicates that the noise power is greater than that of the useful signal. This noise caused some distortion in the signal, even after the application of digital filtering. However, the essential characteristics for double-blink detection were preserved, such as the presence of two consecutive peaks or valleys, as shown in Figure 6.

The model was trained and tested using data from two participants. Initially, the model was trained using data from participant 1 and tested using data from participant 2. The procedure was then reversed, with participant 2 data used for training and participant 1 data used for testing. This approach allowed the model's ability to generalize to individuals whose data were not included in the training set to be evaluated. Additionally, an experiment was conducted in which data from both participants were used for both training and testing the model.

The SVM machine learning model achieved the performance results shown in Table I, II e III. From these results, the following metrics were extracted: accuracy, precision, and recall, as presented in Table IV, V e VI.

TABLE I
Confusion Matrix for Training with Participant 1's Data and Testing with Participant 2's Data

	Predicted Class	
Actual Class	**No blink**	**Double blink**
No blink	250	12
Double blink	10	18

TABLE II
CONFUSION MATRIX FOR TRAINING WITH PARTICIPANT 2'S DATA AND TESTING WITH PARTICIPANT 1'S DATA

	Predicted Class	
Actual Class	**No blink**	**Double blink**
No blink	252	11
Double blink	7	20

TABLE III
CONFUSION MATRIX FOR TRAINING AND TESTING WITH DATA FROM PARTICIPANTS 1 AND 2

	Predicted Class	
Actual Class	**No blink**	**Double blink**
No blink	127	4
Double blink	0	14

According to Tables I and II, the model showed limited performance in generalizing double-blink detection across different participants, indicating the need to expand the dataset with signals acquired from a larger number of individuals. The corresponding performance metrics are presented in Tables IV and V. In contrast, Tables III and VI show that the model achieved better classification performance when data from both participants were combined and subsequently divided into training and test sets, reaching a precision of 78%. However, this experiment does not assess generalization to unseen participants, since data from both individuals were represented in the dataset used for training and testing. Therefore, these results highlight the need for future studies involving a larger and more representative number of participants to enable a more robust evaluation of the generalization capability of the developed system.

Furthermore, the model was deployed on a Raspberry Pi 4 and achieved a prediction execution time of 7.11 ms. The low processing time highlights the feasibility of its use in real-time applications, especially in embedded systems aimed at human-machine interaction.

A. Limitations

Despite the positive results, the project presents some limitations, such as the reduced number of participants used in the system tests, who, moreover, did not have physical disabilities, as well as possible limitations related to the developed circuit,

TABLE IV
SVM MODEL PERFORMANCE METRICS REGARDING TABLE I

Model	Accuracy	Precision	Recall

Model	Accuracy	Precision	Recall
SVM	0.97	0.78	1

including the electrode montage configuration and the choice of a symmetrical power supply.

The reduced number of participants prevents the generalization of the obtained results. Additionally, the participants do not directly represent the target audience of the project, which may present specific difficulties when using the system that were not observed in the evaluated individuals.

The ADS1299-4 chip enables differential signal acquisition through the positive and negative inputs of its channels. This feature could have been explored in the project through a bipolar montage implemented directly in the hardware, instead of performing signal subtraction in software. Such an approach could contribute to the rejection of common-mode noise and simplify the signal processing stage.

In addition to this hardware-level bipolar montage, other measures could further reduce the noise levels observed in the system. The absence of a dedicated notch filter for rejecting power-line frequency interference (50/60 Hz) represents another opportunity for improvement, through an analog notch stage. Furthermore, although the analog and digital ground planes were interconnected through a single point at connector J3, improvements in board routing, with greater isolation between digital and analog traces, could further reduce the coupling between the two sections of the circuit.

Moreover, the circuit was powered using a symmetrical power supply. However, an asymmetrical power supply could be investigated in future versions, provided that the appropriate biasing conditions and input range of the ADS1299-4 are respected. This alternative could simplify the solution by reducing the number of power supplies required for circuit operation.

V. CONCLUSION

This work presented the design, implementation, and preliminary validation of an open-source EOG acquisition platform for assistive human-machine interfaces. The main contribution of this work lies in the open-source hardware itself — the detailed schematics, PCB layout, and signal acquisition methodology — which addresses a recognized gap in the literature regarding reproducibility of custom EOG acquisition circuits and provides a foundation upon which other researchers can build, adapt, and improve.*

The SVM-based classification results, achieving a precision of 78% under the most favorable experimental condition, should be interpreted as an initial indication that the developed hardware is capable of capturing signal features relevant to double-blink detection, rather than as conclusive evidence of the system's readiness for real-world

assistive applications. The limited number of participants, the absence of individuals with motor disabilities among the evaluated subjects. Similarly, the negative SNR obtained indicates that noise levels remain a considerable challenge for the current hardware revision, even though the essential morphological features of double-blink events were still discernible after filtering.*

Future work should therefore prioritize expanding the dataset to include a larger and more representative population, including individuals with motor disabilities; implementing hardware-level improvements to reduce noise, such as a differential bipolar montage, dedicated notch filtering, and improved analog-digital isolation; and conducting more rigorous cross-subject validation to better assess the system's generalization capability. While the results obtained so far are encouraging as a proof of concept, further development and more extensive validation are necessary before the platform can be considered a robust or reliable solution for assistive device interaction.*

***Abstract*—This study investigates the potential of phonocardiogram (PCG) signals to support the classification of elevated blood pressure using supervised machine learning. Heart sound recordings from 78 participants were segmented into S1, systole, S2, and diastole using a Logistic Regression–Hidden Semi-Markov Model (LR-HSMM). Temporal, spectral, and statistical features were extracted with the TSFRESH library, followed by Correlation-based Feature Selection (CFS) to identify the most relevant features. For the binary classification task, participants whose reference blood pressure measurements fell within the pre-hypertensive or hypertensive ranges were grouped into an elevated blood pressure class and compared with normotensive participants. Multiple classifiers were evaluated using three PCG representations: the complete recording, fused segment-specific features, and individual cardiac cycle segments. Each representation was combined with demographic variables comprising age, weight, height, and sex. Among the evaluated segment-specific configurations, S2 features combined with demographic variables yielded the highest observed F1-score of 85.25% with Logistic Regression. These findings suggest that the combination of S2-derived and demographic features contains information associated with elevated blood pressure in the evaluated dataset. Despite the limited sample size and single-dataset evaluation, these exploratory results support further investigation of PCG-based methods for potential use in non-invasive cardiovascular risk screening.**

***Index Terms*—Elevated blood pressure, phonocardiography, segment-specific analysis, machine learning**

I. Introduction

Hypertension (HTN) remains a major global public health challenge and a leading modifiable risk factor for cardiovascular diseases (CVDs) [1]. According to the World Health Organization (WHO), CVDs account for approximately 32% of deaths worldwide [2]. Recent estimates indicate that approximately 1.4 billion adults were living with hypertension in 2024, while around 44% were unaware of their condition, partly because hypertension is frequently asymptomatic [3].

Early identification of altered blood pressure enables timely clinical follow-up and lifestyle interventions that may reduce the risk of cardiovascular complications [4]. Conventional blood pressure assessment relies primarily on cuff-based measurements performed in clinical settings, as well as on ambulatory blood pressure monitoring (ABPM) and home blood pressure monitoring (HBPM) [5]. Although these methods are clinically established, they provide intermittent measurements and may cause discomfort, particularly during repeated or nocturnal assessments. Consequently, blood pressure variations occurring between measurements may remain unobserved [6].

The 2025 Brazilian Hypertension Guideline classifies office blood pressure measurements with systolic blood pressure (SBP) between 120 and 139 mmHg and/or diastolic blood pressure (DBP) between 80 and 89 mmHg as pre-hypertension, whereas measurements with SBP $\geq$ 140 mmHg and/or DBP $\geq$ 90 mmHg fall within the hypertensive range [7]. The guideline also emphasizes out-of-office blood pressure assessment and identifies cuffless and wearable technologies as promising approaches for more frequent and comfortable monitoring.

Within this context, digital phonocardiography (PCG) emerges as a promising complementary modality for non-invasive cardiovascular monitoring. Unlike oscillometric methods, PCG acquisition does not require cuff inflation or arterial

compression, enabling heart sounds to be recorded with minimal physical interference. This characteristic may facilitate repeated measurements and future integration into wearable devices, with potentially less disruption to daily activities and sleep [8].

The physiological rationale for investigating this technology lies in the relationship between heart sounds and cardiovascular hemodynamics. The cardiac cycle is divided into two main phases: systole and diastole. Systole corresponds to ventricular contraction and begins near the first heart sound (S1), which is primarily associated with the closure of the mitral and tricuspid valves. Diastole represents ventricular relaxation and begins near the second heart sound (S2), which is primarily associated with the closure of the aortic and pulmonary valves [9], [10]. The literature suggests that the timing, intensity, and spectral characteristics of heart sounds may be associated with arterial pressure variations and other hemodynamic changes [11], [12].

The complex temporal and spectral information contained in PCG recordings represents a promising opportunity for the development of machine learning techniques for blood pressure estimation and classification. These techniques can identify acoustic patterns associated with blood pressure variations and support the development of non-invasive screening approaches [13]–[15]. However, the discriminative contribution of individual cardiac cycle segments to elevated blood pressure classification remains insufficiently explored.

The present study compares complete, fused, and segment-specific PCG representations for elevated blood pressure classification using a public dataset published in 2025 as an exploratory proof of concept. Automatic cardiac cycle segmentation is used to isolate and individually analyze S1, systole, S2, and diastole, enabling comparison of classification performance across segment-specific representations. A large set of temporal, spectral, and statistical features is subsequently extracted to train supervised machine learning models. For the binary classification task, participants whose reference blood pressure measurements fell within the pre-hypertensive or hypertensive ranges were grouped into a single target class, hereafter referred to as elevated blood pressure, and compared with normotensive participants. Given the limited sample size and controlled acquisition conditions, this study is intended as an exploratory step toward future non-invasive approaches to blood pressure screening.

II. Related Works

In recent years, several studies have investigated the relationship between phonocardiographic (PCG) signals and blood pressure, seeking less invasive alternatives for continuous or intermittent blood pressure estimation. Overall, these works suggest that acoustic information from the cardiac cycle contains relevant physiological patterns associated with hemodynamic variations.

One of the early relevant approaches was proposed in [13], where only the second heart sound (S2) was used for blood pressure estimation. The method extracts frequency-domain features using FFT and employs an SVM regression model. Although moderate correlations between acoustic features and blood pressure were reported, the study did not compare S2 with other cardiac cycle segments, preventing an assessment of their relative contributions.

In [14], the authors adopt a deep learning-based approach combining Mel-frequency cepstral coefficients (MFCCs), deltas, and delta-deltas with demographic information. The architecture employs convolutional neural networks with Squeeze-and-Excitation attention blocks, achieving improved performance in systolic and diastolic blood pressure regression. However, as is common in deep learning-based approaches, the physiological interpretability of the learned representations remains limited.

To exploit complementary mechanical information, a multimodal approach combining PCG and ballistocardiogram (BCG) signals was proposed in [16], with temporal intervals extracted between mechanical cardiac events. These intervals showed strong correlations with systolic blood pressure and were used as input to Random Forest-based regression models. Despite leveraging multiple modalities, the method still relies on handcrafted interval definitions and does not investigate the contribution of individual cardiac cycle segments.

More recently, a real-time blood pressure monitoring framework based on nonlinear relationships between heart sound features and blood pressure was proposed in [17]. The method employs multifeature heart sound analysis combined with an improved Whale Optimization Algorithm (T-WOA) to estimate systolic and diastolic blood pressure continuously during surgery. Clinical validation demonstrated promising accuracy for intraoperative monitoring. Nevertheless, the study focuses on the regression of absolute blood pressure values and does not investigate the discriminative contribution of individual cardiac cycle segments or compare complete, fused, and segment-specific PCG representations for elevated blood pressure classification.

Unlike the aforementioned studies, the present work does not aim to estimate absolute blood pressure values. Instead, it frames blood pressure assessment as a binary classification task, distinguishing normotensive participants from those with elevated blood pressure. Moreover, the proposed framework automatically segments the cardiac cycle into S1, systole, S2, and diastole, enabling comparison of the segment-specific configurations. Complete, fused, and segment-specific PCG representations are then evaluated using multiple supervised machine learning models.

Table I summarizes and compares the main characteristics of the reviewed works with the proposed approach.

III. Materials and Methods

The proposed framework consists of six sequential stages: (i) PCG dataset acquisition, (ii) signal preprocessing, (iii) cardiac cycle segmentation, (iv) signal reconstruction, (v) feature extraction and selection, and (vi) machine learning-based elevated blood pressure classification. An overview of the complete pipeline is presented in Figure 1, followed by a detailed description of each stage.

TABLE I
COMPARISON OF RELATED STUDIES AND THE PROPOSED APPROACH.

Work/Year	Signals	Features	Model	Task
[13]/2015	PCG (S2 only)	Frequency-domain features (FFT of S2)	SVM regression	Continuous estimation of SBP, DBP, MAP
[14]/2025	PCG + metadata	MFCCs, deltas, and delta-deltas (feature maps)	CNN with Squeeze-and-Excitation blocks	SBP and DBP regression
[16]/2022	PCG + BCG	Temporal intervals between cardiac events (e.g., S1–J, J–S2)	Random Forest regression	SBP estimation
[17]/2026	PCG	Multifeature PCG analysis with nonlinear separation parameters	T-WOA optimized regression model	Real-time estimation of SBP, DBP, and blood pressure variations during surgery
This study	PCG + metadata	Time-, frequency-, statistical-, and derived-domain features from cardiac cycle segments (S1, systole, S2, diastole)	Supervised models (LR, SVM, RF, XGBoost, GB, KNN, MLP)	Binary classification (normotensive vs. elevated blood pressure)

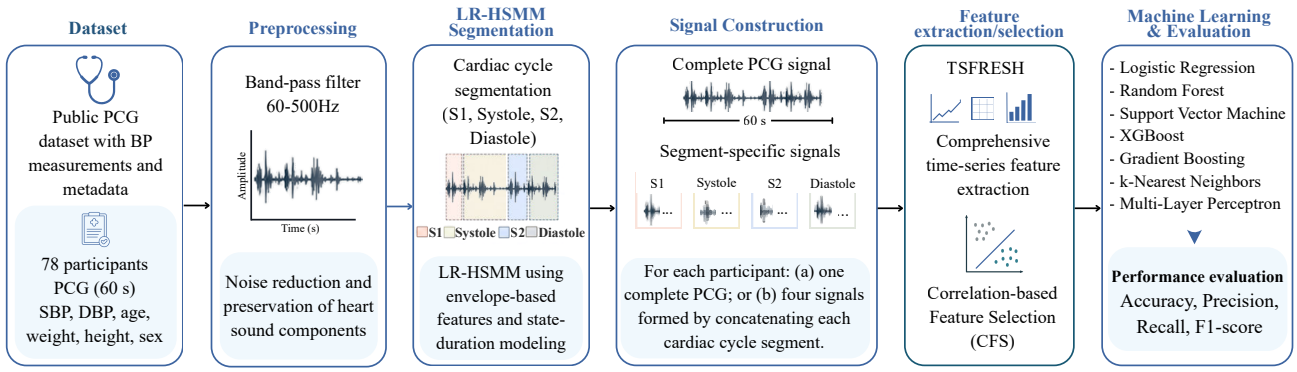

Fig. 1. Pipeline of the proposed PCG-based elevated blood pressure classification framework.

A. Dataset and Class Definition

This study used the publicly available *Phonocardiogram Signal Dataset Paired with Blood Pressure Measurements*, providing one 60-s PCG recording and one retained SBP/DBP pair for each of 78 participants under controlled conditions [18]. BP and PCG were acquired simultaneously, with acquisition repeated only when anomalies were detected. The dataset also includes pulse rate, age, weight, height, and sex. Participants were 21 to 66 years old. No demographic values were missing, and no imputation was required.

Before data acquisition, participants remained seated for 5 min in a quiet, temperature-controlled room. Blood pressure was measured using a NISSEI DSK-1031 automated monitor with the cuff positioned on the upper left arm. Simultaneously, PCG signals were recorded for 60 s using a ThinkLabs One digital stethoscope positioned at the pulmonic auscultation area, located at the second left intercostal space near the sternum. The stethoscope had a frequency response of 20–2000 Hz.

For the binary classification task, participants were categorized using the reference SBP and DBP measurements available in the dataset. Those with SBP below 120 mmHg and DBP below 80 mmHg were assigned to the normotensive class. Participants in the pre-hypertensive range (SBP 120–139 mmHg and/or DBP 80–89 mmHg) and hypertensive range (SBP $\geq$ 140 mmHg and/or DBP $\geq$ 90 mmHg) were combined into a single elevated blood pressure class to reduce class fragmentation in the limited dataset. The final dataset comprised 38 normotensive participants and 40 participants in the elevated blood pressure class. These labels represent blood pressure ranges derived from the available reference measurements and should not be interpreted as independent clinical diagnoses of hypertension.

B. Signal Preprocessing and Segment Construction

For each participant, the 60-s band-pass-filtered PCG recording provided in the dataset was analyzed. The dataset authors applied a band-pass filter between 60 and 500 Hz to attenuate background noise and retain the principal frequency components of the first (S1) and second (S2) heart sounds [18].

Cardiac cycle segmentation was performed using the Logistic Regression–Hidden Semi-Markov Model (LR-HSMM) proposed in [19]. This method combines the temporal modeling capabilities of a HSMM, which explicitly accounts for the expected duration of each cardiac state (S1, systole, S2, and diastole), with logistic regression to estimate the emission probabilities of each hidden state from features extracted from the PCG signal. Unlike conventional HMM-based approaches, which typically model state emissions using Gaussian distributions, logistic regression provides discriminative estimates for distinguishing cardiac states.

Figure 2 illustrates an example of a PCG signal segmented using the LR-HSMM algorithm. The method employs four envelope-based features — homomorphic, Hilbert, wavelet, and Power Spectral Density (PSD) envelopes — to characterize the signal. The most likely sequence of cardiac states is then estimated using an extended version of the Viterbi algorithm capable of handling recordings that do not begin

precisely at the start of a cardiac cycle. The combination of temporal modeling, explicit state-duration information, and discriminative emission estimation supports the segmentation of S1 and S2 in noisy recordings, as reported in the original study.

Two signal representations were investigated. In the first approach, the complete PCG recording was used without modification, preserving the natural temporal structure of the cardiac cycle. The second approach aimed to evaluate whether individual cardiac cycle segments provide distinct information for the classification of elevated blood pressure. After segmenting each recording into S1, systole, S2, and diastole, four segment-specific signals were reconstructed for each participant by sequentially concatenating all occurrences of the same segment type. Consequently, each participant was represented by four additional recordings: one containing only S1 segments, one containing only systolic segments, one containing only S2 segments, and one containing only diastolic segments. This strategy enabled the independent evaluation of each cardiac cycle segment and the investigation of whether specific segments contain more relevant information for elevated blood pressure classification.

C. Feature Extraction

Features were extracted using TSFRESH (Time Series Feature Extraction Based on Scalable Hypothesis Tests) [20], which computes statistical, temporal, spectral, autocorrelation, entropy, wavelet, and peak-related descriptors. In total, 778 PCG-derived features were independently extracted from the complete recording and from each segment-specific signal reconstructed from S1, systole, S2, and diastole.

In an additional feature-level fusion experiment, the feature vectors extracted from S1, systole, S2, and diastole were concatenated before feature selection and classifier training. For all evaluated representations, the PCG-derived features were combined with age, weight, height, and sex.

D. Feature Selection

Correlation-based Feature Selection (CFS) was used to reduce dimensionality and redundancy in the feature vectors [21]. As a filter-based method, CFS favors subsets containing features that are strongly associated with the target class while exhibiting low interfeature correlation. A best-first search strategy was employed to identify the subset with the highest merit.

CFS was applied independently to the complete-PCG, segment-specific, and feature-fusion representations. Within each cross-validation iteration, CFS was fitted using only the training folds, and the resulting feature subset was subsequently applied to the held-out test fold. This procedure prevented information from the test fold from influencing feature selection.

E. Model Training

Machine learning methods are well suited to PCG analysis because they can capture complex temporal, spectral, and nonlinear patterns in heart sounds. Accordingly, this study evaluated a set of supervised classifiers commonly applied to biomedical signal classification.

Logistic Regression (LR) is a probabilistic linear classifier widely used for binary classification tasks. Due to its interpretability, computational efficiency, and competitive performance in problems with approximately linear decision boundaries, it is commonly employed as a baseline model in biomedical signal classification [22].

Random Forest (RF) is an algorithm based on multiple decision trees combined through the bagging technique. This strategy reduces unwanted variance and helps mitigate overfitting, while also enabling the capture of nonlinear relationships among variables [23]. Its stability and good generalization ability make it widely used in biomedical tasks.

Support Vector Machine (SVM) models with radial basis function (RBF) and polynomial (Poly) kernels were included due to their ability to project data into higher-dimensional spaces, enabling the definition of nonlinear decision boundaries [24]. SVMs are known for their consistent performance on high-dimensional datasets and for their ability to maximize the margin between classes, a property frequently exploited in physiological signal analysis.

XGBoost is one of the most efficient implementations of gradient boosting methods based on decision trees. It builds models sequentially, where each new tree corrects the residual errors of the previous ones, enabling the capture of complex patterns and feature interactions [25].

K-Nearest Neighbors (KNN) classifies a sample based on the majority class among its nearest neighbors. Although simple, the method often performs well in scenarios where data exhibits well-defined cluster structures [26].

Gradient Boosting (GB) also follows the boosting principle, combining weak learners iteratively to progressively reduce error [27]. Like XGBoost, it performs well on tabular datasets and is effective in capturing complex relationships among features derived from physiological signals.

Finally, the Multilayer Perceptron (MLP) is an artificial neural network architecture composed of multiple fully connected layers [28]. Its flexibility allows it to model highly nonlinear relationships, making it suitable for datasets with a large number of extracted features, such as biomedical signals.

Models were implemented using scikit-learn, except XGBoost, which used the XGBoost library. Default settings were retained, except for LR and MLP, whose maximum iteration limits were set to 1,000 and 500, respectively, and for the SVM models, which used RBF and third-degree polynomial kernels.

F. Evaluation Metrics

The evaluation metrics used in this work were accuracy, precision, recall, F1-score, and confusion matrices, including true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN). The elevated blood pressure class was considered the positive class. In this screening-oriented classification task, false-negative predictions are particularly

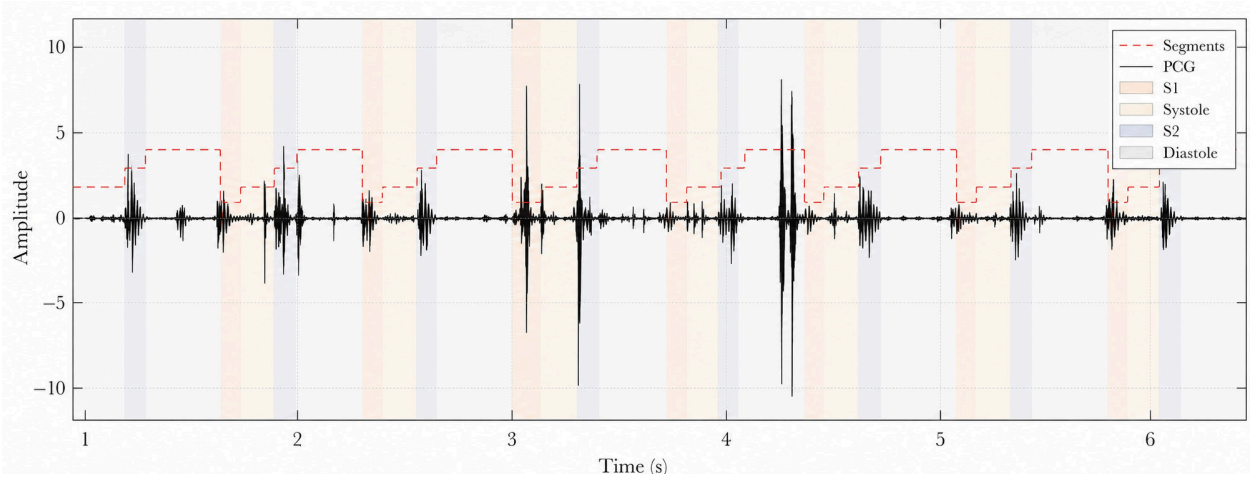

Fig. 2. Example of a phonocardiogram segmentation using the algorithm proposed in [19].

relevant because they correspond to participants with elevated blood pressure measurements incorrectly classified as normotensive. Therefore, precision, recall, and F1-score complement accuracy by providing a more detailed assessment of classification performance. Confusion matrices were normalized by the total number of predictions.

Model performance was evaluated using stratified 10-fold cross-validation. The participants were divided into ten approximately equal folds while preserving the proportion of normotensive and elevated blood pressure samples. In each iteration, nine folds were used for training and the remaining fold was used for testing. This process was repeated until each fold had been used once as the test set. The reported metrics correspond to the average values obtained across the ten folds.

IV. Results

Three experimental scenarios were evaluated. In the first scenario, features were extracted from the complete 60-s PCG recording without cardiac cycle segmentation, establishing the baseline representation. In the second scenario, the feature vectors extracted from S1, systole, S2, and diastole were concatenated into a single representation before feature selection and classification. In the third scenario, the features extracted from each cardiac cycle segment were evaluated independently, resulting in four segment-specific classification experiments. In all three scenarios, the PCG-derived features were combined with age, weight, height, and sex.

A. Complete-PCG Baseline

To establish a baseline performance, full PCG signals were initially used without segmentation into specific cardiac cycle segments. The processing followed the proposed pipeline, starting with feature extraction using the tsfresh package, which generates a large and diverse set of time-domain and spectral descriptors. This process resulted in 778 features extracted from the audio signals.

These features were then concatenated with demographic information provided by the dataset authors: age, weight, height, and sex, resulting in a total of 782 initial features. The inclusion of these physiological attributes is justified by their known relationship with hemodynamic parameters, potentially complementing patterns extracted directly from the cardiac signal.

In the next stage, feature selection was applied using the Correlation-based Feature Selection (CFS) method, whose objective is to identify feature subsets with high correlation to the target class and low redundancy among features. After this process, the feature set was reduced to 18 features, representing less than 3% of the original total, which substantially reduces the dimensionality of the problem and mitigates the risk of overfitting.

These selected features mainly include information related to participant weight, spectral coefficients derived from the Fourier Transform (phase and imaginary components), autoregressive model-derived measures, temporal statistics such as the median, autocorrelation-based attributes, temporal interaction features, and Continuous Wavelet Transform coefficients at different scales. This set suggests that both cardiac signal characteristics and participant-specific information have discriminative potential for blood pressure-related classification.

With the final feature set defined, model training was performed. All classifiers were trained using the same preprocessed data, ensuring comparability across results. Performance metrics indicated that the best performance in this stage was achieved by the Logistic Regression model, which obtained an F1-score of 62.29%, as shown in Table II. The corresponding confusion matrix is presented in Figure 3.

B. Feature-Level Fusion

In the second scenario, the feature vectors independently extracted from S1, systole, S2, and diastole were concatenated into a single representation. Since TSFRESH extracted 778 features from each cardiac cycle segment, the concatenated representation contained 3,112 PCG-derived features. Age, weight, height, and sex were subsequently added, resulting in 3,116 initial attributes per participant.

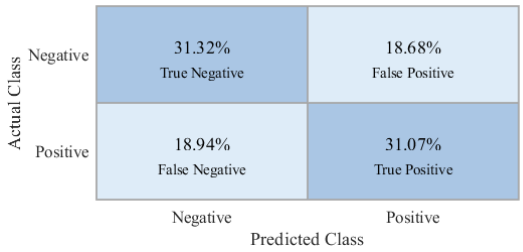

Fig. 3. Confusion matrix of the LR model without segmentation.

TABLE II
MODEL PERFORMANCE USING THE COMPLETE PCG RECORDING.

Model	Accuracy (%)	F1 (%)	Precision (%)	Recall (%)
Logistic Regression	62.39	62.29	62.45	62.13
Random Forest	59.77	58.52	59.89	59.15
SVM (RBF)	58.35	57.89	58.53	57.26
SVM (Poly)	52.06	52.02	52.06	51.99
XGBoost	53.15	53.41	53.11	53.71
KNN	51.03	50.79	51.04	50.54
GB	51.05	50.72	51.06	50.39
MLP	59.44	58.96	59.66	58.28
Average (μ)	55.75	55.65	55.82	55.48

CFS was applied to the expanded feature representation to reduce dimensionality and feature redundancy, retaining 42 attributes for classification. Table III presents the performance obtained by the evaluated classifiers.

Logistic Regression achieved the highest performance in this scenario, with an accuracy of 78.11%, an F1-score of 78.00%, a precision of 78.41%, and a recall of 77.59%. The MLP obtained the second-highest F1-score, reaching 77.14%, followed by SVM-RBF with 73.28%. The mean F1-score across all classifiers was 70.33%.

The normalized confusion matrix of the Logistic Regression model is presented in Fig. 4. True-negative and true-positive predictions accounted for 39.30% and 38.80% of all predictions, respectively, whereas false-positive and false-negative predictions accounted for 10.70% and 11.20%. Compared with the complete-PCG baseline, feature-level fusion increased the highest F1-score from 62.29% to 78.00%, representing a 15.71 percentage-point improvement.

TABLE III
MODEL PERFORMANCE USING CONCATENATED SEGMENT-SPECIFIC FEATURES.

Model	Accuracy (%)	F1 (%)	Precision (%)	Recall (%)
Logistic Regression	78.11	78.00	78.41	77.59
Random Forest	67.88	67.77	68.00	67.54
SVM (RBF)	73.38	73.28	73.56	73.00
SVM (Poly)	69.75	69.62	69.91	69.33
XGBoost	62.74	63.16	62.45	63.89
KNN	73.45	73.07	74.12	72.05
GB	60.72	60.63	60.76	60.51
MLP	77.10	77.14	77.01	77.27
Average (μ)	70.39	70.33	70.40	70.15

C. Segment-Specific Evaluation

In the third scenario, the signals reconstructed from S1, systole, S2, and diastole were evaluated independently. For each cardiac cycle segment, TSFRESH extracted 778 PCG-derived features, which were combined with age, weight, height, and sex, resulting in 782 initial attributes per representation. CFS was then independently applied to each segment-specific feature set.

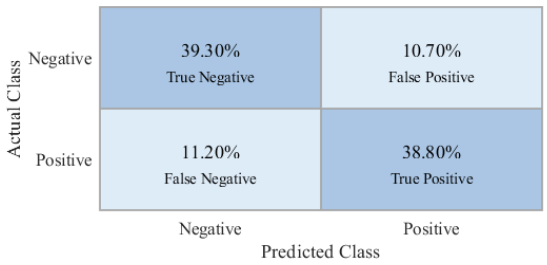

Fig. 4. Confusion matrix of the LR classifier using concatenated features from the S1, systole, S2, and diastole segments.

Tables IV–VII present the classification results obtained for S1, systole, S2, and diastole, respectively. All segment-specific representations achieved higher average F1-scores than the complete-PCG baseline. The average F1-scores were 64.63% for S1, 71.32% for systole, 77.01% for S2, and 64.91% for diastole, compared with 55.58% for the complete recording.

For S1, Logistic Regression achieved the highest F1-score of 69.78%. For systole, the best result was obtained by the MLP, with an F1-score of 77.79%. For diastole, the MLP achieved the highest F1-score of 70.03%. The configuration combining S2 features with demographic variables yielded the highest observed classification performance. Logistic Regression achieved an accuracy of 85.46%, an F1-score of 85.25%, a precision of 86.48%, and a recall of 84.06%. The MLP and SVM-RBF also achieved high performance using S2, with F1-scores of 84.45% and 82.00%, respectively. Overall, the best segment-specific result exceeded the complete-PCG baseline by 22.96 percentage points and the feature-level fusion result by 7.25 percentage points in terms of F1-score.

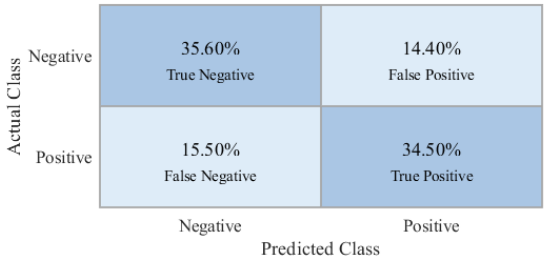

Fig. 5. Confusion matrix for the LR model using the S1 segment.

The confusion matrices of the best-performing classifier for each cardiac cycle segment are shown in Figs. 5–8. The configuration combining S2 features with demographic variables showed the highest concentration of predictions along the main diagonal, with lower false-positive and false-negative proportions than the other segment-specific representations. The systolic representation also produced a comparatively

balanced distribution of correct classifications, whereas S1 and diastole presented higher proportions of misclassified samples. These findings are consistent with the performance metrics and show that the configuration combining S2 features with demographic variables provided the best balance between identifying normotensive participants and participants with elevated blood pressure.

V. DISCUSSION

This study compared complete, fused, and segment-specific PCG representations, each combined with age, weight, height, and sex. The highest observed F1-scores were 62.29% for complete-PCG and 78.00% for feature-level fusion. Among the segment-specific configurations, S2 features combined with demographic variables yielded the highest observed F1-score of 85.25% with Logistic Regression and the highest mean F1-score across classifiers. Because multiple representations and classifiers were compared using the same cross-validation results, these comparisons are exploratory and the highest observed performance may be optimistic.

One possible physiological explanation for the higher observed performance of the configuration based on S2 features and demographic variables is that S2 is primarily associated with the closure of the aortic and pulmonary valves, whose acoustic characteristics may reflect variations in arterial pressure gradients. This interpretation is consistent with previous studies that identified relationships between S2-derived characteristics and blood pressure variations [11]–[13].

Although feature-level fusion outperformed the complete-PCG configuration, it did not surpass the configuration combining S2 features with demographic variables. Within the evaluated models, adding features from S1, systole, and diastole did not improve performance over the combined S2 and demographic feature set. The additional features may have introduced redundant or less discriminative variability, even after CFS. Further analyses are required to determine the separate contributions of PCG features and demographic variables.

Logistic Regression achieved the best result in the complete-PCG, feature-fusion, and S2 experiments, while more complex models did not consistently improve performance. Considering the limited sample size and the dimensionality reduction performed by CFS, the selected feature space may have favored a comparatively simple decision boundary. This result also suggests that increasing model complexity does not necessarily improve classification when the number of participants is limited.

Several limitations should be considered. The dataset contains only 78 participants and was acquired under controlled conditions using a single PCG device and auscultation location, which restricts the generalization of the findings to other populations and acquisition environments. In addition, the classes were defined from the available reference blood pressure measurements and represent measurement ranges rather than independent clinical diagnoses of hypertension. All experimental scenarios included age, weight, height, and sex. Therefore, we did not separately quantify the contributions of PCG-derived features and participant-related variables. Finally, LR-HSMM segmentation was not evaluated against manual annotations or an independent reference.

VI. CONCLUSION

This study compared complete, fused, and segment-specific PCG representations, all combined with demographic variables, for elevated blood pressure classification. The configuration combining S2 features with demographic variables yielded the highest observed performance, while feature-level fusion did not improve upon it. These findings suggest that PCG information associated with blood pressure ranges may vary across cardiac cycle phases.

If externally validated, segment-specific PCG analysis could support preliminary screening followed by confirmatory cuff-based measurement. However, the limited sample and single controlled dataset currently preclude clinical generalization.

Abstract—Objective and reproducible tools are required to monitor motor rehabilitation in Parkinson's disease (PD) beyond subjective clinical scales. This paper presents a fully automated MATLAB-based software platform for processing surface electromyography (sEMG) signals acquired during serious-gamebased and conventional rehabilitation sessions. The platform integrates four functional modules: data input and loading, signal processing and feature extraction, visualization and graphical user interface (GUI), and statistical analysis with automated reporting. From the raw sEMG recordings of five upper-limb muscles, the system automatically applies a sequential preprocessing pipeline, extracts time-domain, spectral, and nonlinear features, detects muscle activation onset/offset events, and performs paired statistical testing with automated normality assessment via the Shapiro-Wilk test. A preliminary validation was performed on a cohort of fifteen PD patients who completed twelve sessions with the serious game *RehaBEElitation*, plus five patients undergoing conventional physiotherapy. Seven statistically significant intragroup improvements ($p < 0.05$, uncorrected for multiple comparisons) were detected in the experimental group, including increases in task-specific peak amplitude, root mean square (RMS) amplitude, Katz fractal dimension, logarithm of the TeagerKaiser energy operator (log-TKEO), muscle activation rate, and inter-muscular amplitude ratios. The platform constitutes a reproducible, clinician-oriented solution for objective sEMGbased evaluation of PD rehabilitation and is extensible to other neuromuscular disorders. The results presented are preliminary and reflect a development-stage tool requiring further validation with larger samples and intergroup analysis.

Index Terms—Parkinson's disease, surface electromyography, rehabilitation monitoring, serious games, signal processing, MATLAB, automated platform, preliminary validation

I. Introduction

Parkinson's disease (PD) is a progressive neurodegenerative disorder that compromises motor function, manifesting with resting tremor, rigidity, bradykinesia, and postural instability [1], [2]. It is the second most prevalent neurodegenerative disease and the one with the fastest global expansion; projections suggest that the number of affected individuals will exceed 25 million by 2050 [3]. Current pharmacological and surgical treatments—including levodopa administration and deep brain stimulation—provide only symptomatic relief without halting disease progression. Motor rehabilitation therefore emerges as an essential strategy to preserve patient autonomy and quality of life [4].

Serious games and virtual environments have gained relevance as innovative rehabilitation resources, promoting active patient participation and facilitating task-oriented motor training [5], [6]. However, the evaluation of these interventions still depends predominantly on subjective clinical scales—such as the MDS-UPDRS or timed functional tests—which may fail to detect subtle motor changes. More than 70% of rehabilitation studies in PD rely exclusively on such conventional assessments [4], [7].

Surface electromyography (sEMG) offers a noninvasive means of recording neuromuscular activity, enabling objective characterisation of atypical activation patterns in PD [8], [9]. Despite this potential, fully automated computational tools that integrate sEMG processing into serious-game-based rehabilitation protocols for PD remain scarce [7]. Most existing platforms rely on traditional clinical scales, use only kinematic or inertial data, or require manual offline processing of sEMG signals, limiting clinical applicability and reproducibility.

This paper describes the design, functional capabilities, and preliminary validation of a MATLAB-based software

#Restrita

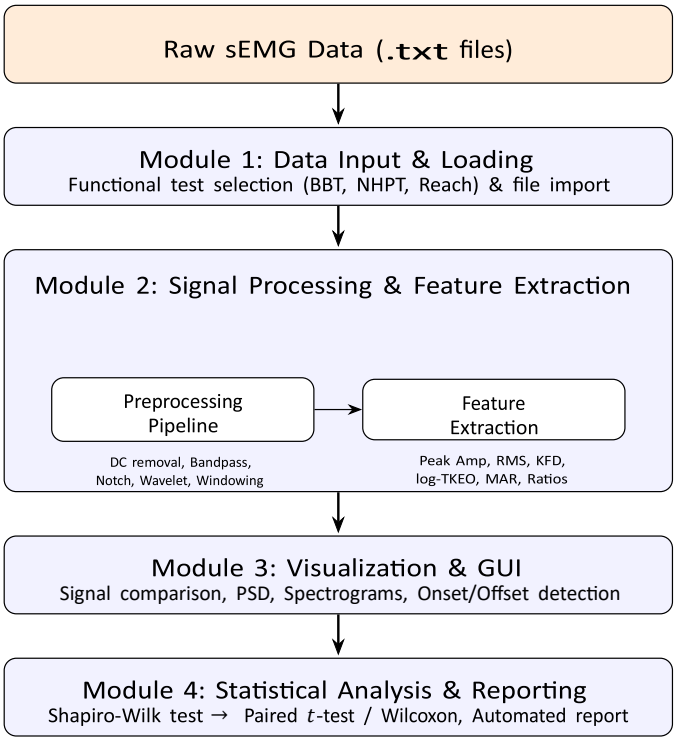

Fig. 1. General workflow and functional diagram of the MATLAB platform.

platform that addresses these gaps. The system performs endto-end sEMG analysis—from raw data import to automated statistical reporting—supporting objective evaluation of PD rehabilitation outcomes. We emphasize that the tool is presented as a development-stage platform; the validation results reported herein are preliminary and intended to demonstrate the tool's functionality and potential, not to establish definitive clinical efficacy.

II. Software Platform Architecture

The platform is organised into four tightly integrated functional modules that operate in a hierarchical manner (Fig. 1): (1) Data Input and Loading, (2) Signal Processing and Feature Extraction, (3) Visualization and GUI, and (4) Statistical Analysis and Reporting. This modular architecture allows the system to function both as an analytical instrument for single-subject exploratory analysis and as a rigorous evaluative platform for group-based clinical research.

A. Module 1: Data Input and Loading

EMG data are provided to the system through a dedicated graphical user interface. The user selects the functional test of interest—Box and Block Test (BBT), Nine Hole Peg Test (NHPT), or reach-and-grasp task—from a dropdown menu in the main application window. A file-selection dialog allows browsing the local file system to import the corresponding .txt files containing raw sEMG signal values. Preintervention (first session) and post-intervention (last session) recordings are loaded separately for each participant. Upon import, signals from all five monitored muscles (Flexor Carpi Radialis, Extensor Carpi Ulnaris, Biceps Brachii, Triceps Brachii, and Anterior Deltoid) automatically enter the complete preprocessing pipeline described in Module 2.

B. Module 2: Signal Processing and Feature Extraction

1) Preprocessing Pipeline: The preprocessing pipeline operates automatically upon data loading and comprises five sequential stages (Fig. 2):

1) DC Offset Removal. The mean of the signal is subtracted, centering it around zero and correcting baseline shifts caused by electrode coupling or impedance variability [10].
2) Bandpass Filtering. A ninth-order IIR Butterworth filter with bidirectional zero-phase processing is applied at 20–350 Hz, preserving muscle-frequency components with a flat passband and suppressing low-frequency motion artifacts and high-frequency noise without phase distortion [11].
3) Notch Filtering. An IIR notch filter centered at 60 Hz and its harmonics (120 Hz, 180 Hz, ...) eliminates power-line interference without affecting the remaining signal spectrum [12].
4) Wavelet-Based Adaptive Denoising. A fourth-order symmetric wavelet with six decomposition levels is applied. Soft thresholding using the BayesShrink method calculates adaptive thresholds to suppress noise without affecting transient muscle patterns [13].
5) Hamming Windowing. A Hamming window of the same length as the signal attenuates edge discontinuities, reducing spectral leakage and improving the accuracy of subsequent time-frequency analyses [14].

All processing parameters are predefined and applied uniformly across all recordings to ensure full reproducibility.

2) Feature Extraction: Following preprocessing, the system automatically extracts the following multi-domain features from each of the five muscle channels:

a) Task-Specific Peak Amplitude: Important methodological note: The metric referred to as "Maximum Voluntary Contraction" (MVC) in this platform is defined as the peak amplitude of the rectified signal during the functional task execution, providing a task-specific index of peak neuromuscular recruitment:

$$\text{Peak} = \max\left|x(t)\right| \tag{1}$$

This is not a true standardized MVC (which would require a maximal isometric contraction against resistance), but rather a task-specific peak amplitude that reflects the maximum activation during the functional tasks (BBT, NHPT, or reachand-grasp). As such, it is better characterized as a taskspecific peak recruitment index. This definition was chosen to avoid the

#Restrita

practical challenges of obtaining standardized MVC measurements in the clinical setting (specific equipment, patient fatigue, compliance issues) and to maintain the fully automated, task-integrated nature of the platform. In PD, decreased peak amplitude values reflect central and peripheral muscle weakness associated with bradykinesia and

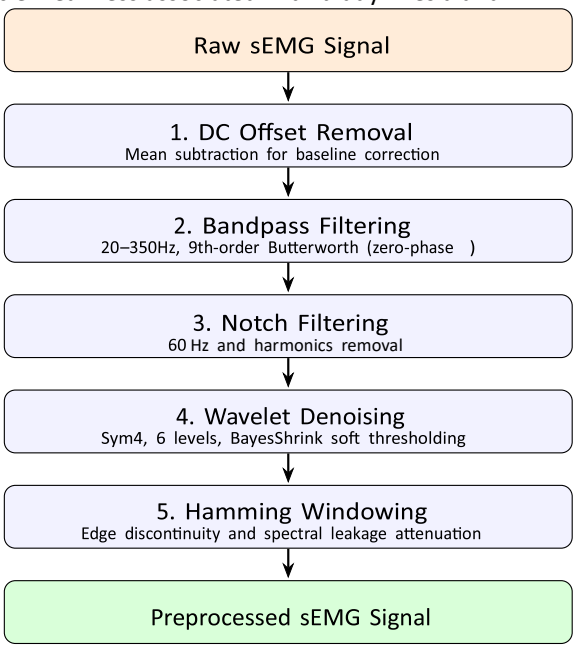

Fig. 2. Sequential preprocessing pipeline for sEMG signals.

rigidity, serving as biomarkers of disease severity [16]. We acknowledge that this metric is sensitive to task execution and may include transient artifacts; future iterations of the platform will incorporate a standardized MVC normalization protocol.

b) Root Mean Square (RMS): Computed over overlapping windows of 200–500 ms:

$$\mathrm{RMS} = \sqrt{\frac{1}{N}\sum_{i=1}^{N} x_i^2}, \tag{2}$$

where N is the number of samples per window. Mean and peak RMS values are extracted. Lower RMS in PD patients reflects reduced motor-unit recruitment and firing associated with bradykinesia [9], [15].

c) Kurtosis: A nonlinear descriptor that quantifies the peakedness and tail behaviour of the amplitude distribution, useful for identifying tremor-related transients and rigidity patterns:

$$\kappa = \frac{\frac{1}{N}\sum_{i=1}^{N}(x_i-\mu)^4}{\left[\frac{1}{N}\sum_{i=1}^{N}(x_i-\mu)^2\right]^2}, \tag{3}$$

where μ is the window mean. High kurtosis indicates burst-like or tremor-related activation; low values reflect more uniform neuromuscular control [17], [18].

d) Central Frequency Variance: The centroidal frequency in the i-th window is:

$$f_{c_i} = \frac{\sum_{k=1}^{M} f_k\, P_i(f_k)}{\sum_{k=1}^{M} P_i(f_k)}, \tag{4}$$

where $P_i(f_k)$ is the power spectral density at frequency f_k. The variance across W windows,

$$\mathrm{Var}_{f_c} = \frac{1}{W}\sum_{i=1}^{W}\left(f_{c_i} - \bar{f}_c\right)^2, \tag{5}$$

quantifies motor-unit recruitment stability. Higher variance in PD reflects unstable, erratic activation related to bradykinesia and tremor [19], [20].

e) Katz's Fractal Dimension (KFD): Quantifies the complexity of the EMG waveform:

$$D_{\mathrm{Katz}} = \frac{\log_{10}(n)}{\log_{10}(n) + \log_{10}(d/L)}, \tag{6}$$

where n is the number of signal points, L is the total arc length, and d is the maximum distance from the first point. Lower KFD in PD indicates reduced complexity due to aberrant motor-unit recruitment [21], [22].

f) Logarithm of the Teager-Kaiser Energy Operator (logTKEO): The TKEO emphasises instantaneous energy changes:

$$\Psi[x(n)] = x(n)^2 - x(n-1)x(n+1). \tag{7}$$

Its logarithm,

$$\log\left(\Psi[x(n)] + \varepsilon\right), \quad \varepsilon = 10^{-10}, \tag{8}$$

compresses instantaneous energy dynamics and improves robustness against noise artefacts [23]. In PD, attenuated logTKEO profiles are biomarkers of bradykinesia and altered motoneuron synchronisation [24].

g) Muscle Activation Rate (MAR): The duty cycle above 10% of the task-specific peak amplitude:

$$\mathrm{MAR} = \frac{1}{N}\sum_{i=1}^{N}\mathcal{H}(|x_i| - 0.1 \cdot \mathrm{Peak}) \times 100, \tag{9}$$

where $\mathrm{H}(\cdot)$ is the Heaviside step function. Reduced MAR in PD indicates briefer, more sporadic activations [25]. We note that the 10% threshold is conventional but may not be optimal for

all patients; this is a limitation of the current implementation that will be addressed through adaptive thresholding in future versions.

*h) Inter-Muscular Amplitude and Temporal Ratios:*Pairwise amplitude ratios (based on the task-specific peak
amplitude),

$$R_{ab} = \frac{\text{Peak}_a}{\text{Peak}_b}, \quad (10)$$

characterise the relative dominance of each muscle during a task (Table I). Relative Temporal Activation Metrics (RTAM), derived from onset/offset detection, quantify changes in muscle synergies and co-contraction patterns [26].

TABLE I

M1: Flexor Carpi Radialis; M2: Extensor Carpi Ulnaris; M3: Biceps Brachii; M4: Triceps Brachii; M5: Anterior Deltoid.

C. Module 3: Visualization and Graphical User Interface

Upon completion of preprocessing, a dedicated comparison window opens automatically. For each selected muscle, the GUI simultaneously displays:

- Raw and filtered waveforms of both sessions (superimposed or side-by-side);
- Rectified signals and linear envelopes;
- Power spectral density (PSD) curves;
- Time-frequency spectrograms computed via short-time Fourier transform (STFT).

A single click on the *Show Statistics* button computes and displays a comprehensive comparative table containing all extracted features for each session and muscle. All values can be exported in tabular form (copy-to-clipboard or .csv) for external processing.

1) Onset/Offset Detection Submodule: Accessible from the comparison window, this submodule applies the TKEO followed by adaptive thresholding and morphological validation to all five channels simultaneously (Fig. 3). The detection algorithm proceeds as follows:

1) Compute the TKEO envelope $\Psi[x(n)]$.
2) Apply a moving-average filter of length L:

$$y(n) = \frac{1}{L}\sum_{k=0}^{L-1}\Psi[x(n-k)] \quad . \quad (11)$$

3) Estimate background noise standard deviation σ from non-activation segments.
4) Define an adaptive activation threshold:

$$U = \mu_{\text{noise}} + M_\sigma \sigma, \quad (12)$$

where M_σ is a user-tunable multiplier. 5) Detect candidate onset/offset events where $y(n)$ crosses U.
6) Apply morphological validation to reject spurious bursts shorter than a minimum duration.

Detected onsets (green vertical lines) and offsets (red vertical lines) are overlaid on the filtered signals, enabling immediate visual inspection of co-contraction changes and sequential activation patterns between sessions. Detection parameters (window size, noise samples, threshold multiplier, minimum burst duration) can be fine-tuned interactively in real time. Important: The user-adjustable parameters are provided

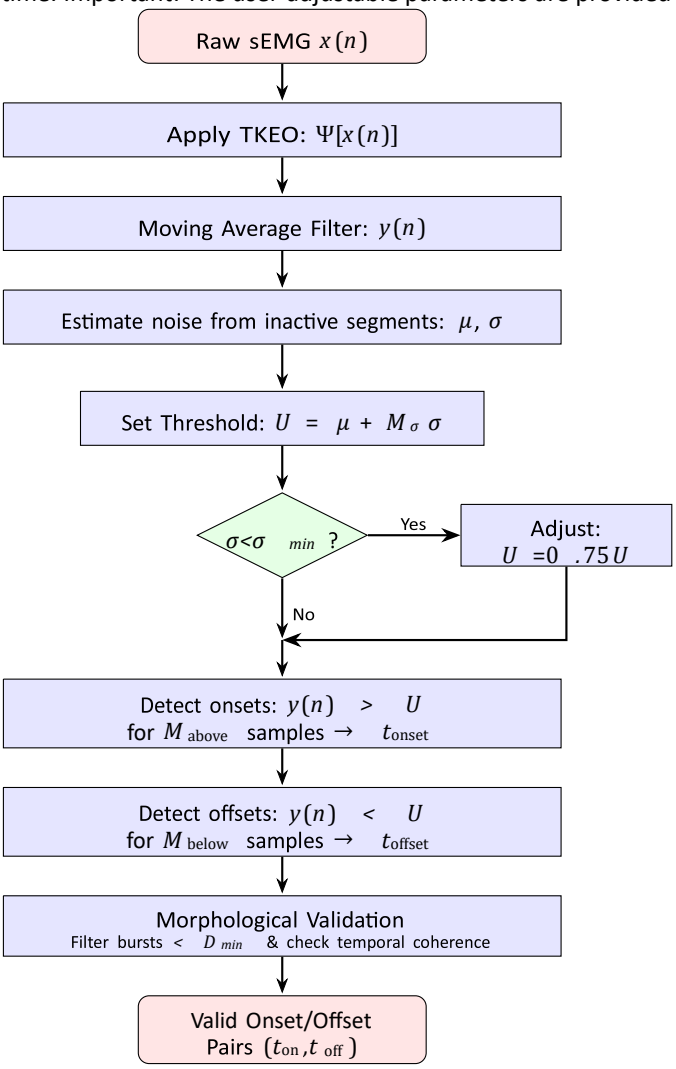

Fig. 3. Automated onset/offset detection algorithm flowchart.

#Restrita

for exploratory analysis and to accommodate signal variability; however, the platform also supports fixed, predefined parameters for automated batch processing. The current implementation has not been formally validated against manual annotation or reference methods, and this validation is planned as future work.

D. Module 4: Statistical Analysis and Reporting

The statistical module performs automatic paired-samples comparison of all features extracted from pre- and postintervention sessions across all monitored muscles and all subjects. The normality of the paired differences is assessed automatically using the Shapiro-Wilk test. Based on this outcome:

- If normality is not rejected, a parametric paired t-test is applied.
- Otherwise, the non-parametric Wilcoxon signed-rank test is used.

This automated decision logic is critical because sEMGderived variables frequently present non-normal distributions due to the inherent variability of neuromuscular activation [27]. Results are displayed as significance tables (p-values and test type) and can be exported to .csv for downstream reporting. We acknowledge that the current implementation does not apply correction for multiple comparisons (e.g., Bonferroni), and does not report effect sizes or confidence intervals. These are planned enhancements for future versions.

III. Platform Validation

A. Study Design and Participants

The platform was validated on a cohort of twenty PD patients: fifteen in the experimental group (EG) who completed twelve serious-game rehabilitation sessions with *RehaBEElitation*, and five in the control group (CG) who underwent conventional physiotherapy (twelve sessions each). Groups were matched by age and sex. Inclusion criteria required confirmed PD diagnosis, Hoehn & Yahr scale stages I–III, MMSE score above 22, and absence of severe sensory or other neurological impairments. All participants provided written informed consent (Ethics Committee protocol 43229921.8.0000.5152 Opinion Number: 8.262.209 (date: 05/03/2026)).

We acknowledge that the sample size is small and unbalanced (EG: n=15, CG: n=5), which limits the statistical power and generalizability of the findings. The results reported are intended as preliminary evidence of platform functionality rather than definitive clinical validation.

B. Data Acquisition

Surface EMG was recorded from five upper-limb muscles per participant (Flexor Carpi Radialis, Extensor Carpi Ulnaris, Biceps Brachii, Triceps Brachii, and Anterior Deltoid) during three standardised functional tasks: BBT, NHPT, and a reachand-grasp task—administered before and after the intervention protocol. Electrode placement followed established guidelines with 2 cm inter-electrode distance and a reference electrode on the acromion of the scapula.

C. Results

The platform processed all recordings automatically without any manual intervention at the signal processing or statistical stages. In the EG, seven statistically significant improvements ($p < 0.05$, uncorrected for multiple comparisons) were identified following the *RehaBEElitation* intervention:

- Significant increase in task-specific peak amplitude and RMS amplitude in the Biceps Brachii, indicating enhanced motor-unit recruitment.
- Increase in Katz Fractal Dimension in forearm muscles, reflecting greater neuromuscular complexity and more diverse activation patterns.
- Increase in log-TKEO, indicating improved instantaneous energy of muscle contractions.
- Increase in Muscle Activation Rate, reflecting longer and more consistent activation above threshold.
- Significant changes in inter-muscular amplitude ratios, suggesting improved coordination and redistribution of force across the monitored muscle group.

Due to the unbalanced sample size (EG: $n = 15$; CG: $n = 5$), analysis was restricted to within-group comparisons. The small CG precluded robust inter-group statistical evaluation; future studies should include larger, balanced cohorts. The lack of intergroup comparison means that the observed changes cannot be definitively attributed to the intervention versus spontaneous recovery or placebo effects.

IV. Discussion

A. Platform Functionality

The results demonstrate that the proposed platform can reliably detect subtle neuromuscular adaptations in PD patients following a serious-game intervention, overcoming the limitations of subjective clinical scales. The fully automated preprocessing, feature extraction, onset/offset detection, and statistical reporting pipeline eliminates operator-dependent variability, ensuring reproducibility across clinical sites.

The multi-domain feature set (time, spectral, and nonlinear) captures complementary aspects of motor recovery. Taskspecific peak amplitude and RMS inform on changes in peak and sustained neuromuscular recruitment; KFD and kurtosis quantify alterations in signal complexity and burst irregularity; log-TKEO highlights changes in instantaneous

#Restrita

energy; and MAR together with RTAM provide information on activation efficiency and inter-muscular coordination. This comprehensive characterisation exceeds the sensitivity of isolated metrics used in prior sEMG-based PD studies [15], [18].

The adaptive normality assessment (Shapiro-Wilk → *t*test or Wilcoxon) is a methodologically sound design choice, given that sEMG features regularly depart from Gaussianity in clinical populations [27]. The interactive onset/offset detection submodule further extends clinical utility by enabling real-time exploration of co-contraction dynamics and muscle synergy changes—phenomena increasingly recognised as key markers of rehabilitation-induced motor reorganisation [26].

B. Limitations and Future Work

Statistical Limitations: The current study has several important limitations. First, the small and unbalanced sample (EG: n=15, CG: n=5) severely limits statistical power and precludes meaningful intergroup comparisons. The reported *p*-values are uncorrected for multiple comparisons, increasing the risk of Type I errors. Effect sizes and confidence intervals were not computed, which are essential for clinical interpretation. Future studies with larger, balanced cohorts and appropriate statistical corrections (e.g., Bonferroni, HolmBonferroni, or FDR) are required to validate these preliminary findings.

Signal Processing Considerations: The Hamming window is applied to the entire signal, which may alter amplitude-based measures (RMS and peak). This is a recognized limitation of the current implementation; we note that for our preliminary analyses, the windowing was applied consistently across all signals, and the primary focus was on relative changes between sessions rather than absolute values. Future versions of the platform will implement windowing only for spectral analysis, preserving raw amplitude for temporal metrics.

The task-specific peak amplitude metric (referred to as MVC in the platform) is not a standardized MVC measurement but rather the peak activation during the functional task. This is a pragmatic choice to maintain automation and avoid the need for separate MVC recording sessions. However, this metric is sensitive to task execution and may include transient artifacts. Future work will incorporate a standardized MVC normalization protocol for more robust comparisons.

The 10% threshold for MAR is conventional but may not be optimal for all patients or muscles. Future versions will explore adaptive thresholding methods to improve comparability across sessions.

The onset/offset detection algorithm has not been formally validated against manual annotation or reference methods. Future work will include systematic validation with ground-truth data and comparison with established detection algorithms.

Performance and Reproducibility: The current paper does not report quantitative performance metrics such as detection accuracy, processing time per subject, failure rate, or testretest reliability. Formal validation with SNR or RMSE metrics for the wavelet denoising stage has not yet been performed. These are critical for clinical adoption and will be addressed in future work. We will also conduct comparative studies with established sEMG processing tools (e.g., EMGlab, OT Bioelettronica software) to benchmark the platform's performance.

Clinical Validation: While the platform demonstrates potential for objective assessment, the current evidence does not establish clinical validity, superior sensitivity to traditional scales, or definitive efficacy of the intervention. The preliminary nature of these results must be emphasized; the primary contribution of this paper is the description of a novel, automated software platform, and the validation is illustrative rather than confirmatory. Future studies with larger samples, intergroup comparisons, and correlation with clinical scales (MDS-UPDRS) are required to establish clinical utility.

Mitigation of Limitations: We are actively working on the following enhancements:

- Expansion of sample size through ongoing data collection.
- Implementation of intergroup analysis with properly matched controls.
- Incorporation of multiple comparison corrections and effect size reporting.
- Formal validation of onset/offset detection against manual annotation.
- Quantitative evaluation of denoising performance using SNR and RMSE metrics.
- Benchmarking against established sEMG processing tools.
- Development of standardized MVC normalization protocols.

V. Conclusions

This paper presented a modular, fully automated MATLABbased software platform for objective sEMG analysis in Parkinson's disease rehabilitation. The system integrates data loading, a five-stage preprocessing pipeline, multi-domain feature extraction (task-specific peak amplitude, RMS, kurtosis, central frequency variance, KFD, log-TKEO, MAR, and intermuscular ratios), interactive visualization with onset/offset detection, and automated paired statistical testing into a single, clinician-oriented workflow.

Preliminary validation on a cohort of PD patients confirmed the platform's sensitivity, detecting seven significant intragroup neuromuscular improvements following twelve sessions of serious-game rehabilitation ($p < 0.05$, uncorrected for multiple comparisons). The platform is available as open-source software [30] and represents a reproducible foundation

#Restrita

for future large-scale clinical trials aimed at definitively evaluating the efficacy of game-based rehabilitation in PD.

We emphasize that the results presented are preliminary and reflect a development-stage tool. The primary contribution of this work is the platform architecture and automation capabilities, not definitive clinical validation. Substantial future work is required, including larger sample sizes, intergroup comparisons, multiple comparison corrections, effect size reporting, onset/offset validation, SNR quantification, and clinical validation against established scales.

***Abstract*—This work presents the development of a digital signal processing and machine learning system for epileptic seizure detection. The primary objective is to differentiate between interictal and ictal states using electroencephalogram (EEG) recordings from the Siena Scalp EEG Database. The proposed methodology employs a processing pipeline comprising channel selection, filtering, temporal window segmentation, and conversion of these segments into time-frequency representations via the Continuous Wavelet Transform (CWT). The approach frames the problem as a computer vision task, wherein the generated time-frequency images (scalograms) are fed into a pre-trained Convolutional Neural Network (CNN) for deep feature extraction. Final classification is carried out through a comparative evaluation of decision tree-based models. Preliminary results indicate that the image-based representation of EEG signals reveals distinct activity patterns across frequency bands, demonstrating the applicability of machine learning to this classification task. The CWT yielded time-resolved frequency information both during and outside seizure episodes, while spatial interpolation of electrode data enabled the generation of scalp topographic maps for each frequency band.**

I. Introduction

Epilepsy is one of the most prevalent neurological conditions worldwide, affecting approximately 50 million people globally, according to the World Health Organization (WHO) [1]. This syndrome significantly impacts patients' quality of life, potentially leading to physical, psychological, and social implications. Therefore, early detection, continuous monitoring and management, and accurate classification of epileptic states—such as interictal and ictal—are fundamental steps for therapeutic planning and seizure prediction [2]. In this context, the development of supportive technologies becomes essential to advance clinical decision-making and patient care.

Currently, the electroencephalogram (EEG) has become established as the primary non-invasive tool for studying, diagnosing, and monitoring brain activity in real time, offering high temporal resolution and sensitivity to neurological alterations associated with epilepsy and other seizure disorders [3]. Notably, EEG plays a critical role in identifying the epileptogenic zone, which may vary significantly across patients [4]. However, manual analysis of EEG recordings is extremely labor-intensive, subjective, and prone to human error—particularly in long-term monitoring scenarios. Furthermore, epileptic patterns often manifest subtly and exhibit high clinical variability among individuals [5]. This transient and non-stationary nature of the biological signal challenges traditional methods based on spectral analysis (such as the Fourier Transform) or purely time-domain features, as these approaches fail to capture localized frequency changes occurring at the precise onset of a seizure [6].

Therefore, this work proposes the development and evaluation of an automated system for classifying epileptic states from EEG signals. The approach integrates the Wavelet Transform for multiresolution signal analysis, capturing both abrupt transitions and subtle variations in brain activity [7]. This transform was selected to simultaneously capture the time and frequency characteristics of ictal, interictal, and transitional events, as EEG signals are inherently non-stationary and tracking state dynamics is a key objective of this study [2]. This time-frequency feature extraction step serves as the foundation for deep learning models, specifically designed to identify complex, nonlinear patterns that are often imperceptible to conventional analysis. The integration of these techniques aims not only to automate detection but also to enhance accuracy and reliability in distinguishing between ictal and interictal periods, ultimately contributing to more precise and accessible

brain activity monitoring.

II. Methodology

This study employs a series of steps to process neural signals, enabling the classification of epileptic phases using neural networks. These procedures are described in the flowchart shown in Fig. 1

A. Dataset Selection

This study utilized the Siena Scalp EEG Database, publicly available on the PhysioNet platform [8]. The dataset comprises electroencephalogram (EEG) recordings from 14 patients (9 male and 5 female), aged 20 to 71 years, acquired at the Neurology and Neurophysiology Unit of the University of Siena. Signals were recorded at a sampling rate of 512 Hz and include expert annotations marking seizure onset and offset.

The sample exhibits significant clinical heterogeneity, with patients presenting different seizure types, including focal impaired awareness seizures (FIAS), focal aware seizures (FAS), and those evolving to bilateral tonic-clonic seizures. Additionally, variability is observed regarding the localization of epileptic activity (temporal region) and lateralization—previously diagnosed as right hemisphere, left hemisphere, or bilateral involvement [9].

To ensure that the machine learning model was exposed to broad physiological and clinical variability while minimizing sampling bias, patient allocation to training and testing sets was performed following stringent criteria. The training set comprised six patients, encompassing both sexes, diverse age ranges, multiple seizure types, and left, right, and bilateral lateralization. The test set included three patients, selected to maintain comparable heterogeneity in terms of sex, age, and clinical manifestations. With a total of 9 out of the 14 patients included in this split, the adopted division enables a more robust and clinically representative validation of the proposed approach without requiring the use of the entire dataset [8].

B. Preprocessing

Following patient selection, the preprocessing stage was initiated. Initially, only channels corresponding to the International 10-20 system for EEG electrode placement were retained, excluding spurious or unannotated channels [10]. Subsequently, the spatial signals underwent digital filtering using a Finite Impulse Response (FIR) bandpass filter. The FIR topology was selected due to its linear phase property, which prevents time-domain distortions and preserves the original morphology of brain waves—a critical requirement for subsequent feature extraction via the Continuous Wavelet Transform (CWT). The passband was set between 0.5 Hz and 45 Hz, using the firwin filtering method from the MNE-Python library to calculate the FIR filter coefficients based on the sampling band; the order of the filter was not fixed, as it depends on the sampling frequency of each of the processed signals. The data were restricted to the physiologically relevant EEG frequency range while simultaneously attenuating baseline drift and high-frequency noise [4].

To characterize the non-stationary dynamics of cerebral activity, the filtered spatial signals were segmented into short temporal windows of 500 ms. This window duration was selected to provide high temporal resolution, facilitating the analysis of low- and mid-frequency EEG components, albeit with partial representation of slower frequencies (< 2 Hz). Additionally, a 25% overlap was applied between consecutive windows. This strategy aims to mitigate edge artifacts inherent to frequency-domain transforms and ensure uninterrupted capture of information across brain state transitions [11] and [6].

Given that continuous EEG recordings exhibit severe class imbalance—with the interictal state representing the vast majority of the data—an extraction strategy based on regions of interest (ROIs) was adopted. Processing was restricted to approximately 100-second epochs aligned with each epileptic event. This interval was evenly split into 50 s of ictal activity (a value reflecting the average seizure duration in the selected cohort) and the 50 s immediately preceding clinical onset (interictal activity, with emphasis on the pre-ictal period) [12]. For seizures lasting less than 50 s, the actual ictal duration is retained; for longer events, only the initial 50 s are used. This constraint not only ensures representative class balancing for training the final classifier but also drastically reduces the computational cost associated with generating multi-channel images from the complete original recordings [13].

The entire methodology described herein was implemented in Python within the Google Colab environment, with access to the database files provided via Google Drive. The MNE-Python library (version 1.11.0) [14] was employed for reading EDF-format files, selecting and renaming channels according to the 10-20 system, applying the spatial montage, and performing FIR bandpass filtering. Numerical array manipulation, including the computation of windowing indices and segment extraction, was carried out using the NumPy library (version 2.0.2) [15].

C. Wavelet Transform

A key methodological contribution of the proposed approach lies in the signal processing stage, which is based on the Continuous Wavelet Transform (CWT) using the Morlet mother wavelet. This wavelet was selected due to its ability to provide an effective balance between time and frequency resolution, as well as its high morphological similarity to the sinusoidal oscillations typically observed in neural signals [16].

Specifically, the CWT was applied independently to each one-dimensional EEG channel within each already-isolated 500 ms temporal window, generating a matrix of time-frequency coefficients for each segment. For each temporal window, the spectral energy obtained from the CWT was integrated and averaged within the frequency ranges corresponding to four clinically relevant EEG bands: Delta ($\leq 3,5$ Hz), Theta (4–7,5 Hz), Alpha (8–12 Hz), and Beta (14–30 Hz).

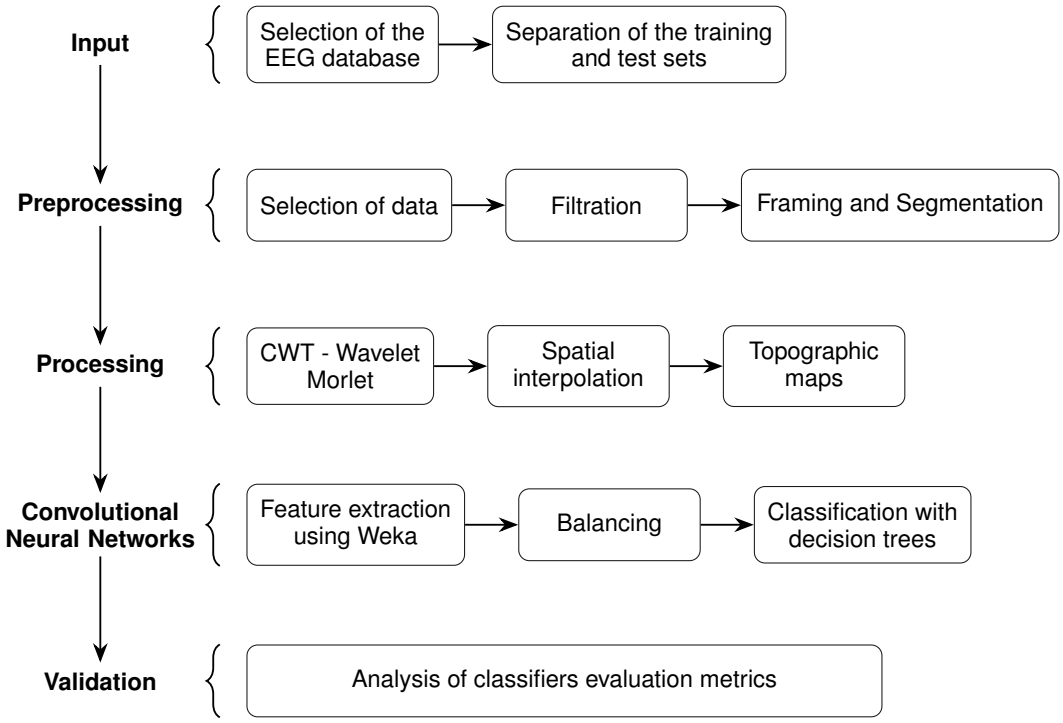

Fig. 1. Detailed flowchart of the proposed methodology for processing and classifying EEG signals.

To convert the channel-wise energy values into a continuous two-dimensional spatial representation, the three-dimensional coordinates of the EEG electrodes, positioned according to the international 10–20 system, were projected onto a two-dimensional plane. Subsequently, a spline-based spatial interpolation algorithm was applied to estimate neural activity in the unsampled regions between electrodes, producing a dense pixel matrix for each of the four frequency bands [17].

This procedure generated four independent topographic maps for each temporal window. These maps were then combined into a single EEG-derived topographic image through horizontal concatenation, resulting in a unified visual representation with a resolution of 564 × 2416 pixels (height × width). Such a representation enables deep learning architectures, such as ResNet, to extract complex patterns based on the simultaneous analysis of spatial and spectral correlations [17] [18].

Additionally, during the colormap generation process, a logarithmic transformation was applied to the spectral power values (ranging from $0.01\,\mu V$ to $100\,\mu V$) prior to normalization into the RGB color space. This procedure was essential for accommodating the high dynamic range of EEG signals, allowing low-amplitude fluctuations to remain visible while preventing clipping and information loss caused by large-amplitude variations. Consequently, the visual representation preserved the temporal evolution of the signal across its full amplitude range while maintaining the fidelity of the underlying neurophysiological information [19].

The rendering of topographic maps was performed using the Matplotlib library, both directly and as the underlying rendering engine for MNE-Python's plotting functions [14]. Logarithmic amplitude normalization was applied via the LogNorm class from the matplotlib.colors module (version 3.10.0) [20], ensuring consistent color mapping across the full dynamic range of EEG amplitudes. Finally, the four frequency-band maps generated for each temporal window were spatially concatenated into a single composite image using the Pillow (PIL) library (version 11.3.0) [21], producing the multichannel representations subsequently used as input to the deep learning model.

D. Machine Learning and Weka

The data mining and machine learning stage was entirely conducted using the Weka platform (Waikato Environment for Knowledge Analysis) [22]. Initially, the generated topographic representations were structured into .arff files, organized into training and testing sets. For feature extraction, the ResNet-50 architecture [23]—a Convolutional Neural Network (CNN) pre-trained with ImageNet dataset—was employed to identify complex visual, spatial, and spectral patterns within each temporal window.

During dataset organization, a natural class imbalance was observed. This occurred because several recordings contained seizures with clinical durations shorter than the standard 50-second window, resulting in an underrepresentation of ictal instances relative to interictal ones. To address this asymmetry in the training set and prevent classifier bias toward the majority class, the SMOTE algorithm (Synthetic Minority Over-sampling Technique) was applied [24]. This synthetic oversampling technique goes beyond simple data duplication;

it operates in feature space by interpolating values between neighboring instances of the minority class, thereby generating new, representative, and consistent samples that support robust model learning.

Finally, the classification of deep features was performed using decision tree-based supervised learning models. These algorithms were selected due to their low complexity for good computational performance. The evaluated classifiers included: Random Forest (with the number of trees ranging from 100 to 500 in increments of 100), Random Tree, and J48. These models were evaluated using cross-validation, which was applied exclusively to the training set for hyperparameter tuning. The test set was strictly isolated at the subject level, ensuring that no data from the test subjects were included in the training or validation sets. This approach prevents data leakage and guarantees an unbiased assessment of the model's generalization capability across different individuals [25].

The hyperparameter regarding the number of decision trees in the Random Forest ensemble was varied across 100, 200, 300, 400, and 500, in addition to the evaluation of Random Tree and J48 algorithms. The quantitative selection of this parameter is substantiated by stability tests to identify an optimal convergence point for minimizing generalization error and model variance, ensuring high accuracy without incurring computational saturation or overfitting [26].

These algorithms were evaluated and benchmarked to determine the most effective approach for the classification of ictal (seizure) and interictal (non-seizure) periods in patients.

III. Results and Discussion

Following the previously described methodology, Wavelet transform images were generated to spatially represent the intensity of brain activity, segmented into four distinct frequency bands: delta (1 to 3.5 Hz), theta (4 to 7.5 Hz), alpha (8 to 12 Hz) and beta (13 to 30 Hz). Approximately 266 images were obtained for each examination of the selected patients, comprising both ictal and interictal activity phases. These images were constructed as topographical maps, where color scales indicate the intensity of cerebral activity within specific regions [19]. The resulting multichannel images, characterized by the concatenation of these frequency bands, are illustrated in Fig. 2 and Fig. 3 below:

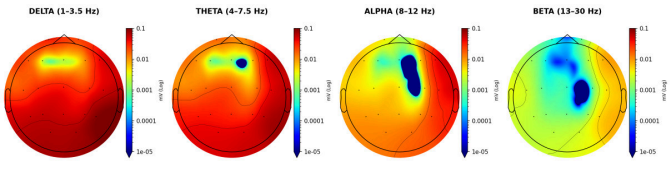

Fig. 2. Topographical representation of ictal activity.

From the processed images, an .arff dataset was compiled, comprising 1,729 interictal and 1,441 ictal instances. To address the class imbalance, the Synthetic Minority Oversampling Technique (SMOTE) was applied at a 20% rate, resulting in a balanced distribution of 1,729 samples for each class. Regarding the training set, following the same experimental pipeline, a final count of 1,333 instances per class was obtained.

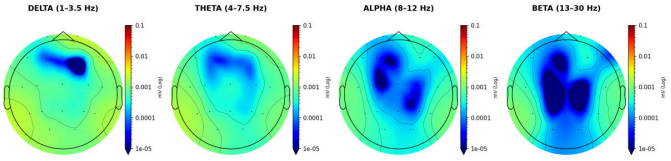

Fig. 3. Topographical representation of interictal activity.

Following feature extraction using the ResNet-50 architecture, a total of 2,048 features were yielded for both the training and testing datasets. Subsequently, the upcoming decision tree-based classifiers were evaluated: Random Forest (with the number of trees ranging from 100 to 500), Random Tree, and the J48 algorithm.

Through 10-fold cross-validation, it was observed that the highest performance metrics—including accuracy, sensitivity, specificity, Kappa index, and Area Under the ROC Curve (AUC)—were achieved by the Random Forest classifiers with 300, 400 and 500 trees, as illustrated in Tab. I. Given the highly similar performance across these models, multiple comparisons were performed using the ROC area as the primary metric, as it was the only parameter exhibiting variance among the three. Statistical analysis revealed that the three classifiers are practically equivalent, as the p-value for the significance of the difference was p = 1.0. Consequently, the model with the lowest computational overhead, the Random Forest with 300 trees, was selected as the optimal choice.

Performance metrics obtained via 10-fold cross-validation for the evaluated classifiers are presented in Table I, while the corresponding multiple comparison analysis is shown in Table II. Furthermore, the results of the selected RF 300 classifier, when applied to the independent test set, are summarized in Table III, with its respective confusion matrix illustrated in Table IV.

An analysis of the images generated for each patient reveals a high degree of correspondence with their clinical characteristics. Specifically, patients with diagnosed left-side lateralization exhibited heightened activity in the left regions of the generated topographical maps. For instance, the maps for Patient 5, who has a diagnosed epileptic focus in the left hemisphere, reflect this localization as shown in Fig. 4. Conversely, Patient 17, whose seizures predominantly affect the right hemisphere, presents images characterized by right-side activity, as illustrated in Fig. 5.

Regarding the machine learning performance metrics, the results demonstrated significant robustness, with consistent values indicating a low-bias classification. Furthermore, the model exhibited high discriminative power, effectively distinguishing between the ictal and interictal classes.

The confusion matrix further reveals that the model achieves higher classification accuracy for interictal activity compared to ictal events. Despite this variance, a promising application

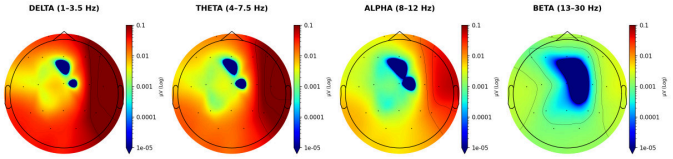

Fig. 5. Ictal activity mapping of a subject with a diagnosed right-hemisphere epileptic focus.

of these results lies in seizure prediction, which can provide patients with enhanced safety, improved quality of life, and the potential for early therapeutic intervention.

Furthermore, the integration of machine learning techniques with high-performance computing enables the development of personalized models tailored to the specific neurophysiological characteristics of each patient. This approach not only enhances classification performance but also facilitates integration into real-time monitoring and alert systems for both patients and caregivers.

Despite the promising performance achieved by the proposed framework, some methodological aspects could be further investigated. Future work should improve: the use of a window duration greater than 500 ms to include the minimum frequencies of the delta band, without compromising the number of frames available to construct the dataset used in Weka; the normalization of the global EEG signal voltage scale for each patient to obtain more precise results; and the use of feature extraction strategies specifically adapted to EEG spatial and spectral representations. In particular, fine-tuning the ResNet-50 network using EEG-derived topographic maps could allow the learned representations to become more sensitive to neurophysiological patterns that may not be adequately captured by features learned exclusively from natural images. In addition, comparative experiments involving ImageNet-pre-trained models, EEG-specific architectures, and domain-adapted convolutional neural networks could help determine the most appropriate feature representation for epileptic-state classification.

IV. CONCLUSION

This study presented a hybrid architecture for classifying epileptic states based on EEG signals, using topographic mapping derived from the Continuous Wavelet Transform (CWT), pre-trained deep neural networks for image feature extraction, and a Random Forest classifier. Through topographic mapping,

it was possible to visualize brain activity in specific time windows across various frequency bands. This provided an informative and well-structured topographic representation for application in deep learning applications.

The quantitative and qualitative results demonstrate that the hybrid architecture proposed in this study, which integrates topographic mapping using wavelet transforms with pre-trained neural networks for image feature extraction, combined with a Random Forest classifier comprising 300 trees, achieves significant performance. Promising results were obtained, including an accuracy of 82.1% and an area under the ROC curve of 0.87, indicating a balanced overall discriminatory capacity in distinguishing between ictal and interictal states. Notably, the interictal state achieved a higher detection rate of approximately 94.1%. In summary, the results indicate that the proposed framework is a promising approach to automatic identification of epileptic states from EEG signals, demonstrating the feasibility of combining wavelet-based topographic mapping, deep feature extraction, and machine learning techniques for EEG analysis.

Although the proposed framework achieved promising results, its evaluation was restricted to a single public dataset. Future work should investigate its performance on larger and more diverse EEG databases, as well as explore architectures specifically designed for biomedical signals. Such efforts may contribute to improving model generalization and facilitating its future translation into clinical decision-support systems.

***Abstract*—The simultaneous availability of clinical and dermoscopic skin lesion images is relevant for multimodal dermatological analysis, but paired datasets remain limited. This work investigates the translation of dermoscopic images into clinical skin lesion images using a Pix2Pix-based generative adversarial framework trained on paired samples from the MILK10k dataset. The proposed model uses an encoder-residual-decoder generator and a PatchGAN-like discriminator, combined with adversarial supervision and VGG16-based perceptual losses extracted from different feature layers. The generated images were evaluated using the Frechet Inception Distance to quantify their distributional similarity to real clinical images. The results show that perceptual losses based on earlier VGG16 layers achieved lower FID values than the evaluated MAE baseline when compared with a pixel-wise MAE baseline. The best configuration, vgg16.10L2, achieved the lowest FID score of 67.47, followed by vgg16.L2 with an FID of 69.74, while the MAE baseline obtained an FID of 82.50. Qualitative analysis indicated that the proposed approach can generate plausible clinical images and showed visually plausible lesion appearance in successful cases, although failure cases revealed limitations related to lesion morphology, localization, and semantic consistency. These findings suggest that feature-level supervision is a promising strategy for dermoscopic-to-clinical image translation, while also highlighting the need for clinically oriented evaluation metrics in future studies.**

***Index Terms*—Dermoscopic images, clinical skin lesion images, image-to-image translation, generative adversarial networks, Pix2Pix, perceptual loss, VGG16, Frechet Inception Distance, medical image synthesis, dermatology.**

I. Introduction

Skin cancer is among the common neoplasms worldwide, and early detection is closely associated with better clinical outcomes and reduced patient morbidity [1]. In dermatological practice, imaging methods support the visual assessment of lesion morphology before histopathological confirmation [2]. In recent years, deep learning techniques have been explored in dermatology for tasks such as classification, segmentation, and computer-aided diagnosis, with studies reporting specialist-level performance in specific diagnostic scenarios [3]–[5].

Clinical and dermoscopic images are two used modalities in skin lesion assessment. Clinical images capture the macroscopic appearance of the lesion and its surrounding tissue, resembling the visual inspection performed during routine examination. Dermoscopic images, in turn, are acquired using optical systems that reduce surface reflection and reveal pigmentary structures, vascular patterns, and other subsurface details that are not visible to the naked eye [2]. These modalities may provide complementary information for dermatological assessment, motivating the development of computational methods capable of exploiting both image domains [5].

Despite this complementarity, the availability of paired clinical and dermoscopic images remains limited when compared with datasets focused on a single modality, especially dermoscopy [5], [6]. This limitation constrains the development of multimodal models, image fusion strategies, and supervised translation methods between dermatological imaging domains. Recent multimodal initiatives, such as MILK10k, provide paired clinical and dermoscopic images and enable the investigation of learning-based approaches for cross-modality image synthesis in skin lesion analysis [7].

In this context, image-to-image translation has emerged as a suitable framework for learning mappings between different visual domains [8], [9]. GAN-based approaches are particularly relevant for this task, since they combine a generative model with an adversarial training strategy to synthesize images with realistic visual characteristics [10]. Pix2Pix introduced a supervised conditional GAN formulation for paired image translation [8], whereas CycleGAN extended this idea to unpaired domains through cycle-consistency constraints [9]. These approaches have also been adapted to medical

imaging, where preserving anatomically or clinically structures is essential during the synthesis process [11].

However, translating dermoscopic images into clinical images remains challenging due to differences in illumination, texture, field of view, scale, hair visibility, and anatomical context [5]. In addition, losses based only on pixel-wise differences may produce overly smoothed outputs and fail to preserve perceptually details [12]. Perceptual losses address this limitation by comparing feature representations extracted from pretrained convolutional neural networks, allowing the optimization process to consider image characteristics at different levels of abstraction [12], [13].

Therefore, this work investigates dermoscopic-to-clinical image translation using a Pix2Pix-based conditional GAN trained on paired multimodal skin lesion images. The method incorporates a VGG16-based perceptual loss, and different feature extraction layers are evaluated to analyze how distinct representation levels influence the quality of synthesized clinical images. The generated images are quantitatively assessed using the Fréchet Inception Distance (FID), providing a comparative analysis of the effect of perceptual representations on the translation from dermoscopic to clinical images [14].

II. Methods

A. Dataset and Preprocessing

MILK10k is a large-scale multimodal skin lesion dataset developed to advance artificial intelligence research in dermatology. It contains 10,480 images corresponding to 5,240 skin lesions, where each lesion is represented by a paired clinical close-up photograph and a dermoscopic image [7].

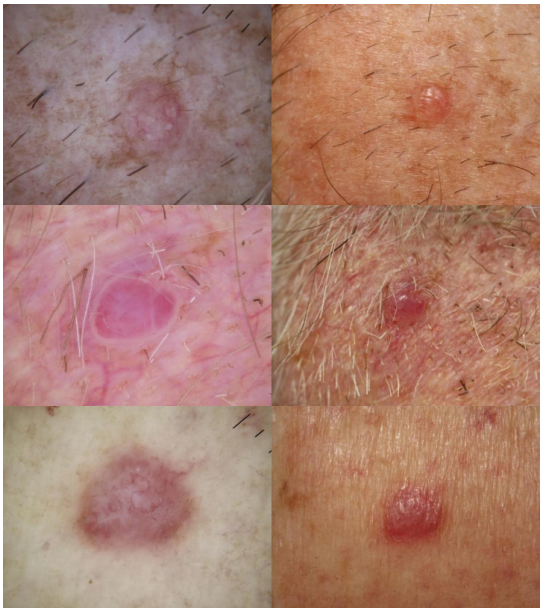

Fig. 1. Representative samples from the dataset. The left column contains dermoscopic images of skin lesions, and the right column shows the corresponding clinical images of the same lesions.

The dataset was collected from five international centers and includes metadata such as patient age, sex, skin tone, anatomical site, and diagnostic information. Importantly, more than 95% of the lesions were confirmed through histopathological examination, providing a reliable ground truth for machine learning studies [7].

Figure 1 presents examples from the MILK10k dataset. Each pair consists of a dermoscopic image and its corresponding clinical photograph acquired from the same skin lesion.

All images in the MILK10k dataset were originally stored in a $4:3$ aspect ratio. During preprocessing, each image was resized while preserving its aspect ratio such that the smallest spatial dimension measured 142 pixels. A random crop of size (128×128) was extracted, producing RGB images with final dimensions of $(128 \times 128 \times 3)$. In addition to standardizing the input size, the random cropping operation acted as a lightweight data augmentation strategy, introducing small spatial variations that helped mitigate overfitting during training. Finally, pixel intensities, originally represented in the $([0, 255])$ range, were normalized to have zero mean and unit standard deviation.

B. Proposed Dermoscopic-to-Clinical Translation Framework

Figure 2 presents the generator and discriminator architectures used in this work. The overall framework follows the generative adversarial learning paradigm originally introduced in [10], in which a generator learns to synthesize images while a discriminator is trained to distinguish generated samples from real ones. In this work, the generator is designed for image-to-image translation, following the same general task formulation explored in conditional adversarial models such as Pix2Pix [8], CycleGAN [9], and medical image translation approaches such as MedGAN [11].

The generator follows an encoder–residual–decoder design. The encoder receives an RGB image and progressively reduces its spatial resolution through convolutional blocks with stride 2. Each block is composed of a convolutional layer followed by instance normalization and ReLU activation. This structure is closely related to the convolutional encoders commonly adopted in image-to-image translation networks, where spatial downsampling is used to map the input image into a compact feature representation before reconstruction [8], [9]. This stage maps the input image to a latent representation with increased feature depth, allowing the network to extract structural and textural information from the source domain.

The latent stage is composed of five residual convolutional blocks. The use of residual blocks is consistent with architectures adopted in neural image transformation and translation models, where residual mappings are used to refine feature representations while preserving information through identity connections [9], [12]. Each residual block applies a sequence of convolution, normalization, and nonlinear activation operations, while preserving an identity shortcut connection between the block input and output. The residual output is obtained through an element-wise summation, which helps preserve low-level information and improves gradient propagation during training. In this work, the residual blocks operate at the

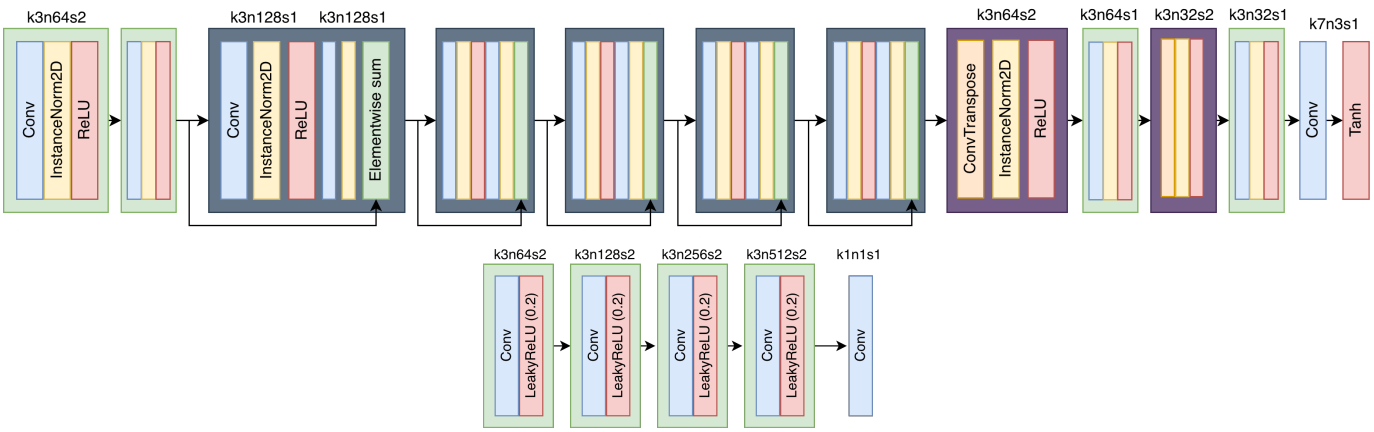

Fig. 2. Block diagram of the proposed model architecture. The upper diagram represents the generator architecture, while the lower diagram represents the discriminator architecture.

same spatial resolution and channel depth, refining the encoded representation before reconstruction.

The decoder reconstructs the output image from the latent representation using transposed convolutional layers for spatial upsampling. After each upsampling operation, convolutional blocks are used to refine the generated feature maps. This encoder–decoder organization is related to previous image-to-image translation architectures, in which the decoder progressively restores the spatial resolution of the feature maps to generate an image in the target domain [8], [9]. The final layer consists of a convolution followed by a hyperbolic tangent activation function, producing a three-channel RGB image with normalized pixel values. Overall, the generator is designed to transform the input image into the target domain while preserving anatomical and visual structures.

The discriminator follows a convolutional PatchGAN-like architecture, similar to the discriminator design used in conditional image-to-image translation models [8]. It receives an RGB image and progressively downsamples it through a sequence of convolutional layers with increasing numbers of feature channels. LeakyReLU activations are used after each intermediate convolution to improve gradient flow and allow nonzero responses for negative activations. The final convolutional layer maps the extracted features to a single-channel output, representing local real/fake decisions over image patches rather than a single global classification score. This design encourages the generator to synthesize realistic local textures and spatial details [5], [11].

C. Objective Functions and Training Strategy

The discriminator loss, defined in Eq. (1), follows the Least Squares GAN (LSGAN) formulation [15], encouraging the discriminator to assign values close to one for real clinical images y and zero for generated images $G(x)$.

$$\mathcal{L}_D = \mathbb{E}_{(x,y)\sim p_{\text{data}}}\left[(D(y)-1)^2 + D(G(x))^2\right] \tag{1}$$

The adversarial loss of the generator, given by Eq. (2), encourages the generated images to be classified as real by the discriminator. In addition, the perceptual loss in Eq. (3) computes the mean absolute error (MAE) between the feature maps extracted from the ℓ-th layer of a pretrained VGG16 network for the real and generated images, where C_ℓ, H_ℓ and W_ℓ denote the number of channels, height, and width of the corresponding feature maps, respectively [14].

$$\mathcal{L}_{AdvG} = \mathbb{E}_{(x,y)\sim p_{\text{data}}}\left[(D(G(x))-1)^2\right] \tag{2}$$

$$\mathcal{L}_{VGG}^{(\ell)} = \mathbb{E}_{(x,y)\sim p_{\text{data}}}\left[\frac{1}{C_\ell H_\ell W_\ell}\left\|\phi_\ell(y)-\phi_\ell(G(x))\right\|_1\right] \tag{3}$$

Finally, the generator is optimized by minimizing the weighted sum of the adversarial and perceptual losses, as defined in Eq. (4), where λ controls the contribution of the perceptual term.

$$\mathcal{L}_G = \mathcal{L}_{AdvG} + \lambda \mathcal{L}_{VGG}^{(\ell)} \tag{4}$$

Differently from the original Pix2Pix formulation [8], the discriminator was not conditioned on the input dermoscopic image. This simplification was adopted to keep the experimental comparison focused on the perceptual loss configurations. Instead, it received only clinical-domain images, either real samples y or generated samples $G(x)$. The training flow is represented in Fig. 3.

The model was trained for 1000 epochs using a mini-batch size of 40. Each epoch consisted of 131 optimization steps, corresponding to approximately $131 \times 40 = 5240$ image pairs processed per epoch. Therefore, over the complete training procedure, the model processed approximately $5240 \times 1000 = 5{,}240{,}000$ image-pair presentations.

D. Evaluation Metrics

The quality of the generated clinical images was quantitatively evaluated using the Fréchet Inception Distance (FID). FID is used to assess the similarity between the distribution of real images and the distribution of generated images in a deep feature space [16].

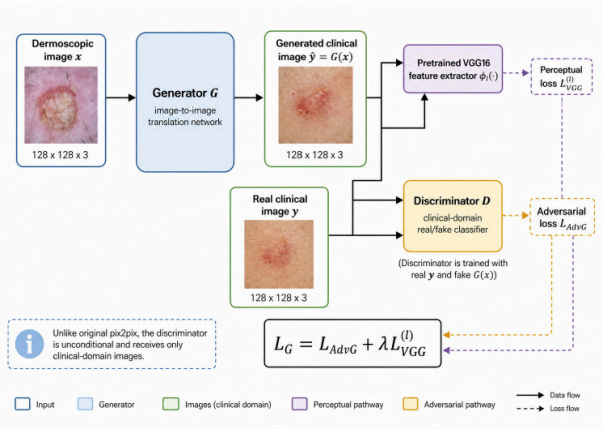

Fig. 3. Block diagram of the proposed generator training scheme for dermoscopic-to-clinical image translation.

Instead of comparing images directly at the pixel level, FID extracts feature representations from a pretrained Inception network and models the real and generated image sets as multivariate Gaussian distributions [16]. Lower FID values indicate that the generated images are closer to the real images in terms of feature statistics, suggesting better visual realism and distributional similarity.

Let (μ_r, Σ_r) denote the mean vector and covariance matrix of the feature representations extracted from real clinical images, and let (μ_g, Σ_g) denote the corresponding statistics extracted from generated clinical images. The FID is defined as

$$\mathrm{FID} = \|\mu_r - \mu_g\|_2^2 + \mathrm{Tr}\left(\Sigma_r + \Sigma_g - 2(\Sigma_r\Sigma_g)^{1/2}\right) \quad (5)$$

where $\|\cdot\|_2$ is the Euclidean norm and $\mathrm{Tr}(\cdot)$ denotes the trace operator. In this work, FID was used to compare the generated clinical-domain images against the corresponding distribution of real clinical images, providing an objective measure of how closely each trained model reproduced the target image domain.

III. Results

The notation used to identify each loss configuration indicates the type of reconstruction or perceptual constraint adopted during training. The term *MAE* denotes the pixel-wise mean absolute error baseline. Configurations identified as *vgg16* use perceptual losses computed from feature maps extracted by a pretrained VGG16 network. The suffixes *L2*, *L9*, and *L16* indicate the VGG16 layer used to extract the feature representation. When the prefix *10* is included, as in *vgg16.10L2*, the corresponding perceptual loss term is multiplied by a weight of 10 in the generator objective. Therefore, *vgg16.10L2* denotes a VGG16-based perceptual loss extracted from layer 2 with a weighting factor of 10.

The quantitative results obtained for the evaluated loss configurations are presented in Table I. Among the evaluated configurations, the best result was obtained by the model trained with the *vgg16.10L2* loss configuration, which achieved an FID of 67.47. The second-best result was obtained with *vgg16.L2*, with an FID of 69.74. These results suggest that using perceptual information extracted from earlier VGG16 layers contributed to the generation of images with greater distributional similarity to the target clinical domain.

TABLE I
FID scores obtained for the different loss configurations evaluated in the dermoscopic-to-clinical image translation task. Lower FID values indicate higher similarity between the generated and ground-truth clinical image distributions.

Loss configuration	FID
10MAE	82.50
vgg16.L2	69.74
vgg16.10L2	**67.47**
vgg16.L9	86.35
vgg16.10L9	75.06
vgg16.L16	77.55
vgg16.10L16	76.17

The baseline configuration based on the MAE loss achieved an FID of 82.50, indicating lower performance when compared with the best VGG16-based configurations. This behavior is consistent with the visual limitations often observed in pixel-wise reconstruction losses, which tend to favor average solutions and may reduce the preservation of perceptually details. In contrast, the use of perceptual losses based on VGG16 feature maps allowed the generator to compare images in a learned feature space, improving the visual correspondence between generated and real clinical images.

Figure 4 shows examples of successful dermoscopic-to-clinical image translation. In these cases, the generated images preserve aspects of the corresponding ground-truth clinical images, including the global skin appearance, lesion location, and local color patterns. Although differences in texture and sharpness can still be observed across the generated outputs, the models were generally able to synthesize plausible clinical images from the dermoscopic inputs. The results also show that different VGG16 layers influence the generated appearance in distinct ways. Configurations based on shallower layers, particularly *vgg16.L2* and *vgg16.10L2*, tended to produce images with better global consistency and fewer severe structural artifacts.

However, the qualitative analysis also revealed failure cases, as shown in Figure 5. In these examples, the generated images present deviations from the corresponding ground-truth clinical images. The observed errors include changes in lesion morphology, incorrect lesion localization, hallucinated pigmented structures, excessive texture smoothing, and inconsistent skin color.

The configurations associated with deeper VGG16 layers did not necessarily improve the synthesis quality. In particular, *vgg16.L9* produced the highest FID value among the evaluated models, reaching 86.35, while *vgg16.L16* and *vgg16.10L16* achieved FID values of 77.55 and 76.17, respectively. This suggests that features extracted from deeper layers may emphasize more abstract semantic representations while being

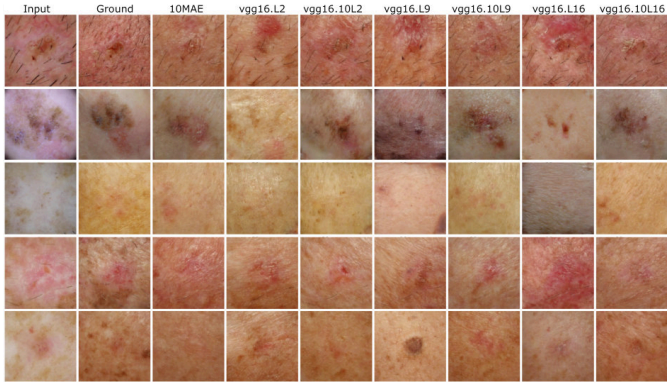

Fig. 4. Examples of successful dermoscopic-to-clinical image translation. Each row presents the input dermoscopic image, the ground-truth clinical image, and the images generated using different MAE and VGG16-based perceptual loss configurations. The selected cases show good preservation of lesion location, skin texture, and global clinical appearance across the synthesized outputs.

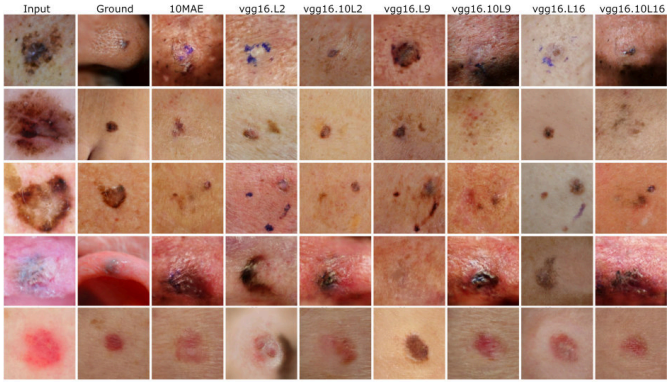

Fig. 5. Examples of failure cases in dermoscopic-to-clinical image translation. Each row presents the input dermoscopic image, the ground-truth clinical image, and outputs generated under different MAE and VGG16-based perceptual loss configurations. The selected cases highlight limitations such as lesion distortion, incorrect localization, hallucinated visual patterns, and loss of correspondence with the target clinical image.

less effective at preserving low-level visual characteristics such as texture, color distribution, and fine lesion boundaries. Since the target task requires the generation of visually realistic clinical images with coherent local appearance, the use of earlier perceptual representations appears to be more suitable.

Overall, the results indicate that the inclusion of VGG16-based perceptual losses improved the dermoscopic-to-clinical translation performance when compared with the MAE-based configuration alone. The best quantitative performance was achieved by *vgg16.10L2*, while the qualitative examples suggest that this configuration provides a better balance between visual realism, lesion preservation, and skin texture consistency. Nevertheless, the failure cases highlight that the proposed approach is still limited in scenarios involving modality discrepancies, complex lesion structures, or differences in field of view between dermoscopic and clinical images.

IV. Limitations

This study has several limitations. First, the evaluation is based primarily on FID and qualitative inspection; therefore, clinical usefulness, diagnostic consistency, and preservation of clinically relevant morphology were not directly validated. Second, no dermatologist-based evaluation or downstream diagnostic task was performed. Third, the study does not provide cross-dataset validation or comparison with contemporary image-to-image translation architectures. Fourth, the isolated effect of the simplified discriminator was not evaluated through an ablation study.

Finally, although successful cases showed plausible outputs, failure cases included changes in lesion morphology, localization, color, and hallucinated structures, indicating that the generated images should not be interpreted as clinically validated evidence.

V. Conclusion

The present study was conducted using the MILK10k dataset and does not evaluate cross-dataset generalization. Therefore, the reported results should not be interpreted as evidence of robustness across different acquisition domains or clinical settings. The objective of this study is not to establish a comprehensive benchmark among image-to-image translation architectures, but to investigate the effect of different perceptual loss configurations within a Pix2Pix-based dermoscopic-to-clinical translation framework.

This work investigated the generation of clinical skin lesion images from dermoscopic images using a Pix2Pix-based generative adversarial framework. The proposed approach explored the use of perceptual losses extracted from different layers of a pretrained VGG16 network, aiming to evaluate how distinct levels of visual representation influence the quality of the synthesized images. The results indicate that the choice of the perceptual layer affects both the visual appearance of the generated samples and the quantitative performance measured by FID, reinforcing the relevance of feature-level supervision in medical image-to-image translation tasks.

Future work should investigate architectural modifications that increase the generator's ability to perform semantic transformations. In the current formulation, allowing the generator to operate at a lower spatial resolution, such as a 16×16 latent representation, may provide greater capacity to modify global structures and contextual attributes of the image, rather than focusing predominantly on local texture reconstruction. This modification could improve the model's ability to synthesize clinical images whose overall organization is more consistent with the target domain.

Another important direction is to approximate the model more closely to the original Pix2Pix formulation by providing the real input image to the discriminator. In this configuration, the discriminator would evaluate not only whether the generated clinical image appears realistic, but also whether it is conditionally coherent with the corresponding dermoscopic image. This could encourage the generator to preserve lesion-

specific characteristics more consistently during the translation process.

In addition, future evaluations should go beyond general image quality metrics such as FID. Although FID is useful for estimating distributional similarity, it does not directly measure whether clinically relevant attributes were preserved. For this reason, a promising direction is to use a neural network trained specifically for dermatological pathology classification to verify whether the diagnostic semantics of the lesion remain consistent before and after image translation. Such an analysis would provide a more clinically meaningful assessment of the generated images.

Other future improvements include evaluating larger and more diverse datasets, performing cross-dataset validation, comparing the proposed model with alternative architectures such as CycleGAN, attention-based GANs, and diffusion models, and incorporating additional metrics such as LPIPS, SSIM, or task-oriented classification consistency. Furthermore, qualitative assessment by dermatology specialists could provide valuable insight into the clinical plausibility and potential utility of the synthesized images. These extensions may contribute to the development of more reliable multimodal image synthesis systems for dermatological applications.

***Resumo*—A doença de Alzheimer (DA) é uma condição neurodegenerativa progressiva associada a alterações estruturais, metabólicas e funcionais. A ressonância magnética funcional (RMf) permite investigar, de maneira não invasiva, a atividade e a conectividade de redes envolvidas no comprometimento cognitivo leve (CCL) e na DA. Esta revisão de escopo teve como objetivo mapear achados de RMf investigados como potenciais biomarcadores nessas condições, caracterizando populações, paradigmas de aquisição, métodos de análise, regiões e redes estudadas e lacunas para validação clínica. Foram consultadas as bases SciELO, PubMed e Google Acadêmico, com a última busca em 20/03/2026. Os cinco estudos primários clínicos totalizaram 451 participantes declarados, embora possa haver sobreposição entre amostras provenientes das mesmas bases de dados. Os achados mapeados concentraram-se na rede de modo padrão, no hipocampo, em circuitos subcorticais e em redes do tronco encefálico e do cerebelo. A literatura descreve tanto aumento quanto redução da conectividade no CCL e predomínio de hipoconectividade na DA, mas a heterogeneidade de populações, protocolos e métodos analíticos impede interpretar esse comportamento como trajetória universal. Os resultados referem-se predominantemente a diferenças entre grupos e devem ser considerados candidatos a biomarcadores, ainda sem validação suficiente para emprego diagnóstico individual. Estudos multicêntricos, longitudinais e padronizados devem estabelecer reprodutibilidade e utilidade clínica.**

***Index Terms*—doença de Alzheimer, comprometimento cognitivo leve, imagem por ressonância magnética funcional, conectividade funcional, biomarcadores**

I. Introdução

As demências são doenças neurodegenerativas progressivas que comprometem a cognição e a funcionalidade [1]. A doença de Alzheimer (DA) destaca-se como a forma mais prevalente, sendo caracterizada pela perda neuronal, redução sináptica e atrofia cerebral [2].

Clinicamente, a DA envolve comprometimento da memória, alterações comportamentais e declínio das funções executivas [3]. A progressão da doença ocorre em estágios, desde alterações iniciais até incapacidade severa [4].

Do ponto de vista fisiopatológico, a DA está associada ao acúmulo de placas de beta-amiloide e à formação de emaranhados neurofibrilares de proteína tau, resultando em disfunção sináptica e morte neuronal [5]. Esses processos iniciam-se décadas antes da manifestação clínica [6].

O comprometimento cognitivo leve corresponde a uma síndrome clínica em que o desempenho cognitivo se encontra abaixo do esperado, sem perda funcional suficiente para caracterizar demência. Pode ser classificado em apresentações amnésticas ou não amnésticas, de domínio único ou de múltiplos domínios [7], [8]. O CCL não possui necessariamente etiologia da doença de Alzheimer: parte dos indivíduos permanece estável, retorna a um desempenho considerado normal ou progride para outras condições. Ainda assim, apresentações amnésticas estão associadas a maior probabilidade de progressão para demência por DA [9]. Essa heterogeneidade torna indispensável informar os critérios clínicos e a eventual confirmação etiológica adotados em cada estudo de neuroimagem.

Também existem apresentações atípicas da DA, com predomínio de alterações linguísticas, visuoespaciais, comportamentais ou executivas. Entre elas estão a variante logopênica da afasia progressiva primária, a atrofia cortical posterior e a variante comportamental/disexecutiva [10]. A inclusão dessas apresentações sem estratificação pode contribuir para a variabilidade dos padrões relatados.

O crescimento da população idosa e a elevada dependência do Sistema Único de Saúde (SUS) reforçam a relevância de estratégias diagnósticas reprodutíveis e acessíveis no Brasil [11]–[14]. Biomarcadores moleculares obtidos por tomografia por emissão de pósitrons (PET) podem contribuir para a caracterização da patologia amiloide e tau, mas seu acesso permanece limitado em muitos contextos. A escolha dos exames deve ser compreendida como parte de uma avaliação integrada, e não como substituição isolada da avaliação clínica e neuropsicológica [15], [16].

Nesse contexto, a ressonância magnética (RM) assume papel estratégico por sua disponibilidade e ausência de radiação ionizante, fornecendo informações estruturais, funcionais e

metabólicas do sistema nervoso central [17].

Entre suas modalidades, a ressonância magnética funcional (RMf) destaca-se pela possibilidade de investigar a conectividade funcional cerebral de maneira não invasiva, permitindo a análise integrada de redes neurais envolvidas nos processos cognitivos afetados pela DA [6], [17].

A RMf baseada no contraste dependente do nível de oxigenação sanguínea (BOLD) fornece uma medida indireta da atividade neural, mediada pelo acoplamento neurovascular. Na aquisição em repouso, correlações temporais espontâneas do sinal permitem estimar a conectividade funcional entre regiões. Alterações na rede de modo padrão (RMP) e em outras redes de larga escala têm sido descritas no CCL e na DA, embora sua direção e magnitude variem conforme a população, o estágio clínico e o método analítico [6], [18].

Tradicionalmente, os estudos de neuroimagem na doença concentraram-se no lobo temporal medial, particularmente no hipocampo e no córtex entorrinal. Entretanto, evidências recentes indicam que a DA não deve ser compreendida exclusivamente como uma doença cortical ou hipocampal, mas como uma desordem de redes distribuídas [17], [19].

Alterações na RMP, nos circuitos talamocorticais, em núcleos monoaminérgicos do tronco encefálico e em regiões cerebelares associadas à cognição têm sido investigadas em estudos de RMf em repouso [20]–[23].

A relevância dessa abordagem é ampliada pelo fato de que a aquisição em repouso dispensa a execução de tarefas cognitivas complexas, permitindo sua aplicação em indivíduos com diferentes graus de comprometimento cognitivo [17]. Estudos investigam se a conectividade pode revelar alterações nas fases iniciais, mas sua utilidade diagnóstica individual permanece incerta [18], [19].

Diante desse cenário, esta revisão de escopo tem como objetivo mapear os achados de RMf investigados como potenciais biomarcadores no CCL e na DA, caracterizando as populações estudadas, os paradigmas de aquisição, os métodos de análise, as redes e regiões envolvidas, as direções das alterações funcionais e as principais lacunas para sua validação clínica. Secundariamente, discutem-se os requisitos que ainda limitam sua potencial aplicabilidade no contexto da saúde pública brasileira.

II. Metodologia

Foi conduzida uma revisão de escopo orientada pelas recomendações metodológicas do JBI e relatada conforme a extensão PRISMA para revisões de escopo (PRISMA-ScR) [24], [25]. O processo de identificação, seleção e elegibilidade dos estudos foi estruturado com base nas recomendações da declaração PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses), utilizando seus princípios como guia para a organização e transparência das etapas da revisão, sem adoção integral de todos os seus itens e procedimentos.

A pergunta e os critérios de elegibilidade foram organizados segundo a estratégia População–Conceito–Contexto (PCC). A população compreendeu adultos cognitivamente saudáveis, com CCL ou com DA; o conceito correspondeu a medidas obtidas por RMf/BOLD investigadas como achados funcionais ou potenciais biomarcadores; e o contexto incluiu estudos clínicos e de pesquisa sem restrição geográfica. A pergunta principal foi: "Quais achados de ressonância magnética funcional têm sido investigados como potenciais biomarcadores em indivíduos com comprometimento cognitivo leve e doença de Alzheimer?"

Foram elegíveis estudos sobre a progressão da doença, com seres humanos na faixa etária a partir de 60 anos de idade, que utilizaram RMf em repouso ou com tarefa e incluíram participantes com CCL ou DA, com ou sem comparação com controles cognitivamente saudáveis. Estudos multimodais foram considerados apenas quando os resultados de RMf puderam ser extraídos separadamente. Foram excluídos trabalhos exclusivamente baseados em RM estrutural, difusão, espectroscopia, arterial spin labeling (ASL), PET ou SPECT, sem componente de RMf. Foram aceitas revisões sistemáticas e revisões da literatura. Estudos de aprendizado de máquina foram incluídos como fontes de evidências experimentais sobre biomarcadores.

Os estudos selecionaram participantes que atenderam aos critérios do National Institute on Aging–Alzheimer's Association (NIA-AA), com base em testes de rastreio cognitivo, como a Avaliação Cognitiva de Montreal (MoCA) e o Mini-Exame do Estado Mental. Alguns estudos relataram a investigação de biomarcadores no líquido cefalorraquidiano, como Aβ1–42, t-tau e p-tau, como ocorreu no estudo de Tang et al. [23].

As buscas foram realizadas em bases como PubMed e SciELO e complementadas pelo Google Acadêmico, com filtro para um período de 5 a 10 anos, dependendo da disponibilidade de temas recuperados, utilizando os termos de busca: Neuroimage AND biomarkers AND magnetic Alzheimer, functional magnetic resonance AND Alzheimer disease, cerebellar alzheimer's disease MRI. A busca compreendeu publicações entre 2016 e 2026, nos idiomas inglês e português, e foi atualizada pela última vez em 20/03/2026.

A estratégia combinou termos controlados e palavras livres relacionadas à DA, ao CCL e à RMf. Na PubMed, foram feitas buscas nos campos título e resumo, com os operadores AND e OR nas seguintes expressões: fMRI OR functional magnetic resonance AND Alzheimer's disease, (Alzheimer's disease) AND (functional MRI), cerebellum MRI AND alzheimer disease, com filtro de tempo para 10 anos. A consulta sobre barreira hematoencefálica foi retirada por não corresponder diretamente ao conceito desta revisão.

Os registros recuperados foram exportados para o gerenciador de referências Mendeley, no qual foram removidas as duplicatas. A seleção, realizada pela autora principal, ocorreu em duas etapas: triagem de títulos e resumos e avaliação dos textos completos. As dúvidas de elegibilidade foram discutidas com o segundo autor, e os motivos de exclusão na etapa de texto completo foram registrados.

Elaborou-se formulário de extração com autores, ano, país, desenho, grupos, tamanho amostral, critérios diagnósticos,

aquisição, paradigma de repouso ou tarefa, método analítico, região ou rede, comparação, direção do achado, associação clínica, desempenho diagnóstico e limitações.

O formulário, redigido pelos autores, buscou contemplar as regiões encefálicas descritas na literatura, o tipo de achado em RMf, o paradigma, isto é, se o exame foi realizado de forma dinâmica ou em repouso e quais interpretações os achados sugerem de acordo com a progressão da doença. Além disso, os achados foram classificados conforme sua relevância para o CCL e a DA.

Os estudos foram agrupados por paradigma, população, rede ou região e desfecho. A síntese foi descritiva, com contagens por categoria, sem metanálise.

III. Resultados

A. Seleção e características das fontes

Entre os estudos incluídos, 1 avaliou o CCL, 5 contemplaram DA e CCL e 8 artigos abordaram aspectos da DA. Quanto ao paradigma, 10 artigos mencionaram ressonância magnética funcional em repouso. A modalidade tem ganhado visibilidade por possibilitar o estudo das redes sem necessidade de esforço físico ou cognitivo do paciente. A síntese também informa a distribuição por método analítico, tamanho amostral e presença de confirmação da patologia da doença de Alzheimer. Foram selecionados estudos que abordassem a doença de Alzheimer e seus biomarcadores, contemplando participantes classificados como comprometimento cognitivo leve (CCL) ou doença de Alzheimer (DA). Além disso, os estudos elegíveis deveriam apresentar a descrição dos biomarcadores investigados e discutir a interpretação de seus achados, incluindo sua relevância e seu significado no contexto fisiopatológico da doença. A conferência das citações no texto de resultados e na tabela do manuscrito identificou 12 fontes únicas: seis publicações primárias e seis revisões. Entre as primárias,

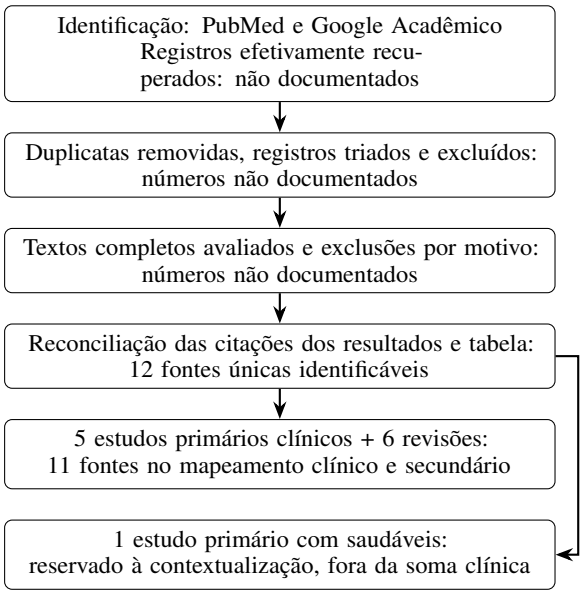

Figura 1. Fluxo retrospectivo de documentação e reconciliação. As contagens finais descrevem fontes identificáveis no manuscrito, não uma reprodução integral da seleção histórica. Não se inferiram exclusões a partir da diferença para totais anteriormente declarados.

cinco investigaram grupos clínicos [20], [22], [23], [26], [27]; a sexta avaliou adultos saudáveis e foi reservada à contextualização [28]. Assim, o mapeamento clínico e sua síntese secundária compreendem 11 fontes, discriminadas nas Tabelas II e IV. A Figura 1 distingue essa reconciliação do processo histórico de busca.

Os tamanhos explicitados na Tabela II somam 451 participantes entre estudos: $95+206+65+61+24$. Esse total combina os tamanhos declarados nas etapas disponíveis de

RMf em repouso sob citalopram e galantamina; efeito farmacológico sobre conectividade. Parâmetros de aquisição e número utilizável por condição: NC.

cada publicação, utilizando a amostra pós-exclusão de Liu et al.; não representa uma amostra combinada uniformemente pós-controle de qualidade nem indivíduos comprovadamente distintos. Os 193 adultos saudáveis de Saiz-Masvidal et al. não integram essa soma clínica [28]. As revisões não possuem amostra primária própria atribuível a este artigo.

B. Evidências clínicas primárias

Os estudos investigam desfechos diferentes, resumidos na Tabela III. Wu et al. identificaram redução de conectividade das subdivisões intralaminar e medial do tálamo com o precuneus esquerdo. A associação com MMSE foi relatada para a conexão do núcleo medial, não indistintamente para todas as conexões talâmicas [20].

Serra et al. examinaram diferenças de conectividade da área tegmental ventral (ATV) e do locus coeruleus. Os contrastes clínicos sustentam envolvimento mesencefálico, mas não equivalem a medição de dopamina ou a demonstração longitudinal de conversão. O resultado negativo do locus coeruleus deve ser interpretado com as limitações espaciais reconhecidas pelos autores [22].

Tang et al. investigaram conexões de sementes cerebelares e encontraram diferenças dependentes da região e do grupo. A descrição preserva essa especificidade, sem atribuir aumento ou redução ao cerebelo inteiro [23]. Liu et al. avaliaram lateralização funcional global; o iLI não é uma medida volumétrica hipocampal e seus resultados não foram convertidos em perda anatômica localizada [26].

Klaassens et al. estudaram modulação farmacológica da conectividade. Seu desenho permite discutir responsividade de sistemas neuromodulatórios, mas deve permanecer separado de comparações observacionais basais e de estudos de acurácia diagnóstica [27].

C. Evidências secundárias e contextualização

As seis revisões têm funções distintas (Tabela IV). A literatura secundária descreve alterações da RMP e de circuitos relacionados à memória, além da heterogeneidade dos métodos e das populações. Os relatos de redução posterior e de aumentos regionais não foram contados como replicações independentes quando provenientes de revisões potencialmente sobrepostas [17]–[19].

Paradigmas com tarefa são discutidos nas revisões, mas os cinco estudos clínicos primários identificados neste conjunto não constituem uma amostra de experimentos de codificação e recuperação de memória. Não se atribuiu a Liu et al. um paradigma com tarefa. Também não se presumiu que toda alteração de ativação em tarefa correspondesse a alteração equivalente de conectividade em repouso [6], [17].

A revisão de Patthy et al. discute mecanismos monoaminérgicos, mas não permite atribuir à RMf a mensuração direta da disponibilidade de transportadores [21]. O estudo de Saiz-Masvidal et al., realizado em adultos saudáveis, foi utilizado apenas como contexto de mapeamento multimodal e não como demonstração de alteração clínica na DA [28].

D. RMf em repouso

Os achados de conectividade funcional concentraram-se na RMP, que inclui o córtex cingulado posterior, o precuneus e o córtex pré-frontal medial. Reduções de conectividade nessas regiões foram recorrentes em grupos com DA [17], [18]. Em grupos com CCL, foram descritos tanto aumentos quanto reduções regionais, comportamento interpretado em parte da literatura como possível reorganização compensatória [17], [19]. Como a maior parte dessas comparações é transversal, os dados não estabelecem uma trajetória universal de hiperconectividade seguida por hipoconectividade.

Tabela III. Correspondência entre evidência primária, achado funcional e limite interpretativo. A direção refere-se à comparação original, não a uma trajetória universal.

Fonte	Achado ou desfecho	Interpretação delimitada
Wu et al. [20]	Redução da conectividade tálamo–precuneus nos pacientes; classificação por SVM explorada.	Associação cognitiva e discriminação na amostra não demonstram utilidade clínica externa.
Serra et al. [22]	Desconexão da ATV predominantemente parietal no CCL amnéstico e em nós posteriores da RMP na DA; sem evidência de desconexão do locus coeruleus.	Comparação entre grupos, sem acompanhamento da conversão em 24 meses. Ausência de diferença não comprova integridade do núcleo.
Tang et al. [23]	Padrões distintos de conectividade de Crus II e lóbulo IX, com aumentos e reduções conforme a conexão e o contraste.	Evidência regional cerebelocortical; não comprova compensação ou progressão intraindividual.
Liu et al. [26]	Mudanças no padrão de lateralização funcional entre controles, CCL e DA.	Métrica global de conectividade em repouso; não corresponde à ativação hipocampal durante tarefa nem a uma medida estrutural.
Klaassens et al. [27]	Resposta da conectividade a intervenções colinérgica e serotoninérgica.	Evidência farmacológica; não demonstra redução direta de transportadores por RMf.

Tabela IV. Fontes secundárias identificadas nos resultados e na tabela original. Nenhuma acrescenta participantes primários próprios à soma clínica.

Fonte	Tipo de publicação	Função na síntese e limite
Forouzannezhad et al. (2019) [6]	Revisão de aplicações e métodos	Contextualiza paradigmas e processamento de RMf; não constitui uma coorte clínica adicional.
Zhang et al. (2023) [17]	Revisão sobre patogênese e imagem	Contextualiza achados de diferentes modalidades; resultados estruturais não foram convertidos em BOLD.
Ibrahim et al. (2021) [18]	Revisão sistemática	Sintetiza investigação diagnóstica por RMf em repouso; os estudos que a compõem não foram automaticamente incorporados como novas inclusões.
Jalilianhasanpour et al. (2019) [19]	Revisão	Contextualiza conectividade em doenças neurodegenerativas; associações genéticas não demonstram especificidade diagnóstica.
Patthy et al. (2021) [21]	Revisão neuropatológica e mecanística	Fundamenta o interesse por núcleos monoaminérgicos; não constitui evidência primária de redução rafe–precuneus por BOLD em pacientes.
Seoane et al. (2024) [29]	Revisão sistemática e metanálise	Amplia o mapeamento subcortical da RMP; sobreposição de estudos exige cautela ao interpretar convergência.

Alterações funcionais envolvendo hipocampo, giro parahipocampal e córtex cingulado posterior também foram relatadas [17], [18]. A redução de conectividade entre componentes posteriores e temporais mediais da RMP foi descrita tanto no CCL amnéstico quanto na DA. Em alguns contrastes, aumentos em regiões frontais coexistiram com reduções posteriores, mostrando que a direção do efeito depende da conexão e da métrica analisadas. O estudo de Liu et al. avaliou lateralização da conectividade funcional em repouso e encontrou mudanças nos padrões de lateralização entre controles, CCL e DA [26]. Medidas anatômicas de assimetria ou perda de substância cinzenta pertencem à RM estrutural e foram excluídas dos resultados BOLD.

Estudos de estruturas subcorticais relataram alterações de conectividade em subdivisões talâmicas, incluindo núcleos intralaminares e conexões com o precuneus, algumas associadas ao desempenho cognitivo [20]. A especificidade espacial desses resultados depende, contudo, do método de segmentação e da resolução empregada.

A área tegmental ventral e outros núcleos do tronco encefálico também foram investigados [21], [22]. Em estudo longitudinal com participantes com CCL atribuído à DA, aqueles que converteram para demência em 24 meses apresentaram, no início do seguimento, menor conectividade dirigida da área tegmental ventral com o córtex cingulado posterior e o córtex pré-central [22]. Esse resultado é relevante para o prognóstico, mas não autoriza generalizar a redução para todas as projeções dopaminérgicas ou para todos os indivíduos com CCL.

Quanto ao núcleo da rafe dorsal, estudos neuropatológicos, farmacológicos e mapas de conectividade em adultos saudáveis oferecem plausibilidade para o envolvimento de sistemas serotoninérgicos na DA [21], [27], [28]. Entretanto, a evidência para uma redução específica e reprodutível da conexão rafe–precuneus como marcador diagnóstico ainda é limitada. Em razão do pequeno volume desses núcleos e da resolução espacial convencional da RMf, os achados do tronco encefálico exigem cautela e replicação externa.

No cerebelo, alterações envolvendo Crus I, Crus II e lóbulo IX foram descritas no CCL e na DA [23], [29]. No estudo de Tang et al., o Crus II esquerdo apresentou diferenças de conectividade com tálamo, caudado e regiões frontais, temporais, límbicas e parietais; parte dessas alterações esteve associada ao desempenho cognitivo [23]. O lóbulo IX, por sua vez, participa da representação cerebelar da RMP; foram relatadas alterações em suas conexões com regiões parietais próximas ao precuneus [23], [29]. As direções dos efeitos variaram conforme a região-semente e o contraste, o que

impede resumir o envolvimento cerebelar como aumento ou redução global. Estudos exclusivamente volumétricos não foram considerados evidência funcional direta.

Paradigmas de codificação e recuperação da memória revelaram diferenças de ativação hipocampal entre controles, CCL e DA em ressonância magnética com tarefa [17]. No CCL, a literatura descreve aumento de ativação durante alguns paradigmas de codificação e redução durante a recuperação, enquanto grupos com DA apresentam, com maior frequência, menor recrutamento hipocampal. A aparente hiperativação foi interpretada como possível compensação, mas também pode refletir dificuldade da tarefa, desempenho desigual ou menor eficiência neural. Esses achados requerem interpretação separada da conectividade em repouso, pois dependem do paradigma, desempenho e contraste.

A Tabela V sintetiza os principais padrões funcionais por estágio e sistema cerebral. A versão detalhada, com todos os achados e limites interpretativos, está disponível na tabela suplementar online.

IV. Discussão

O mapeamento indica que a literatura de RMf no CCL e na DA se concentra na conectividade da RMP e de regiões relacionadas à memória. Alterações no córtex cingulado posterior, no precuneus, no córtex pré-frontal medial e no sistema temporal medial aparecem de forma recorrente [17], [18]. Isso sustenta a compreensão da DA como condição que envolve redes distribuídas, e não apenas o hipocampo. Contudo, a recorrência em comparações entre grupos não constitui validação diagnóstica individual.

O córtex cingulado posterior e o precuneus ocupam posição central na integração da RMP e se relacionam a processos de memória episódica e cognição autorreferencial. Sua desconexão do hipocampo e do giro parahipocampal pode indicar menor eficiência de comunicação entre os subsistemas posterior e temporal medial. O aumento da conectividade em regiões frontais, quando observado, pode representar recrutamento adicional diante da disfunção posterior; alternativamente, pode refletir perda de especialização e segregação entre redes. Essas interpretações não são mutuamente exclusivas e exigem associação longitudinal com desempenho cognitivo e carga patológica.

A coexistência de aumentos e reduções de conectividade, sobretudo no CCL, pode refletir diferenças de estágio, seleção de amostras, reserva cognitiva, carga neuropatológica e processamento dos dados. A interpretação da hiperconectividade como compensação é biologicamente plausível, mas permanece uma hipótese quando não há acompanhamento longitudinal ou relação direta com manutenção do desempenho. Da mesma forma, estudos transversais não demonstram que todos os indivíduos percorram uma sequência de hiperconectividade seguida por hipoconectividade [17], [19].

O envolvimento do tálamo, da área tegmental ventral e de outros núcleos do tronco encefálico amplia o modelo centrado em regiões corticais e hipocampais [20]–[22]. Entretanto, a segmentação de núcleos pequenos é vulnerável à resolução espacial, ao movimento, ao registro anatômico e aos efeitos de volume parcial. A evidência neuropatológica e a conectividade observada em adultos saudáveis oferecem plausibilidade biológica, mas não validam, isoladamente, uma conexão específica como biomarcador da DA.

A área tegmental ventral origina projeções dopaminérgicas mesocorticolímbicas relacionadas à memória, à motivação e ao comportamento. Alterações desse sistema podem contribuir para sintomas como apatia, anedonia e redução da motivação, além do declínio cognitivo [30]. O núcleo da rafe dorsal, por sua vez, constitui uma importante origem de projeções serotoninérgicas para regiões límbicas e corticais; sua disfunção tem sido relacionada a sintomas neuropsiquiátricos e distúrbios do sono [31]. A passagem da plausibilidade mecanística para um biomarcador requer demonstração independente de especificidade, repetibilidade e valor prognóstico.

As alterações descritas em Crus II e no lóbulo IX apoiam a participação do cerebelo em redes cognitivas [23], [29], [32]. A direção dos efeitos, porém, depende da região-semente e do contraste analisado. Por isso, expressões como "envolvimento cerebelar" são mais adequadas do que uma afirmação de aumento ou redução global da conectividade.

Esse conjunto de achados é compatível com a compreensão contemporânea de que regiões cerebelares posteriores participam de circuitos associados à memória de trabalho, linguagem, atenção e regulação afetiva [32]. O interesse no cerebelo amplia o campo para além das regiões corticais tradicionalmente enfatizadas, mas ainda há menos estudos e maior diversidade de sementes e métodos do que na investigação da RMP. Assim, os resultados cerebelares devem ser apresentados como uma frente promissora de pesquisa, e não como marcador consolidado.

Os estudos incluídos também devem ser interpretados à luz da heterogeneidade clínica. O CCL não possui necessariamente etiologia da doença de Alzheimer e pode permanecer estável ou decorrer de outras condições [7], [9]. Além disso, apresentações atípicas da DA podem produzir perfis funcionais diferentes da forma amnéstica [10]. Estudos futuros devem estratificar participantes por fenótipo e por evidência de patologia amiloide e tau.

A heterogeneidade metodológica é igualmente relevante. Análises baseadas em sementes dependem da definição da região de interesse; decomposição por componentes independentes, métricas de amplitude local e análises de grafos descrevem aspectos diferentes da função cerebral. Movimento de cabeça, duração da aquisição, estado de vigília, correção do sinal global, atrofia e fatores vasculares podem modificar as estimativas de conectividade. Um mapa de evidências deve tornar essas diferenças visíveis, evitando agrupar desfechos distintos como "conectividade alterada".

Para uso clínico, um potencial biomarcador deve demonstrar repetibilidade, sensibilidade, especificidade, validação externa e benefício adicional em relação à avaliação clínica, neuropsicológica e aos biomarcadores disponíveis. A RMf não utiliza radiação ionizante, mas requer aquisição padronizada, controle rigoroso de movimento, processamento especializado e validação multicêntrica. Assim, a maior disponibilidade de

Tabela V. Versão resumida dos principais achados funcionais mapeados no CCL e na DA. A tabela completa, com a discriminação de regiões e comparações, está disponível online. CCL: comprometimento cognitivo leve; CCLa: comprometimento cognitivo leve amnéstico; DA: doença de Alzheimer; RMP: rede de modo padrão; ATV: área tegmental ventral; CCP: córtex cingulado posterior.

Estrutura ou rede	Achado resumido	Estágio e técnica	Síntese clínica e limite	Fontes
Hipocampo e RMP	Na tarefa, menor ativação na recuperação e maior na codificação; em repouso, redução da conectividade CCP–parahipocampo e alteração da lateralização hipocampal.	CCL; RMf em tarefa e repouso (BOLD)	Padrão dependente da etapa da memória e da métrica; aumentos não comprovam compensação.	[17], [18], [26]
Redes cerebelares	Aumentos e reduções envolvendo tálamo, regiões frontoparietais, Crus II e lóbulo IX.	CCL/CCLa; RMf em repouso (BOLD)	Reorganização regional heterogênea, sem trajetória ou mecanismo compensatório demonstrado.	[23]
RMP e lobo temporal medial	Predomínio de redução da conectividade no CCP, precuneus, hipocampo e córtex entorrinal; aumentos frontais ou durante a codificação em alguns contrastes.	DA; RMf em repouso e com tarefa (BOLD)	Desorganização de redes de memória; direção variável por conexão, sem inferência causal ou diagnóstica individual.	[17], [18]
Redes corticais e lateralização	Alterações sensoriomotoras, visuais e auditivas, interrupção parahipocampal e redução da assimetria funcional.	DA; RMf em repouso e tarefa (BOLD)	Distribuição ampla e dependente do método; achados morfológicos não equivalem a medidas BOLD.	[6], [26]
Tálamo–precuneus	Redução da conectividade de subdivisões talâmicas, incluindo núcleos intralaminares, com o precuneus.	DA; RMf em repouso (BOLD)	Associação com pior desempenho cognitivo, ainda sem validação clínica externa.	[20]
Núcleos do tronco encefálico	Redução de conexões da ATV com redes parietais/RMP e associações neuropsiquiátricas; alteração da conexão rafe–precuneus descrita; ausência de diferença significativa no locus coeruleus.	CCL e DA; RMf em repouso (BOLD)	Evidência regional; a resolução e os efeitos de volume parcial limitam a análise de núcleos pequenos, e a RMf não mede neurotransmissores diretamente.	[21], [22]
Crus II e lóbulo IX	Redução de conexões cerebelares com regiões frontais, temporais, límbicas, parietais e subcorticais.	DA; RMf em repouso (BOLD)	Comprometimento cerebelocortical específico por semente; não indica redução global do cerebelo.	[23]

equipamentos de RM em comparação com PET não permite concluir, por si só, que a RMf constitua alternativa acessível ou custo-efetiva no SUS.

No contexto brasileiro, a elevada dependência do SUS e a distribuição desigual de recursos diagnósticos justificam investigar métodos potencialmente escaláveis. Entretanto, a eventual incorporação da RMf dependerá não apenas da disponibilidade do equipamento, mas também do tempo de aquisição, da capacidade de processamento, do treinamento das equipes, do controle de qualidade e da demonstração de benefício clínico. Nesse estágio, sua contribuição mais bem sustentada está na compreensão fisiopatológica e na pesquisa de candidatos a biomarcadores complementares.

V. Conclusão

A literatura mapeada indica que alterações funcionais na RMP, no hipocampo, em circuitos subcorticais e em redes do tronco encefálico e do cerebelo são investigadas como potenciais biomarcadores no CCL e na DA. Entretanto, a heterogeneidade das populações, dos protocolos e dos métodos analíticos, aliada à limitada validação longitudinal e externa, ainda restringe sua aplicação clínica individual. Os achados devem, portanto, ser compreendidos como candidatos a biomarcadores em pesquisa. Estudos futuros devem priorizar protocolos padronizados, coortes multicêntricas, confirmação etiológica e avaliação do valor incremental da RMf em relação aos métodos diagnósticos existentes.

***Abstract*—Microcalcifications are relevant mammographic findings whose identification can be challenging because of their small size and low local contrast. This study evaluated and compared three convolutional neural network architectures pre-trained on ImageNet (VGG19, InceptionV3, and ResNet50V2) for binary classification of mammographic regions of interest according to the presence or absence of microcalcifications. A balanced dataset containing 5,378 ROIs derived from the INbreast database was used, comprising 2,689 samples from each class. The dataset was divided into training, validation, and test subsets using an 80/10/10 ratio. The models were trained using data augmentation and a two-stage transfer-learning strategy, in which the model was trained before fine-tuning the last 20 backbone layers. Performance was evaluated on a test set containing 538 ROIs. VGG19 achieved the highest overall performance, with an accuracy of 92.75%, sensitivity of 91.45%, specificity of 94.05%, F1-score of 92.66%, and AUC of 0.9708. ResNet50V2 achieved an accuracy of 88.85% and an AUC of 0.9344, whereas InceptionV3 achieved an accuracy of 86.25% and an AUC of 0.9305. Under the evaluated conditions, VGG19 provided the best balance between positive-class detection and overall discrimination.**

***Index Terms*—Breast cancer, convolutional neural networks, deep learning, mammography, microcalcifications, transfer learning.**

I. Introduction

Breast cancer still ranks high among public health issues, mainly because it remains very common and because late diagnosis directly affects the prognosis. For this reason, early detection is essential for improving clinical outcomes. In this context, mammography plays a central role, as it is the most widely used screening method and allows the identification of breast changes even before obvious clinical manifestations appear [1]. Among the most relevant mammographic findings, microcalcifications stand out as potential indicators of malignancy. Microcalcifications are small calcium deposits in breast tissue that may be associated with benign or malignant lesions, depending on their morphological characteristics and distribution. Traditionally, microcalcification analysis is performed by experienced radiologists, a process that requires time and expertise and is subject to interobserver variability [2]. Furthermore, mammography depends not only on the image itself but also on the experience of the interpreter. Interpretation can vary among observers, and this point becomes even more important when dealing with subtle findings. In such situations, computational tools that help highlight relevant patterns become highly useful, primarily as support for the specialist and not as substitute for medical analysis [3]. In this scenario, artificial intelligence methods have increasingly been investigated within medical image analysis. Among these computational approaches, deep learning frameworks, particularly convolutional neural networks (CNNs), distinguish themselves by automatically extracting hierarchical feature representations directly from raw pixel data, eliminating the dependency on operator-dependent and handcrafted features. This sub-surface feature learning is very useful in digital mammography, where microcalcification detection relies on capturing highly subtle variations in local contrast, granular texture, and complex spatial distributions that are difficult to formalize into static, rule-based algorithms [3]. Another important factor is that, in medical applications, massive image datasets are not commonly available. For this reason, the use of pre-trained models with transfer learning has become a very

useful strategy. Instead of starting training from scratch, one benefits from an architecture that has already been trained on a large dataset and adapts that knowledge to a specific task. In practice, this helps make the process more feasible and often improves the model's performance on smaller, more specialized datasets [4]. In recent years, several studies have demonstrated the application of convolutional neural networks in mammography for segmentation, detection, and classification. Even so, there are still differences among published studies, particularly regarding the type of image used, preprocessing methods, and chosen models. Therefore, it still makes sense to compare well-established architectures when seeking to understand which one performs best on a specific problem, such as distinguishing regions with microcalcifications from regions without microcalcifications [5]. To facilitate microcalcification detection, this study aims to evaluate and compare the performance of three pre-trained convolutional neural network (CNN) architectures for binary classification of digital mammographic regions of interest (ROIs) containing or lacking microcalcifications. Using transfer learning and data augmentation strategies on data derived from the public INbreast database, this research explores how residual connections, multi-scale feature extraction, and architectural depth impact the model's ability to capture subtle contrast and textural patterns in a small medical dataset. This study compares VGG19, ResNet50V2, and InceptionV3 for the binary classification of mammographic ROIs with and without microcalcifications. To improve the fairness of the comparison, all architectures were evaluated using the same dataset split, batch size, optimizer, learning rates, classification head, data-augmentation strategy, and fine-tuning procedure. Performance was assessed using accuracy, sensitivity, specificity, precision, F1-score, and AUC.

II. Methods

A. Dataset

The images used in this study consist of regions of interest (ROIs) extracted from digital mammograms provided by the public database InBreast [6], divided into two classes as seen in Table I:

TABLE I
Distribution and Categorization of the Extracted Mammographic Regions of Interest

Class	Description	Quantity
With Microcalcification	ROIs containing microcalcifications (suspicious or benign)	2689 samples
Without Microcalcification	ROIs without microcalcifications (normal breast tissue)	2689 samples

In total, 5,378 ROIs with size of 100×100 pixels were provided in a 16-bit format (pixel values ranging from 0 to 4,095), preserving the original radiographic resolution. To ensure compatibility with the pre-trained models (which expect RGB images), the following preprocessing methods were applied:

1) Conversion to 3 channels (simulating RGB images)
2) Normalization of pixels to the range [0, 1] (division by 4,095)
3) Resizing pixel spatial resolution to the CNN model input

The 100×100 pixel size is the most appropriately area to represent a breast region containing microcalcifications (usually smaller than 1 millimeter), allowing visualization of local anatomical context without including unnecessary areas. However, the regions of interest were resized to 224×224 pixel size for input compatibility with the ResNet50V2 and VGG19 models. On the InceptionV3 model, the spatial resolution was resized to 299×299, as necessary for the input size.

B. Data Division

The data were divided into training, validation, and test sets using an 80/10/10 ratio, as shown in Table II, ensuring that all models were evaluated on the same test set.

TABLE II
Data Partitioning Strategy for Model Training, Validation, and Test

Set	Proportion	Quantity	Purpose
Training	80%	4302 ROIs	Model weight tuning
Validation	10%	538 ROIs	Hyperparameter tuning and early stopping
Test	10%	538 ROIs	Final performance evaluation

The dataset was stratified to maintain class proportion across the splits, and a fixed random seed was used to ensure the reproducibility of the experiments.

C. Architectures of the Evaluated Models

Three pre-trained architectures widely used in the medical computer vision literature – VGG19, InceptionV3 and ResNet50V2 – were evaluated. These models were pre-trained on ImageNet [7] [8], an image dataset with over a million training images and 1,000 object classes. The original ImageNet classification head was removed from each architecture and replaced with the same custom binary classification head. Table III summarizes the main structural characteristics and the input configuration adopted for each backbone.

1) VGG19 (Visual Geometry Group - 19 layers):

VGG19 is a sequential convolutional neural network developed by the Visual Geometry Group at the University of Oxford. As summarized in Table III, it comprises 16 convolutional layers organized into five blocks. The architecture applies successive 3×3 convolutional filters to progressively extract image features, with max-pooling operations used between blocks to reduce spatial resolution. The simplicity and uniformity of its architecture have made VGG19 a widely used benchmark model [9]. In the original ImageNet architecture, the convolutional backbone is followed by three fully connected layers. However, these original classification layers

TABLE III
STRUCTURAL CHARACTERISTICS AND FEATURES OF THE EVALUATED CNN BACKBONES

Characteristic	**VGG19**	**InceptionV3**	**ResNet50V2**
Main architectural design	Sequential convolutional blocks	Parallel multi-scale convolutional modules	Residual bottleneck blocks with skip connections
Structural organization	16 convolutional layers organized into five blocks	11 Inception modules with parallel processing paths	16 residual bottleneck blocks
Main convolutional operations	Successive 3×3 convolutions	Parallel and factorized convolutions	1×1 and 3×3 bottleneck convolutions
Distinctive mechanism	Uniform sequential feature extraction	Multi-scale feature extraction	Residual learning with identity mappings
Approximate backbone parameters	20.0 million	21.8 million	23.6 million
Backbone output channels	512	2048	2048
Input size used in this study	$224 \times 224 \times 3$	$299 \times 299 \times 3$	$224 \times 224 \times 3$
Custom classification head	Global average pooling, dropout (0.3), and sigmoid output	Global average pooling, dropout (0.3), and sigmoid output	Global average pooling, dropout (0.3), and sigmoid output

were not used in the present study. Instead, the convolutional backbone was connected to the common classification head described in Table III, consisting of global average pooling, dropout with a rate of 0.3, and a sigmoid output unit. The original 100×100-pixel mammographic ROIs were resized to 224×224 pixels and replicated across three channels before being provided to VGG19. The model was initialized with ImageNet weights and subsequently adapted to the microcalcification classification task using fine-tuning described in Section II-D [9].

2) InceptionV3:

The InceptionV3 architecture focuses on increasing computational efficiency and network width, performing convolutions of different sizes (1x1 and 3x3) and pooling operations in parallel. This allows the network to capture features at multiple scales within the same module. InceptionV3 differs from the original Inception concept by transforming a 5×5 convolution into two stacked 3×3 convolutions to reduce the number of parameters and computational cost, together with batch normalization to stabilize and accelerate training. The architecture is relatively deep but computationally more efficient than VGG19, requiring a minimum input size of 75×75 pixels and being optimized for an input of 299×299 pixels. This architectural optimization makes InceptionV3 a strong candidate for clinical environments where computational bandwidth and memory efficiency are critical operational constraints [10]. InceptionV3 architecture is summarized in Table III. The original mammographic ROIs were resized to 299×299 pixels and converted to three channels before being provided to the backbone. The model was initialized with ImageNet weights and fine-tuned for the classification of ROIs according to the presence of microcalcifications [10].

3) ResNet50V2 (Residual Network - 50 layers):

ResNet50V2 is an evolution of the original residual network (ResNet), proposed to facilitate the training of deep neural networks through residual connections, also known as skip connections. This approach allows gradients to propagate directly through the network during training, mitigating the vanishing gradient problem common in deep architectures. ResNet50V2 introduces a pre-activation design, in which batch normalization and ReLU activation are applied before each convolution rather than after. This configuration, with its 50 weighted layers, employs "bottleneck" blocks that are computationally more efficient, making the network faster than other architectures [11]. Table III presents the architecture of ResNet50V2. Each bottleneck block combines 1×1 convolutions, used to reduce or restore channel dimensionality, with 3×3 convolutions for spatial feature extraction. The mammographic ROIs were resized to 224×224 pixels, converted to three channels, and provided to the backbone initialized with ImageNet weights [11].

D. Transfer Learning

To initialize the network with a feature representations, a transfer learning approach was adopted [12]. The backbone architectures were pre-trained on ImageNet [7], a large-scale natural image dataset. This initialization provides a advantage by using general visual patterns learned from millions of images [13], thereby accelerating convergence and mitigating the risk of overfitting [14], especially given the relatively limited size of medical imaging datasets. To fine-tune the models, training was carried out in two stages. In the first stage, the backbone was kept fully frozen and the model was trained for 5 epochs, using a learning rate of 1×10^{-3}. In the second stage, the last 20 layers of the backbone were unfrozen and retrained with a reduced learning rate of 1×10^{-5}, allowing these layers to adapt to the specific characteristics of the dataset while minimizing the risk of disrupting the pre-trained weights.

E. Data Augmentation for Mammograms

To artificially expand the training set and enhance the model's generalization capability, a set of data augmentation strategies was employed [15]. These transformations were

selected to preserve the clinical integrity of the mammographic images while simulating realistic variations encountered in routine screening [16]. The following geometric augmentations were applied, inspired by techniques commonly used in deep learning [17], [18]:

- **Rotation (±20 degrees):** Accounts for minor variations in breast positioning and compression during image acquisition [19].
- **Horizontal and Vertical Shifts (±20%):** Simulates small displacements of the region of interest (ROI) relative to the image frame.
- **Zoom (±20%):** Introduces variability in the magnification scale, compensating for differences in imaging equipment and patient anatomy.
- **Horizontal Flip (Enabled):** Exploits the bilateral symmetry between left and right breasts, allowing the model to learn invariant features from both sides.

Transformations that could distort the morphological characteristics of microcalcifications, such as shearing, elastic deformations, or non-rigid warping, were intentionally omitted. Preserving the shape, size, and spatial distribution of microcalcifications is important in medical analysis, as these features are often indicators of malignancy in mammographic findings [20]. Therefore, all augmentations were constrained to rigid and affine transformations that maintain pixel intensity relationships and structural fidelity.

F. Hyperparameters

The same training configuration was applied to VGG19, ResNet50V2, and InceptionV3. The hyperparameters were empirically selected using the training and validation subsets, without using information from the test set. The Adam optimizer was adopted because of its adaptive learning-rate mechanism and suitability for stochastic optimization [21]. The main training and fine-tuning parameters are summarized in Table IV.

TABLE IV
MAIN TRAINING AND FINE-TUNING PARAMETERS

Parameter	Value	Purpose
Batch size	16	Common batch size for all models
Optimizer	Adam; weight decay: 1×10^{-4}	Optimization and regularization
Initial training	5 epochs; LR: 1×10^{-3}	Training with the backbone frozen
Fine-tuning	Last 20 layers; LR: 1×10^{-5}	Adaptation of high-level features
Early stopping	Validation AUC; patience: 5	Prevention of unnecessary training
LR scheduler	Factor: 0.5; patience: 3	Learning-rate reduction after a plateau

Binary cross-entropy was used as the loss function. The custom classification head consisted of a global average pooling layer, followed by a dropout layer with a rate of 0.3, and a single sigmoid output unit. Dropout and weight decay were adopted to reduce the risk of overfitting during training [22]. A threshold of 0.5 was applied to convert the sigmoid probabilities into binary predictions. EarlyStopping and ReduceLROnPlateau were applied only during the second training stage, with both callbacks monitoring validation AUC. EarlyStopping terminated training after five consecutive epochs without improvement, limiting unnecessary training and reducing the risk of overfitting [22]. ReduceLROnPlateau reduced the learning rate by a factor of 0.5 after three consecutive epochs without improvement, allowing smaller updates to the model weights after the validation metric reached a plateau.

G. Evaluation Metrics

The evaluation metrics employed to assess the performance of the models are summarized in Table V. Accuracy measures the overall proportion of correct diagnoses, while sensitivity and specificity evaluate the model's ability to detect true microcalcifications and correctly identify normal tissue, respectively. Precision assesses the reliability of positive predictions, and the F1 score was adopted as a balanced measure between precision and recall, particularly relevant for handling potential class imbalance [23]. The Area Under the Receiver Operating Characteristic Curve (AUC-ROC) was employed to evaluate the overall discriminating capacity of the models across all classification thresholds [24].

TABLE V
DEFINITIONS OF THE BINARY CLASSIFICATION PERFORMANCE METRICS

Metric	Formula	Interpretation
Accuracy	(TP+TN)/Total	Overall proportion of correct predictions
Sensitivity (Recall)	TP/(TP+FN)	Ability to detect true microcalcifications
Specificity	TN/(TN+FP)	Ability to identify normal tissue
Precision	TP/(TP+FP)	Probability that a finding is truly a microcalcification
F1 Score	$2 \times (P \times R)/(P + R)$	Balance between precision and recall
AUC-ROC	Area under ROC curve	Overall discriminative capacity of the test

Where: TP = True Positives, TN = True Negatives, FP = False Positives, FN = False Negatives, P = Precision and R = Recall. High sensitivity indicates a low rate of false negatives, which is critical to avoid undetected cancer cases, while high specificity indicates a low rate of false positives, which is essential to avoid unnecessary biopsies and patient recall. The F1-Score provides a balanced measure when both precision and recall are equally important for the clinical application.

III. RESULTS

The classification performance of each evaluated CNN architecture was assessed on the independent test set. The metrics acquired from these experiments, encompassing overall classification accuracy, sensitivity, specificity, precision, F1-score, and AUC-ROC, are consolidated and cross-compared in Table VI.

TABLE VI
CLASSIFICATION PERFORMANCE COMPARISON ACROSS THE THREE CNN ARCHITECTURES

Metrics	ResNet50V2	InceptionV3	VGG19
Accuracy (%)	88.85	86.25	92.75
Sensitivity (Recall) (%)	82.53	81.04	91.45
Specificity (%)	95.17	91.45	94.05
Precision (%)	94.47	90.46	93.89
F1-Score (%)	88.09	85.49	92.66
AUC (%)	93.44	93.05	97.08

A. Analysis by Model

1) VGG19: VGG19 produced the best overall results among the three architectures. It achieved the highest sensitivity (91.45%), detecting approximately 91 out of 100 microcalcifications, along with the highest AUC (97.08%) and F1-score (92.66%), reflecting a balanced relationship between precision and recall. During fine-tuning, the learning rate was reduced to 5×10^{-6} at epoch 28 after validation AUC plateaued, and early stopping was triggered at epoch 38. The binary confusion matrix for the VGG19 model is shown in Fig. 1. The model correctly identified 246 true positives and 253 true negatives, with only 16 false positives and 23 false negatives.

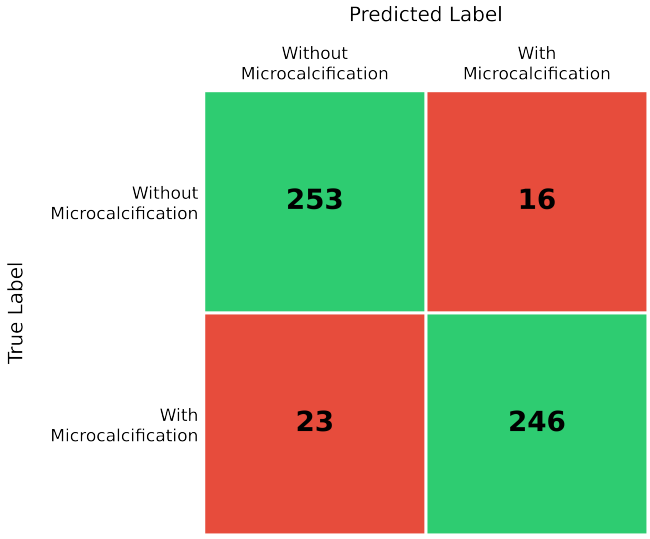

Fig. 1. Binary Confusion Matrix for VGG19

2) ResNet50V2: ResNet50V2 obtained the highest specificity among the three architectures (95.17%), indicating a low rate of false positives, and the highest precision (94.47%), although both metrics are close to VGG19 results. The confusion matrix in Fig. 2 shows 222 true positives, 256 true negatives, 13 false positives, and 47 false negatives, corresponding to a sensitivity of 82.53%. The learning rate was reduced to 5×10^{-6} at epoch 30, and early stopping was triggered at epoch 34.

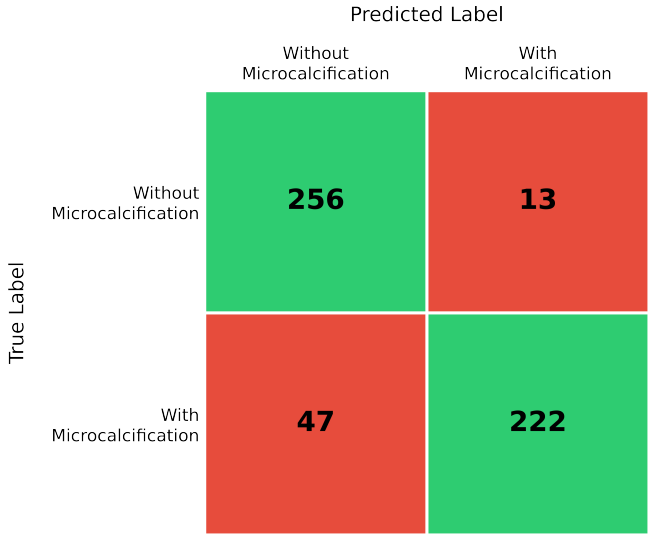

Fig. 2. Binary Confusion Matrix for ResNet50V2

3) Inception V3: InceptionV3 achieved the lowest results among the three architectures, although some metrics are close to ResNet50V2 performance. During fine-tuning, the learning rate was reduced to 5×10^{-6} at epoch 45, and early stopping was triggered at epoch 48. It obtained a sensitivity of 81.04%, specificity of 91.45%, and precision of 90.46%. Fig. 3 displays the confusion matrix for InceptionV3, indicating that the model correctly identified 218 true positives and 246 true negatives, but produced 23 false positives and 51 false negatives, the highest false-negative count among the three models.

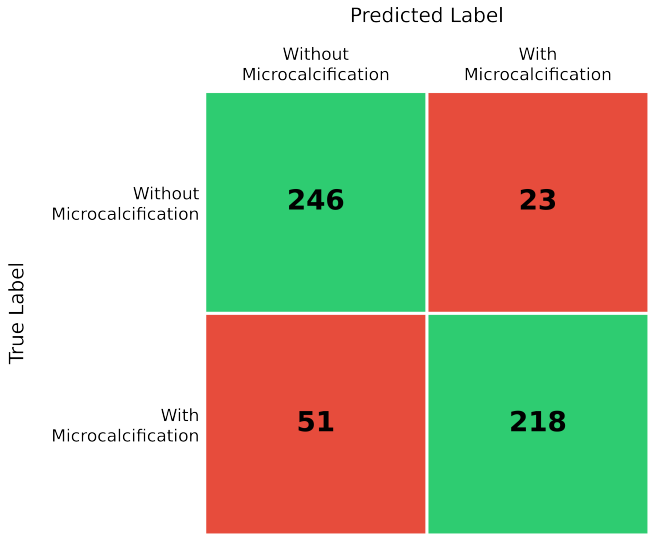

Fig. 3. Binary Confusion Matrix for InceptionV3

Fig. 4 provides a comparative performance analysis of the three CNN architectures evaluated for microcalcification detection. The multi-bar chart compares Accuracy, Recall, and

F1-Score, showing the superior performance of the VGG19 model.

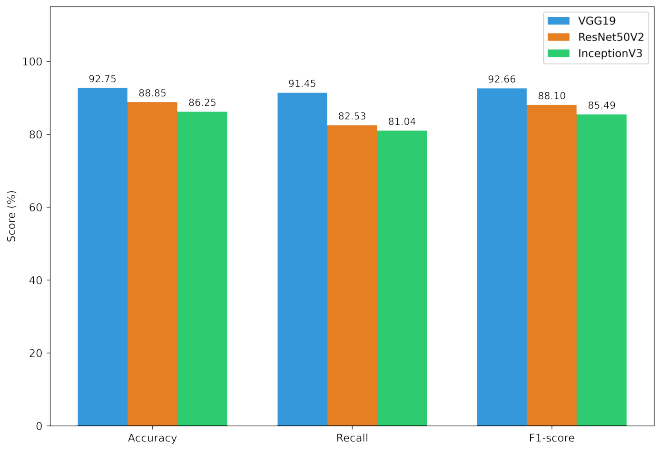

Fig. 4. Visual comparison of key metrics among models for the detection of microcalcifications

Fig. 5 presents the ROC curves for the three architectures. VGG19 (AUC = 0.97) maintains the highest true positive rate across nearly all false positive rate thresholds. ResNet50V2 and InceptionV3 achieve nearly identical overall performance (AUC = 0.93 for both), with their curves closely overlapping throughout most of the plot, but ResNet50V2 shows a minimal advantage over InceptionV3 at lower false positive rates. As the false positive rate increases, however, the two curves progressively converge, indicating that the two architectures achieve comparable discriminative performance at higher decision thresholds.

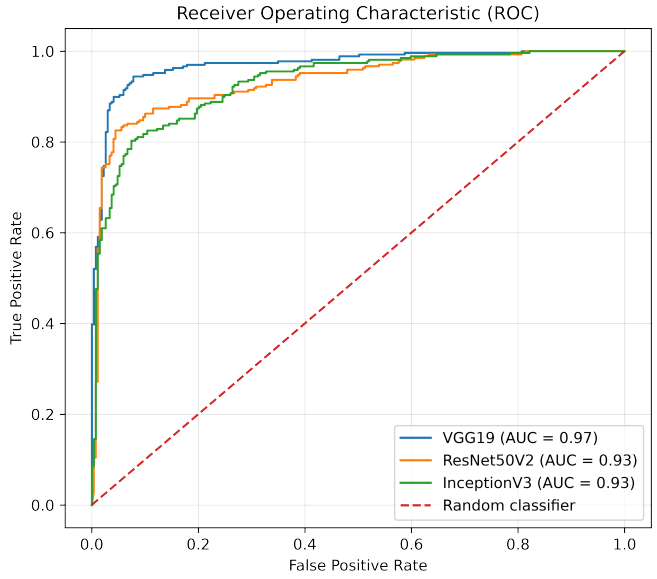

Fig. 5. Visual comparison of ROC curves across the CNN models

IV. Discussion

The experimental results support the premise of this study, that the architecture of a pre-trained convolutional neural network influences its capacity to capture the subtle contrast, morphology, and textural patterns that characterize mammographic microcalcifications. Among the three models evaluated, VGG19 achieved the best overall performance, with an accuracy of 92.75%, an F1-score of 92.66%, and an AUC of 0.971. Although VGG19 is the oldest and structurally simplest of the three architectures, its performance may be explained by the interaction between its architecture and the fine-tuning strategy employed. VGG19's uniform stack of small 3×3 convolutional filters allows the network to progressively build fine-grained, hierarchical representations of localized textural patterns such as microcalcifications. Unfreezing the last 20 layers during the second training stage, with a reduced learning rate of 1×10^{-5}, likely allowed these late-stage filters to adapt closely to the specific texture and contrast signatures of microcalcifications. The confusion matrix for VGG19 (Fig. 1) reveals that the model misclassified 39 ROIs, comprising 16 false positives and 23 false negatives. When the model indicates a microcalcification, there is a 93.89% precision probability that the finding is correct, supporting its potential as a candidate for microcalcification detection workflows. ResNet50V2 also achieved well-balanced results, obtaining the highest specificity (95.17%) and precision (94.47%) among the three architectures, indicating a low rate of false positives. This behavior is consistent with the stabilizing effect of its identity skip connections, which allow high-frequency features to propagate directly across deeper layers and mitigate the vanishing gradient phenomenon common in deep sequential networks. The model achieved an overall accuracy of 88.85% and an AUC of 0.934, with a sensitivity of 82.53%, correctly detecting 222 of the 269 microcalcifications present in the test set while missing 47. Although its sensitivity trails VGG19's, its low false-positive rate makes it a viable choice in clinical contexts where minimizing false positives is prioritized over maximizing detection rate. InceptionV3 achieved the lowest overall performance among the three architectures, although its results remain promising, with an AUC of 0.931. The network obtained a sensitivity of 81.04%, capturing 218 of the 269 true microcalcifications in the test set, alongside a specificity of 91.45% and a precision of 90.46%. This relatively lower performance may stem from the parallel 1×1, 3×3, and 5×5 filters within its Inception modules, which concatenate features after each block. This design may make the network more prone to mistaking dense parenchymal tissue patterns for microcalcifications, contributing to its comparatively higher false-negative count (51) relative to VGG19 and ResNet50V2. It is also possible that InceptionV3's greater architectural complexity required more extensive fine-tuning of its multi-branch modules than the fixed 20-layer unfreezing strategy allowed, limiting its ability to fully adapt its feature extractors to this specific classification task. Even so, InceptionV3's overall discriminative capacity remains meaningful, suggesting it retains value as a possible classification tool, albeit with a higher expected rate of missed detections than the other two architectures evaluated. Taken together, these results indicate a clear trade-off among the three architectures rather than a

single unambiguous winner. VGG19 offers the greatest overall discriminative capacity and the most balanced error profile, making it the most promising candidate where maximizing detection accuracy is the priority. ResNet50V2, by contrast, offers conservative and precise predictions, which may be preferable in workflows where reducing false positives is prioritized over sensitivity. InceptionV3, while the weakest of the three in this study, still performed well and may benefit from a fine-tuning strategy tailored more specifically to its multi-branch structure in future work. Furthermore, the relatively small test set size (538 ROIs) limits the extent to which these findings can be generalized without further validation on larger dataset.

V. Conclusion

This study compared convolutional neural networks with transfer learning for binary classification of microcalcifications in digital mammography. By evaluating the performance of three distinct architectures (VGG19, InceptionV3, and ResNet50V2) on a dataset extracted from the INbreast database, the results indicate that VGG19 outperforms the other models on this specific microcalcification classification task, achieving an accuracy of 92.75% and an AUC of 0.971. The findings offer insights into the potential deployment of deep learning models as microcalcification detection support tools. ResNet50V2's high specificity and precision suggest it may be particularly well suited to minimizing false positives, while VGG19's better overall sensitivity and discriminative capacity make it the most promising candidate among the three for maximizing detection of true microcalcifications. InceptionV3, while achieving the weakest results of the three, still demonstrated meaningful results, indicating that all three architectures retain some value as classification algorithms. Future research will focus on evaluating these architectures against larger and imbalanced databases, exploring advanced attention mechanisms to further improve classification performance, and developing an end-to-end microcalcification detection algorithm for full-field mammography.

***Abstract*— Hospital readmission within 30 days of discharge is a significant challenge to healthcare systems, because it is associated with worse patient outcomes and higher costs. In this work, we investigated the prediction of early hospital readmission using clinical variables and temporal features extracted from wearable accelerometry signals. The experiments were carried out on the Bosch Dataset after preprocessing steps to retain patients with sufficient number of valid measurements. Different configurations were evaluated, including progressive feature combinations and scenarios with and without feature selection. The models were trained and evaluated using five outer folds and two inner folds approach, which ensured that hyperparameter tuning and performance estimation were independent. Nine machine learning classifiers were assessed with hyperparameter tuning performed using Grid Search and Optuna. The best result was obtained with SVM with Feature Set 4, Optuna and Pearson-based feature selection, with a mean F1-score of 90.00% and a average accuracy of 93.33% over the five outer folds. These findings suggest potential value in combining temporal accelerometry descriptors and patient-related information, although the small cohort and substantial between-fold variability should be interpreted as exploratory internal validation.**

Keywords*— *hospital readmission prediction, wearable devices, machine learning, temporal feature extraction, feature selection, hyperparameter optimization, nested cross-validation.

I. INTRODUCTION

Hospital readmission is commonly used as an indicator of healthcare quality and is also associated with avoidable costs, especially during the transition from hospital to home. Large studies in the United States have shown that many readmissions occur within 30 days after discharge and are often associated with clinical complications, including in surgical patients [1]. Due to the clinical and economic impact of readmission, programs such as the Hospital Readmissions Reduction Program have increased interest in methods that can identify high-risk patients before adverse outcomes occur [2].

However, predicting readmission is still difficult as it is related to the severity of diseases, comorbidities, care transitions, and patient-specific characteristics. Previous research has demonstrated that models based on routine clinical and social variables often have only moderate predictive performance [3]. Structured scores such as the LACE index and the HOSPITAL score are popular as they are easy to use but they rely mostly on information available at discharge and frequently show poor discrimination across clinical settings [4], [5].

With the increasing availability of digital health data, machine learning models based on electronic health records (EHR) and claims databases have been investigated to improve readmission prediction. Some studies reported that large-scale feature extraction from EMR data can improve performance compared with more traditional approaches, although important challenges related to model generalization and real-world implementation still remain [6]. Similar results have been reported for chronic diseases such as COPD, where combining knowledge-driven and data-driven features improved the area under the receive operating characteristic curve (ROC), while more complex deep learning models did not consistently outperform strong traditional baselines [7].

A limitation of many existing models is that they estimate readmission risk using only information collected at or before discharge. In practice, however, patient recovery continues after leaving the hospital and is influenced by physiological and behavioral changes over time. In this context, remote patient monitoring and wearable devices provide an important source of information because they allow the collection of daily-life signals that are usually not present in hospital records. Recent randomized evidence suggests that post-discharge features related to activity and sleep can improve the prediction of 30-day readmission or death [8].

Recent studies have also explored temporal and behavioral patterns extracted from wearable data. Continuous multi-sensor

monitoring combined with machine learning has identified early signs of impending hospitalization in heart failure patients several days in advance [9]. Consumer wearable data have also shown that disruptions in circadian and biobehavioral rhythms during perioperative stages may be associated with readmission risk [10]. Moreover, wearable-derived descriptors related to variability and signal complexity, including entropy-based measures from heart rate and step-count series, have improved readmission prediction when combined with clinical variables [11], [12]. Probabilistic deep models have further been proposed to estimate how readmission risk evolves day by day after discharge, rather than representing it as a fixed score [13].

Wearable data are increasingly used for readmission prediction. However, the impact of alternative temporal representations of repeated in-hospital accelerometry observations is little studied. This study thus investigates if the combination of independent hourly descriptors, gradually cumulative windows and sequential measurement pairs might improve 30-day readmission prediction. The main contributions are: (i) a multiscale temporal representation for accelerometry signals; (ii) a progressive analysis of feature sets designed to assess the impact of cumulative and contextual information; and (iii) a leakage-aware patient-level nested cross-validation protocol where preprocessing and hyperparameter tuning are confined to the training patients.

II. Materials and Methods

A. Materials

The study used the Bosch Dataset [14], whose data were collected at Robert Bosch Hospital, located in Stuttgart, Germany, throughout 2016. The dataset is publicly available on the PhysioNet platform, version 1.0, published in 2020.

According to the dataset documentation, the cohort is composed of data from 58 hospitalized adult patients admitted for different clinical conditions, including acute infections, chronic obstructive pulmonary disease exacerbations, heart failure, and oncological complications; however, data from only 47 patients were made available, where 16 patients (34,0%), experienced hospital readmission within 30 days, while 31 patients (66.0%), were not readmitted during this period.

B. Methods

During preprocessing, an eligibility procedure was applied to ensure that the final cohort contained patients with sufficient temporal information for feature extraction and longitudinal analysis. Only data sequences containing at least 8 hours of valid data were considered for this study. In addition, only patients with at least two valid data sequences were included, since the proposed strategy was designed to analyze temporal changes between different observation moments rather than isolated records.

These criteria were adopted to ensure that each patient has enough longitudinal information to support the temporal strategy. Patients with only one measurement could not provide consecutive observations, while measurements shorter than 8 hours would not satisfy the window defined for feature generation. After applying these criteria, the final dataset was reduced to 20 patients with a total of 76 valid data sequences.

Within this subset, each patient has an average of 3.8 valid data sequences, with a standard deviation of 2.19, indicating moderate heterogeneity in the number of records per individual. Regarding the clinical outcome, 8 patients experienced hospital readmission, while 12 patients were not readmitted, resulting in a relatively balanced class distribution.

Additional signal-cleaning procedures were not applied, since, according to the dataset documentation, the main preprocessing and signal validation had already been performed during database construction. The preprocessing adopted focuses only on sample selection, temporal standardization, and signal preparation for feature extraction.

Every data sequence was standardized to an 8-hour observation window. From this time window, two complementary temporal representations were defined. The first one was based on individual intervals, in which the 8-hour observation period was divided into eight independent hourly segments, as illustrated in Fig. 1. This method focuses on local information and short-term dynamics.

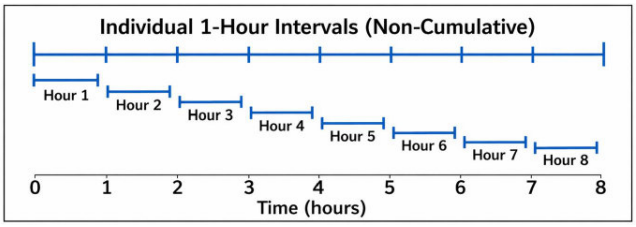

Fig. 1. Individual Hourly Method

The second representation focuses on cumulative strategy, as illustrated in Fig. 2. In this case, features were progressively calculated over the temporal windows starting from the last hour up to the 8 hours period. This method focuses on temporal information that captures changes over the time.

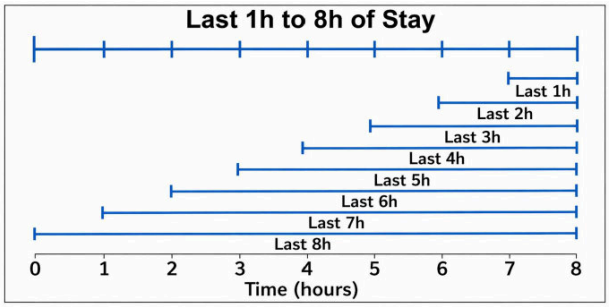

Fig. 2. Cumulative feature Methods

Taken together, these two representations were treated as complementary. While the hourly representation captures immediate and localized fluctuations, the cumulative representation provides a longitudinal view of motor behavior throughout the observation period. This combination was adopted to preserve both short-term variability and progressive temporal evolution in the extracted signal descriptors.

As shown in Table I, a diverse set of time-series derived attributes were extracted from raw accelerometry data, following the general rationale of large-scale time-series feature extraction methods [15]. The features were calculated using 1-hour time windows. Considering 8 hours of monitoring per data sequence, 8 values were generated for each feature, preserving the temporal dynamics of the signals [16].

TABLE I. FEATURES EXTRACTED FROM RAW ACCELEROMETER DATA

PARAMETER	MEASURE
MOVEMENT INTENSITY	MAGNITUDE OF THE ACCELEROMETER
AVERAGED ACCELERATION	STATISTIC CLASSIC TIME DOMAIN
SKEWNESS	KURTOSIS
ENERGY	ROOT MEAN SQUARE
AVERAGED ROTATION ENERGY	SIGNAL MAGNITUDE AREA
AVERAGED VELOCITY	FIRST ORDER DERIVATIVE
SECOND ORDER DERIVATIVE	ZERO CROSSING RATE
CORRELATION BETWEEN AXIS	MEAN CROSSING RATE
SPECTRAL ENTROPY	EIGENVALUES OF THE COVARIANCE MATRIX
AVERAGED ROTATION ANGLES	DOMINANT FREQUENCY

To assess the impact of richer input representations on model performance, four nested feature sets were developed. For each feature set, variables from the previous set were kept and a further source of information was added. This incremental architecture permitted the separate investigation of the contribution of basic statistics, signal dynamics, cumulative temporal information, and patient-related data. Table II summarizes the composition of the four feature sets.

Feature Set 1 was the most basic representation of the movement behavior. Feature Set 2 further developed this representation with descriptors relating to signal dynamics, oscillatory patterns, the intensity of movement and the inter-axis correlations of the accelerometer. Feature Set 3 incorporated cumulative temporal information to account for the gradual changes during the eight-hour period of observation. Finally, Feature Set 4 was the most complete setup by integrating wearable-derived features and patient-related information.

To incorporate temporal information without using sequential deep architectures, the model´s input was constructed by pairs of consecutive measurements, as illustrated in Fig. 3. For each patient with N valid data sequences, N−1 pairs were generated by combining each data sequence with its immediate successor. In each pair, one column represented the previous data sequence and the other, the current data sequence. By doing this, the transitions between consecutive states were preserved.

For labeling, the positive labels were assigned only to the final data sequence pair of readmitted patients. All other pairs, including prior pairs from patients that were readmitted, were labeled as negative. The pair-wise training labels were not identical to the patient-level clinical outcome: a negative label for an earlier pair did not mean that the patient stayed free of readmission for the entire follow-up period. Predictions were made for pairs of measurements, but inner and outer cross-validation partitions were generated based on patient identity so that all pairs from the same patient remained in the same partition.

In the outer-test evaluation, the selected pairs were based on the observed outcome on the patient level. All available measurement pairs with negative reference labels for patients discharged without readmission within 30 days were evaluated. For patients readmitted, only the most recent pair was labeled as positive; earlier pairs of these patients were excluded from test scoring. Confusion-matrix counts and test metrics were computed on these selected pairs. Hence, each readmitted patient results in one positive evaluation pair, while each non-readmitted patient can result in several negative evaluation pairs. This retrospective selection based on the outcome should be differentiated from the assignment of a single prediction for each patient.

TABLE II. COMPOSITION OF THE FEATURE SETS

Feature set	Composition	Number of features
Feature Set 1	Basic statistical descriptors extracted from the accelerometer magnitude, including mean, median, maximum, minimum, and standard deviation.	80
Feature Set 2	Feature Set 1 combined with additional time-domain, frequency-domain, statistical, and inter-axis descriptors, including signal energy, RMS, derivatives, crossing rates, spectral entropy, dominant frequency, movement intensity, and correlations between axes.	496
Feature Set 3	Feature Set 2 combined with cumulative descriptors progressively calculated over observation windows ranging from 1 to 8 hours.	992

Feature Set 4	Feature Set 3 combined with demographic, clinical, and contextual information, including age, sex, anthropometric characteristics, lifestyle variables, medication use, length of hospital stay, housing status, and comorbidity index.	1006

In addition to the experiments reported on all available variables, the performance of reduced feature sets was examined using feature selection based on Pearson correlation. For each feature set, candidate variables were ranked according to the absolute value of Pearson correlation with the pair-level training target and the top 50 ranked variables were retained.

Feature selection was performed inside the nested cross-validation procedure. The correlations were calculated during hyperparameter optimization only with the inner-training partition. The selection resulting from this was then applied unchanged to the corresponding inner-validation partition. The hyperparameters were chosen and the Pearson ranking was computed again on all outer-training patients and the resulting subset was directly applied to the outer-test patients. Thus, the inner-validation and outer-test results were not used for feature selection to assess those partitions.

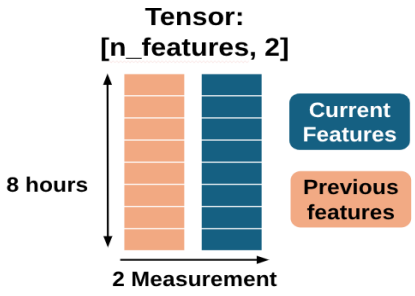

Fig. 3. Model input

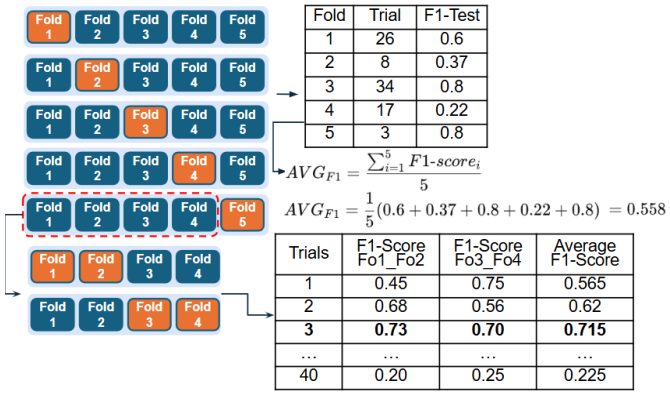

This procedure reduced the input dimensionality and allowed the comparison of complete and reduced feature sets. We conducted four experimental setups by testing each feature set with and without feature selection, using Grid Search and Optuna. As feature selection was done within each training partition separately, the selected variables might be different across folds.

To examine various learning algorithms for hospital readmission prediction, nine machine learning classifiers were assessed. Also, several combinations of hyperparameters were evaluated for each classifier. The purpose of this stage was to determine which arrangement produces best results. Since the F1-score is more informative for imbalanced data, it was chosen as the optimization target.

For the optimization of the models, each classifier was tuned with the main hyper-parameters associated to its learning mechanism. We optimized tree-based models, Random Forest, Decision Tree, Gradient Boosting and Extra Trees by varying parameters such as number of estimators, tree depth, split and leaf criteria, feature selection strategy and, where applicable, learning rate and subsampling. KNN: number of neighbors, weighting strategy, distance metric and p value were evaluated. Logistic Regression and SVM were tuned by regularization and kernel related parameters, and Naive Bayes were tuned by variance smoothing. Finally, the SGD was tuned by modifying the loss function, penalty, alpha, learning rate and initial learning rate. The proposed tuning strategy allows a comparison between different families of models in their most relevant configurations.

Model development and performance estimation were performed using nested cross-validation with five outer and two inner folds [17] as shown in Fig. 4. The outer loop was used to estimate the performance on held-out patients and the inner loop was used to select hyperparameters. This protocol was applied to all the proposed feature sets, with and without feature selection, offering a common evaluation framework to the different input representations and experimental settings.

In the outer loop patients were divided into five folds. For each iteration, one-fold was left out as the test set and the remaining four folds were used for hyperparameter optimization and subsequent fitting the model. All consecutive measurements of the same patient were put into the same fold. Thus, no patient contributed measurement pairs to both the model-development and outer-test partitions in the same iteration.

Fold	Trial	F1-Test
1	26	0.6
2	8	0.37
3	34	0.8
4	17	0.22
5	3	0.8

Trials	F1-Score Fo1_Fo2	F1-Score Fo3_Fo4	Average F1-Score
1	0.45	0.75	0.565
2	0.68	0.56	0.62
3	**0.73**	**0.70**	**0.715**
…	…	…	…
40	0.20	0.25	0.225

Fig. 4. Training Methodology

In each outer loop the patients of the four model development folds were further split into 2 inner folds. This division was also performed at the patient level to keep all the measurement pairs from the same individual together. The two inner folds alternated between training and validation so that each hyperparameter configuration was evaluated without using the outer-test patients.

Several hyperparameter settings were tested in the inner loop. The model was trained two times for each configuration, by swapping the roles of the two inner folds. Each training run was evaluated on a validation F1-score and the two scores were averaged. The configurations were then ranked according to

this mean validation F1-score and the one with the highest value was selected for the particular outer iteration.

All preprocessing operations that required estimation from the data were fit only on the training partition used for each run. In the case of Pearson-based feature selection experiments, correlations between the candidate variables and the training target were computed only with the inner-training data. The 50 variables with the highest absolute correlations were kept and this selection was applied unchanged to the corresponding inner-validation data. The ranking was recomputed for each inner-training split instead of being computed once before cross-validation. Therefore, the chosen variables can differ between the two inner training runs as well as between different outer iterations.

Once the optimal hyperparameter setting was identified, the whole preprocessing and classification pipeline was retrained on all patients of the four outer-training folds. For feature selection configurations, Pearson correlations were recomputed only on this complete outer-training partition, and its top 50 ranked variables were kept. And, any other training-dependent preprocessing operations and the classifier were fit on the outer-training data only. This pipeline was then applied to the outer test patients without any modification. Their predictor values and outcomes were not used for fitting of preprocessing operations, feature selection, and hyperparameter optimization.

This procedure was repeated until all five outer folds had used once for testing. Performance was summarized by the mean and standard deviation of the five outer-test F1 scores. The nesting design decoupled the choice of hyperparameters from the estimation of outer-test performance. We performed partitioning at the patient level, ensuring no overlap between individuals in the partitions, and preprocessing and feature selection were done on the fit from the corresponding training data alone, so that held-out observations did not affect these operations.

The same framework was repeated for all feature sets, that is, with and without feature selection, allowing performance comparison to be attributed to the input representation rather than to changes in the protocol.

III. Results and Discussion

Figure 5 shows the F1-scores obtained across the four feature sets using Grid Search and Optuna, with and without Pearson-based feature selection. Points indicate the average F1-score over the 5 outer-test folds, error bars indicate the standard deviation over folds. These summaries report the average performance and the variability between folds, not the confidence intervals.

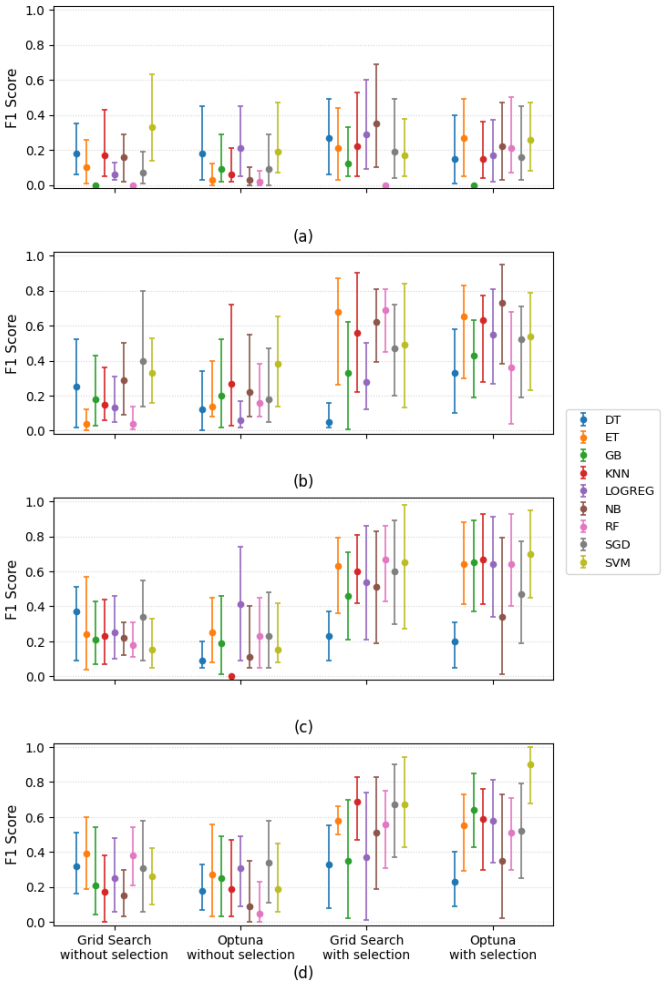

Fig. 5. Mean F1-score of the evaluated classifiers across the four feature sets under different optimization and feature selection settings: (a) feature set 1, (b) feature set 2, (c) feature set 3, and (d) feature set 4.

When Pearson-based feature selection was employed, there was a major improvement. The configurations that used selected features performed better than those that used the all features. This effect became clearer as the number of features in the sets augment, which suggests this selection cut down redundancy. The results also showed an improvement with greater input sets. As shown, feature set 1 had the lowest overall F1-score. This means that basic statistical descriptors were not enough to describe patterns related to readmission. In feature set 2, the performance was more competitive, which suggests that temporal, frequency-domain, and augmented statistical descriptors made a better representation of patient behavior.

The best results were observed in feature sets 3 and 4. These sets included cumulative temporal information, which let the models see changes over time. The best overall performance came from feature set 4, which also included demographic and contextual variables. Therefore, combining wearable descriptors with patient information provided a more robust representation for predicting hospital readmission up to 30 days.

When we look at the optimization strategies, both Grid Search and Optuna perform well. But the best overall results came from using Optuna with feature set 4 and Pearson-based feature selection. The best performance was obtained with SVM achieving, an F1-score of 90.0%. This result shows how important it is using richer temporal representations along with dimensionality reduction and hyperparameter optimization.

Table III shows the performance of the SVM using Feature Set 4, Optuna, and Pearson-based feature selection. The model achieved mean F1-score of 90.00% and mean accuracy of 93.33%. The mean sensitivity, precision and specificity were 100%, 86.67% and 92.00% respectively. Means and sample standard deviations were computed across the five outer-test folds with equal weighting for each fold.

TABLE III. PERFORMANCE OF BEST SVM WITH OPTUNA, AND PEARSON-BASED FEATURE SELECTION.

Metric	Mean Value	Standard Deviation
Accuracy	0.9333	0.1491
F1-score	0.9000	0.2236
Precision	0.8667	0.2981
Sensitivity	1.0000	0.0000
Specificity	0.9200	0.1789

A comparison with the literature was included as a contextual reference because the study used the same original data source. Nevertheless, a direct numerical comparison is not appropriate. The studies differ in prediction tasks, input modalities, model families, and evaluation design. Ali et al [18]. jointly addressed readmission state and length of stay using a multitask deep learning framework and multimodal physical-activity sensory data, whereas the present study focuses on temporal accelerometry representations and patient-level nested evaluation for 30-day readmission.

These results should be seen as exploratory internal validation. The cohort was small, consisting of only 20 patients (8 of whom were readmitted) and the candidate feature sets contained as many as 1006 variables. The small number of independent patients and the large dimensionality constitute a serious risk of overfitting and inaccurate performance estimates. The reported standard deviations describe the variance across folds, and do not replace confidence intervals. Also, the observed sensitivity of 1.0000 does not guarantee that all future readmissions will be captured.

IV. CONCLUSION

This work investigated the prediction of 30-day hospital readmission based on clinical variables and features extracted from accelerometry data. The results showed that feature selection contributed to reducing redundancy in the input set and improving the generalization capability of the models.

The use of Optuna made it possible to obtain more refined models than those previously adjusted with Grid Search, due to its automatic hyperparameter selection strategy, with the SVM classifier standing out by achieving an F1-score of 90.00% and greater consistency throughout the iterations. This result highlights the potential of the proposed strategy for building more robust and effective models in the context of readmission prediction.

***Abstract*—The amputation of the upper limbs represents a significant clinical and social challenge, which requires assistive technologies that restore functionality in an intuitive and accessible manner. Although myoelectric prostheses controlled by surface electromyography (sEMG) are the current standard, their performance is still limited by signal variability and the scarcity of robust public datasets for training control algorithms. Widely used datasets such as Ninapro, CapgMyo, and BioPatRec present limitations including small data volume, scarcity of participants with amputations, and lack of standardized acquisition protocols, which hinder their comparison or integration. This study proposes the development of a biosignal acquisition protocol aimed at the development of natural control systems for upper limb prostheses, especially those in development in our group, with more than 10 degrees of freedom and suitable for amputation at the wrist level. The methodology includes the collection of signals from volunteers using an eight-channel wireless sEMG system. Data are acquired during the execution of a set of movements and rest with repeated trials, and the experimental setup aims to minimize artifacts and variability in the data through the electrode placement, the use of wireless equipment and a support structure, and the repetition of movements with rest periods in synchronization with video demonstrations. Although the experimental setup is designed to accommodate individuals with amputations in future data collection, this manuscript describes the preliminary results validated with a sample of 10 able-bodied participants. In the future, the complete dataset, following further expansion, will be made publicly available to support research on upper-limb prosthetics.**

***Index Terms*—Upper-limb prosthesis, surface electromyography, data acquisition protocol, EMG control.**

I. Introduction

Loss of an upper limb can significantly affect an individual's daily life, affecting mobility and balance, compromising the ability to interact with the environment, and introducing psychological and social barriers associated with limb difference [1]. The demand for assistive technologies can be evaluated by the prevalence of this challenge. In 2021, an estimated 140 million people worldwide were living with amputations [2], and approximately 1,500 upper-limb amputations are recorded annually in Brazil through the Unified Health System (SUS) [3].

Prostheses can restore motor function or address the appearance of a missing limb, and their capabilities are continuously improving. However, while complex bionic hand and arm systems are commercially available [4]–[10], their interfaces still present limitations that hinder their use. The cost of these devices is high, the deployment in embedded devices can be restrictive, and control strategies are often limited to a small set of gestures or parameters and are not intuitive, requiring extensive training and cognitive effort from the user [11].

As a control principle, surface electromyography (sEMG) has become the standard. This method is non-invasive, using electrodes placed on the skin to detect biopotential differences caused by ionic currents flowing in the body. These currents are associated with the electrical activity of tissues such as muscles and nerves [12]. In the context of amputations, the residual limb can still receive signals from the nervous system related to the intention to move the amputated limb, and their spatial distribution across the skin contains functional information [13]. Thus, sEMG can be used to decode the user's intention and control a prosthetic device, and there are many studies and commercial prostheses that use this approach. However, this method has limitations that restrict its applicability and performance.

Frequently, surface electrodes are positioned on the forearm to target muscles that control hand and wrist movements, limiting their use to amputations that retain that part of the anatomy [14]. However, over 30% of individuals with upper-limb amputation do not retain the complete forearm musculature [15], which limits the number of electrodes that can be placed on the residual limb and the amount of information that can be captured.

This approach also suffers from the low amplitude of the sEMG signal and its susceptibility to noise and artifacts, which can be caused by several factors such as skin impedance,

This study was financed in part by the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) - grant #409948/2022-5, by the São Paulo Research Foundation (FAPESP) - grant #2024/01468-0 and #2022/06183-9, by the Dean's Office for Research and Innovation of the University of Sao Paulo, by the Endowment Fund Amigos da Poli, and by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior — Brasil (CAPES) — Finance Code 001.

sweat, imprecise electrode placement, crosstalk between adjacent muscles, variations in contraction force, and fatigue. These parameters can vary between individuals and across different sessions for the same individual, which can compromise the performance of the control system [16]. Pattern recognition and machine learning techniques have been used to address these issues, but they require representative training data and robust validation to ensure adequate performance in real-world scenarios [17].

An obstacle to advancing sEMG approaches is the lack of available labeled data. Although known databases exist, including Ninapro, BioPatRec, CAPG-MYO, and HD-FW KIN [18]–[22], they present limitations including small sample sizes, relatively few participants with amputations, and the execution of a single repetition per gesture. This prevents control algorithms from being able to generalize between individuals and across different sessions. Additionally, differences in the hardware and acquisition protocols used for each database hinder any comparison or integration [23], [24]. Moreover, these datasets focus on electrodes placed on the forearm, with Ninapro being the only one to include targeting two specific arm muscles and the hand. With such a limited number of signals from the arm, systems produced from the data may not be capable of producing a functional set of gestures for individuals with amputations at higher levels.

The choice of the number of electrodes is also a factor in the design of an sEMG interface. Currently available databases often employ multi-channel setups to capture detailed muscle activity, ranging from 8 to 16 channels. Although these configurations improve pattern recognition accuracy, they increase hardware complexity and computational demand, which can limit their viability. This is reflected in commercial prostheses, which were observed to use 2 to 8 channels. Alternatively, a single-channel system was shown to be capable of identifying finger flexions by mapping the magnitude and density of signal peaks to different muscle layers [25]. However, the performance of this approach can be restrictive when applied to a larger set of gestures, requiring feature reduction methods [26].

In our laboratory, we are developing upper limb prostheses with more than 10 degrees of freedom [27]. One of the prototypes, as shown in Fig. 1, has the capability to perform the main power and precision grips. We intend to control these prostheses using the biosignals generated by muscles and nerves. To solve the problems described earlier, we are building a large dataset to train signal processing algorithms to extract the motion intention of the user. This paper presents the preliminary results of this dataset. The proposed method uses an 8-channel wireless sEMG system to acquire biosignals during the execution of 17 functional gestures. As dexterous prosthetic hand control demands richer information than conventional sEMG alone, this study opted for the placement of electrodes on the arm and forearm without targeting specific muscles. This approach aims to capture information reflecting both neural drive and muscle activation, enabling more natural and robust decoding of movement intention and extending the applicability of the dataset to cases in which a limited number of muscles are available.

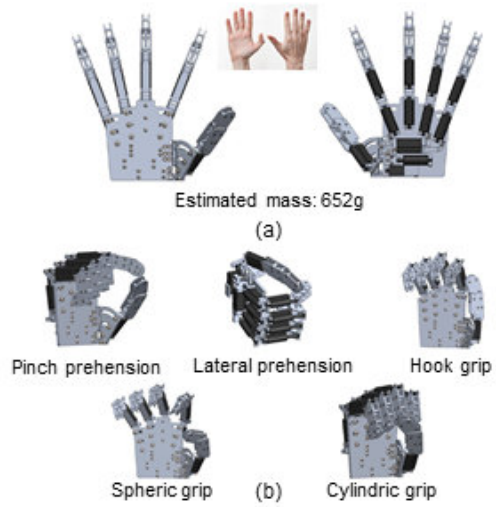

Fig. 1. One of the prototypes of upper limb prostheses under development in our laboratory. (a) Its ventral and dorsal view, (b) the main possible prehensions and grasps

Through the standardization of factors such as electrode placement, rest position, and movement repetition cycles, this work proposes a reproducible data acquisition protocol and introduces a dataset applicable to users with different levels of upper-limb amputations. These contributions aim to support the development of more robust, intuitive, and accessible prosthetic control systems.

II. Methods

A. Experimental Setup

This study uses a sEMG system configured with 8 wireless probes (FREEEMG 1000, BTS Bioengineering S.p.A., Brazil). The use of a wireless system was motivated by electrical safety, achieving electrical isolation from the power supply and thus reducing the risk of electrical shock. Another advantage of this system is the mobility available to participants due to the absence of cables between the probes and the acquisition device, eliminating forces acting on the probes that could compromise adequate positioning and signal acquisition. Additionally, the absence of wires allows movements that better represent gestures performed in daily life.

The eight channels (Ch 1 - Ch 8) were divided into two groups of four, one group (G1) positioned on the arm and the other (G2) on the forearm, as shown in Fig. 2. In the future, in cases of volunteers with amputation, where the forearm is not available, only group G1 will be used.

Aiming to further reduce artifacts from undesired muscle tension, the patients were instructed to remain seated in a comfortable position, with the upper limbs supported on the arm of an armchair. An armchair with adjustable height of the seat and armrests was used to ensure that participants could maintain a relaxed posture independently of their height. As

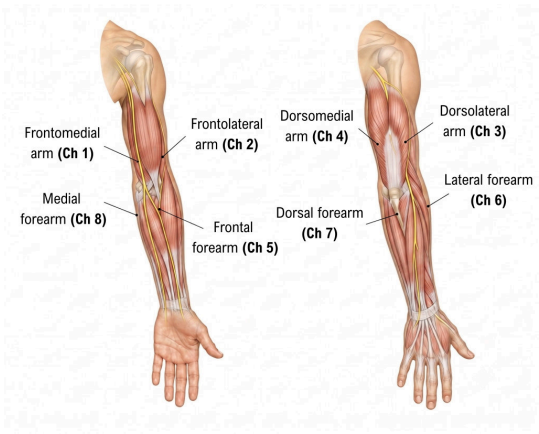

Fig. 2. Target probe placement on the upper limb for biosignal acquisition. The eight measurement sites are organized into two sets of four: group G1 (Ch 1 – Ch 4) targeting the upper arm, and group G2 (Ch 5 – Ch 8) targeting the forearm. The left and right illustrations depict the anterior and posterior views, respectively.

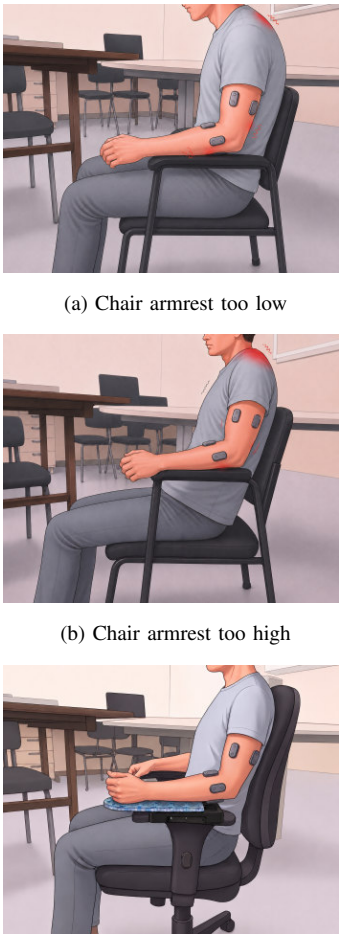
shown in Fig. 3, a chair armrest too low or too high may cause unwanted muscle tension on the back or shoulder of the volunteer.

To avoid forcing the electrodes against the skin due to contact with the chair's armrest, a support structure was developed and manufactured using 3D printing technology. The structure can be mounted on the chair's armrest to elevate the limb and support the hand and forearm in a neutral position, as shown in Fig. 3, preventing pressure on the probes located at the dorsal forearm position. This is defined as the rest position and used as a baseline for gesture executions.



The biosignals are captured using disposable Ag/AgCl electrodes, which are attached to the probes and placed on the skin. Such electrodes are widely used in clinical and research applications due to their low contact impedance, high potential stability, and good adherence to the skin surface, minimizing variability [28]. To minimize the impedance between the skin and the electrodes, the skin was prepared by cleaning the area with 70% isopropyl alcohol.

The data are transmitted to a computer and recorded using the BTS EMGAnalyzer software (BTS Bioengineering S.p.A., Brazil). The software allows for real-time visualization of the signals and data storage, and it is directly compatible with the acquisition system.

B. Participants

The experimental protocol was approved by a research ethics committee, ensured that all procedures were in accordance with the standards for human subjects research, and obtained informed consent from all participants. For this paper, we recruited 10 adult volunteers without upper-limb amputation to evaluate our methodology.

To investigate factors that may introduce variability in sEMG signals, the protocol was designed to document demographic characteristics such as age, sex, height, weight, and dominant hand. These allow for the calculation of the body

(a) Chair armrest too low

(b) Chair armrest too high

(c) Support structure maintaining a neutral posture

Fig. 3. Comparison of forearm support conditions. (a) A low chair armrest causes the participant to lean forward, increasing muscle tension and compressing the dorsal forearm probe. (b) A high chair armrest requires shoulder elevation, increasing muscle tension while the probe remains under pressure. (c) The support structure maintains a neutral forearm posture and prevents pressure on the probes.

mass index (BMI), for example, which may negatively affect the quality of the sEMG signal [29].

III. Execution Procedure

The protocol includes the execution of a set of 17 movements from a baseline rest condition, listed in Table I. The gestures include hand poses and grasp patterns that are functional for daily activities.

To maintain consistency in the execution of the movements, a video demonstration of each gesture was presented to the participants prior to data collection. During execution, the participants were instructed to perform the movement in synchronization with the video, following the same speed and range of motion. For each gesture, participants completed a sequence of 3 repeated trials following the workflow shown in Fig. 4.

The protocol was designed to include rest periods of 5 seconds between each movement to minimize fatigue, which can alter the properties of the biosignal and degrade the quality

TABLE I
MOVEMENTS INCLUDED IN THE EXPERIMENTAL PROTOCOL

ID	Movement
M1	Thumb Abduction/Adduction
M2	Thumb Flexion/Extension
M3	Thumb Opposition/Reposition
M4	Metacarpophalangeal (MCP) Flexion/Extension[a]
M5	Interphalangeal (IP) Flexion/Extension[a]
M6	One (Thumbs Up)
M7	One (Pointing)
M8	Two (V Sign)
M9	Three
M10	Four
M11	Five (Open Hand)
M12	Closed Fist
M13	Pinch Grasp
M14	Lateral Grasp
M15	Spherical Grasp
M16	Cylindrical Grasp
M17	Hook Grasp

[a]For M4 and M5, movements were performed with all four fingers simultaneously and with each finger individually.

of the collected data. Although a 3-second rest period was used in other studies [19], an extended interval was chosen so that it would be longer than the maximum duration of a gesture (4 seconds, including the transition from the rest position to the gesture and back). This ensures that the participant has sufficient time to return to a relaxed state before executing the next movement.

IV. RESULTS

Table II summarizes the baseline characteristics collected for the 10 participants, providing a characterization of the recruited sample.

TABLE II
CHARACTERISTICS OF THE SAMPLE

Characteristic	Total ($N = 10$)
Age (years)	22.0 ± 2.18
Height (cm)	170.3 ± 6.36
Weight (kg)	70.8 ± 14.49
Female	4
Male	6
Right-hand dominant	8
Left-hand dominant	2

Values are mean $\pm$ SD or count (n).

To verify that the experimental setup was effective in minimizing noise in the acquired data, the average Root Mean Square (RMS) amplitude of the signals was calculated for a 10-second interval in the baseline rest position with and without the support structure. The data represent the averaged values across 2 recording sessions from 2 participants, and the results are shown in Table III.

The introduction of the support structure resulted in a clear overall reduction in baseline noise, decreasing the average RMS across the active channels by $39.23\,\%$ (from $12.46\,\mu\text{V}$ to $7.57\,\mu\text{V}$). This behavior was most pronounced in Channel 7, which is the probe located on the dorsal forearm and

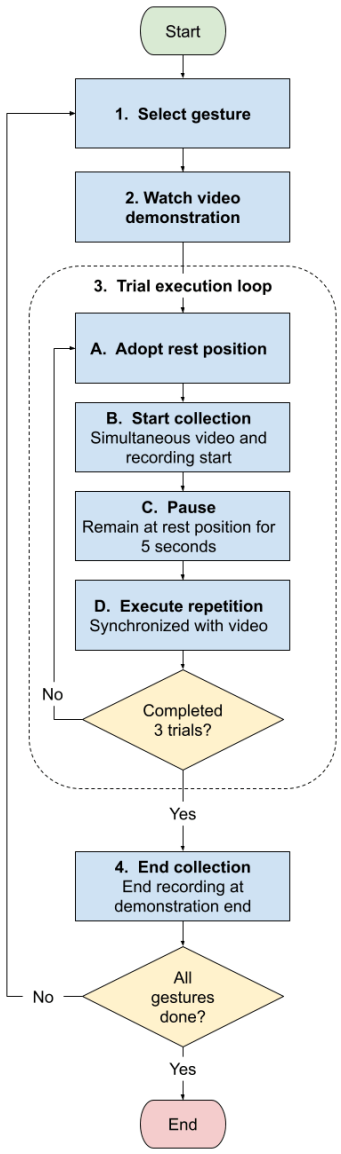


Fig. 4. Workflow of the experimental protocol for biosignal acquisition.

is highly susceptible to artifacts caused by contact with the support chair. Implementing the support structure stabilized this interface, reducing Channel 7's average RMS noise by over $50\,\%$ (averaging a drop from $27.92\,\mu\text{V}$ to $11.32\,\mu\text{V}$).

Noise was minimized in nearly all instances, with 7 out of the 8 evaluated channels showing a direct reduction in baseline RMS. Minor fluctuations were isolated to Channels 4 and 5, which likely reflect small movements during resting. Overall, these results demonstrate that the support structure successfully improves the quality of the collected signals by reducing baseline noise.

To further evaluate how this stabilization impacts control signals, the Signal-to-Noise Ratio (SNR) during active move-

TABLE III
EMG BASELINE NOISE COMPARISON WITH AND WITHOUT MECHANICAL SUPPORT STRUCTURE.

	RMS Noise (μV)		Peak-to-Peak (μV)	
Channel	**No Support**	**Support**	**No Support**	**Support**
Ch 1	6.48	6.27	66.35	62.65
Ch 2	4.46	3.72	44.55	34.45
Ch 3	28.41	11.56	292.10	106.15
Ch 4	14.92	12.78	164.90	124.55
Ch 5	5.14	5.66	46.55	48.95
Ch 6	6.32	4.92	58.85	44.05
Ch 7	27.92	11.32	392.35	160.90
Ch 8	6.03	4.34	72.35	46.75

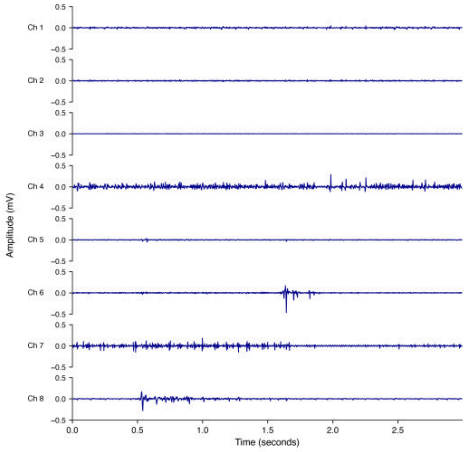
Reduction		**-39.23%**		**-44.78%**

ment tasks was assessed using the data from the 2 participants across their 2 respective recording sessions. To obtain the hypothetical SNR without the support (as shown in Table IV), it was assumed that the support structure does not alter the amplitude of the signals captured during gesture execution. Under this assumption, the hypothetical SNR was calculated by comparing the RMS amplitude of the active movement signals (measured with the support structure) against the baseline noise floor measured without the support structure. The actual SNR with support was calculated using the baseline noise floor measured with the structure. The results shown in Table IV indicate that the SNR improved across all evaluated sessions when the support structure was used, with an average gain of $+3.79\,\mathrm{dB}$ across both sessions.

TABLE IV
IMPACT OF THE SUPPORT STRUCTURE ON ACTIVE MOVEMENT SIGNAL-TO-NOISE RATIO (SNR).

Data Group	**Hypothetical SNR (No Support)**	**Actual SNR (With Support)**	**Average SNR Gain**
Trial 1	-2.81 dB	-1.86 dB	+0.94 dB
Trial 2	-3.37 dB	3.26 dB	+6.63 dB
Overall	**-3.09 dB**	**0.70 dB**	**+3.79 dB**

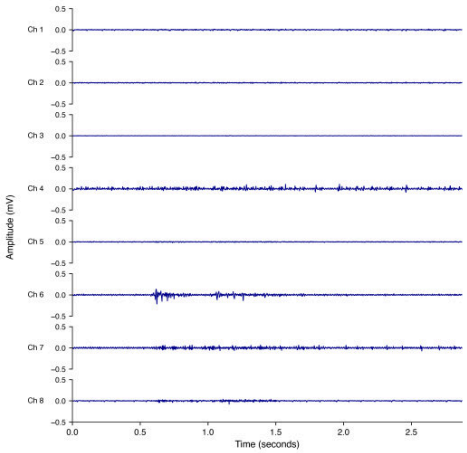


The execution of the movements was also evaluated to verify that the protocol was effective in capturing distinct biosignals for each gesture. Fig. 5 and Fig. 6 illustrate movements M7 (One – Pointing) and M16 (Cylindrical Grasp), respectively, and present the raw signals from a single execution of each gesture from the rest position, demonstrating that the protocol captures distinct activation patterns.

V. DISCUSSION

The experimental protocol proposed in this study addresses gaps in current sEMG datasets by prioritizing standardization while considering anatomical variability. The distribution of probes across the arm and forearm is intentionally designed to support control strategies applicable to different amputation levels where not enough residual musculature is available for conventional electrode placement. By capturing signals from multiple locations without relying on specific muscle targets, the dataset can be used with a broad range of control

(a) One (pointing) gesture



(b) Raw biosignals

Fig. 5. M7 (One – Pointing) gesture and the corresponding raw biosignals recorded by the eight probes.

(a) Cylindrical grasp

(b) Raw biosignals

algorithms for pattern recognition and still provide information for gesture classification.

Design choices such as the use of a wireless system, the design of a support structure, the video demonstrations, and the inclusion of rest periods between movements were made to enhance the quality of the collected data. The wireless system and support structure allow for more natural movements and avoid artifacts caused by cable movement, pressure on the electrodes, and muscle tension due to the need to maintain the limb position. Additionally, to avoid undesired variability in the data, video demonstrations are introduced to ensure that participants perform the movements consistently, and rest periods between movements are included to reduce fatigue-related changes in the sEMG signal.

Furthermore, by not using a muscle-specific approach, this work aims to reduce the cognitive load on users, who often must train the isolated contraction of specific muscles to operate a prosthesis. Instead, the protocol allows for the capture of activity from natural movements, potentially leading to more intuitive control strategies that are not limited to the activation of a restricted set of muscles and thus can be more easily generalized to users with different amputation levels.

VI. Conclusion and Future Work

This study developed a standardized protocol for biosignal acquisition to support the development of control systems for upper-limb prostheses. The protocol includes the use of a wireless system, a support structure, video demonstrations, and repetition cycles with rest periods to limit variability in the data. The protocol was developed to capture signals from a set of 17 functional movements and a rest state, with electrode placement that does not target specific muscles, designed to allow data collection from individuals with different amputation levels by isolating specific channel groups.

A sample of 10 able-bodied participants was used to validate the changes introduced in the protocol, and more data will be collected to constitute the dataset. We started the collection of biosignals with participants without amputation because the upper-limb prostheses being developed in our laboratory are suitable for amputations at the wrist level, and we assume that there will be little difference in biosignals between an individual without amputation and with amputation at the wrist level, considering that the location of the probes is around the elbow, far from the amputation site.

Future work will focus on expanding the data with a larger and more diverse sample, specifically including volunteers with upper-limb amputations to validate the protocol's adaptability and improve generalizability. Upon completion of the ongoing data collection, the full dataset will be made publicly available. Moreover, it will be used to develop and validate control algorithms for upper-limb prostheses, to improve the intuitiveness and expand the applicability of these systems.

Acknowledgment

The authors would like to thank the volunteer subjects who agreed to participate in this study.

***Abstract*—The pupillary light response (PLR) is the autonomic iris response to light and enables noninvasive observation of pupil diameter changes. Dynamic PLR responses were acquired with a smartphone-based system during a clinical study of depression treatment in elderly. We proposed a preprocessing and model-fitting pipeline for the acquired PLR signals. 1438 videos from 62 patients were analyzed, considering acquisitions from both eyes across different treatment weeks. The recordings were intrinsically noisy and presented common challenges such as missing samples, blink-related artifacts, and tracking errors. We proposed a data quality assessment that retained 1069 videos from 60 patients. Outliers were removed using the Hampel method, short intervals of missing samples were interpolated according to their duration, and complete recordings were excluded considering the amount of missing values thresholds. The resulting curves were fit to a second-order nonlinear PLR model using Nelder-Mead optimization. We analyzed different weights for the light stimulation region in the cost function. Patient medians of root mean squared error (RMSE) were compared using two-sided Wilcoxon signed-rank tests with Holm correction. Median stimulation RMSE decreased from 0.180 to 0.084 and 0.052, whereas global RMSE increased from 0.097 to 0.109 and 0.188. Early accommodation error also increased. All nine comparisons were significant (adjusted p ¡ 0.001). However, 99.8% of runs reached the 300-iteration limit; numerically valid fits were retained regardless of convergence. Under the same configuration, increasing the stimulation weight improved local agreement at the expense of other regions, and did not provide a general improvement in PLR fitting.**

I. Introduction

The pupillary light reflex (PLR) is the constriction and subsequent dilation of the pupil in response to light stimulation. This response is mediated by the antagonistic action of the iris sphincter and dilator muscles, which are modulated by the parasympathetic and sympathetic branches of the autonomic nervous system. Because of this relationship, PLR analysis has been explored as a noninvasive approach to assess autonomic function and neurological or psychiatric conditions [4], [5], [8].

Previous work developed a low-cost smartphone-based pupillometer and a computer vision pipeline to extract pupil size from PLR videos [3]. In that study, the authors used *YOLOv4* to estimate pupil radius and fitted the resulting pupilograms to a second-order nonlinear physiological model [3], [5]. The initial dataset included 80 recordings from five patients, collected as part of a clinical study involving older adults with depression [1]–[3].

The present work extends this previous effort by evaluating a larger set of clinical PLR recordings and addressing the methodological challenges that arise before biomarker analysis. This paper investigates the preprocessing steps used to prepare pupilograms for model fitting and the limitations of fitting a physiological PLR model using Nelder-Mead optimization with a weighted cost function [3], [10]. This focus is relevant because noisy pupil-size data, missing samples, blinks, saccades, and tracking errors can distort the estimated curve and lead to unstable or physiologically implausible model parameters [4], [7]–[9].

The main contributions of this work are: (i) a regional preprocessing strategy for smartphone-based PLR recordings; (ii) a data quality assessment of 1438 clinical videos; (iii) a segment-specific exclusion criterion based on missing samples after preprocessing; and (iv) an evaluation of how different weights in the fitting cost function affect global and regional fitting errors.

II. Methods and Materials

A. Data Source and Acquisition Protocol

The analyzed data were obtained from PLR videos acquired using the smartphone-based pupillometer developed in previous work [3]. The recordings were collected from 62 patients diagnosed with depression as part of a clinical research protocol conducted from January 2019 to March 2023 at the Institute of Psychiatry, Hospital das Clínicas FMUSP, University of São Paulo [1], [2]. Participants were between 60 and 87 years old, with a mean age of 67.5 years. The sample included xx men and yy women.

Recordings were planned at three time points: before the first theta-burst stimulation session, after the first session, and four weeks after treatment initiation, following the treatment session scheduled for that week. Before each set of recordings, participants underwent a 5 min period of adaptation to darkness in a dark room. At each time point, recordings were planned for both eyes under four auditory conditions: no audio, neutral audio, pleasant audio, and unpleasant audio. Each video lasted 20 s and was acquired at 20 Hz, yielding 400 samples per recording. The first 5 s were recorded in darkness to estimate the baseline pupil diameter. This interval was followed by 1 s of smartphone light stimulation to induce pupil constriction. The remaining 14 s were recorded in darkness to capture pupil redilation and recovery [3]. At 20 Hz, consecutive samples are separated by 50 ms. This sampling rate has been described as sufficient for comparisons of pupil size between experimental conditions in cognitive pupillometry, although higher sampling rates are desirable for measures such as maximum constriction velocity [7].

A total of 1438 videos were analyzed. 369 videos were discarded after preprocessing and exclusion based on recording quality, leaving 1069 videos from 60 patients. Two patients had no recordings that met the quality criteria. Across the original cohort of 62 patients, the mean number of videos per patient decreased from 23.2 (SD = 2.4) before filtering to 17.2 (SD = 6.4) after filtering. The latter calculation included the two patients with no retained recordings.

B. PLR Segmentation

Each recording was divided into four temporal regions according to the expected physiological behavior of the PLR curve and the acquisition protocol. The segmentation was also used to guide outlier removal, missing values assessment, exclusion criteria, and regional fitting evaluation. Each recording was divided into four regions: pupil baseline, frames 0 to 5.00 s; light stimulation, from 5.00 s to 6.00 s; early accommodation, from 6.00 s to 12.00 s; and final accommodation, from 12.00 s to 20.00 s. The boundary between early and final accommodation corresponded to 6 s after light offset, or 12 s after the start of the recording. This region defines the PLR feature named post-illumination pupil response (PIPR), quantified approximately six seconds after light offset in studies of depressive disorders [13].

C. Data Treatment Pipeline

Fitting nonlinear physiological models described by ordinary differential equations (ODEs) can be challenging when the objective function contains multiple local minima. Different parameter sets may produce similar fitted curves. Local derivative-free algorithms such as Nelder-Mead may converge to suboptimal solutions, particularly when the available data are noisy or incomplete [6]. The preprocessing pipeline was therefore designed to address two issues relevant to subsequent model fitting: outliers that could disproportionately influence the cost function and missing samples in regions containing rapid changes in pupil size. This approach follows pupillometry guidelines that recommend identifying invalid samples and addressing missing data and artifacts before analysis [7]–[9].

Missing samples reduce the information available for fitting and can leave some portions of the response less represented in the objective function. We therefore quantified the proportion of missing samples in each recording and in each region described in Section II-B, defined as the number of missing samples over the expected number of samples for the period. This assessment characterized the temporal distribution of missing data, while the duration of each consecutive gap was evaluated to determine its eligibility for interpolation.

Outliers can disproportionately influence the cost function. Following recommendations to identify invalid samples before interpolation [7], [8], we applied the Hampel method to the complete recording. This method evaluates the deviation of each sample from the local median using the median absolute deviation (MAD) as a measure of local variability [12]. The implementation was configured with `window_size = 5` and `n_sigma = 2.0`. Samples identified as outliers were marked as missing for subsequent gap filling.

Following outlier removal, gaps were filled according to the number of consecutive missing samples. Linear and cubic spline interpolation have both been described as approaches to reconstruct short missing intervals in pupillometry [7], [8]. Gap duration was defined as the number of missing samples divided by the sampling rate. Gaps of one or two samples, corresponding to up to 100 ms, were filled using linear interpolation. Gaps of three to five samples, corresponding to more than 100 ms and up to 250 ms, were filled using cubic spline interpolation. Both methods required two consecutive valid samples immediately before and two immediately after the gap. Neighbor eligibility was assessed using the missing-data mask before interpolation, so interpolated samples could not support the filling of another gap. No extrapolation was performed. Gaps longer than five samples or without the required neighbors were left unfilled. The 250-ms cutoff was informed by a configuration reported by Kret and Sjak-Shie [8].

D. Recording Exclusion Criteria

Previous studies have discussed the use of missing-data thresholds to exclude recordings with insufficient usable data [4], [8], [9]. After outlier removal and gap filling, the proportion of remaining missing samples was evaluated separately

for each PLR region. A stricter threshold was applied to the light stimulation region because it was shorter and had a lower proportion of missing samples in the raw recordings. A recording was excluded if the proportion of missing samples exceeded 10% during light stimulation or 30% in any of the other three regions.

E. Trial Aggregation

After recording exclusion, recordings from the same patient, eye, and acquisition time point were aggregated across auditory conditions by computing the mean of the available values at each corresponding frame. This strategy was intended to attenuate variability unrelated to the light stimulus, following the principle of averaging responses aligned to a common event [9]. Frames with no available values across the contributing recordings remained missing. Auditory conditions were not compared in the present analysis; each resulting curve represented the average response across the available conditions. This provided 328 PLR signals for 60 patients, with a mena number of 5.5 (SD=0.9) signals per patient.

F. Physiological PLR Model

We fitted the data to a second-order nonlinear physiological model proposed for transient PLR responses induced by short light flashes [5]. This model represents the iris dynamics using viscoelastic properties and autonomic inputs associated with parasympathetic and sympathetic modulation. We cosnidered this model for the present study because it provides a compact physiological description of PLR dynamics while remaining feasible for numerical fitting.

The model can be written in simplified form as a second-order differential equation:

$$\frac{d^2r}{dt^2}+D\frac{dr}{dt}+K_c(r-l_{0c})^2+K_d(r-L_{0d})^2 = F_s(t)-F_p(t)+P_0, \tag{1}$$

where r represents pupil radius, D is the damping term, K_c and K_d are elastic constants, l_{0c} and L_{0d} are resting-related parameters, $F_p(t)$ and $F_s(t)$ represent parasympathetic and sympathetic inputs, and P_0 is a static force term [5].

G. Nelder-Mead Optimization

The model parameters were estimated using the Nelder–Mead algorithm, a derivative-free simplex method for function minimization [10]. This algorithm was retained from the previous smartphone pupillometer implementation [3]. The same initial parameter vector and optimization settings were used for every mean curve and weight condition, as summarized in Table I. Each fit used a single initialization, and sensitivity to alternative initial values was not evaluated.

Before optimization, each mean curve was smoothed using a Savitzky-Golay filter with a window of five samples and a polynomial order of three. Remaining missing samples were temporarily filled to permit filtering: interior gaps were filled by linear interpolation, and missing values at the recording boundaries were filled using the nearest available value. The missing-data mask obtained before this temporary filling was then restored. These positions were excluded from both the error sums and the corresponding sample counts in the objective function. Values reconstructed during the earlier preprocessing stage remained eligible for inclusion.

Let I denote the set of sample indices with available values in the input mean curve before temporary filling, and let I_L denote the subset within the light stimulation interval. For either set A, the mean squared error was defined as

$$\mathrm{MSE}_A(\theta) = \frac{1}{|A|}\sum_{i\in A}\left[\tilde{y}_i - \hat{y}_i(\theta)\right]^2, \tag{2}$$

where $\tilde{y}_i$ is the smoothed reference value and $\hat{y}_i(\theta)$ is the model output for parameter vector θ. The objective function was

$$J(\theta) = 10^{-4}\left[\mathrm{MSE}_I(\theta) + (w-1)\mathrm{MSE}_{I_L}(\theta)\right], \tag{3}$$

where w was set to 1, 2, or 10. The factor 10^{-4} corresponds to dividing each residual by 100 before squaring, as implemented in the optimization routine. With $w = 1$, the objective reduces to the scaled global mean squared error. Larger values of w increase the contribution of the additional error term for the light stimulation interval. These conditions were compared to assess how emphasizing this interval affected global and regional fitting errors.

The model equations were integrated using `odeint`, which uses the LSODA solver, with the default integration tolerances of the recorded SciPy version. Parameter admissibility was checked using the restrictions listed in Table I. Optimization was limited to 300 iterations. Convergence required both the parameter tolerance of 10^{-4} and the objective-function tolerance of 10^{-6} to be satisfied, as assessed from the spread of the simplex vertices and their objective values in the SciPy implementation. Termination at the iteration limit was recorded separately from successful convergence.

For each fit, we recorded the optimizer termination status, number of iterations, number of objective-function evaluations, final integration status, and compliance with the implemented parameter restrictions. Failed integrations during objective-function evaluations were also counted, and distances from the final parameter values to the applicable limits were stored. Numerical convergence was distinguished from successful integration and parameter admissibility. These diagnostics characterize numerical behavior and do not establish the physiological accuracy of the fitted parameters.

H. Fitting Evaluation and Statistical Analysis

Fitting performance was evaluated using global and regional root mean squared error (RMSE), comparing the model output with the preprocessed mean curve before Savitzky-Golay smoothing. Remaining missing samples were excluded, whereas samples reconstructed during preprocessing were retained. Numerical validity required successful final integration, compliance with the implemented parameter restrictions, and

TABLE I
PREPROCESSING SETTINGS, INITIAL PARAMETER VALUES, AND OPTIMIZATION CRITERIA.

Model parameter	**Initial value**	**Implemented restriction**
r_0	3.00	No explicit bound
l_{0d}	3.59	$l_{0d} \geq 0$
l_{0c}	0.92	$l_{0c} \geq 0$
k_d	1.29	$k_d \geq 0$
k_c	0.059	$k_c \geq 0$
D	3.78	No explicit bound
f_p	12.73	No explicit bound
f_s	9.10	No explicit bound
p_0	-0.736	No explicit bound
t_p	0.26	$0 < t_p < 1$ s
t_s	0.64	$0 < t_s < 1$ s
Processing setting	**Value**	**Details**
Sampling rate	20 Hz	400 samples per recording
Hampel parameters	`window_size = 5; n_sigma = 2.0`	Applied to the complete recording; detected outliers marked as missing
Linear interpolation	1–2 missing samples	Gap duration up to 100 ms
Cubic spline interpolation	3–5 missing samples	Gap duration greater than 100 ms and up to 250 ms
Interpolation support	Two valid samples on each side	Consecutive samples immediately adjacent to the gap; eligibility assessed before filling; no extrapolation
Recording exclusion	$> 10\%$ missing during light stimulation; $> 30\%$ in any other region	Assessed after outlier removal and gap filling
Savitzky–Golay filter	Window: 5 samples; polynomial order: 3	SciPy default edge mode, `interp`
Residual scaling	Division by 100	Equivalent to multiplying the combined MSE terms by 10^{-4}
Light stimulation weights	1, 2, 10	Same initialization and optimization settings for all weights
Optimization setting	**Value**	**Details**
Algorithm	Nelder–Mead	Same initialization per curve and weight; default SciPy initial simplex
Initial model state	$r(0) = r_0$; $\dot{r}(0) = 0$	r_0 estimated during optimization
ODE integration	`odeint` / LSODA	Default SciPy integration tolerances
Maximum iterations	300	`maxiter`
Parameter tolerance	10^{-4}	`xatol`
Objective-function tolerance	10^{-6}	`fatol`, applied to the scaled objective
Software versions	SciPy: 1.17.1; `hampel`: 1.0.2	Versions used for the reported analysis

finite RMSE values. Optimizer convergence was assessed separately, and reaching the iteration limit did not by itself invalidate a fit. Failure and convergence rates were summarized by weight and patient, together with the number of eligible curves per patient [16].

Patients were eligible if at least one of their mean curves produced valid, converged fits under all three weights. For these patients, the primary analysis also included additional curves with numerically valid fits under all three weights, even when the optimizer reached the iteration limit. For each patient and weight, RMSE was summarized by the median over the same eligible curves, preserving comparisons within patients and avoiding treatment of repeated curves as independent observations.

Patient medians were compared using two-sided Wilcoxon signed-rank tests for weights 1 versus 2, 1 versus 10, and 2 versus 10 [14]. Comparisons covered global, light stimulation, and early accommodation RMSE. Holm correction was applied jointly to these nine comparisons at a significance level of 0.05 [15]. The tests assume approximately symmetric paired differences. Patient medians were summarized using the median and interquartile range. Pairwise comparisons were reported with rank-biserial effect sizes and Holm-adjusted p-values. The number of patients included in the analysis was also reported.

III. RESULTS AND DISCUSSION

A total of 1438 PLR videos from 62 patients were analyzed. After data treatment and quality assessment, 369 videos were discarded (25.7%), leaving 1069 videos from 60 patients. Two patients had all their recordings excluded. Across the original 62 patients, the mean number of videos decreased from 23.2 (SD = 2.4) before filtering to 17.2 (SD = 6.4) afterward, including patients with no remaining recordings. The greater dispersion in the number of retained recordings indicates that exclusion affected some patients more than others.

Fig. 1 shows the distribution of the proportion of missing samples across recordings, separately for each PLR region, before and after data treatment. The light stimulation interval presented a lower proportion of missing samples, whereas early accommodation showed greater missingness. Improved pupil detection under illumination and artifacts associated with blinking or tracking instability are possible explanations for

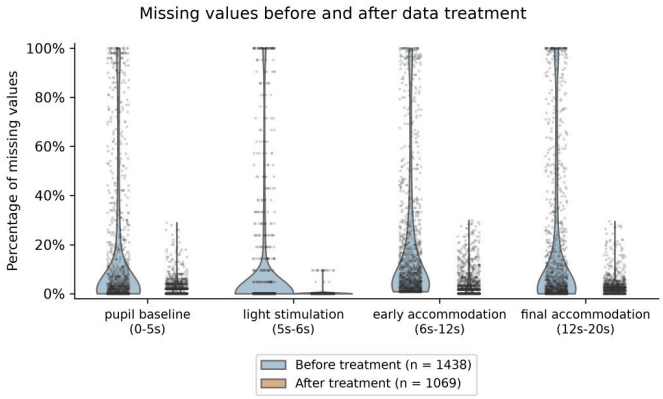

Fig. 1. Distribution of the proportion of missing samples per recording in the four PLR regions, before and after data treatment.

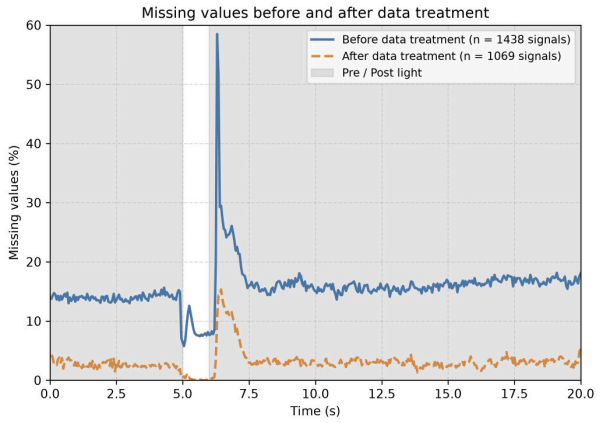

Fig. 2. Percentage of recordings with a missing sample at each time point, before and after data treatment.

these differences, but their contributions were not directly assessed. Some recordings contained few or no valid samples within individual regions, supporting the use of regional quality assessment.

The temporal distribution of missing data was also assessed by computing the percentage of recordings with a missing value at each frame, as shown in Fig. 2. Missing samples were more frequent near stimulus onset and during early accommodation, indicating that data availability varied throughout the acquisition protocol. Interpolation reduced missingness in eligible intervals, but the resulting values were reconstructed estimates. These temporal patterns alone do not establish the cause of data loss.

The retained recordings yielded 328 mean curves after trial aggregation. Each curve was fitted using weights of 1, 2, and 10, resulting in 984 optimization runs. Final ODE integration was successful in all runs. However, only one run under weight 1 and one under weight 2 satisfied the optimizer convergence criteria before reaching the iteration limit; none did so under weight 10. The remaining 982 runs (99.8%) reached the limit of 300 iterations. Visual inspection of the objective-function histories showed little further reduction in cost near

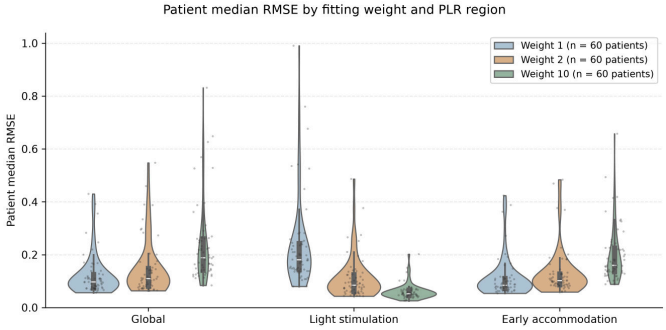

Fig. 3. Distributions of patient median RMSE for the global curve,light stimulation, and early accommodation under weights 1, 2, and 10. Each point represents one patient. Internal boxplots summarize the distributions, and the same eligible curves were used across weights within each patient.

the iteration limit, despite the unmet convergence criteria. Fits without optimizer convergence were retained when their final integration was successful, the implemented parameter restrictions were satisfied, and the required RMSE values were finite under all three weights. The resulting comparisons included 60 patients.

We assessed how the weight assigned to the light stimulation interval affected global RMSE, light stimulation RMSE, and early accommodation RMSE. Fig. 3 shows the distributions of the patient medians for these measures. With weight 1, the median RMSE during light stimulation was 0.180, exceeding the global median of 0.097. Thus, under the unweighted objective, the stimulation interval showed greater error than the recording as a whole.

Increasing the stimulation weight reduced the median RMSE within that interval to 0.084 and 0.052 for weights 2 and 10, respectively. However, the global median RMSE increased from 0.097 to 0.109 and 0.188, while the early accommodation median increased from 0.085 to 0.102 and 0.160. The interquartile range also increased with weight for global and early accommodation RMSE, whereas it decreased for light stimulation RMSE.

All nine paired comparisons were statistically significant after Holm correction (Table II). Weight 10 produced higher patient median RMSE than weights 1 and 2 for both the global and early accommodation measures in all 60 patients. Conversely, weights 2 and 10 produced lower light stimulation RMSE than weight 1 in every patient. These consistent directions yielded rank-biserial correlations of $+1$ or -1, indicating unanimity in the direction of the paired differences rather than a proportional change in error.

Most fits reached the iteration limit, so these findings describe performance with the selected initialization and a maximum of 300 iterations. Apparent plateaus in the objective function can coexist with unmet convergence criteria. Initialization, parameter scaling, objective-function geometry, and recording characteristics may contribute to this behavior, but their effects were not assessed separately. The observed errors therefore reflect the combined effects of preprocessing, the

TABLE II

model, and optimizer configuration.

The model did not explicitly account for variation in eye position. Furthermore, physiological parameter accuracy was not established through comparison with a reference pupillometer or repeatability analysis. Lower fitting error should therefore be interpreted as closer agreement with the processed recordings, without establishing the suitability of the estimated parameters as biomarkers.

IV. CONCLUSION

This work evaluated a data treatment and model fitting pipeline for smartphone-based PLR recordings acquired in a clinical context. Of 1438 videos, 369 were excluded using regional quality criteria, leaving 1069 recordings from 60 patients. Averaging recordings across auditory conditions within each patient, eye, and acquisition time point yielded 328 mean curves for fitting.

Motivated by the suggestion that greater emphasis on the light stimulation interval could improve PLR fitting [3], this study examined the consequences of increasing its weight in the objective function. Under the evaluated settings, this strategy reduced stimulation error but increased global and early accommodation error, despite the lower proportion of missing samples during stimulation. These findings do not support increasing the stimulation weight alone as a general solution for improving the complete PLR fit. Agreement outside this interval also matters when the fitted curve is used to estimate baseline pupil diameter or PIPR, since errors in the corresponding regions may affect these measurements.

The fact that 99.8% of optimization runs reached the iteration limit constrains the interpretation of these findings. Only one initialization was evaluated, and the effects of alternative initial values, parameter scaling, and stopping criteria were not examined. The observed lack of convergence may reflect a combination of these choices and the characteristics of the model and recordings. This study therefore does not establish whether Nelder-Mead is suitable for this problem under other configurations; it characterizes the fitting errors obtained with the selected initialization and computational budget.

Future work should evaluate these optimization choices jointly with the weighting strategy, including alternative optimization methods and robust loss functions. Comparison with reference measurements and repeatability assessment are also needed to establish the physiological accuracy and stability of the estimated parameters before biomarker analysis.

ACKNOWLEDGMENT

The authors thank the University of Sao Paulo research team and all collaborators involved in the clinical data collection and previous smartphone-based pupillometer work.

Abstract*—The assessment of the Vibration Perception Threshold (VPT) is an important quantitative method for analyzing the function of peripheral Aβ nerve fibers. Changes in this sensitivity threshold are indicators for a possible diagnosis of peripheral neuropathies, such as the hereditary Charcot-Marie-Tooth (CMT) disease. The objective of this study is to develop a vibratory stimulation prototype using a state-of-the-art technological approach that combines a Linear Resonant Actuator (LRA) vibration motor with the physical quantity of acceleration to quantify the VPT. The use of this physical quantity differs from the parameter adopted by more traditional commercial devices, which use, for example, the physical quantity of displacement. The device consists of a microcontroller connected to a haptic driver, which controls the vibration amplitude of the LRA motor, which has a resonance frequency of 235 Hz, in a gradual (step-by-step) and progressive manner. To characterize the prototype's tuning curve, measurements of the RMS acceleration (m/s²) produced at each vibration step were taken using a laser vibrometer. The results demonstrated that the prototype operates with an RMS acceleration ranging from 7.655 m/s² to 29.993 m/s². During system validation tests, a harmonic distortion of 3.32% was also observed, a value that falls within regulatory standards (ISO 13091-1). In the evaluations of the VPT in the distal segment of the lower limbs, there was a statistically significant difference between the groups (p = 0.0016), with higher VPT values for the group of patients with CMT, reflecting a possible impairment of peripheral somatosensory nerve fibers, specifically Aβ fibers, suggesting a potential of the prototype in clinical evaluation.

Keywords— Vibratory stimulation, peripheral somatosensory nerve fibers, vibration perception threshold (VPT), Charcot-Marie-Tooth.

I. INTRODUCTION

The somatosensory system, also known as the general somatic sensory system, is responsible for perceiving sensory information detected throughout the body, as distinct from the sensory signals associated with the special senses, such as vision, hearing, smell, taste, and balance [1].

The somatosensory system encompasses three main functions: proprioception, exteroception, and interoception [2, p. 475]. Proprioception refers to the perception of the body's own position and movement; exteroception is characterized by the perception of stimuli arising from the direct interaction of the external environment with the body; and interoception corresponds to the perception of the functioning of organ systems and the body's internal states.

The somatosensory system is composed of somatosensory neurons, and since they transmit information to the central nervous system (CNS), they are called afferent fibers or somatosensory peripheral nerve fibers [3].

Afferent fibers differ in terms of the presence or absence of a myelin sheath and are classified, respectively, as myelinated or unmyelinated [4]. These fibers also vary in diameter and are classified as thin fibers (type C – unmyelinated and type Aδ – myelinated) and thick fibers (type Aβ – myelinated and type Aα – myelinated, groups Ia and Ib). It should be noted that there are also efferent fibers, which connect the CNS to muscles and glands, designated as Aα [2, p. 770].

For action potentials to be generated in response to physical or physiological stimuli, the process of sensory transduction must occur, in which different forms of energy are converted into electrical signals in the nervous system. In the somatosensory system, mechanical stimuli are detected by specialized receptors called cutaneous mechanoreceptors, which are responsible for the perception of pressure, vibration, touch, stretch (tissue extension), and body position (proprioception). Among the main cutaneous mechanoreceptors are Merkel discs, Meissner corpuscles, Ruffini corpuscles, and Pacini corpuscles, each of which exhibits specific characteristics of adaptation and sensitivity when subjected to different mechanical stimuli [5]. Pacini corpuscles exhibit high sensitivity to high-frequency vibrations, in the approximate range of 40 to 400 Hz [6].

The perception of mechanical stimuli on the skin is mediated by myelinated Aβ nerve fibers. Diseases that more specifically affect myelinated fibers, such as Charcot-Marie-Tooth disease (CMT), cause significant impairment of functions related to the perception of vibratory sensation, especially in the early stages of the disease, when more severe motor symptoms are not yet present. Thus, the assessment of vibratory sensation serves as an important clinical diagnostic method in the functional evaluation of somatosensory peripheral nerve fibers [7].

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

One parameter used in the assessment of vibration sensitivity is the Vibration Perception Threshold (VPT), defined as the lowest intensity of a vibratory stimulus that an individual can perceive. Devices for quantitatively assessing the VPT in clinical trials have shown greater reliability compared to tuning fork tests [8].

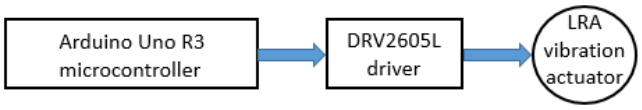
In this regard, this study presents the development and characterization of a vibratory stimulator designed for the quantitative assessment of vibratory sensitivity. The proposal adopts a more recent technological approach, which combines the use of a Linear Resonant Actuator (LRA) vibration motor with the physical quantity RMS acceleration (a_{RMS} in m/s²) to quantify VPT, thus differing from more traditional commercial systems, which use, for example, the physical quantity of displacement (µm) as a parameter for quantifying VPT [8], [9].

A preliminary study evaluating the VPT in patients with the hereditary disease Charcot-Marie-Tooth (CMT) is presented.

II. Materials and Methods

A. Vibration System Architecture

The architecture of the vibration stimulation system was designed around three key components: an Arduino Uno R3 microcontroller, a DRV2605L haptic driver, and a Linear Resonant Actuator (LRA), as shown in Fig. 1.



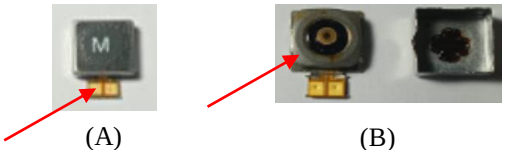


Fig. 1. Block diagram of the implemented system, consisting of an Arduino Uno R3 microcontroller, a DRV2605L haptic driver, and an LRA-type vibration actuator.

The Arduino Uno R3 microcontroller, based on the ATmega328P, controls the system by executing code written in C++. This code allows for 128 vibration amplitude steps (from 0 to 127). Parameters such as the duration of the vibration stimulus at each step, the interval between stimuli, the initial step, and the step increment can be configured. Communication with the haptic driver is carried out via the I²C interface.

The DRV2605L haptic driver, developed by Texas Instruments, is a low-voltage integrated circuit that provides a library of haptic effects, offering capabilities for controlling and driving vibratory actuators [10]. In this study, the DRV2605L is responsible for driving the Linear Resonant Actuator (LRA), enabling control of the vibration amplitude at each step, according to the parameters defined by the microcontroller.

Vibration actuators are electromechanical devices capable of converting electrical signals into mechanical vibrations; they are typically used in haptic interfaces found in various electronic devices, such as cell phones, video game controllers, and medical equipment designed for tactile stimulation [11], [12].

Among vibratory actuators, LRA-type devices stand out for their precision and efficiency in generating controlled stimuli. These actuators generate vibration when subjected to an alternating voltage through the linear displacement of an internal mass, driven by the magnetic field of a coil and restored by an elastic system [13]. Fig. 2 shows the LRA motor used in the prototype.

(A) (B)

Fig. 2. LRA vibration motor. In (A), its external configuration is shown, with the terminals for soldering the conductors (red arrow). In (B), the internal structure of the LRA motor is shown, highlighting (red arrow) the oscillating mass, which is responsible for the linear vibrational motion without any rotational component.

LRA-type motors exhibit maximum vibration amplitude when excited by a periodic signal at their resonance frequency (f_R), defined as the natural frequency at which the system exhibits the greatest dynamic response [14].

This frequency can be described by a mass–spring system model, as shown in Equation (1) [15].

$$f_R = \frac{1}{2\pi}\sqrt{\frac{k}{m}} \quad (1)$$

Wherein:

- f_R is the resonance frequency of the LRA motor, in Hz;
- k is the spring constant, in N/m;
- m is the effective mass of the vibrating system, in kg.

Fig. 3 illustrates the (typical) frequency response of an LRA vibration motor, showing a peak in RMS acceleration amplitude (a_{RMS}), in m/s², at the resonance frequency (f_R) of the LRA motor used in the study (235 Hz).

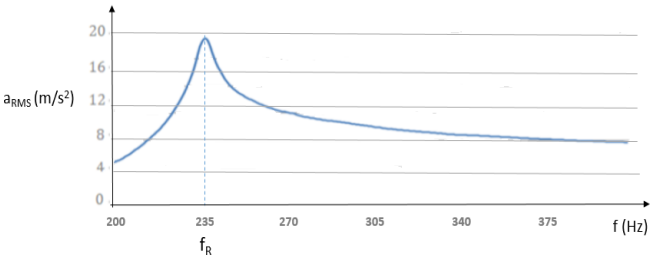

Fig. 3. RMS acceleration (a_{RMS}) response curve, in m/s², at the resonance frequency of an LRA vibration motor (adapted from [16]).

B. Step adjustment curve vs RMS acceleration

Measurements of the vibrations produced by the LRA motor at each step were taken using a laser vibrometer (PDV100 – Polytec) and a 01dB – NETDB multichannel analyzer. Fig. 4 shows the equipment used.

(A) (B)

Fig. 4. Equipment used to measure the calibration curve: (A) laser vibrometer (PDV100 – Polytec); (B) 01dB multichannel analyzer – NETDB.

The PDV100 is a high-precision device that enables the non-contact measurement of mechanical vibrations on surfaces, using laser technology to obtain vibration velocity values [17], [18].

The 01dB – NETDB multichannel analyzer is a data acquisition system used for acoustic and vibration applications, offering spectral analysis and signal processing capabilities via the dBFA Suite software [19].

On the PDV100, the following settings were used for the experiment.

- Peak scale range of 100 mm/s;
- Low-pass filter with a cutoff frequency of 1 kHz;
- High-pass filter with a cutoff frequency of 100 Hz.

The following parameters were configured in the NETDB software:

- Acquisition time of 10 seconds per step;
- 1-second post-trigger for stabilization purposes.

In the experiment, a silicone hand, supported and stabilized on a base, was used to simulate realistic contact conditions between the LRA motor and the index finger of the hand. The LRA motor was attached to the distal pad of the index finger, as shown in Fig. 5 (highlighted with a red arrow).

Fig. 5. Experimental setup for measuring the adjustment of the step curve vs RMS acceleration.

With this setup, a C++ language code was implemented to generate individual vibrations (per step), with intensities ranging from 0 to 127. Following data acquisition by PDV-100, post-processing was performed using the NETDB software, including the following actions:

- Application of a bandpass filter from 200 to 270 Hz, with a slope of 24 dB/eighth (4th order), centered on the resonance frequency of the LRA motor (235 Hz);
- Derivation of the velocity signal to obtain the acceleration (a) at each step;
- Calculation of the effective acceleration value (a_{RMS}) at each step, in m/s^2.

C. Experimental Protocol for Assessing the Vibration Perception Threshold (VPT)

Experimental evaluations were conducted on human participants to assess their perception of the vibrational stimulus generated by the developed system. The participants were divided into two distinct groups, as classified below:

- Group 1 – Control group, consisting of healthy individuals with no symptoms of neuropathy;
- Group 2 – Individuals diagnosed with CMT-related peripheral neuropathy.

The study was conducted in accordance with the ethical guidelines for research involving human subjects (Brazilian CNS Resolution 466/12). The protocol was approved by the Research Ethics Committee of the School of Dentistry – Federal University of Rio de Janeiro (UFRJ) under CAAE 95585626.0.0000.0268 on March 27, 2026, with written informed consent obtained from all participants.

Group 1 consisted of nine participants. The inclusion criteria were: being between 18 and 75 years of age, with no history of peripheral neuropathies. The exclusion criteria were: use of antidepressants or sedatives that impair attention and/or the locomotor and somatosensory systems; or having any type of neurodegenerative disease.

Group 2 consisted of three participants. The inclusion criteria were: being between 18 and 75 years of age and having a diagnosis of CMT; and being under medical care for this hereditary disease. The exclusion criteria were: individuals with CMT who had cognitive decline, dementia, cerebellar ataxia, or other peripheral neuropathies, such as those caused by diabetes.

The participants were seated in an air-conditioned room with a temperature of approximately 25°C (± 1°C) and dim lighting; they were instructed to remain relaxed throughout the assessment period.

The assessments were performed on the upper limbs (UL) and lower limbs (LL), ipsilaterally, on the left side. In the UL, the pulp of the distal phalanx of the index finger was used to attach the LRA motor. In the LL, the LRA motor was attached to the proximal phalanx of the hallux (big toe), on the dorsal side.

The procedure for evaluating the Vibration Perception Threshold (VPT) consisted of the following steps:

- Step 1: measure the temperature of the limb to be evaluated using a digital infrared thermometer (FLUKE 62 MAX+);
- Step 2: position of the LRA motor at the body points used in the study;
- Step 3: generation of vibratory stimuli (four events), with gradual increases in vibration amplitude (m/s^2), until the participant signals perception of the stimulus by pressing a stop button;
- Step 4: calculation of the arithmetic mean of the values obtained in the four events, which determines the participant's VPT value.

Fig. 6 shows the setup as it was assembled during the evaluations of one participant.

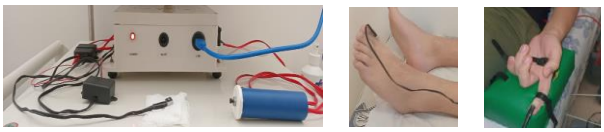

Fig. 6. Experimental setup assembled and evaluations.

III. RESULTS

A. *Prototype adjustment curve*

For each step, the a_{RMS} values were collected and tabulated in m/s². Table 1 shows the a_{RMS} values obtained, with an initial value of 7.655 m/s² (step 24) and a final value of 29.993 m/s² (step 127).

TABLE 1

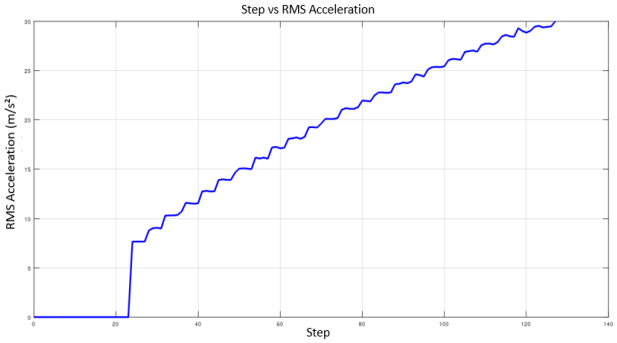
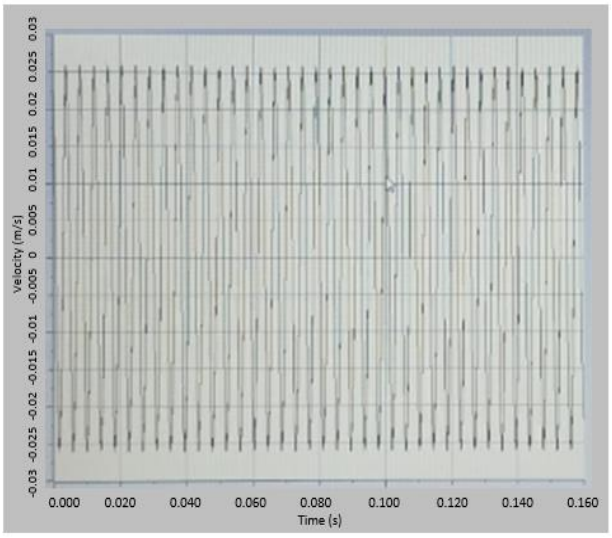
Based on the acceleration (a_{RMS}) values presented in Table 1, a curve showing the RMS acceleration (a_{RMS}) as a function of step increments was generated using GNU Octave software. A gradual and progressive increase in RMS acceleration is observed as the number of steps increases, as illustrated in Fig. 7.





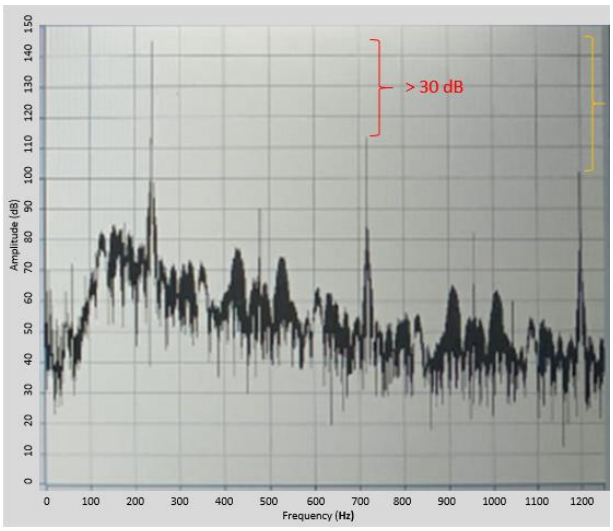


Fig. 7. RMS Acceleration (a_{RMS}) Curve as a Function of Step Increments for the LRA Motor.

As can be seen in Table 1 and Fig. 7, the vibration begins at step 24. This behavior is associated with an adjustment made to a specific parameter in the microcontroller code, which limits the amplitude of the LRA motor's excitation signal. This adjustment made it possible to minimize the presence of harmonic distortions, contributing to an improvement in the quality of the vibration signal, but causing the vibration to be generated only starting at step 24.

Fig. 8 (A) illustrates the vibration signal corresponding to step 111 in the time-domain, as recorded by the PDV-100. The signal shows distortion. Fig. 8 (B) shows the frequency-domain analysis of the signal, where the odd harmonics are more evident. There is a difference of more than 30 dB (highlighted in red) between the amplitudes of the fundamental (235 Hz) and the 3rd harmonic (at 705 Hz). This corresponds, considering 30 dB on the linear scale, to an amplitude of the fundamental component that is 31.62 times greater than that of the 3rd harmonic and, in terms of power, to a difference of approximately 1,000 times. It can also be observed in (B) that there is a difference of more than 40 dB (highlighted in orange) between the amplitudes of the fundamental (235 Hz) and the 5th harmonic (1,175 Hz). This latter frequency lies outside the response band of Pacini corpuscles.

(A)

(B)

Fig. 8. In (A), analysis in the time-domain, and in (B), in the frequency-domain.

The ISO 13091-1 standard (Mechanical vibration - Vibrotactile perception thresholds for the assessment of nerve dysfunction), establishes the purity criteria for the vibrational

stimulus wave. According to the technical literature, the guidelines of this standard require that a stimulation system have a Total Harmonic Distortion (THD) within the following parameters [20]:

- < 30% from 4 Hz to 50 Hz;
- < 10% from 63 Hz to 250 Hz.

The calculated THD value for the stimulus at the fundamental frequency of the LRA motor (235 Hz), considering the 3rd and 5th harmonics as the main distortion components (705 Hz and 1,175 Hz) was 3.32%. This THD value falls well within the limits specified in ISO 13091-1, demonstrating that the developed system complies with the required international limits.

B. Assessment of the Vibration Perception Threshold (VPT)

Table 2 shows the VPT values obtained in the assessment of Group 1—Control. It can be seen that all participants (9 in total) reported perceiving vibration at step 24, where the RMS acceleration (a_{RMS}) was 7.655 m/s², in both the lower and upper limbs.

Minimum	—	21	7.655	7.655
Maximum	—	34	7.655	7.655

Table 3 presents the data collected during the vibration assessment of Group 2, participants with CMT-related peripheral neuropathy, comprising a total of three participants.

TABLE 3

Values of Group 2 – CMT holders

ID	Gender	Age (years)	Foot VPT (m/s^2)	Hand VPT (m/s^2)
10	M	53	27.739	7.655
11	F	46	29.993	29.993
12	M	18	10.005	7.655
Median	—	46	27.739	7.655
Minimum	—	18	10.005	7.655
Maximum	—	53	29.993	29.993

The VPT values for Group 2 – patients with CMT, were higher than those for Group 1 – the control group. Participant No. 10 presented a typical phenotype in the lower extremities, with pes cavus, hammertoes, and distal muscle atrophy (peroneal and tibialis anterior), along with difficulties with walking, balance, and postural stability, symptoms characteristic of CMT-related peripheral neuropathy [21]. In the upper extremities, there were no visible symptoms of CMT. Participant No. 11 exhibited the same symptoms in the lower extremities as those described for Participant No. 10, with even more visual evidence. In addition, impairment of the intrinsic hand muscles, characteristic of CMT, was observed in the upper extremities, consistent with the degree of disease progression [22]. Participant No. 12 did not exhibit symptoms characteristic of CMT in either the lower or upper extremities.

For the statistical comparison between the groups (Control vs. CMT), the non-parametric Wilcoxon-Mann-Whitney test was applied. In the evaluation of the vibration perception threshold in the lower limbs (foot), inferential statistical analysis indicated a significant difference between the Control group and the CMT group, presenting a large effect size ($W = 0$; $p = 0.0016$; Cliff's Delta $\delta = 1.00$; 95% CI = [0.816; 1.000]). In contrast, for the upper limbs (hand), no statistically significant difference was observed between the groups, with a small to moderate effect size ($W = 9$; $p = 0.124$; Cliff's Delta $\delta = 0.33$; 95% CI = [-0.391; 0.803]).

IV. Discussion

The study presented the implementation of a prototype vibratory stimulator designed to assess the sensitivity of peripheral Aβ nerve fibers by quantifying VPT. The device produces vibratory stimuli in a gradual and progressive manner, employing a state-of-the-art technological approach that combines the use of an LRA motor with the physical quantity RMS acceleration (a_{RMS}), expressed in m/s², to quantify VPT. This methodology differs from more traditional commercial systems, which typically operate using displacement, in µm, as the unit of measurement for vibration. From the perspective of the prototype's functional reliability, the Total Harmonic Distortion (THD) was only 3.32%, with the 3rd and 5th harmonics being the main distortion components, indicating a strong predominance of the fundamental component at 235 Hz. This level of spectral purity meets the harmonic distortion criterion established by the ISO 13091-1 standard, although full compliance with the standard depends on other technical parameters, such as the incorporation of contact force control systems. Although experimental validation with the non-contact laser vibrometer (Polytec PDV100) ensures adjustment accuracy and the reliability of the generated stimulus, the formal calculation of the expanded measurement uncertainty of the entire instrumental system constitutes a step to be addressed in future work. In the VPT assessments, the results showed a statistically significant difference in the distal segment of the lower limbs ($p = 0.0016$), which was not observed in the upper limbs ($p = 0.124$), suggesting a possible trend associated with the length-dependent pattern of CMT neuropathy [23]. However, a central limitation of the current device is the floor effect observed in the Control Group, given that all healthy participants detected the vibration at the minimum level of the prototype (7.655 m/s²). This indicates that the true threshold for this population may lie below the current dynamic range of the hardware, and this value should be interpreted as an operational limit of the system, rather

than an absolute normative threshold of sensitivity. Furthermore, the detection of altered thresholds in the asymptomatic participant (No. 12) represents a preliminary exploratory observation. Although it suggests the potential of the device for early screening of somatosensory changes, the confirmation of a diagnostic capability at a subclinical stage requires cross-validation with reference examinations (such as electroneuromyography) and longitudinal follow-up. The chosen frequency of 235 Hz, which preferentially stimulates Pacinian corpuscles, limits the evaluation of other mechanoreceptors that may be compromised by different types of peripheral neuropathies. Future work will address multifrequency stimulation. Additionally, subsequent developments will focus on operation at lower acceleration levels to minimize the floor effect, contact force control, the incorporation of new algorithms into the firmware to enhance measurement rigor, measurement uncertainty evaluation, performance comparison with consolidated commercial devices, and the execution of studies with larger samples.

V. Conclusion

The implemented prototype is a promising tool for the quantitative assessment of vibratory sensitivity, especially in conditions that cause peripheral neuropathies. Although the study presents a preliminary investigation with a reduced number of participants in the CMT peripheral neuropathy group (n=3), the results obtained indicated a possible differentiation when compared to the healthy group, suggesting a potential of the system for clinical application. Additional tests, considering a significantly larger sample, must be performed for the purpose of full validation of the produced equipment.

THANKS

The authors thank the study participants for their cooperation and willingness to take part in the assessments. This work was supported by the following Brazilian research funding agencies: CAPES/PRONEX, through the Biomedical Engineering Program at the Alberto Luiz Coimbra Institute for Graduate Studies and Engineering Research (COPPE); and the National Council for Scientific and Technological Development (CNPq).

***Abstract*—Early detection is essential for reducing breast cancer mortality, driving ongoing research to improve lesion diagnosis in mammograms. However, the development of CAD and CADx systems is hindered by a lack of large, standardized, and clinically annotated datasets. Anthropomorphic breast phantoms provide a standardized alternative by simulating realistic breast structures. This study evaluates three 3D-printed materials—polylactic acid (PLA), thermoplastic polyurethane (TPU), and photopolymer resin—for their visual and textural equivalence to actual breast lesions. Test structures with varying geometries and infill densities were embedded in beeswax plates, which simulate adipose tissue. Mammograms from 11 configurations were analyzed using radiomic texture features to assess the effects of material, shape, and size. Results showed that TPU exhibited the most pronounced deviations from the PLA reference, particularly in Contrast, Sum Variance, IMC1, IMC2, and MCC. Additionally, geometric shape and size marked textural discrepancies in the radiomic responses, specifically affecting Sum Variance, Inverse Difference Moment, Difference Variance, and Entropy. Ultimately, TPU's variable radiographic response makes it unsuitable for simulating glandular tissues and lesions. Photopolymer resin showed high similarity to PLA, but PLA remains the most suitable material for simulating lesions, optimizing the development of anthropomorphic phantoms.**

***Index Terms*—mammography, breast cancer, plates, Additive manufacturing,**

I. Introduction

Breast cancer is a leading cause of death among women and one of the most prevalent malignant neoplasms worldwide [1], [2]. Early detection is crucial, as treatment in the initial stages halts disease progression, prevents metastasis, and significantly improves patient survival [3], [4]. Accordingly, the World Health Organization (WHO) recognizes mammography as the gold standard for population-based screening in asymptomatic women [5].

To enhance image interpretation efficiency and accuracy, ongoing research focuses on developing Computer-Aided Detection (CAD) and Diagnosis (CADx) systems [6]. However, developing and validating these algorithms requires large datasets of mammographic images, which poses a significant challenge. Private databases are often restricted to their owners, while public repositories frequently suffer from bureaucratic access, unstandardized file formats, and inconsistent image acquisition protocols. Crucially, these public datasets often lack the physical and structural diversity necessary to train robust, modern models [7]–[9]. Given this scenario, image sets based on radiographic exposure of breast phantoms, prostheses specially designed to simulate real breasts in various aspects, have proven to be a promising alternative to replace or complement real-image databases [10]. These phantoms can be physical or virtual [11], and their use presents notable advantages: precise knowledge of the structural attributes of the exposed phantom, the ability to control and vary the location and morphology of lesions, repeatability in image acquisition, generation of large volumes of data without exposing patients to additional radiation doses, and elimination of the need for medical reports or biopsies for result validation [12]–[14]. These phantoms are used not only in research but also for calibration, quality assurance, and accuracy assessment of images acquired through mammography [15]. However, the use of commercial phantoms still face barriers regarding accessibility, cost, and fidelity to actual breast tissue, particularly for lesions mimicking glandular tissue [16]. This fidelity issue arises because the radiological response of a phantom depends on the attenuation and texture of the materials used, which in commercial phantoms are fixed and often not representative of breast tissue. Additive manufacturing (3D printing) directly addresses this limitation: by selecting the printing material

and controlling the infill pattern and percentage, the resulting attenuation and texture can be adjusted to approximate those of breast tissue. It also offers lower cost and greater ease of customization compared to commercial phantoms, making it an accessible route for producing phantoms that more closely reproduce breast tissue. As a result, diverse tumor models varying in size, shape, density, and morphology can be created. Recent studies have begun to explore this avenue; for instance, Pinheiro [17] investigated materials and printing parameters specifically for radiological applications. In this context, optimizing anthropomorphic phantoms through careful material selection and quantitative radiological analysis is essential for advancing breast imaging research. This study aims to evaluate 3D-printed materials for the fabrication of new plates to be integrated into a phantom currently under development by the research group [18]. To assess this, the materials were evaluated through visual inspection and quantitative radiomic analysis of mammograms acquired from printed test objects.

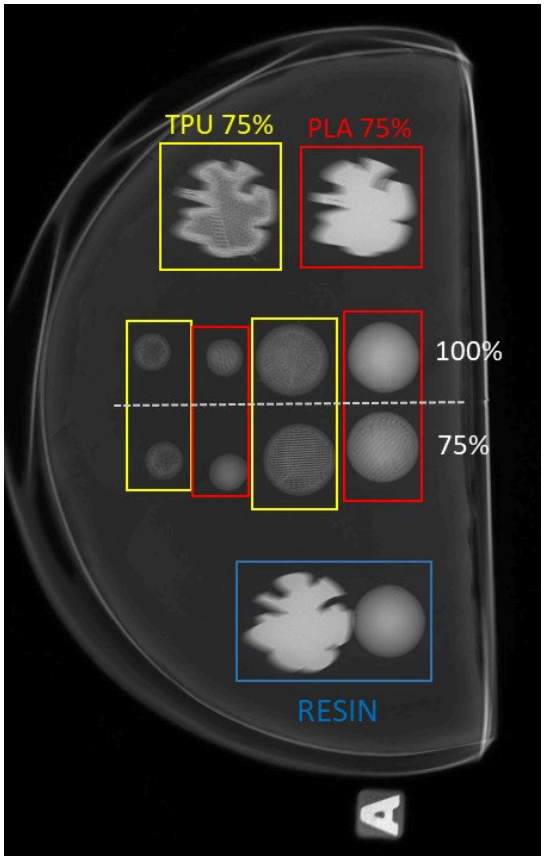

Fig. 1. Different structures used to simulate nodules with varying materials, geometries, and infill percentages.

II. METHODS

It is important to emphasize this study was conducted to evaluate the radiographic behavior of materials manufactured using additive manufacturing for application in anthropomorphic breast phantom plates. Test objects of various shapes and sizes were 3D-printed using three different materials and varying infill configurations. Mammograms of these objects were then acquired and processed to extract radiomic features, enabling quantitative texture analysis and comparison of the materials' radiographic behavior.

A. Design and Fabrication of the Test Objects

The structures simulating different nodules were manufactured using 3D printing with polylactic acid (PLA), thermoplastic polyurethane (TPU), and photopolymer resin. Components with different geometries, including circular and irregular shapes in both large and small sizes, as well as internal infill percentages of 75% and 100%, were produced to evaluate the influence of these variables on the radiographic behavior of the materials. These structures can be seen in Fig.1

The test objects were positioned on plates designed to simulate adipose and fibroglandular tissues. These background plates comprise: (1) an adipose-equivalent base, for which both beeswax and paraffin gel were evaluated as candidate materials [ref]; and (2) a higher-density mixture of beeswax, fiberglass, and polyvinyl chloride (PVC) film, replicating fibroglandular tissue [ref]. Originally developed for the BeeMamma phantom [ref], these plates provide varying X-ray attenuation properties to reproduce the radiographic characteristics of glandular breast tissue. A total of eleven mammographic images were analyzed. Eleven images corresponded to the experimental configurations (0A–10A), comprising different combinations of printing materials, filling formulations, and lesion-simulating structures. One additional image was acquired using the AEC (Automatic Exposure Control),that being configuration 7E, while another corresponded to configuration 10E, consisting of a phantom without lateral supports, containing a resin block and additional lesion-simulating structures. The experimental configurations are summarized in Table.1.

TABLE I
EXPERIMENTAL PHANTOM CONFIGURATIONS USED FOR MAMMOGRAPHIC IMAGE ACQUISITION

Config.	Experimental Configuration
0A	PLA, TPU and resin structures (75% and 100% infill) embedded in beeswax.
1A	Large PLA, TPU and resin structures embedded in beeswax.
2A	Small PLA, TPU and resin structures embedded in beeswax.
3A	Small PLA, TPU and resin structures embedded in beeswax and dental wax.
4A	Comparison of beeswax, aged beeswax and beeswax with paraffin.
5A	Beeswax and dental wax reinforced with fiberglass and 6 g of PVC.
6A	Beeswax and dental wax reinforced with fiberglass and 12 g of PVC.
7A	Beeswax and dental wax reinforced with fiberglass and 18 g of PVC.
7E	Same configuration as 7A acquired using the AOP DOSE exposure mode.
8A	Beeswax with fiberglass and 6 g PVC, beeswax with paraffin lesions, and dental wax with paraffin lesions.
10E	Modified phantom without lateral supports, containing a resin block, simulated microcalcifications and a gold enamel inclusion.

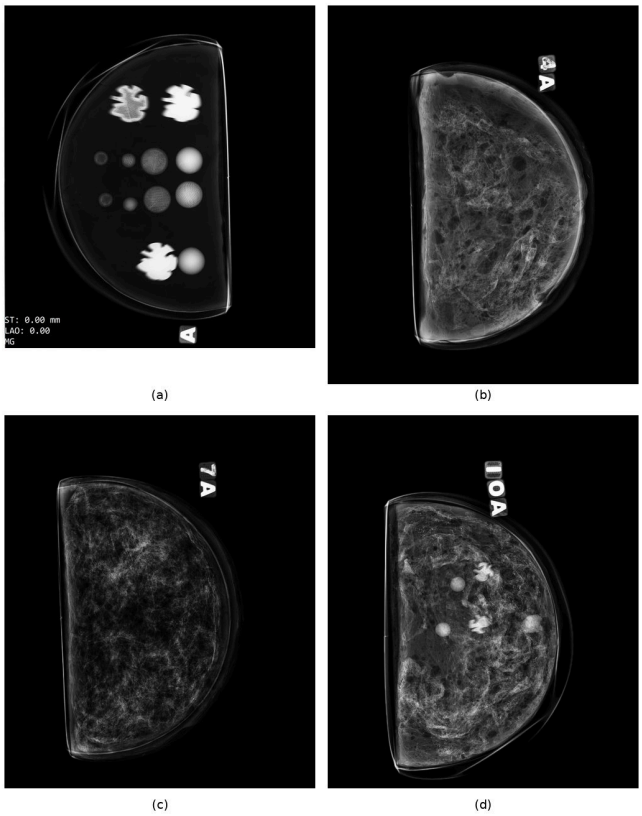

Fig. 2. Representative mammographic images acquired from different anthropomorphic phantom configurations: (a) configuration 0A, (b) configuration 4A, (c) configuration 7A, and (d) configuration 10A.

B. Image acquisition

A total of 11 images, representing various combinations of materials and infill configurations, were acquired using a full-field digital mammography system, model Senographe Crystal, in Automatic Exposure Control (AEC) mode. The specific configuration for each image is detailed in Table 1. Figure 1 presents four representative mammograms (configurations 0A, 4A, 7A, and 10A), selected to illustrate key stages of testing and optimization for the BeeMamma phantom.

C. Radiomic Feature Extraction

Quantitative characterization was performed by extracting radiomic texture features from the mammographic images acquired for the different phantom configurations. The analysis considered the distribution of gray-level values among pixels within regions of interest (ROIs) defined for each object and each material. This distribution allows the identification of texture patterns associated with the radiographic characteristics of the different materials evaluated. The comparison was performed using three complementary approaches: (i) visual assessment of the mammographic images; (ii) analysis of normalized Haralick feature curves (including skewness and kurtosis) with PLA as reference; and (iii) comparison of the Gaussian distribution curves of each feature. The visual assessment consisted of inspecting the mammographic images for structure visibility, edge definition, and texture realism, comparing each material against PLA as the reference. For texture characterization, Haralick descriptors were used [19], obtained from the Gray-Level Co-occurrence Matrix (GLCM), which describes the spatial relationship between the gray levels of image pixels, allowing the extraction of several statistical measures. A total of 14 Haralick features were extracted from each ROI, providing a comprehensive characterization of the texture properties of the mammographic images. These features, derived from the GLCM, describe different aspects of the spatial organization of grayscale values and are briefly described as follows [11]:

- **Angular Second Moment (ASM):** Measures texture homogeneity; higher values indicate more uniform textures.
- **Contrast:** Estimates local intensity variation by quantifying differences between gray levels of adjacent pixels; lower values correspond to smoother regions.
- **Correlation:** Assesses the linear dependency between gray levels of neighboring pixels, revealing periodic patterns or smooth areas.
- **Variance:** Quantifies the dispersion of gray-level intensities, reflecting image contrast.
- **Inverse Difference Moment (IDM):** Evaluates local homogeneity, being sensitive to subtle textural changes.
- **Sum Average:** Represents the mean of the gray-level distribution.
- **Sum Variance:** Indicates the variability of the gray-level distribution.
- **Sum Entropy:** Measures the information content associated with the sum of gray-level pairs.
- **Entropy:** Quantifies the randomness or disorder in the

gray-level distribution, with higher values indicating more complex textures.

- **Difference Variance:** Measures the variability of gray-level differences, centered at zero.
- **Difference Entropy:** Quantifies the disorder or randomness among pixel differences.
- **Information Measure of Correlation 1 (IMC1):** Quantifies correlation by analyzing the entropy of individual elements and their paired combinations.
- **Information Measure of Correlation 2 (IMC2):** Assesses correlation based on the similarity between entropies.
- **Maximal Correlation Coefficient (MCC):** Indicates the heterogeneity of the gray-level distribution.

In addition to the GLCM-based features, two first-order statistical measures were computed from the gray-level intensity distribution within each ROI [20]:

- **Skewness:** Measures the asymmetry of the gray-level intensity distribution. Positive skewness indicates a tail toward higher intensities, while negative skewness indicates a tail toward lower intensities.
- **Kurtosis:** Quantifies the "tailedness" or peakedness of the intensity distribution. Higher kurtosis values indicate a distribution with heavier tails and a sharper peak, suggesting the presence of outliers or extreme intensity values.

These descriptors collectively evaluate textural properties such as homogeneity, contrast, correlation, entropy, heterogeneity, and intensity distribution shape, allowing a quantitative comparison of the radiographic behavior of the materials under investigation.

The feature extraction was performed using a MATLAB script. The GLCM was computed considering a pixel distance of one and four orientations (0°, 45°, 90° and 135°). For each feature, the final value was obtained by calculating the arithmetic mean of the values computed for the four analyzed orientations.

D. Statistical analysis

The extracted radiomic features enabled the analysis of the texture characteristics of the different phantom configurations, as well as the identification of the materials with radiographic behavior most similar to glandular breast tissue. Initially, a descriptive analysis of the features obtained for each experimental configuration was performed.

Subsequently, Gaussian curves were used to evaluate the distribution of radiomic features among the different configurations. For this purpose, normal distributions were constructed based on the normalized mean and standard deviation values of each feature, considering both the material type and the lesion shape represented. The overlap between the curves was used as an indicator of similarity among the evaluated materials and the nodule geometries employed in the manufacture of the test structures, allowing the identification of the features that exhibited the most stable behavior.

Finally, a comparative analysis was performed to evaluate the radiomic response of the different materials across all experimental configurations. For this purpose, the value of each Haralick feature extracted from the TPU and photopolymer resin structures was divided by the corresponding feature value extracted from the PLA structures, which was adopted as the reference material.

PLA was chosen as the baseline material for the comparative analysis for three reasons. First, within the context of the phantom currently under development by the research group [18], PLA was previously employed as the primary material for fabricating tumor-simulating structures. further supported by a previous study [17], which demonstrated that PLA is suitable for simulating both circumscribed and spiculated nodules in mammographic phantoms, validating its use through comparison of mass attenuation coefficients with invasive ductal carcinoma across the mammographic energy range (10–30 keV). The phantom developed in that study, named Cleopatra, employed PLA to simulate nodules and was validated using 14 Haralick texture descriptors, showing good detectability of test structures. Additionally, radiographic results obtained from PLA demonstrated excellent visibility and realistic texture in mammographic images, further supporting its suitability for simulating biological lesions. Second, PLA is widely available, cost-effective, and well-characterized in the additive manufacturing literature, with studies confirming that its X-ray attenuation properties are compatible with breast tissue equivalents under clinical mammography [**?**]. Third, by adopting PLA as the reference, the influence of absolute intensity variations is eliminated, and the relative differences in texture properties between PLA and the other materials (TPU and photopolymer resin) can be directly assessed. This normalization approach enables a fair and consistent comparison of the radiographic behavior of the three materials, highlighting which features exhibit the greatest similarity or divergence relative to the established PLA baseline. Mathematically, for each feature f and material $m \in \{\text{TPU}, \text{Resin}\}$, the normalized value R_m was calculated as:

$$R_m = \frac{V_m}{V_{\text{PLA}}} \tag{1}$$

where V_m is the raw feature value for material m and V_{PLA} is the corresponding value for PLA.

The resulting normalized values were plotted using line charts, with each material represented by a separate line and each point corresponding to a specific Haralick feature. This visualization allowed the identification of which characteristics exhibited the greatest similarity or divergence between materials relative to the PLA baseline.

III. Results

The radiomic analysis revealed distinct texture patterns among the three 3D-printed materials and also indicated alterations in radiomic features due to the shape used in the lesion representation. As a first approach, the normalized line chart using PLA as the reference was analyzed. This chart

provides a visual comparison of how each Haralick feature behaves in TPU and photopolymer resin relative to the PLA baseline.

The Fig.3 presents the normalized Haralick features for TPU and photopolymer resin relative to PLA. As can be observed, TPU exhibits the most pronounced deviations from the PLA baseline, particularly for the Contrast, MeanSum, VarSumQ, VarSum and IMC1. The photopolymer resin presents a lower variation in values compared to TPU, while still exhibiting comparable differences in certain features such as Uniformity (Angular Second Moment), Inverse Difference Moment (IDM) and MCC. The observed differences in skewness and kurtosis across the three materials underscore their sensitivity to material composition and structural characteristics, as they are heavily influenced by the shape of the nodules in each test configuration.

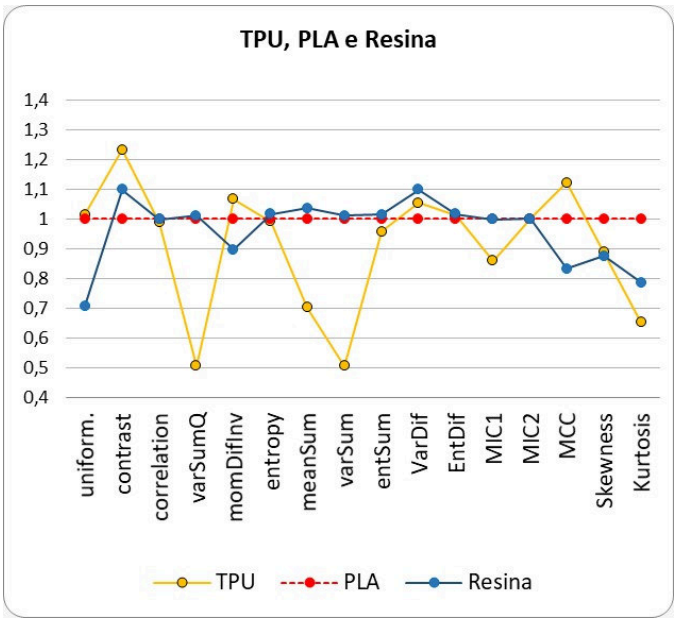

Fig. 3. Normalized Haralick features for TPU and photopolymer resin relative to PLA (reference).

The Gaussian curve analysis further supported these findings. Among the evaluated materials, the Information Measures of Correlation (IMC1 and IMC2) exhibited the most pronounced differences between the Gaussian curves, particularly when comparing TPU to both PLA and the photopolymer resin, as can be observed in Figures 4 and 5, shown below.

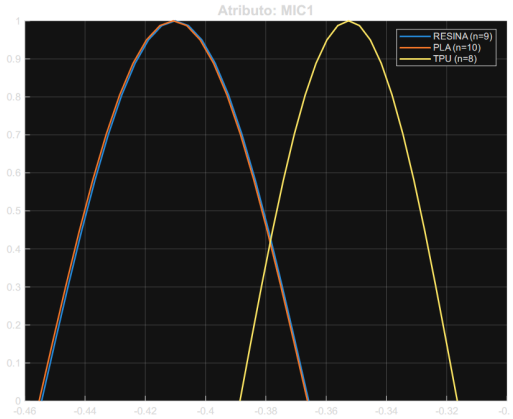

Fig. 4. Gaussian curve overlap for IMC1 across TPU (yellow), PLA (red), and photopolymer resin (blue).

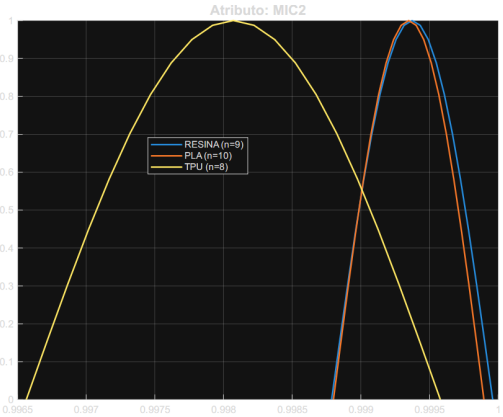

Fig. 5. Gaussian curve overlap for IMC2 across TPU (yellow), PLA (red), and photopolymer resin (blue).

The radiomic analysis revealed that TPU exhibits the most pronounced deviations from the PLA baseline, particularly in features related to texture heterogeneity, such as Contrast, Sum Variance, IMC1, IMC2, and MCC. These differences indicate that the radiographic texture response of TPU differs considerably from that of PLA, which has been previously supported as a suitable material for simulating tumorous structures in the phantom under development [18]. The observed discrepancies can be attributed to the intrinsic physical properties of TPU. Unlike PLA, which is rigid and provides consistent internal structures during 3D printing, TPU is an elastomeric material with high flexibility. This characteristic leads to less precise control over infill geometry and surface finish during additive manufacturing, resulting in greater textural heterogeneity. The Gaussian curves, analyzed according to the shapes of the printed lesions, further demonstrate that both the size and the regularity of the lesion-simulating structures have a considerable influence on the radiomic response of the acquired images. The attributes that most clearly demonstrate the influence of size and shape regularity are presented in the Gaussian curves of Figs. 6–9. These include the contrast difference between regular and irregular shapes, as well as

the Inverse Difference Moment, with skewness and kurtosis highlighting the differentiation of objects by size.

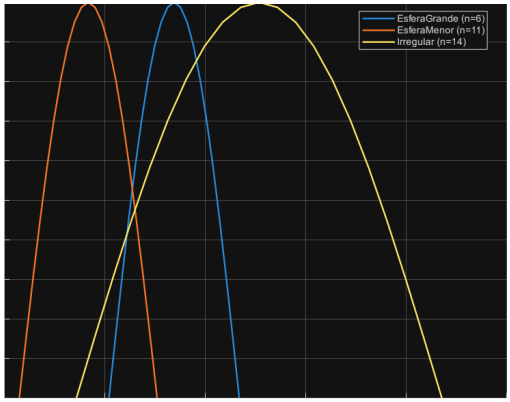

Fig. 6. Gaussian curve overlap for Sum Variance across big spheres (blue), small spheres (red), and irregular lesions (yellow).

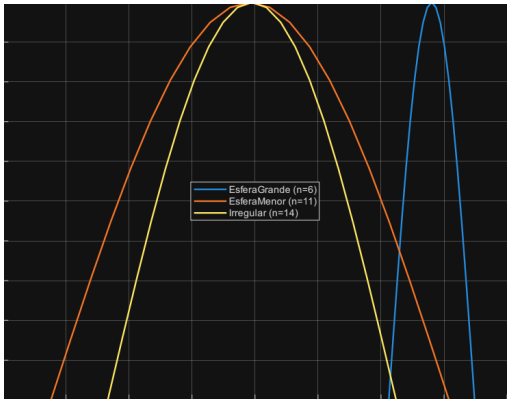

Fig. 7. Gaussian curve overlap for Inverse Difference Moment across big spheres (blue), small spheres (red), and irregular lesions (yellow).

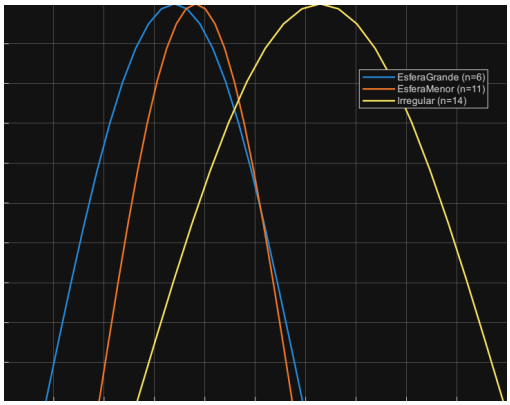

Fig. 8. Gaussian curve overlap for Difference Variance across big spheres (blue), small spheres (red), and irregular lesions (yellow).

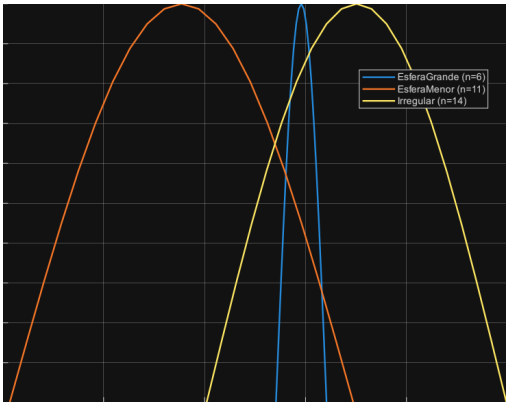

Fig. 9. Gaussian curve overlap for Entropy across big spheres (blue), small spheres (red), and irregular lesions (yellow).

IV. Conclusion

This study evaluated PLA, TPU, and photopolymer resin for application in anthropomorphic breast phantoms via radiomic analysis of mammographic images. The comparison was performed through three approaches: visual assessment; normalized Haralick feature curves, including skewness and kurtosis, referenced to PLA; and differences in the distribution of the Gaussian curves for each feature. TPU exhibited the most pronounced deviations from PLA in all three analyses, particularly in texture features such as Contrast, IMC1, IMC2, and MCC, indicating a distinct and variable radiographic response. Gaussian curve analysis of the different shapes and infill patterns revealed that these parameters influence the radiomic features, with Sum Variance, Inverse Difference Moment, Difference Variance, and Entropy displaying the most divergent distributions. Conversely, photopolymer resin demonstrated greater radiomic similarity to PLA, suggesting it is a viable alternative. Overall, PLA remains the preferred material for simulating tumor structures, whereas TPU showed both textural discrepancies and poor visual quality. Notably, the TPU exemplar differed markedly from the PLA exemplar even when printed from the same geometry. Future studies should explore additional materials and validate them against clinical images to ensure their efficacy in mammography research.

***Abstract*—Speech foundation models have commonly been used in *Speech Emotion Recognition* (SER) tasks. However, as mostly researches focus on controlled datasets, evaluating the efficiency of those architectures in real world environments is fundamental. This paper focus on investigating the *domain shift* and channel noise impact on the automatic classification of vocal stress in public security communication. By using the foundation model Wav2Vec2/XLS-R, has been analyzed the performance degradation of trained classifiers in clean lab environment (RAVDESS and SAVEE) when exposed to a real emergency calls dataset, EmerCall-VoiceStress (EC-VS). To counter this problem, it's proposed a adversarial architecture based on DANN Networks, composed by a *Gradient Reversal Layer* (GRL) for minimax optimization. The results show that studio trained models suffer from severe collapses of generalization because of the audio noise and compression, proving that the acoustic invariance is not native for those models. The proposed adversarial adaptation approach mitigated the collapse, elevating the *Macro F1-Score* in the operational noisy scenario to 0.7238), suggesting that the alignment of local distribution efficacy for trial critics infrastructure.**

***Index Terms*—Biomarcadores de voz, Estresse vocal, Wav2Vec2/XLS-R, Deslocamento de domínio, Segurança pública.**

I. Introdução

O avanço recente de pesquisas em *Machine Learning* (ML) e *Deep Learning* (DL) impulsionou o desenvolvimento de modelos cada vez mais eficientes e robustos para aplicações em diversas áreas, como detecção e reconhecimento em imagens, processamento de sinais e análise de áudio. Entre essas aplicações, destaca-se o reconhecimento de emoções na fala (Speech Emotion Recognition – SER), cujo objetivo é identificar estados emocionais a partir das características presentes na voz humana.

A voz pode ser representada por um sinal acústico *s=s(t)*. Onde s(t) é amplitude do sinal para determinado instante t. Esses sinais possuem propriedades que carregam informações relevantes sobre o estado emocional do falante. Para facilitar a análise, é comum representar o sinal no domínio da frequência. Com isso, é possível extrair características como frequência fundamental, energia e conteúdo espectral. Permitindo identificar padrões espectrais que podem ser explorados por modelos de aprendizado de máquina.

Diversos estudos investigam o desempenho de diferentes arquiteturas nessa tarefa. [3] realiza uma análise comparativa entre *Support Vector Machine (SVM)*, *Classification And Regression Tree (CART)* e *Long-Short Term Memory (LSTM)* para reconhecimento de emoções utilizando uma base de dados, composta por amostras rotuladas em categorias como neutralidade, raiva, tristeza e felicidade. Em todos os experimentos, os autores empregam um estágio de pré-processamento para extração dos coeficientes cepstrais em escala Mel (Mel-Frequency Cepstral Coefficients - MFCC). De forma semelhante, [19] propõe um modelo para classificação de choros de recém-nascidos, destacando as dificuldades de obtenção de bases de dados em ambientes reais e o impacto da presença de ruídos na qualidade das amostras e, consequentemente, no desempenho dos classificadores.

Apesar desses avanços, a maioria dos modelos é treinada e avaliada em bases de dados coletadas sob condições laboratoriais controladas, nas quais fatores como ruído ambiente, distância do microfone e qualidade de gravação são cuidadosamente monitorados. Essa condição difere substancialmente dos cenários operacionais encontrados em aplicações reais. A presença de ruídos intensos, múltiplos interlocutores, interferências de comunicação e sons urbanos aumenta significativamente a variabilidade acústica, degradando as fronteiras de decisão aprendidas durante o treinamento.

Esse problema torna-se particularmente relevante em aplicações voltadas à segurança pública. Policiais, bombeiros e

demais agentes de emergência estão constantemente expostos a situações de elevado estresse físico e emocional, sendo a voz um potencial indicador de seu estado psicofisiológico. Entretanto, as comunicações desses profissionais ocorrem, predominantemente, por meio de rádios transmissores sujeitos a severas degradações de canal, ruídos impulsivos e interferências eletromagnéticas, dificultando a aplicação direta de modelos treinados em ambientes laboratoriais.

A Figura 1 ilustra esse cenário ao comparar espectrogramas de sinais obtidos em condições controladas com sinais provenientes de comunicações reais submetidas a ruído de canal, bem como o efeito da aplicação de técnicas clássicas de processamento digital de sinais na redução dessas degradações.

No contexto de SER, modelos auto-supervisionados, como Wav2Vec2 e XLS-R, têm demonstrado elevada capacidade de extrair representações profundas da fala, alcançando resultados expressivos na identificação de emoções primárias, como felicidade, raiva e medo. Diante desse contexto, este trabalho investiga sistematicamente o impacto das discrepâncias de domínio provocadas por ruídos e degradações de canal na tarefa de reconhecimento de padrões vocais associados a estresse/emoções negativas. Para isso, são avaliados três cenários de referência: (i) um modelo clássico baseado em estatísticas de MFCCs e SVM; (ii) modelos *XLS-R* e *HuBERT* utilizando transferência direta de domínio; e (iii) um pipeline híbrido que combina Subtração Espectral Clássica com modelos *XLS-R* e *HuBERT*.

Com base nas limitações observadas nesses *benchmarks*, propõe-se uma arquitetura baseada em Redes Neurais Adversariais de Domínio (*Domain-Adversarial Neural Network – DANN*), acoplada ao modelo Wav2Vec2/XLS-R. A proposta busca aprender representações latentes invariantes ao domínio de aquisição, reduzindo os efeitos do ruído diretamente no espaço de características e promovendo um sistema de reconhecimento de padrões vocais associados a estresse/emoções negativas mais robusto.

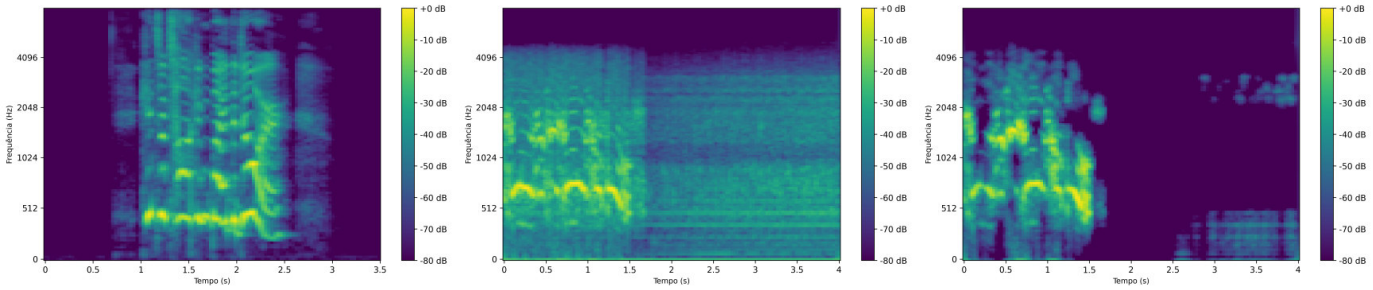
II. Trabalhos Relacionados

A área de Reconhecimento de Emoções na Fala (SER-*Speech Emotion Recognition*) passou de modelos estatísticos rasos para arquiteturas fundacionais de grande escala. Para contextualizar essa evolução, esta seção percorre desde os algoritmos clássicos de classificação até o aprendizado autossupervisionado e as técnicas de adaptação de domínio.

Nos primeiros avanços da área, classificadores como as Redes de Vetores de Suporte (SVM) ganharam espaço ao delimitar hiperplanos de margem máxima para separar classes [1]. Essa abordagem, contudo, dependia do enquadramento manual de atributos acústicos — a exemplo de MFCCs e variações de pitch [2]. Embora métodos baseados em árvores (como CART) e as próprias SVMs apresentem boa estabilidade, a literatura aponta que arquiteturas recorrentes do tipo LSTM lidam melhor com a dinâmica temporal intrínseca ao sinal de áudio, alcançando maior precisão [3].

Com a ascensão do Aprendizado Profundo, o foco migrou para a extração automática de feições. O uso de Redes Neurais Convolucionais (CNN) aplicadas a espectrogramas permitiu capturar padrões hierárquicos do áudio sem engenharia de recursos manual, superando os baselines anteriores [4]. Esse avanço refletiu-se também na visão computacional: modelos como a VGGNet atingiram marcas expressivas na detecção de expressões faciais [5]–[7], enquanto variações de DNNs e CNNs vêm sendo empregadas na saúde mental para mapear quadros de ansiedade e depressão [8].

Posteriormente, a introdução dos Transformers [9] estabeleceu um novo patamar ao modelar dependências de longa distância com mais eficiência que as redes recorrentes. No áudio, o framework wav2vec 2.0 consolidou o pretreinamento autossupervisionado direto do sinal bruto, reduzindo a dependência de grandes volumes de dados rotulados [10]. Analisando a representação interna dessas redes, Pepino et al. [11] observaram que a informação emocional se concentra nas camadas intermediárias, o que justifica a fusão ponderada de representações para aprimorar o desempenho em SER.



A capacidade de generalização expandiu-se com modelos multilíngues como o XLS-R, treinado em 128 idiomas [12], e com o HuBERT, que emprega agrupamento para inferir unidades ocultas da fala [13]. Estudos comparativos indicam que arquiteturas como XLS-R e Whisper retêm características do locutor de maneiras distintas ao longo de suas camadas [14], sustentando aplicações que vão da síntese de voz a sistemas de diálogo complexos [15].

Apesar desses avanços, a implantação em cenários reais esbarra no deslocamento de domínio (*domain shift*), recorrente em canais de emergência. Para atenuar essa variação acústica, abordagens adversariais como a DANN utilizam classificadores que forçam a rede a extrair atributos invariantes ao ambiente [16]. Em complemento, Hsu et al. [17] mostraram que incorporar áudio não rotulado do domínio-alvo no pré-treino reduz em até 73% a perda de desempenho causada pelo ruído.

Em cenários com restrição de acesso aos dados de origem, estratégias de adaptação contrastiva (como a ECAN) preservam a coerência emocional local e global [18]. Por fim, o monitoramento contínuo de estados emocionais é crítico em ambientes ocupacionais de alto risco, nos quais o estresse afeta a tomada de decisão [20]. Em vez de estimativas estáticas, o uso de Transformers para acompanhar a transição temporal do estresse permite capturar a evolução do estado do indivíduo [20]. Tais sistemas auxiliam desde diagnósticos terapêuticos multimodais [21] até a proteção de profissionais de segurança em situações extremas, contexto que fundamenta o modelo proposto neste trabalho.

III. Materiais e Métodos

Os conjuntos de dados comumente utilizados no treinamento de modelos de *DL* e *ML* são construídos sob condições controladas para garantir que suas amostras se aproximem de cenários ideais. Por exemplo, os sinais de áudio do *dataset* RAVDESS possuem uma duração fixa de 4 segundos, iniciam e terminam invariavelmente com pausas de fala e apresentam ausência de ruídos intensos. O conjunto de dados EmergCall-VoiceStress-(EC-VS) foi construído com base em amostras

(a) Classe *Fear* (RAVDESS). (b) Classe *Stress* (EC-VS Ruidoso). (c) Classe *Stress* (EC-VS Filtrado via DSP).

Fig. 1: Comparativo tempo-frequência do impacto do ruído de canal e da filtragem analítica no espectro da fala.

de áudios em ambientes operacionais de segurança pública. Há a presença de diferentes tipos de ruído, como sirenes de viaturas, estática de rádio, ruído em virtude trânsito etc. Inicialmente, foi realizada uma análise comparativa entre diferentes abordagens para reconhecimento de emoções na fala (SER), com o objetivo de avaliar seu desempenho no conjunto de dados EC-VS. Para isso, foram definidos cinco procedimentos representativos da literatura. Os procedimentos do ceneário 1 empregas um classificador SVM utilizando coeficientes cepstrais em frequência Mel (MFCC) como descritores acústicos. Os procedimentos do cenário 2 utilizas modelos auto-supervisionados pré-treinados (HuBERT e XLS-R) para extração de representações latentes da fala. Nos procedimentos do cenário 3, os mesmos modelos são empregados após a aplicação da técnica de subtração espectral e Digital Signal Processing - (DSP), com o objetivo de investigar o impacto da redução de ruído sobre o desempenho dos classificadores. O último procedimento correspondem à arquitetura proposta baseada em adaptação de domínio adversarial, sendo utilizados para comparação com as abordagens convencionais.

A fim de reduzir o efeito da aleatoriedade inerente ao processo de treinamento, cada experimento foi executado utilizando cinco sementes aleatórias (*seeds*), correspondentes aos valores 42, 123, 777, 999 e 2024. Os resultados apresentados correspondem à média e ao desvio padrão obtidos entre essas execuções, proporcionando uma avaliação estatisticamente mais representativa do desempenho dos modelos. Em todos os experimentos de referência, os modelos foram treinados durante cinco épocas (*epochs*). Os resultados são mostrados nas Tabelas I e II.

O modelo de extração de características acústicas adotado foi o **Wav2Vec2/XLS-R (300M)**, pré-treinado em 436 mil horas de fala multi-idioma. O sinal de áudio bruto foi remodelado nativamente para 16 kHz e truncado em janelas máximas de 4 segundos (64.000 amostras). As camadas convolucionais internas do *feature encoder* foram congeladas (requires_grad = False), atuando estritamente como extratoras de tensores latentes para classificação lineares. Também fora usado o HuBERT Base (LS-960), pré-treinado de forma auto-supervisionada em aproximadamente 960 horas do corpus LibriSpeech.

A. Mapeamento de classes

Devido à indisponibilidade de conjuntos de dados públicos contendo amostras de fala de indivíduos diagnosticados por profissionais de saúde com estresse ocupacional, foi necessário estabelecer um mapeamento entre as emoções presentes nos conjuntos de dados RAVDESS e SAVEE e as classes de interesse deste trabalho.

No conjunto de dados RAVDESS, as emoções *Neutral* e *Calm* foram agrupadas e mapeadas para a classe *Normal/Calm*, enquanto as emoções *Fearful* e *Angry* foram agrupadas e mapeadas para a classe *Stress/Fear*. De forma análoga, no conjunto de dados SAVEE, a emoção *Neutral* foi associada à classe *Normal/Calm*, ao passo que as emoções *Anger* e *Fear* foram agrupadas e mapeadas para a classe *Stress/Fear*.

Esse mapeamento teve como objetivo aproximar emoções negativas frequentemente associadas a estados de tensão e sofrimento psicológico da classe *Stress/Fear*, preservando as emoções neutras e de calma na classe *Normal/Calm*. Embora essa simplificação não represente um diagnóstico clínico de estresse ocupacional, ela permite investigar a viabilidade do uso de modelos de aprendizado profundo na identificação de padrões vocais potencialmente relacionados a estados de estresse em um cenário de classificação binária.

B. Datasets

Três bases de dados com características acústicas distintas foram empregadas neste trabalho:

- **RAVDESS:** Base de dados audiovisual de fala e canção emocional validada academicamente. Foram extraídas amostras de falas limpas gravadas em estúdio de alta fidelidade, mapeando as classes neutra (*Normal*) e medo (*Stress*).
- **SAVEE:** Banco de dados focado em expressões emocionais masculinas gravadas sob condições controladas de laboratório. Utilizou-se um *script* de filtragem para extrair as amostras com base na nomenclatura dos arquivos, separando expressões neutras (*Normal*) de manifestações de medo (*Stress*).
- **EmergCall-VoiceStress (EC-VS):** Conjunto de dados do mundo real contendo 591 amostras de áudio provenientes de chamadas de emergência autênticas de segurança

pública. Inicialmente havia 90 amostras para a classe de Stress/Fear e 501 para classe Normal. Este conjunto caracteriza-se pela presença severa de ruídos de fundo, estática de rádio, compressão telefônica e estresse psicológico operacional real. Todas as amostras foram devidamente rotuladas analisando seu conteúdo, contexto emocional, tom de voz, presença ou não de ruídos indicadores de disparos de armas de fogo, sineres ou qualquer outro elementos que influenciem no comportamento e elementos prosódicos dos falantes. Para extrair amostras com duração de 4s, utilizou-se um script em linguagem *Python*. Os nomes das amostras contém a *string* 'sample' seguido de _ e um número que indica a sequência de extração da amostra, seguida de _ e um valor numérico, 1 para amostras com classificadas contendo estresse e 0 caso contrário. As amostras possuem o seguinte formato: *sample_XXXX_X.wav*). Este será o conjunto de teste para verificarmos a generalização do modelo proposto e realização dos teste t e McNemar.

C. Balanceamento e Data Augmentation dos Domínios

Para mitigar o desbalanceamento severo de classes e prevenir vieses algorítmicos durante o treinamento e alinhamento de domínios, aplicaram-se técnicas de aumento de dados (*Data Augmentation*) via *software* utilizando a biblioteca *librosa*.

Nos domínios de origem (RAVDESS e SAVEE), o procedimento foi executado estritamente sobre a partição de treinamento ($80/20$), garantindo a total blindagem dos conjuntos de validação. Após o procedimento, o conjunto RAVDESS alcançou 960 instâncias (480 por classe) e o SAVEE totalizou 360 amostras (180 por classe).

No domínio alvo (EC-VS), observou-se uma forte assimetria nativa entre as classes. Para evitar que a disparidade amostral comprometesse a representação do espaço de características do domínio alvo durante o alinhamento adverso-dominial, realizou-se a equalização *a priori* da classe minoritária. O processo identificou automaticamente a classe minoritária e gerou amostras complementares em disco até paridade com a classe majoritária, consolidando o conjunto EC-VS em 1.002 instâncias (501 da classe Normal e 501 da classe *Stress*).

Para a geração das novas amostras em todos os conjuntos, alternaram-se duas técnicas de processamento de sinais de áudio:

1) **Deslocamento de Frequência (*Pitch Shifting*):** com variação aleatória de passos entre $[-2{,}0; -1{,}2]$ e $[1{,}2; 2{,}0]$;
2) **Variação de Velocidade (*Time Stretching*):** com fatores de escala aleatórios entre $[0{,}85; 0{,}95]$ e $[1{,}1; 1{,}25]$.

A reprodutibilidade ponta a ponta do *pipeline* de geração foi assegurada pela fixação da semente pseudoaleatória global (seed $= 42$).

D. Primeiro Cenário - coeficientes MFCC e SVM

O primeiro procedimento abordou a engenharia clássica de características acústicas através da extração manual de Coeficientes Cepstrais de Frequência Mel (MFCCs). Os vetores resultantes, contendo as médias e desvios padrões dos coeficientes, alimentaram um classificador SVM de margens suaves com *kernel* de Função de Base Radial (RBF). Os modelos SVM foram treinados em cada conjunto (RAVDESS e SAVEE), utilizando a estratégia de validação cruzada 5-fold e avaliados diretamente no EC-VS. Os resultados obtidos para ambos os cenários *cross-domain* são apresentados na Tabela I.

TABLE I: Desempenho da Validação Cruzada Stratified 5-Fold na Transferência de Domínio para EC-VS no cenário 1.

Dataset	Acurácia Média	F1-score macro médio
RAVDESS	$0{,}4636 \pm 0{,}0633$	$0{,}4145 \pm 0{,}0281$
SAVEE	$0{,}2244 \pm 0{,}0041$	$0{,}2207 \pm 0{,}0047$

E. Segundo cenário - XLS-R e HuBERT padrões

Os procedimentos a seguir verificaram as performances de generalização dos modelos fundacionais XLS-R (facebook/wav2vec2-xls-r-300m) e HuBERT, treinados em RAVDESS e SAVEE, aplicados ao EC-VS sem qualquer processamento ou filtragem de ruídos nos amostras de entrada. Neste cenário, o extrator de características convolucional nativo do modelo foi congelado e as camadas do *Transformer* foram refinadas através de *fine-tuning*. Os resultado são apesentado na tabela III.

F. Terceiro cenário - XLS-R e HuBERT com subtração espectral

Estes Procedimentos avaliaram o impacto do tratamento clássico de sinais no nível de entrada (*input-level adaptation*). Para este fim, os áudios ruidosos do EC-VS foram submetidos a um algoritmo de redução de ruído por Subtração Espectral Clássica (*Spectral Gating*), utilizando os primeiros 0.3 segundos de sinal para a estimativa e atenuação do ruído estacionário de fundo. O sinal tratado foi então injetado nos modelos fundacional XLS-R e HuBERT (previamente tunado nos RAVDESS, SAVEE) para quantificar o ganho obtido pela filtragem analítica isolada. O resultado desse experimento pode ser visualizado na tabela III.

G. Arquitetura proposta - Rede Domain-Adversarial Neural Network (DANN)

Por fim, definiu-se e implementou-se a Arquitetura proposta, composta pelo modelo fundacional XLS-R acoplado a uma Rede DANN atuando diretamente no espaço latente. Para a obtenção de um extrator de características invariante ao canal e ao ruído, a função de perda total do sistema foi modelada pela soma ponderada da perda do classificador de tarefa e da perda do classificador de domínio, otimizadas de forma *minimax* por meio de uma Camada de Reversão de Gradiente (*Gradient Reversal Layer* – GRL). Desta forma, o modelo é forçado a aprender representações que retêm o conteúdo emocional da fala, enquanto ignora ativamente as assinaturas acústicas dos canais ruidosos do EC-VS. Vale salientar que os sinais de entradas também foram submetidos a processamento de sinais com subtração espectral. Durante o passo de otimização, o classificador de emoção opera de forma

TABLE II: Desempenho de treinamento de HuBERT e XLS-R (Média ± desvio padrão).

supervisionada utilizando as amostras rotuladas do RAVDESS. Simultaneamente, o classificador de domínio atua sobre os dados do EC-VS sem processar seus rótulos de estresse, configurando uma estratégia de adaptação de domínio não-supervisionada (*Unsupervised Domain Adaptation* – UDA). A inferência final do modelo proposto foi validada de maneira holística nos domínios RAVDESS, SAVEE e EC-VS. Os resultados são apresentados na Tabela V e na Figura 2.

IV. Resultados e Discussão

A. Análise do Espaço Latente via t-SNE

Antes de avaliar o desempenho linear dos classificadores, investigou-se a distribuição geométrica das características acústicas extraídas pelo modelo Wav2Vec2/XLS-R. Para tanto, os tensores de alta dimensão gerados pela última camada oculta do *encoder* foram projetados em um espaço bidimensional utilizando a técnica de redução de dimensionalidade não-linear t-SNE (*t-Distributed Stochastic Neighbor Embedding*). O resultado dessa projeção está ilustrado na Fig. 3.

A análise visual da Fig. 3 revela um comportamento crítico para a compreensão dos colapsos de generalização: as amostras

TABLE IV: Resumo de performance do modelo proposto na tarefa de predição nos conjuntos de dados

Domínio (Métricas Globais)	Precision	Recall	F1-Score	support
RAVDESS (Acc: 0.9979 — Macro F1: 0.9979)				
Normal / Calm	0.9959	1.0000	0.9979	480
Stress / Fear	1.0000	0.9958	0.9979	480
SAVEE (Acc: 0.8717 — Macro F1: 0.8382)				
Normal / Calm	0.7639	0.9889	0.8620	180
Stress / Fear	0.9843	0.6944	0.8143	180
EC-VS (Acc: 0.7295 — Macro F1: 0.7238)				
Normal / Calm	0.6780	**0.8743**	**0.7637**	501
Stress / Fear	**0.8230**	0.5848	0.6838	501

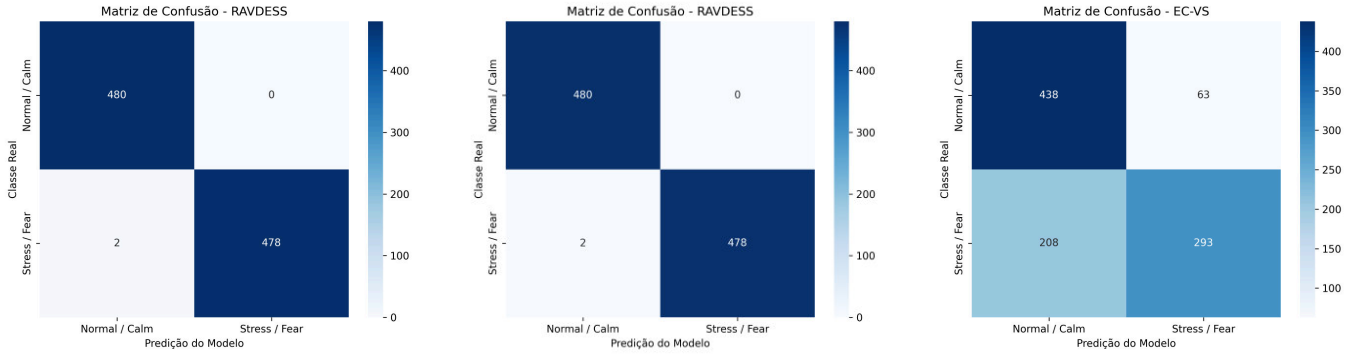

Fig. 2: Matrizes de confusão obtidas como resultados da predição do modelo proposto aplicada aos conjuntos RAVDESS, SAVEE e EC-VS.

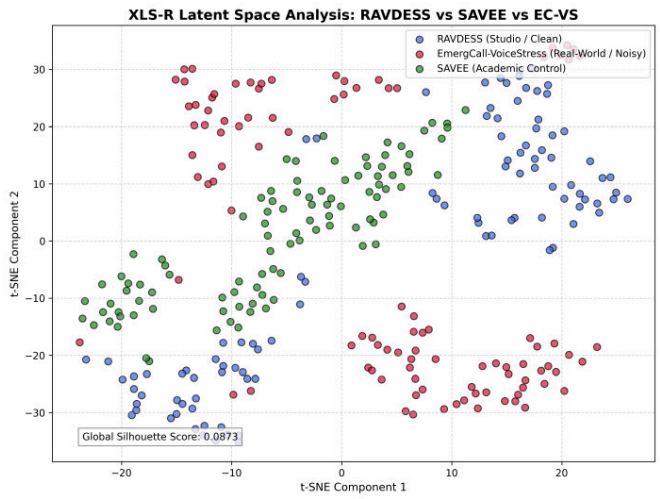

Fig. 3: Projeção t-SNE dos tensores latentes extraídos pelo XLS-R para os datasets RAVDESS, SAVEE e EC-VS. Observa-se a tendência de agrupamento de amostras em razão da qualidade do sinal em detrimento da separação semântica das classes emocionais.

não se agrupam com base nas classes emocionais alvo (*Normal* vs. *Stress*), mas sim de forma estritamente segregada por *dataset* de origem. Os clusters do RAVDESS e do SAVEE (ambos gravados em ambientes controlados de laboratório) apresentam fronteiras bem definidas e isoladas do cluster pertencente ao EmergCall-VoiceStress (EC-VS).

Essa separação baseada no domínio físico e de captação é quantificada pelo Escore de Silhueta Global, que computou um valor de apenas **0,0873**. Esse índice próximo de zero confirma estatisticamente a sobreposição quase completa das distribuições de estresse e neutralidade entre domínios distintos. O modelo fundacional, em seu estado pré-treinado, demonstra maior sensibilidade às variações físicas do meio de transmissão (ruído de rádio, resposta de frequência do microfone e compressão de codec) do que aos biomarcadores prosódicos e dinâmicos do estresse vocal humano. Essa distorção geométrica no espaço de Hilbert da rede justifica e antecipa os colapsos observados nos testes cruzados convencionais.

O cálculo do Maximum Mean Discrepancy (MMD) após o treinamento adversarial da DANN resultou em um valor de **0,5259**. Embora teoricamente o alinhamento perfeito tenda a zero, na adaptação de domínio aplicada à fala operável, a convergência para um valor intermediário reflete o equilíbrio ótimo do jogo minimax. Este índice demonstra que a rede mitigou as discrepâncias severas causadas pela estática de rádio e codecs de compressão do domínio alvo (EC-VS), preservando simultaneamente a separação geométrica necessária para a discriminação dos biomarcadores prosódicos de estresse, o que é empiricamente validado pelo expressivo Macro F1-Score de 85,87% obtido no cenário real.

B. Procedimentos

A tabela III mostra que as abordagens com SVM, XLS-R, e XLS-R com subtração espectral obtiveram resultados

similares. E os resultados sugerem que todos os modelos tendem a encontrar similaridades presentes em sinais ruidosos com características de stress/Fear presentes nas amostras. Os modelos tendem classificar os sinais ruidosos inerentes aos ambientes de comunicação policial operacional

C. Resultados da Arquitetura DANN

Conforme apresentado na Tabela IV, o modelo proposto atingiu uma precisão de 82,30% para a Classe *Stress/Fear*, demonstrando indícios de reconhecimento dos elementos componentes do fala apesar da presença de ruído característico de ambientes operacionais policiais. Além disso, o modelo alcançou uma acurácia global de 72,95% no conjunto de teste.

D. Teste t Pareado e Bootstrap

Com o objetivo de fundamentar a significância estatística da diferença de desempenho entre a arquitetura proposta (DANN) e o modelo *baseline* (XLS-R com DSP), aplicou-se o Teste t de Student pareado sobre a taxa de erro individual por instância e a técnica de *Bootstrap* sobre a métrica F1-Macro.

O Teste t pareado avaliou a inferência de ambas as arquiteturas para cada uma das $N = 1002$ amostras contidas no conjunto de teste EC-VS (composto por 501 amostras para cada classe). Para cada instância i, atribuiu-se o valor 1 em caso de erro de classificação e 0 em caso de acerto, obtendo-se os vetores binários de erro para cada modelo. A diferença pareada por amostra d_i é calculada conforme a Equação 1:

$$d_i = x_{\text{DANN},i} - x_{\text{DSP},i} \tag{1}$$

em que $d_i = 0$ representa empate no resultado da predição (ambos os modelos acertaram ou ambos erraram), $d_i = -1$ denota acerto exclusivo do modelo DANN e $d_i = 1$ indica acerto exclusivo do modelo DSP.

A estatística do Teste t pareado é calculada por meio da Equação 2:

$$t = \frac{\bar{d}}{\frac{s_d}{\sqrt{N}}} \tag{2}$$

onde $\bar{d}$ é a diferença média observada nas predições (Equação 3), s_d é o desvio-padrão amostral das diferenças (Equação 4) e N é o tamanho total da amostra pareada:

$$\bar{d} = \frac{1}{N}\sum_{i=1}^{N} d_i \tag{3}$$

$$s_d = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(d_i - \bar{d})^2} \tag{4}$$

Com $N = 1002$ observações, o teste dispõe de $df = N - 1 = 1001$ graus de liberdade. A aplicação do teste paramétrico é respaldada pelo Teorema do Limite Central, o qual assegura que a distribuição da média amostral das diferenças ($\bar{d}$) aproxima-se de uma distribuição normal para amostras de grande porte ($N \gg 30$). Dito isto, definem-se as seguintes hipóteses estatísticas para o Teste t pareado sobre a taxa de erro:

- H_0: $\bar{d} = 0$ — não existe diferença estatisticamente significante entre a taxa de erro média dos dois modelos no conjunto de teste;
- H_1: $\bar{d} \neq 0$ — existe diferença estatisticamente significante entre a taxa de erro média dos dois modelos no conjunto de teste.

Para o procedimento de *Bootstrap*, realizou-se a reamostragem aleatória com reposição sobre o conjunto de teste EC-VS, repetida 1.000 vezes, utilizando a métrica F1-Macro e intervalo de confiança de 95%. Os resultados detalhados dos testes e da reamostragem são apresentados na Tabela V.

Os resultados evidenciam a superioridade da abordagem de adaptação adverso-dominial (DANN) em relação aos*baselines* do cenário 3. Conforme apresentado na Tabela V, o modelo DANN alcançou uma acurácia de $72{,}95\%$ e um F1-Macro de $0{,}7238$, superando o modelo DSP, que registrou $60{,}68\%$ de acurácia e $0{,}5824$ de F1-Macro — representando um ganho absoluto de $+14{,}14\%$ no F1-Macro.

A análise de reamostragem por *Bootstrap* (1.000 iterações) confirmou a consistência desse ganho, resultando em um Intervalo de Confiança a 95% para a diferença de desempenho de $[0{,}0992;\ 0{,}1789]$. Como o intervalo de confiança da diferença está estritamente acima de zero, a superioridade da arquitetura proposta é confirmada.

Para validar formalmente a significância estatística sobre as 1.002 instâncias de teste do EC-VS, foram aplicados o Teste de McNemar e o Teste t de Student pareado sobre a taxa de erro individual por amostra. Ambos os testes rejeitaram a hipótese nula (H_0) de equivalência entre os modelos com elevada significância estatística ($\chi^2 = 33{,}9043$, $p < 0{,}001$; $t = -5{,}9711$, $p < 0{,}001$). Esses resultados comprovam que a arquitetura proposta inferiu de forma significativamente mais robusta no conjunto de teste EC-VS.

V. Conclusão

Os resultados obtidos no conjunto de teste EC-VS (F1-Macro de $72{,}38\%$), combinados com os resultados da validação estatística (*Bootstrap*, Teste de McNemar e Teste t pareado), sugerem que a abordagem de adaptação adverso-dominial proposta apresenta indícios de ser uma solução mais promissora e robusta para o Reconhecimento de Emoções na Fala (SER) em ambientes operacionais ruidosos do que o emprego de modelos fundacionais submetidos exclusivamente ao processamento digital de sinais (DSP).

VI. Limitações

Para este trabalho utilizamos apenas um conjunto de dados, a saber, EmergCall-VoiceStress (EC-VS). Que é conjunto com gravações de comunicação de rádio em ambiente operacional de segurança pública. Conjuntos de dados dessa natureza são bastante restritos. Portanto, a obtenção de múltiplos conjuntos de dados desse domínio é inerentemente rigorosa e restrita. Dada dificuldade de obtenção, que decorre de questões de legislação e ética, de um conjunto de dados com amostras reais rotulados por profissionais de saúde para casos de estresse.

TABLE V: Resultados Comparativos do Desempenho Cross-Domain no dataset EC-VS

Modelo	**Acurácia**	**F1-Macro**	**IC 95% (F1-Macro)***	**McNemar** (χ^2)	**Teste** t (t)	p**-valor**
XLS-R/DSP	0,6068	0,5824	[0,5509; 0,6144]	—	—	—
DANN/DSP (Proposto)	**0,7295**	**0,7238**	**[0,6946; 0,7496]**	**33,9043**	**-5,9711**	$< 0,001$

*Intervalo de Confiança estimado via Bootstrap (1.000 reamostragens).

Fizemos a aproximação para a classe de stress com as classe de *fearful* (medo) e *angry*(raiva) que estão presentes nos conjuntos RAVDESS e *Fear* e *Anger* no SAVEE. Para EC-VS, a rotulação deu-se manualmente, ouvindo cada amostra e observando a presença da quantidade de interlocutores, de ruído causado por sirenes, ruídos inerentes ao trânsito, de ruídos ocasionados por disparos por arma de fogo e de gritos ou choros. A presença de disparos de arma de fogo e gritos atua como um forte indicador contextual de estresse agudo, justificando a associação semântica entre as classes.

***Abstract*—Stroke is a leading cause of long-term disability, and there is growing interest in combining transcranial direct current stimulation (tDCS) with extended reality (XR) to enhance motor recovery. Most electroencephalography (EEG) evaluations of such protocols rely on linear measures, which may overlook the non-linear, non-stationary nature of brain activity. This work applies Recurrence Quantification Analysis (RQA) to eyes-closed resting-state EEG from chronic stroke survivors undergoing a ten-session rehabilitation program, comparing a real tDCS group of ten patients with a sham group of eight patients. Broadband (1–50 Hz) motor-cortex signals were embedded in phase space without selective narrowband filtering, and determinism, laminarity, and diagonal-line entropy were computed per channel and averaged within the affected and non-affected hemispheres. The change between baseline and post-rehabilitation was contrasted between groups with non-parametric tests and false discovery rate correction. Determinism and laminarity in the affected hemisphere increased significantly in the real tDCS group while decreasing in the sham group; the remaining comparisons followed the same opposite-direction trend at borderline significance. These findings are consistent with changes toward more deterministic recurrence patterns after real stimulation, and suggest that RQA is a promising complementary tool for assessing XR- and tDCS-based stroke rehabilitation.**

***Index Terms*—recurrence quantification analysis, electroencephalography, stroke rehabilitation, transcranial direct current stimulation, extended reality**

I. Introduction

Stroke is one of the leading causes of physical disability in adults and the leading cause of premature death in Brazil [1]. The damage to descending neural pathways caused by stroke impairs neuromotor control and leads to functional and structural alterations, resulting in chronic disability and loss of autonomy in performing daily activities [2]–[4]. Persistent muscle weakness and paresis arise, to a large extent, from deficits in voluntary muscle activation, a condition that represents one of the main causes of neurological disability after stroke [5], [6]. Despite advances in rehabilitation strategies, approximately 80% of patients continue to present limitations when treated only with traditional therapeutic approaches [7], [8], which motivates the search for new interventions.

In this context, several neurotechnologies have been incorporated into motor rehabilitation programs. Among them, extended reality (XR) applications stand out by providing engaging and safe environments for exercise practice, as does transcranial direct current stimulation (tDCS), a non-invasive technique that modulates cortical excitability through the direct application of low-intensity electrical current to target brain areas [9]–[11]. Recent studies indicate that the combination of XR and tDCS may enhance the recovery of post-stroke patients [9], [12]. In particular, investigations conducted by our group, based on the same protocol whose data are analyzed in the present work, found greater muscle activation during hip flexion of the affected limb and improvement in the Timed Up and Go test after XR+tDCS rehabilitation [13].

Traditionally, the effects of these interventions are assessed by means of clinical and functional scales. More recently,

electroencephalography (EEG) has stood out as a tool for assessing neurophysiological correlates, by combining high temporal resolution, low cost, and portability, features that allow the reorganization of neural circuits to be recorded at the same site where the intervention is performed [11], [13]. In [14], the authors found increased EEG interhemispheric symmetry and functional connectivity in the alpha band after XR+tDCS rehabilitation [14]. The EEG analyses in these studies, however, have relied predominantly on linear measures, such as spectral, symmetry, and connectivity indices. Since the EEG signal is complex, non-stationary, and nonlinear in nature, such measures may fail to capture relevant aspects of brain dynamics. Complex systems approaches have proven valuable across a wide range of domains, from climate and Earth system dynamics [15], [16] to the near-Earth electromagnetic environment [17], providing a general and physically grounded framework for characterizing nonlinear, non-stationary processes [18]. In this scenario, approaches based on dynamical systems emerge as a robust quantitative alternative for modeling the stability, variability, and complexity of brain activity over time [19].

Recurrence Quantification Analysis (RQA) is one such approach. Grounded in recurrence plots [20], which identify when a system revisits similar states in phase space, RQA quantifies the structures formed by the diagonal and vertical lines of these plots through a set of complexity measures [21]. Although the recurrence rate (RR) expresses the overall density of recurrent states, the present work focuses on the structural measures derived from the line distributions: determinism (DET), associated with the predictability of the system [22]; laminarity (LAM), related to the occurrence of intermittent or laminar states [23], [24]; and the Shannon entropy of the diagonal line lengths (ENTR), which quantifies the complexity of the recurrence patterns [22], [25]. RQA is particularly suitable for the analysis of short, noisy, and non-stationary signals such as EEG [26], [27], and has been successfully employed to characterize transitions and dynamical brain states, including the distinction between normal and epileptiform states [28]–[31].

Despite the potential of RQA to reveal aspects of brain dynamics not accessible to linear analyses, its application to the assessment of post-stroke rehabilitation protocols based on XR and tDCS is still little explored. Therefore, the aim of this work is to apply RQA to resting-state (eyes-closed) EEG signals from post-stroke patients undergoing a rehabilitation program that combines XR and tDCS, contrasting a group that received real stimulation with a sham group. The analysis focuses on the motor cortex channels, organized by hemisphere (affected and non-affected), and quantifies, for the DET, LAM, and ENTR metrics, the change between the beginning (pre-rehabilitation) and the end (post-rehabilitation) of the program. The central question is whether this pre- to post-rehabilitation change differs between the real and sham groups, that is, whether RQA is able to discriminate the neurodynamic effects of real stimulation. An overview of the complete analysis workflow, from the experimental protocol and EEG preprocessing to the RQA pipeline, is presented in Fig. 1.

TABLE I

II. MATERIALS AND METHODS

A. Experimental protocol and data acquisition

The data analyzed in this work were collected in a clinical trial of XR combined with tDCS for chronic stroke rehabilitation [13], [14]. The study was approved by the Research Ethics Committee of the University of Campinas (CEP 5404-CAAE 35771314.4.0000.5404) and conducted in accordance with the Declaration of Helsinki and the CONSORT guidelines [32]. All participants provided written consent before entering the study. Eighteen chronic stroke survivors were allocated into two parallel groups in a block randomized controlled design: ten patients received real anodal tDCS (tDCS group) and eight received sham stimulation (Sham group). Both groups performed the same rehabilitation program. The participants and the remaining testers and instructors were blinded to the stimulation condition and group allocations. Table I summarizes the demographic and clinical characteristics of the participants, including age, sex, affected hemisphere, and time since stroke. All 18 participants included in this study completed all rehabilitation sessions. Clinical and functional assessments were performed in sessions 1, 5, and 10 of the rehabilitation program, in addition to the resting-state EEG recordings analyzed in this work. These included the Fugl-Meyer Assessment for upper- and lower-limb motor function [33], the Mini-Mental State Examination [34], the Berg Balance Scale [35], the Functional Independence Measure [36], the Timed Up and Go test [37], and the 10-m walk test, following the protocol described in [13].

The rehabilitation program comprised ten sessions of 30 min, carried out daily (five times a week) over two weeks, organized into two blocks of five sessions separated by a 48-h interval. In each session, participants interacted with the BRAINN_XR software [38], positioned 2 m from a large

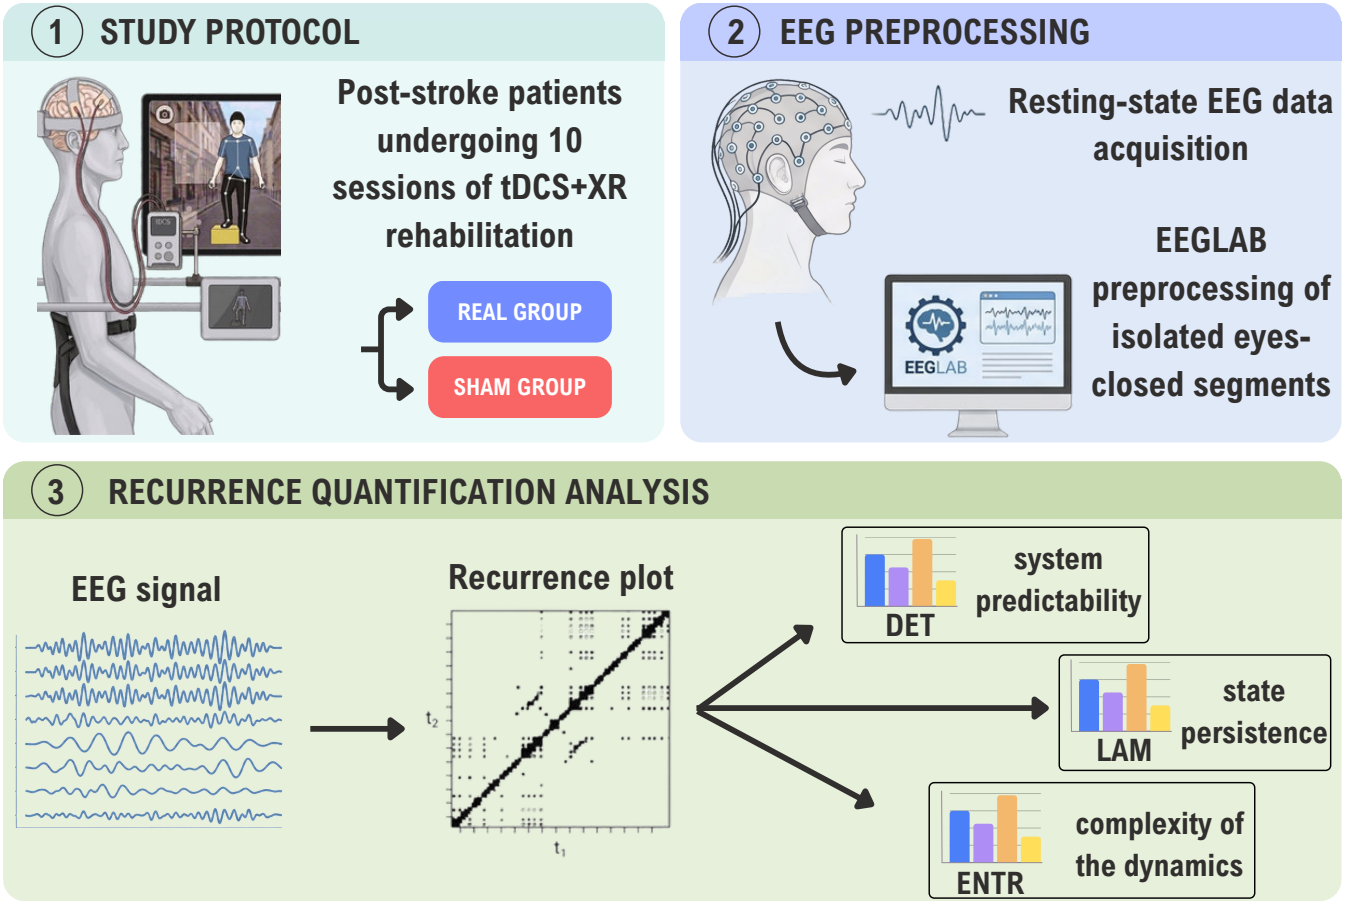

Fig. 1. Overview of the analysis workflow. (1) Study protocol: post-stroke patients underwent ten sessions of combined tDCS and XR rehabilitation and were assigned to a real-stimulation group or a sham group. (2) EEG preprocessing: resting-state signals were acquired and the eyes-closed segments were isolated and preprocessed in EEGLAB. (3) Recurrence Quantification Analysis: each EEG channel was reconstructed in phase space to build its recurrence plot, from which the determinism (DET), laminarity (LAM), and entropy (ENTR) metrics were extracted, quantifying system predictability, state persistence, and the complexity of the dynamics, respectively.

screen that displayed their body image. The protocol included upper-limb exercises (a jigsaw puzzle task, ePuzzle, performed while sitting, standing, and standing on an unstable surface) and lower-limb exercises (stepping over virtual obstacles and stationary walking through an interactive street-view environment, eMaps), emphasizing both the paretic and non-paretic limbs [39].

During the exercises, the tDCS group received low-intensity anodal stimulation (2 mA) delivered for the full duration of each session (30 min), with the anode placed over the ipsilesional primary motor cortex (M1; C3 or C4) and the cathode over the contralesional supraorbital area (Fp1 or Fp2). For the Sham group, the current was ramped up to 2 mA over the first 30 s and ramped down shortly after, remaining off for the rest of the session, thus reproducing the initial sensation of stimulation without delivering an effective dose.

Resting-state EEG was recorded before the tDCS intervention, in session 1 (baseline) and session 10 (post-rehabilitation). Signals were acquired at 256 Hz with 16 monopolar electrodes positioned according to the 10/20 system (F1, F2, Cz, AFz, F5, F6, C1, C2, C3, C4, C5, C6, P1, P2, P5, P6), as shown in Fig. 2, with the reference electrode on the left mastoid and the ground electrode on the right mastoid. The resting-state paradigm consisted of 64 s with eyes open followed by 64 s with eyes closed, beginning with a short transient interval and separated by a second transient interval between the two conditions. This work used the eyes-closed segment, which favors more stable and reproducible alpha oscillations and better test–retest reliability. The motor-cortex channels (C1–C6) were the focus of the present analysis.

B. Data analysis

1) Preprocessing and segmentation: EEG signals were preprocessed in EEGLAB. The first second of each recording was discarded to remove acquisition transients, and data were band-pass filtered (FIR, 1–50 Hz). For the resting-state segments, artifacts were removed using Artifact Subspace Reconstruction (ASR, Clean Rawdata plugin), followed by removal of power-line noise (60 Hz) with Zapline-plus [40]. Signals were then re-referenced to a robust common average reference (rCAR), with no channels excluded from the average computation, to correct for the electrical asymmetry

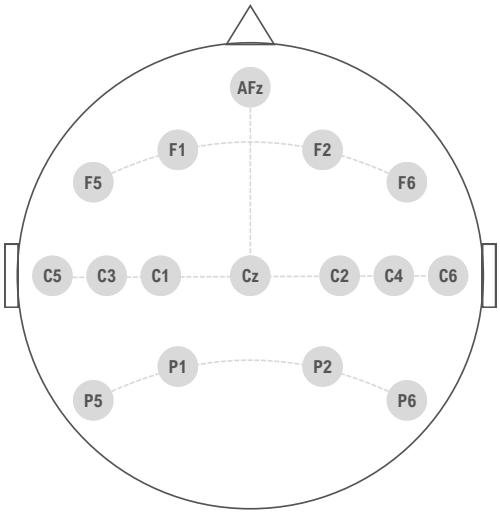

Fig. 2. Spatial layout of the 16 monopolar electrodes positioned according to the 10/20 system. The reference electrode was placed on the left mastoid and the ground on the right mastoid. The motor-cortex channels analyzed in this work (C1–C6) lie along the central row.

introduced by the original left-mastoid reference. No channels were rejected in their entirety. Independent component analysis (ICA) was applied to the data. Artifactual components were initially flagged using the ICLabel plugin and subsequently removed after manual confirmation based on visual inspection of component topography, time courses, and power spectra.

From each recording, the eyes-closed resting-state segment was extracted, corresponding to the final 64 s of the acquisition. To ensure anatomical comparability across patients, a left–right channel flip was applied whenever the lesion was on the left hemisphere, so that the right side consistently corresponds to the affected hemisphere for all participants. The six motor channels were then grouped into the affected (C2, C4, C6) and non-affected (C1, C3, C5) hemispheres. All analyses compared the baseline condition (session 1) with the post-rehabilitation condition (session 10).

2) Recurrence Quantification Analysis: A dynamical system exhibits recurrence when its trajectory returns to a neighborhood of states previously visited in phase space. This property is captured by the recurrence matrix [20], [21]:

$$\mathbf{R}_{ij}(\epsilon) = \Theta(\epsilon - \|\vec{x}_i - \vec{x}_j\|) \qquad i, j = 1, ..., N \tag{1}$$

where $\vec{x}_i$ are the phase-space vectors reconstructed by time-delay embedding, Θ is the Heaviside step function, ε is a threshold distance, and N is the number of states. The graphical representation of this matrix is the recurrence plot (RP), whose small-scale structures, formed by diagonal and vertical lines, reveal the nature of the underlying process: deterministic systems produce long diagonal lines, whereas stochastic processes yield isolated, scattered points (Fig. 3).

From the RP, a set of complexity measures was computed [21], [22], [23]. Determinism (DET) quantifies the predictability of the system; laminarity (LAM) quantifies the occurrence

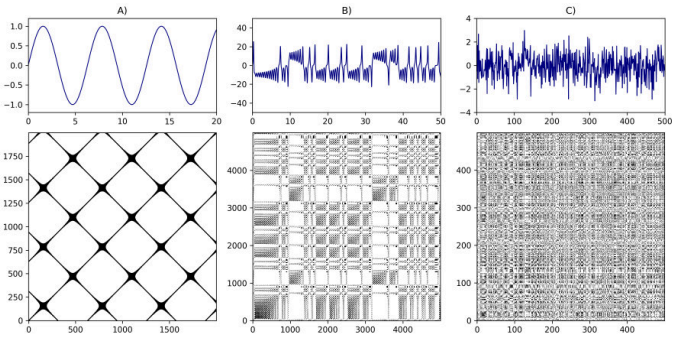

Fig. 3. Time series (top) and corresponding recurrence plots (bottom) for three types of dynamical processes: (A) periodic (sine), (B) chaotic (Lorenz attractor), and (C) stochastic (white noise).

of laminar (intermittent) states; and the Shannon entropy of the diagonal-line lengths (ENTR) quantifies the complexity of the recurrence patterns:

$$DET = \frac{\sum_{l=l_{\min}}^{N} l\, P(l)}{\sum_{l=1}^{N} l\, P(l)}, \tag{2}$$

$$LAM = \frac{\sum_{v=v_{\min}}^{N} v\, P(v)}{\sum_{v=1}^{N} v\, P(v)}, \tag{3}$$

$$ENTR = -\sum_{l=l_{\min}}^{N} p(l)\, \ln p(l). \tag{4}$$

where $P(l)$ and $P(v)$ are the histograms of diagonal and vertical line lengths, respectively, and $p(l)$ is the probability distribution of the diagonal-line lengths. No selective narrow-band filtering (e.g., isolating a single frequency band such as alpha) was applied; signals retained their broadband structure within the 1–50 Hz range used in preprocessing, preserving the joint contribution of multiple frequency components to the analysis. The phase space was reconstructed via time-delay embedding of the EEG signals. To guarantee topological comparability across subjects and groups reconstruction parameters were kept constant. The embedding dimension was set to m = 6, guided by evaluations using the False Nearest Neighbors (FNN) algorithm. For the time delay, we selected τ = 10 samples (approx. 39 ms at 256 Hz) based strictly on the physiological properties of eyes-closed resting-state EEG; this value corresponds to a quarter-cycle of the dominant alpha-band oscillations (10 Hz), ensuring optimal temporal decoupling. The recurrence threshold ε was adapted per channel, from the distribution of pairwise distances, so as to target a recurrence rate of approximately 5%, preventing matrix saturation and controlling for signal amplitude variations. The metrics were computed per channel and then averaged (arithmetic mean) within each hemisphere, rather than from a global signal. The RQA pipeline was implemented in Julia (using the RecurrenceAnalysis.jl and MAT.jl packages).

3) Statistical analysis: Given the small sample size and the non-normal, highly variable nature of the data, all comparisons

relied on non-parametric tests (implemented in Python with scipy). For each patient and metric, the change between baseline (session 1) and post-rehabilitation (session 10) was computed as $\Delta = \text{post} - \text{baseline}$.

The primary inferential comparison was performed between groups: for each metric and hemisphere, the distribution of Δ in the tDCS group was contrasted with that of the Sham group using the Mann–Whitney U test, assessing whether the pre- to post-rehabilitation change differed between real and sham stimulation. As supporting evidence, within-group changes were evaluated with the Wilcoxon signed-rank test (baseline vs. post-rehabilitation) for each group separately. Effect sizes were estimated as $r = |Z|/\sqrt{N}$ (large, $r > 0.5$; medium, $0.3 \leq r \leq 0.5$; small, $r < 0.3$).

To account for multiple comparisons, p-values were corrected with the Benjamini–Hochberg false discovery rate (FDR) procedure, applied separately within each family of tests. The between-group family comprised the six Mann–Whitney comparisons (three metrics $\times$ two hemispheres), and the within-group Wilcoxon tests of the tDCS and Sham groups formed two additional families of the same size. Corrected values are reported as q-values, with significance set at $q < 0.05$. Results were summarized at the hemisphere level (affected and non-affected).

III. Results and Discussion

The RQA metrics were compared between baseline (session 1) and post-rehabilitation (session 10) at the hemisphere level, for the affected and non-affected hemispheres. After FDR correction, statistically significant between-group differences were found for determinism (DET) and laminarity (LAM) in the affected hemisphere; diagonal-line entropy (ENTR) in the affected hemisphere and all three metrics in the non-affected hemisphere reached only borderline significance (q = 0.056). Across all six hemisphere-level comparisons, however, a consistent pattern was observed: the real tDCS group tended to increase the metrics from baseline to post-rehabilitation, whereas the Sham group tended to decrease them, so that the two groups followed opposite trajectories irrespective of whether the contrast crossed the corrected threshold (Figs. 4 and 5).

Between-group changes (Δ = post $-$ baseline) were the primary inferential comparison (Mann–Whitney U, Benjamini–Hochberg FDR; Fig. 4). In the affected hemisphere, both DET and LAM differed significantly between groups (q = 0.044, r = 0.59; uncorrected p = 0.015), with the real group increasing and the Sham group decreasing. The corresponding effect for ENTR in the affected hemisphere was in the same direction but did not survive correction (q = 0.056, r = 0.52). In the non-affected hemisphere, the three metrics followed the same real-increase / sham-decrease pattern, yet all remained just above threshold after correction (DET, r = 0.48; LAM and ENTR, r = 0.46; q = 0.056 for the three).

Higher DET and LAM reflect, respectively, a larger proportion of recurrence points organized into diagonal structures (more predictable, regular trajectories in phase space) and a greater occurrence of laminar, persistent states; ENTR captures the complexity of these recurrence structures [21], [22], [23]. The increases observed in the real tDCS group are consistent with an increase in recurrence-based determinism and laminarity after rehabilitation, a signature that did not emerge, and was often reversed, in the Sham group. This stabilization was most clearly expressed in the affected (ipsilesional) hemisphere, where the DET and LAM changes were robust to correction, whereas the non-affected hemisphere displayed the same directional trend at borderline significance, suggesting a predominantly ipsilesional, but possibly bilateral, pattern of

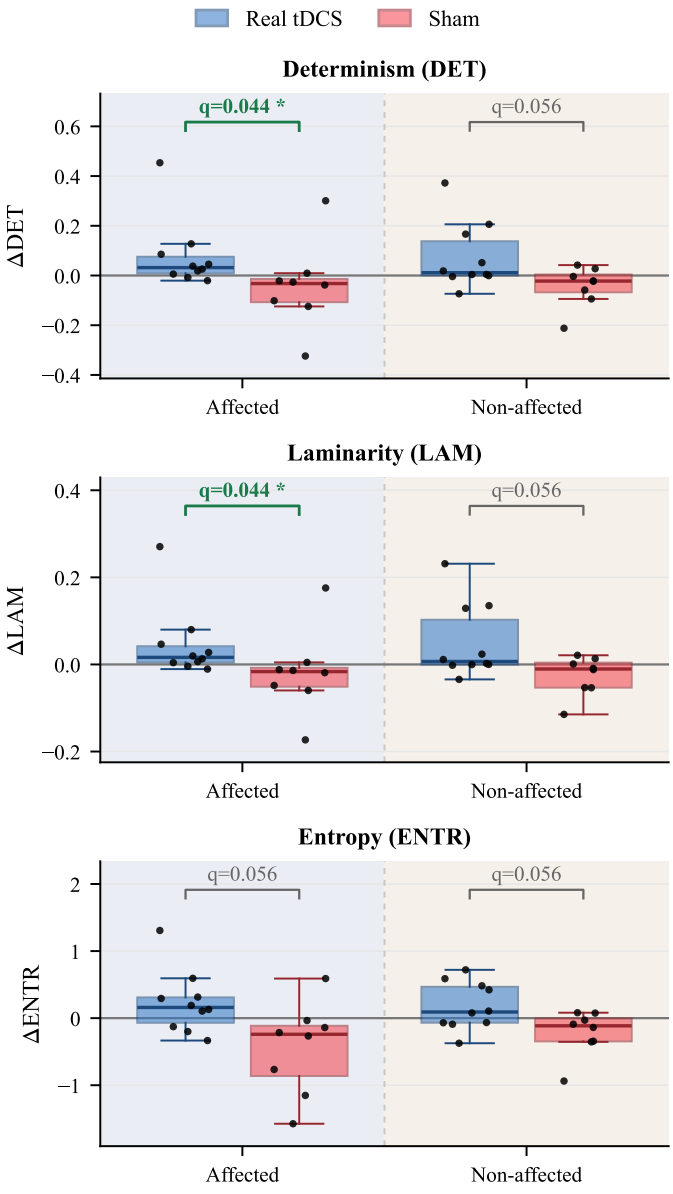

Fig. 4. Per-patient change (Δ = S10 $-$ S1) in the RQA metrics (DET, LAM, ENTR) for the real tDCS and Sham groups, in the affected and non-affected hemispheres. Boxes show the distribution of Δ and points are individual patients; the horizontal line marks no change. Between-group contrasts (Mann–Whitney U, FDR-corrected q-values) are indicated above each pair, and † marks a within-group change (Wilcoxon, $q < 0.05$).

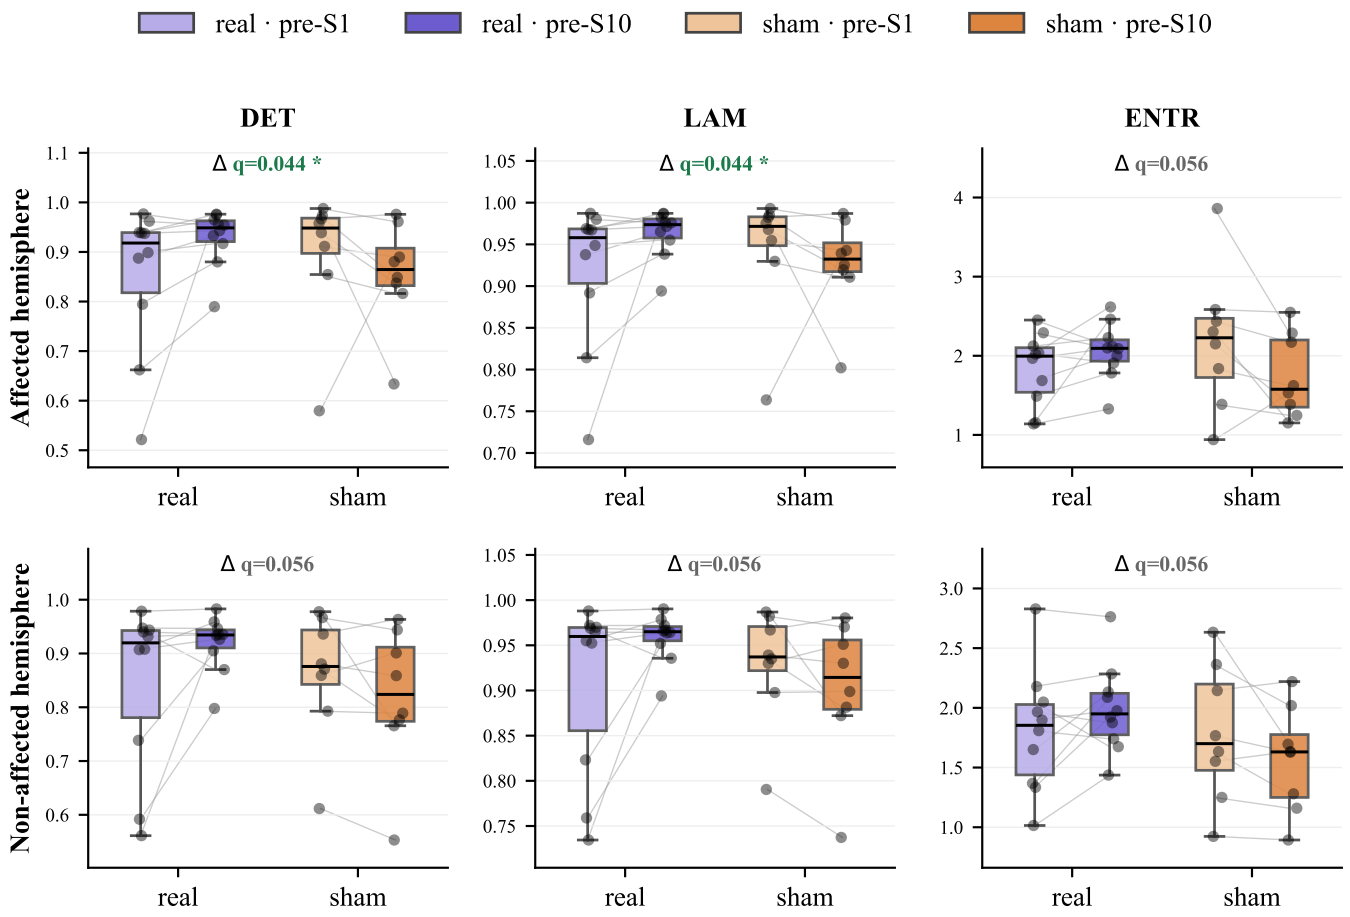

Fig. 5. RQA metrics at baseline (S1) and post-rehabilitation (S10) for the real tDCS and Sham groups, organized by hemisphere (rows) and metric (columns). Thin lines connect the two sessions of each patient. The between-group comparison of the pre- to post-rehabilitation change (Δ; Mann–Whitney U, FDR q-value) is shown at the top of each panel.

change of cortical dynamics.

These findings are consistent with, and complement, previous analyses of the same dataset, in which the combination of XR and tDCS was associated with increased interhemispheric symmetry and alpha-band functional connectivity in chronic stroke patients [11], [14], [41]. Whereas those descriptors are essentially linear, the present results show that a nonlinear, dynamical-systems approach captures convergent changes in cortical activity after real stimulation, which may reflect underlying neural reorganization. A possible interpretation, consistent with proposed mechanisms of tDCS-induced excitability changes, is that anodal stimulation over the ipsilesional M1 may facilitate corticomotor excitability and neuroplasticity [9], [10], [42]; the same-direction trend observed in the non-affected hemisphere is, in turn, compatible with the role attributed to the contralesional hemisphere in post-stroke recovery.

Finally, the convergence between the present nonlinear results and previously reported linear effects, the robustness of the affected-hemisphere DET and LAM effects, and the consistent opposite-direction trajectories of the two groups across all comparisons, together suggest that RQA is a promising complementary tool for characterizing the neurodynamic effects of XR- and tDCS-based rehabilitation in stroke survivors, and motivate its validation in larger cohorts.

This study has some limitations. The main one is the small sample size. Indeed, recruitment of stroke survivors to perform a two-week rehabilitation program is difficult due to their depending on other people (who usually work, and have to miss work) to bring them to the sessions. Also, it is difficult to recruit a population with the exact same lesion characteristics and exact same motor impairments. Although the inclusion and exclusion criteria intended to form a homogeneous sample, this is not always possible. This pilot, exploratory scope also constrained the analysis in other respects: only resting-state EEG was considered, without task-related recordings or follow-up beyond the ten-session program; the comparison was restricted to three RQA metrics, without benchmarking against other nonlinear complexity measures; phase-space reconstruction parameters were fixed rather than tested through a formal sensitivity analysis; RQA metrics were not directly correlated with clinical outcome scores; and hemisphere-level,

non-parametric group comparisons were used in place of participant-level mixed-effects modeling, given the limited statistical power at this sample size. Studies with larger cohorts, incorporating these extensions, are necessary to validate and extend these findings.

IV. Conclusion

This work applied Recurrence Quantification Analysis to eyes-closed resting-state EEG to characterize the neurodynamic effects of a combined XR and tDCS rehabilitation program in chronic stroke survivors, contrasting a real-stimulation group with a sham group. Determinism, laminarity, and diagonal-line entropy were computed per channel, averaged within the affected and non-affected hemispheres, and their pre- to post-rehabilitation change was compared between groups with non-parametric tests and FDR correction.

The real tDCS group exhibited a significant increase in determinism and laminarity in the affected hemisphere, whereas the Sham group decreased; the remaining comparisons followed the same opposite-direction trend at borderline significance. This convergent pattern points to a transition toward more stable, deterministic, and structured cortical dynamics after real stimulation, expressed most clearly in the ipsilesional hemisphere but possibly bilateral.

Taken together with the linear effects previously reported for the same dataset, these results indicate that RQA captures nonlinear aspects of changes is cortical activity not accessible to linear measures, and is therefore a promising complementary tool for assessing XR- and tDCS-based stroke rehabilitation. Validation in larger cohorts remains necessary to confirm and generalize these findings.

***Abstract*—Vital sign monitoring is essential for evaluating the physiological state of a patient and is typically performed using contact-based medical devices. Nonetheless, non-invasive monitoring approaches offer relevant benefits in both clinical and non-clinical settings by increasing patient comfort, reducing contact-associated risks, and providing greater flexibility of application. In this context, remote photoplethysmography (rPPG) has emerged as a promising technique for estimating physiological parameters such as heart rate, respiratory rate, oxygen saturation and blood pressure by detecting cyclical variations of the cardiovascular system which can be extracted from subtle changes in the color intensity of pixels from the skin region captured by video. Although several methods have been proposed, including unsupervised approaches and deep learning–based techniques, most studies are conducted under controlled conditions and involve predominantly healthy individuals. In view of this limitation, this work aims to assess the performance of the main rPPG algorithms using video recordings of patients in a public Intensive Care Unit (ICU) which is part of the Brazilian Unified Health System (*Sistema Único de Saúde* - SUS). In this preliminary study, the dataset is composed of video recordings acquired using an industrial video camera and reference signals collected directly from bedside multiparameter monitors of an initial cohort of three patients. The results aim to assess the methodological feasibility of evaluating rPPG methods under realistic intensive care conditions of an under-represented population.**

***Index Terms*—remote photoplethysmography, intensive care unit, vital signs**

I. Introduction

Vital sign monitoring plays a significant role in the evaluation of the physiological state of an individual and helps to prevent the deterioration of health conditions [1]. However, the constraints imposed by continuous monitoring using wired devices in direct contact with the body may cause discomfort, particularly during long periods. In fact, these constraints can be considered one of the main stressors for patients in Intensive Care Units (ICUs) [2].

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) – Finance Code 001 and by Amigos da Poli endowment fund under CARE 4.0 project.

Given the challenges associated with vital sign monitoring using contact-based medical devices, camera-based physiological monitoring has emerged as a reliable alternative, offering advantages in terms of cost-effectiveness and ease of deployment [3]. Most of these approaches are based on remote photoplethysmography (rPPG), a technique that aims to capture cyclic cardiovascular variations from subtle temporal changes in the intensity of skin color components caused by blood flow. In this process, imaging devices capture the light that has propagated through skin tissues and is subsequently re-emitted [4].

Remote photoplethysmography signal extraction can be performed either under ambient light or controlled illumination sources, using one or more imaging devices for video acquisition. The typical workflow, as shown in Fig. 1, involves the detection and tracking of a region of interest (ROI), from which a raw signal is obtained through the analysis of the color channels of the pixels in each video frame. This signal is subsequently filtered and processed to reconstruct the blood volume pulse (BVP) waveform, also denoted as the rPPG signal, and its properties can then be exploited to estimate physiological parameters such as heart rate (HR) and respiratory rate (RR). Nonetheless, signal quality is influenced by lighting variations, subject movement, ROI definition and detection and other factors regarding the acquisition method such as video compression or even physiological aspects as skin tone [5], [6].

Numerous algorithms have been proposed for rPPG signal extraction. However, the literature has predominantly focused on controlled laboratory environments and healthy participants [7], [8]. Furthermore, the datasets most commonly used for the development and evaluation of these methods underrepresent older adults and individuals with cardiovascular conditions [9], despite the fact that this technology is intended to capture physiological variations that may support the detection and monitoring of health conditions to which these populations are particularly susceptible. Clinical studies remain comparatively scarce and are concentrated primarily in China, the United States and European countries [10]. In

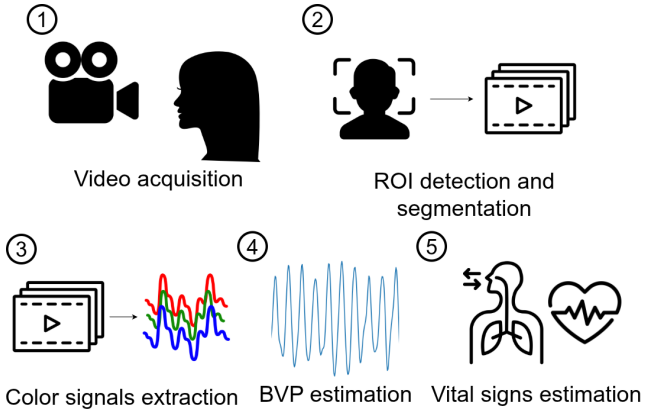

Fig. 1. Remote photoplethysmography-based vital signs estimation workflow. 1) Videos of the subject's face are acquired under natural or artificial lighting. 2) ROI is detected and segmented from video frames. 3) Image color channels are processed for rPPG signal extraction. 4) Final rPPG signal is obtained, corresponding to the estimated BVP waveform. 5) Vital signs such as heart rate and respiratory rate are estimated based on the obtained BVP.

view of these limitations, this pilot study aims to evaluate the methodological feasibility of assessing the main unsupervised and deep learning-based rPPG approaches for HR and RR estimation in an ICU of a hospital within the Brazilian Unified Health System (*Sistema Único de Saúde* - SUS), which is a previously unexplored context, by establishing a video-processing pipeline and an initial data-collection to provide a preliminary qualitative assessment of these algorithms.

II. Related work

Most rPPG signal extraction algorithms are based either on unsupervised methods or on deep learning (DL) approaches. Unsupervised methods estimate physiological signals through color-based analyses of input video data, whereas DL-based approaches include both end-to-end models trained to infer the rPPG signal or physiological parameters directly from video, and hybrid frameworks that integrate traditional signal-processing pipelines with DL components for feature extraction at one or more stages of the estimation process [11].

A. Unsupervised methods

One of the first known rPPG solutions performed a spectral analysis based on the Fast Fourier Transform (FFT) of signals obtained from the spatial mean of pixels of the face region of individuals recorded by an RGB camera. This method resulted in the estimation of HR values and also proposed that the green channel has predominant influence over the rPPG signal [12]. Early rPPG-based systems relied primarily on algorithms and mathematical models designed to process video data acquired from conventional cameras and extract the physiological signal of interest while minimizing the influence of noise. Within the approaches proposed for this purpose, signal separation techniques such as Independent Component Analysis (ICA) and Principal Component Analysis (PCA) became particularly prominent [13], [14]. These methods aim to decompose the observed color variations into underlying components, enabling the isolation of physiological signals associated with cardiovascular activity from motion artifacts, illumination changes, and other confounding factors.

Subsequent model-based approaches primarily rely on modeling color vectors of different components to extract pulse-related information from signals captured by RGB cameras. Among them is the chrominance-based (CHROM) technique, which aims to attenuate the effects of specular reflections and other noise artifacts common to the red, green, and blue channels by projecting the signals onto two orthogonal chrominance components [15]. Similarly, the blood volume pulse signature method, also called PBV, is based on the hypothesis that the different absorption spectra of arterial blood and the cutaneous tissue cause variations in a characteristic vector of the normalized RGB space [16]. In contrast, the Spatial Subspace Rotation (2SR) method defines a subspace from the distribution of skin pixels in the RGB color space, such that pulse-related color variations are represented as rotations within this subspace [17]. Comparably, the Projection Orthogonal to Skin (POS) method proposes a plane orthogonal to the temporally normalized skin-tone vector, in which the specular and diffuse components of reflected light have distinct distributions and can, therefore, be disaggregated [18].

The Local Group Invariance (LGI) method enhances robustness to facial motion and illumination changes by projecting RGB signals onto a subspace orthogonal to dominant interference components. The transformed signal is subsequently modeled as a stochastic oscillatory process that captures the quasi-periodic and non-stationary nature of cardiac activity, enabling heart rate estimation [19]. Lastly, the Orthogonal Matrix Image Transformation (OMIT) method uses QR decomposition to transform RGB signals into an orthogonal basis, from which a projection matrix is derived to extract the BVP waveform from the input color signals [20].

B. Deep-learning-based methods

Deep learning is based on the use of deep neural networks to analyze and identify complex patterns in data. Specifically, Convolutional Neural Networks (CNNs) have been widely used to identify spatial patterns in image and video processing tasks. In fact, in the context of remote photoplethysmography, the DeepPhys model comprises a motion model and an appearance model based on convolutional attention networks. The motion model leverages an attention mechanism to learn motion representations from normalized frame differences, whereas the appearance model uses attention to emphasize skin regions with stronger physiological signals, improving BVP and respiration signal estimation [21]. Similarly, the Multi-Task Temporal Shift Convolutional Attention Network (TSCAN) model uses temporal shift modules such that two-dimensional tensors are shifted through the temporal dimension in order to extract sequential information between multiple frames at the same time that a multi-task mechanism shares pulse and respiratory representations for simultaneous HR and RR estimation [22]. Other solutions comprised three-dimensional CNNs to simultaneously identify temporal and

spatial features. The PhysNet model, for instance, proposes a 3D CNN version capable of extracting the rPPG signal directly from face videos without preprocessing steps [23].

Later applications proposed the use of Transformer architectures to extract the rPPG signal. The PhysFormer model employs the use of a Visual Transformer (ViT) to explore the long-range spatio-temporal relationship for rPPG signal estimation. This solution leverages temporal differences to guide global attention mechanisms and refine local spatio-temporal representations for noise robust signal extraction [24]. The EfficientPhys model employs a Swin Transformer architecture, which is a two-dimensional ViT featuring a shifted-window mechanism which improves computational efficiency. This architecture is combined with a temporal shift module to facilitate the extraction of temporal features, allowing reliable cardiac pulse measurement [25].

III. Materials and Methods

This study aims to assess the methodological feasibility of evaluating the performance of the main rPPG algorithms and models under the context of intensive care. This preliminary work is based on an initial cohort of three videos recorded from patients admitted in the ICU of the University Hospital of the University of São Paulo (HU-USP), which is part of SUS. The workflow comprises the recording of face videos of the patients and corresponding physiological ground truth signals from multiparameter bedside monitors, video processing for rPPG signal extraction, estimation of heart rate and respiratory rate and results evaluation. This work was approved by HU-USP Ethics Committee (*Comitê de Ética em Pesquisa* - CEP) under Certificate of Submission for Ethical Review (*Certificado de Apresentação para Apreciação Ética* - CAAE) No. 86650625.3.0000.0076. All data were acquired with explicit permission of all participants or their legal representatives.

A. Data acquisition

Data were acquired by recording face videos of patients admitted in the ICU under ambient lighting conditions, with no restrictions imposed to the patient during monitoring and no impact on clinical conduct. Initially, after the inclusion of the patient in the study, the recording positioning was defined based on patient disposition inside the room, such that if the patient was lying down in the hospital bed, the camera was positioned at the end of the bed at a distance of approximately 170 cm from the face ROI, whereas if the patient was sitting down in the available chair, the camera was positioned at a distance of approximately 190 cm.

Before each recording, lighting intensity was registered near the face region of the patient with a digital lux meter (Fluke 941, Fluke Corporation, USA). Skin-tone was also measured according to the Fitzpatrick scale using a digital phototype analyzer (Skin Up Beauty Devices, Brazil) positioned in the forehead. Afterwards, videos of approximately two minutes were recorded with an industrial VCXG.2-57C video camera (Baumer, Switzerland) with Ethernet communication to a laptop, configured to capture 25 frames per second with BGR8 pixel format. For each subject, the exposure time, gain, focus and sensor aperture were configured in order to minimize pixel saturation and low illuminance regions caused by underexposure, considering that the exposure time is limited by frame rate. Videos were recorded in uncompressed AVI format with planar YUV 4:2:0 color representation. Natural ICU monitoring conditions were maintained, including patient natural movements, lighting variations and other influencing factors related to the clinical setting.

Physiological ground truth signals were acquired simultaneous to video recordings directly from the bedside monitors (BSM-3000 Series, Nihon Kohden, Japan). The electrocardiogram (ECG) was recorded with a sample rate of 250 Hz, respiratory signal was recorded with sample rate of 125 Hz and the photoplethysmography (PPG) signal was recorded at 62,5 Hz.

B. Data processing

In order to assess different rPPG signal extraction methods in the acquired data, recorded videos were processed in an analysis pipeline implemented based on the open source toolbox rPPG-Toolbox [26]. This platform not only supports the most widely used rPPG model-based algorithms and state-of-the-art deep learning models for training and testing in public datasets, but also supports the addition of new algorithms and customized datasets. Therefore, this work proposes the assessment of the methods shown in Table I in the acquired data using the aforementioned toolbox for rPPG signal extraction.

For each input video, face detection was performed using the Yolo5Face face detector every 25 frames and the resulting bounding box was defined as the ROI [27]. All frames were cropped according to the detected ROI and, specifically for unsupervised algorithms, the spatial mean of the ROI pixels was used as input. For the supervised algorithms, the models trained on the PURE [28] dataset and on the UBFC-rPPG [29] dataset were used.

After video processing, the resulting BVP waveform obtained from each method was filtered between 0.6–3.3 Hz using a band-pass first order Butterworth filter and used for heart rate estimation through spectral analysis performed on 15-second non-overlapping windows. For each window, the power spectral density (PSD) was estimated using the periodogram method, using a rectangular window and the FFT length zero-padded to the next power of two. The frequency corresponding to the maximum PSD value was identified as the dominant spectral peak and taken as the HR estimate. As a second analysis, in order to obtain a global representation of the distribution of spectral energy over the entire recording, alongside a time-frequency analysis to point out temporal variations of the spectral content during acquisition, the PSD estimate and the spectrogram of the entire signal were computed. This PSD was obtained using the periodogram method, with the FFT length zero-padded to the next power of two and a rectangular window. The spectrogram was computed using the Short-Time Fourier Transform (STFT) with 256-sample

TABLE I
EVALUATED RPPG METHODS

Method	Strategy
GREEN [12]	Green channel intensity analysis

PhysFormer [24]	Visual Transformer
EfficientPhys [25]	Swin Transformer

windows, 50% overlap, and an FFT length zero-padded to twice the next power of two.

The respiratory rate was estimated by extracting the three types of respiratory-induced variations in the obtained BVP signal namely the baseline wander (BW), the amplitude modulation (AM), and the frequency modulation (FM). Firstly, the BW component was obtained using a discrete sequence formed by the mean between the amplitudes of each trough and its subsequent peak. The AM component was demodulated using the discrete sequence formed by the amplitude differences between each trough and its subsequent peak. The demodulation of the FM component was obtained using the discrete sequence formed by the intervals of consecutive peaks. Subsequently, based on the algorithm proposed by Karlen *et al.* [30], the discrete sequences respective to the AM and BW components were resampled in a 4 Hz uniform temporal grid using linear interpolation, whereas the discrete sequence respective to the FM component was resampled to a 4 Hz uniform temporal grid using the Berger algorithm [31]. Finally, RR corresponding to each component was estimated though spectral analysis performed in 30-second non-overlapping windows. For each window, the dominant spectral peak within the 4–65 rpm frequency range identified in the PSD was taken as the RR estimate. In this case, the PSD was obtained using the periodogram method, with the FFT length zero-padded to the next power of two and a rectangular window. Additionally, in order to enhance RR estimation, a fusion strategy was performed, using the mean of the three values obtained from each component as the final estimate [30], [32], [33].

Ground truth values for HR were acquired from the Lead II ECG signal using the HeartPy toolkit [34] considering 15-second windows. The photoplethysmogram acquired by the pulse oximeter was used to evaluate the waveform estimated by each rPPG method based on the Pearson correlation coefficient computed after temporal alignment using normalized cross-correlation. Lastly, the ground truth respiratory rate was obtained by spectral analysis of the ground truth respiratory signal performed in 30-second windows. In this case, for each window, the PSD was estimated using the periodogram method with the FFT length zero-padded to the next power of two and the dominant spectral peak within 4 and 65 rpm was considered as the ground truth respiratory rate.

The HR and RR estimation results were evaluated by the Mean Absolute Error (MAE), Root Mean Square Error (RMSE) and Mean Absolute Percentage Error (MAPE). For additional HR estimation evaluation, the Signal-to-Noise Ratio (SNR) was also obtained by the ratio between the spectral energy associated to the frequency of the ground truth HR value and its first harmonic and the remaining spectral energy, as shown:

$$SNR = 10\log_{10}\left(\frac{\sum_{f=f_{min}}^{f_{max}}\left(U_t(f)S(f)\right)^2}{\sum_{f=f_{min}}^{f_{max}}\left((1-U_t(f))S(f)\right)^2}\right) \quad (1)$$

where S refers to the rPPG signal frequency spectrum, f is the frequency in bpm, $f_{min} = 36$ and $f_{max} = 198$ are respectively the maximum and minimum frequency values considered in bpm and $U_t(f)$ represents a binary mask centered in the fundamental frequency associated to the ground truth HR value and its first harmonic. This mask assumes a unit value in the frequency values of interest, within a tolerance of ±0.1 Hz around these frequencies, and zero elsewhere in the spectrum.

IV. RESULTS

Data were acquired from a total of three patients admitted in the ICU and the acquisition parameters are shown in Table II. Patient 1 was heavily sedated and was receiving respiratory support, whereas patient 2 was active and seated on the chair available in the hospital room. As for the data acquired from patient 3, the pulse oximeter was not connected during recording, therefore waveform comparison between the PPG and rPPG signals could not be obtained. The waveform obtained from each rPPG method for patients 1 and 2 was compared to the ground-truth PPG signal. Pearson correlation coefficients computed after temporal alignment using the lag that maximized the normalized cross-correlation are presented in Table III.

The rPPG methods which resulted in the best Pearson correlation coefficients among the supervised methods were the TSCAN model trained on the UBFC-rPPG dataset for patient 1 and the same model trained on the PURE dataset for patient 2. The signals obtained from unsupervised methods which resulted in the best Pearson correlation coefficients were extracted using the GREEN method for patient 1 and the POS method for patient 2. These signals compared to the respective ground-truth PPG signals are shown in Fig. 2.

A. Heart rate estimation

Table IV reports the MAE, RMSE, MAPE, and SNR of HR estimates derived from rPPG signals, using ECG-based HR as ground truth. The unsupervised method which resulted in the lowest MAE for patient 1 was the CHROM method. As for patient 2, CHROM, ICA and POS resulted in the lowest error values. Comparatively, LGI and POS resulted in the lowest MAE value for HR estimates related to patient 3. In

(a)

(b)

Fig. 2. Comparison of rPPG signals (red) with highest linear correlation to ground-truth PPG (blue) after temporal alignment using normalized cross-correlation for (a) patient 1 and (b) patient 2.

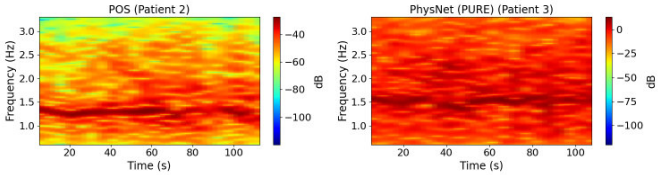

Fig. 3. Spectrograms of the signals which achieved the best heart rate estimation error results. On the left, the spectrogram of the signal extracted with the POS method from the video of patient 2. On the right, the spectrogram of the signal extracted with the PhysNet model trained on the PURE dataset from the video of patient 3.

addition, the supervised methods with the best HR estimates error results were the PhysFormer model for patient 1, TSCAN for patient 2 and PhysNet for patient 3, all trained on the PURE dataset. Regarding the SNR metric, the signal extracted with the POS method showed the best SNR value for patients 2 and 3, whereas the signal extracted with PhysFormer trained on PURE resulted in the best SNR for patient 1.

Fig. 3 shows the spectrograms of the signals that achieved the best HR estimates error results among both types of methods. In both spectrograms, it is possible to distinguishably identify a region with greater spectral density throughout the signal which, in this case, was analyzed in its entirety. Similarly, the corresponding PSD for each signal is presented in Fig. 4 where, in both cases, the dominant frequency can be identified as a distinguishable peak, based on which the HR estimation can be performed. Additionally, the mean absolute error per window for unsupervised methods and for supervised methods for patients 2 and 3 is shown in Fig. 5. It can be observed that, for each patient, both categories of methods exhibit some common error peaks, such as window 5 of the signal for patient 2, which corresponds to the highest error for both types of algorithm. Likewise, window index 0 of the same signal yields the lowest MAE for both method categories. Furthermore, unsupervised methods exhibit lower MAE than supervised methods in most windows for both patients.

B. Respiratory rate estimation

Table V reports the MAE, RMSE and MAPE of respiratory rate estimates derived from rPPG signals, in comparison to estimates obtained from the reference respiratory signal. Among the unsupervised methods, POS and GREEN achieved the best

V. DISCUSSION AND CONCLUSION

The extraction of remote photoplethysmography signals from videos can be based on unsupervised algorithms or on DL-based models. These approaches result in a blood volume pulse waveform that shows significant similarity to the conventional photoplethysmographic signal. The BVP obtained from rPPG methods can be used to estimate heart rate and respiratory rate. Nonetheless, illumination and movement artifacts can greatly impact on signal quality, as could be observed by comparing HR estimates per window, in which windows with greater error values can be related to abrupt patient movement or expressive lighting variations, affecting signal extraction for all methods similarly. Moreover, video compression artifacts can also negatively impact the SNR, which motivated the use of an industrial video camera in this work. In the same way, camera exposure time and image resolution can influence the obtained results and the different values set for each patient recording was observed as one of the limitations of this work.

Definition and detection of the ROI also play an important role in remote vital signs estimation, which can be observed by the results obtained for patient 1. The rPPG signal extracted for this patient showed low linear correlation to the ground truth PPG signal and presented the highest error metrics for HR and RR estimates. This can be due to the fact that the face detector failed to identify any face in the video frames, possibly as a result of the occlusion of the patient's face caused by the mechanical ventilator tubes. As a result, frames were introduced as input to the rPPG algorithms without any ROI segmentation, leading to SNR degradation. Moreover, it is noted that the reference PPG signal was different from the conventional expected waveform, which can be due to physiological factors related to the clinical condition of the patient and a further analysis is necessary to clarify the influence of this factor over the remotely extracted signal. Additionally, specifically for patient 3, although the RR error metrics were similar to those of the other patients, the PSD of the ground-truth respiratory signal revealed that multiple frequency components exhibited comparable power levels, resulting in an ambiguous dominant frequency estimate and, therefore, an ambiguous ground-truth RR value, which can be due to bad signal quality.

Finally, the error metrics for HR and RR estimates for all patients show that evaluating different methods for rPPG signal extraction in an ICU within SUS depends on an effective face detection algorithm in order to account for face occlusion cases common to this context, alongside an evaluation of the quality of reference signals so that comparisons to the remotely extracted signal yield reliable results. Furthermore, albeit the small initial cohort, the dataset used represents a clinical environment and patient population not yet explored in the rPPG literature. In particular, SUS serves a large and socioeconomically and demographically diverse population in Brazil, which may provide an interesting setting for investigating the robustness and capacity of generalization of rPPG methods beyond the controlled environments and populations commonly represented in existing datasets. Overall, these findings demonstrate the feasibility of such evaluations and provide methodological insights for future data acquisition, supporting larger-scale assessments of rPPG performance and applicability in this context.

VI. FUTURE WORK

The main limitation of this work is the limited data. For this reason, future work will include the acquisition of more videos from the ICU with standardized image resolution and exposure time, including diverse lighting conditions and patient clinical and demographic profiles representative of the Brazilian public

health context, providing analyses of the assessed algorithms by patient skin type, age, gender or clinical condition. Furthermore, future work will also include making the additional data acquired in this setting available as an open-source dataset, in order to contribute for data diversity in future rPPG research. Lastly, future video-processing will consider a more robust face detector, in order to address face occlusions caused by medical devices commonly used in intensive care settings, such as mechanical ventilators.

ACKNOWLEDGMENT

The authors thank the University Hospital of the University of São Paulo for all the support regarding data acquisition.

***Resumo*—A retinopatia diabética (RD) é uma das principais causas de perda de visão evitável no mundo e se manifesta, em seus estágios iniciais, por lesões de fundo de olho como microaneurismas, exsudatos duros, exsudatos moles e hemorragias. Sua detecção automatizada é desafiadora, pois as imagens têm alta resolução e as lesões ocupam pouquíssimos *pixels*, sendo os microaneurismas, sinal mais precoce da doença, os mais difíceis. Este trabalho investiga, de forma controlada e estratificada por tipo de lesão, se a inferência assistida por fracionamento de imagem *Slicing Aided Hyper Inference* (SAHI) melhora a detecção de lesões de RD quando aplicada a um detector YOLO moderno, no conjunto de dados público DDR. Sob validação cruzada repetida e estratificada por lesão (5 *folds* $\times$ 3 repetições) e protocolo unificado de avaliação (*mean Average Precision*, mAP, a IoU 0,1 e 0,5), comparam-se três configurações: (A) treino e inferência em imagem cheia; (B) SAHI apenas na inferência; e (C) SAHI também no ajuste fino. A Config. B *reduziu* significativamente o desempenho global em relação ao *baseline* YOLOv8m ($p < 0{,}01$, Wilcoxon pareado), enquanto a Config. C aproximou o mAP global do *baseline*, sem diferença detectável sob o teste corrigido para a não-independência dos *folds*. O ganho concentrou-se nos microaneurismas: a Config. C elevou significativamente o AP@0,1 ($p_{\mathrm{Holm}} = 0{,}009$; $r = 0{,}82$) e aumentou o AP@0,5 de 0,059 para 0,111, ao custo de piora nas lesões maiores e difusas. Conclui-se que, para detectores YOLO modernos em alta resolução, o ganho do SAHI é localizado: não melhora o mAP global, mostra-se eficaz na detecção de microaneurismas no DDR.**

***Palavras-chave*—retinopatia diabética, detecção de lesões, YOLO, SAHI.**

I. Introdução

A retinopatia diabética (RD) é uma complicação microvascular da retina e uma das principais causas de perda irreversível de visão em pessoas com diabetes [1], [2]. No Brasil, mais de 13 milhões de pessoas vivem com diabetes, cerca de 6,9% da população [3], e a RD atinge entre 24% e 39% desse grupo [4]. Quando diagnosticada e tratada precocemente, o risco de cegueira pode ser reduzido para menos de 5% [4].

A RD pode ser caracterizada pela presença de determinados tipos de lesões na retina, tais como exsudatos duros (EX), exsudatos moles ou algodonosos (SE), microaneurismas (MA) e hemorragias (HE) [2]. Os microaneurismas, em particular, costumam ser as primeiras alterações visíveis associadas à doença e, ao mesmo tempo, as mais difíceis de detectar, por ocuparem pouquíssimos *pixels* nas imagens de fundo de olho. A identificação dessas lesões em fases iniciais é essencial para prevenir a progressão da doença a estágios mais graves e a consequente perda de visão.

Os exames que identificam essas lesões dependem de médicos especializados, cuja disponibilidade é limitada, o que pode retardar o diagnóstico, sobretudo em regiões remotas e de difícil acesso [5]. A análise humana está ainda sujeita a fatores subjetivos, como cansaço e nível de experiência do especialista [6], o que compromete a precisão justamente nos estágios iniciais, quando as alterações são sutis. Nesse cenário, a detecção automática por aprendizado profundo tem sido proposta como ferramenta de apoio ao especialista: detectar e classificar cada lesão, e não apenas graduar a imagem, oferece informação para o diagnóstico precoce, de forma mais rápida e menos suscetível à subjetividade do avaliador.

Automatizar essa tarefa, contudo, permanece um problema em aberto. No conjunto de dados público DDR (*Dataset for Diabetic Retinopathy*) [1], um dos maiores *benchmarks* da área, os detectores genéricos avaliados pelos próprios autores obtiveram mAP inferior a $0{,}01$ a IoU 0,5, com AP de microaneurismas abaixo de 1% [1], [7]. Esse desempenho reduzido decorre do tamanho e do formato das lesões, do ruído e do contraste das imagens, do reduzido número de exemplos anotados e da dificuldade dos algoritmos de aprendizado profundo em detectar objetos muito pequenos [5].

Para mitigar o problema dos objetos minúsculos, a literatura recente tem explorado estratégias diversas: realçar seletivamente as regiões mais informativas da imagem [8], [9], ampliar artificialmente sua resolução [10] ou modelar relações entre regiões distantes, em vez de apenas vizinhanças locais [11]. Uma alternativa independente da arquitetura do detector consiste em fracionar a imagem em janelas sobrepostas (*tiling*/*slicing*), de modo que cada janela seja processada em resolução efetiva mais alta. O *framework* SAHI (*Slicing Aided Hyper Inference*) [12] implementa essa ideia de forma

Os autores agradecem ao Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), sob o Processo nº 315447/2023-0, e à Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) — Código de Financiamento 001, pelo apoio a esta pesquisa.

genérica, aplicável na inferência e, opcionalmente, também no ajuste fino do detector. No contexto do DDR, trabalhos anteriores demonstraram que o fracionamento eleva o desempenho da detecção de lesões, seja por *tiling* convencional [5], seja pelo SAHI [7]. Entretanto, esses estudos empregaram arquiteturas YOLO de gerações anteriores (YOLOv4/v5, YOLOR-CSP), permanecendo uma lacuna de investigação do SAHI combinado a detectores YOLO mais recentes, sob um protocolo de comparação controlado e com análise estratificada por tipo de lesão.

Diante dessa lacuna, este trabalho avalia, de forma controlada e estratificada por tipo de lesão, se o SAHI melhora a detecção de lesões de RD quando aplicado a um detector YOLO moderno (YOLOv8m), em comparação com a inferência em imagem completa, utilizando o conjunto de dados DDR. As principais contribuições deste trabalho são:

- o emprego de um detector YOLO moderno (YOLOv8m) combinado ao SAHI no DDR;
- uma comparação *controlada* entre YOLO e YOLO+SAHI sob um protocolo unificado de pré-processamento, resolução, validação cruzada e avaliação, que isola o efeito do *slicing* (mesmo detector, mesmos *folds*);
- uma análise *estratificada por classe* de lesão (MA, EX, SE e HE), com teste estatístico pareado, que evidencia o *trade-off* do *slicing*, ganho nas menores lesões (microaneurismas) e perda nas maiores e mais difusas (exsudatos moles e hemorragias), demonstrando que seu benefício sobre um YOLO moderno em alta resolução é condicional à classe de lesão e ao regime de treino.

O restante do artigo apresenta a fundamentação teórica (Seção II), os trabalhos relacionados (Seção III), os materiais e métodos (Seção IV), os resultados e a discussão (Seção V) e as considerações finais (Seção VI).

II. Fundamentação Teórica

A. Detecção de objetos

A detecção de objetos consiste em delimitar cada instância presente na imagem por uma *bounding box* (caixa retangular que circunscreve o objeto) e atribuir-lhe uma classe [13]. Os detectores baseados em aprendizado profundo dividem-se em detectores de dois estágios, que primeiro propõem regiões de interesse e depois as classificam, como o Faster R-CNN [14], e detectores de estágio único, que tratam a detecção como um problema de regressão e predizem simultaneamente as caixas e as probabilidades de classe sobre a imagem completa, como o SSD [15] e a família YOLO (*You Only Look Once*) [16]. A principal vantagem dos detectores de estágio único é a velocidade de inferência, o que os torna adequados a aplicações em tempo real e a *hardware* de menor custo.

B. A arquitetura YOLOv8

Neste trabalho adota-se o YOLOv8 [17], na variante `m` (*medium*). Trata-se de um detector *anchor-free* com *backbone* do tipo CSPDarknet, *neck* PAN-FPN e cabeça de detecção desacoplada, que realiza a predição em três escalas (P3/P4/P5) com cabeças especializadas em objetos pequenos, médios e grandes, característica relevante para a detecção de lesões de tamanhos variados na retina. A variante `m` equilibra capacidade e custo computacional, sendo compatível com o treino em uma única GPU.

C. Slicing Aided Hyper Inference (SAHI)

O SAHI, proposto por Akyon *et al.* [12], é uma solução de código aberto que fornece um processo genérico de inferência e ajuste fino auxiliado por fracionamento. A imagem de entrada é dividida em janelas (*tiles*) sobrepostas; a detecção é realizada em cada janela e as predições são reagrupadas na imagem original por pós-processamento (por exemplo, supressão não máxima gulosa, *GREEDYNMM*). Ao processar regiões menores em resolução efetiva mais alta, o método amplia a visibilidade de objetos pequenos, sendo promissor para o problema dos microaneurismas. Pode ser aplicado apenas na inferência (*sliced inference*) ou também no treinamento (*slicing-aided fine-tuning*), regime no qual a literatura reporta ganhos maiores [12].

III. Trabalhos Relacionados

A. Evolução da família YOLO

A família YOLO evoluiu por sucessivas versões (YOLOv3, YOLOv4, YOLOv5, YOLOR, YOLOv7, YOLOv8, YOLOv11, entre outras), incorporando aprimoramentos de *backbone*, *neck* e *head*, além de técnicas de aumento de dados e funções de perda mais robustas. Essa evolução importa aqui porque os trabalhos que aplicaram *slicing* à detecção de lesões de RD empregaram gerações anteriores da família [5], [7], cujas limitações na detecção de objetos pequenos podem ter sido atenuadas nas versões recentes.

B. Detecção de lesões de RD no DDR

No estudo que apresentou o conjunto de dados, Li *et al.* [1] avaliaram detectores genéricos (SSD, YOLO e Faster R-CNN) e demonstraram a dificuldade central da tarefa: enquanto a classificação alcançou acurácia da ordem de 0,83 com a arquitetura SE-BN-Inception, os modelos de segmentação e de detecção tiveram desempenho fraco, com AP de microaneurismas abaixo de 1%, o que evidencia a necessidade de aprimorar o reconhecimento de microlesões para viabilizar a aplicação clínica. Alyoubi *et al.* [18] combinaram uma rede de classificação (CNN512) a um YOLOv3 para localização de lesões, obtendo mAP de 0,216 na detecção no DDR.

Uma linha de trabalhos correlatos explorou progressivamente a família YOLO nessa base. Santos *et al.* [19] propuseram uma abordagem baseada em YOLOv4 e, depois [5], um método baseado em YOLOv5 com pré-processamento, aumento de dados e *Tiling*, alcançando mAP de 0,2630 na validação e 0,1540 no teste do DDR (IoU 0,5). Em seguida, Pereira *et al.* [7] combinaram a arquitetura YOLOR-CSP ao *framework* SAHI, atingindo mAP de 0,3808 na *validação* do DDR (IoU 0,5), mas de apenas 0,2225 no *teste*; essa diferença de 0,16 no mesmo modelo ilustra o quanto números de um único *split* de validação podem ser otimistas.

C. Lacuna de pesquisa

Como a combinação YOLO+SAHI já foi aplicada ao DDR [7], a comparação direta "YOLO vs. YOLO+SAHI" não constitui, por si só, uma novidade. O que permanece em aberto, e é o objeto deste trabalho, é saber se o ganho atribuído ao *slicing* persiste sobre um detector YOLO moderno, quando medido sob protocolo unificado, sem o viés de *split* único e de forma estratificada por tipo de lesão.

IV. Materiais e Métodos

A. Visão geral do método

O fluxo experimental é ilustrado na Fig. 1. Não há aquisição própria de imagens: utilizam-se as 757 imagens do conjunto público DDR [1] que possuem anotações de lesão em nível de *bounding box* (Seção IV-B). Essas anotações, distribuídas em formato Pascal VOC, são convertidas para o formato YOLO, com deduplicação das caixas repetidas e unificação dos três *splits* oficiais em um único *pool* (Seção IV-C), sobre o qual se aplica validação cruzada repetida e estratificada pelo vetor de presença de lesão, tendo a imagem como unidade de divisão (Seção IV-E). Em cada *fold*, o mesmo detector YOLOv8m é treinado sob dois domínios de entrada, imagem completa em alta resolução (Configs. A e B) e *tiles* de 512×512 (Config. C, *slicing-aided fine-tuning*), com hiperparâmetros fixos, de modo que a única variável experimental seja o fracionamento (Seção IV-F). A inferência ocorre sobre a imagem completa (Config. A) ou de forma fracionada com o SAHI (Configs. B e C), caso em que as predições de cada *tile* são reagrupadas nas coordenadas da imagem original por supressão não máxima gulosa. Por fim, as predições são confrontadas com o *Ground Truth* pelo avaliador COCO, calculando-se o mAP a IoU 0,1 e 0,5, global e por classe (Seção IV-G); como as três configurações compartilham os mesmos *folds*, os resultados são pareados e comparados por testes estatísticos pareados (Seção IV-H).

B. Conjunto de dados

Os experimentos utilizam o conjunto de dados público DDR [1], também chamado OIA-DDR, composto por 13.673 imagens de fundo de olho de 9.598 pacientes, coletadas em 147 hospitais de 23 províncias da China; destas, apenas 757 possuem anotações de detecção em nível de *bounding box*, sendo este o subconjunto empregado neste trabalho. As quatro classes consideradas são microaneurismas (MA), exsudatos duros (EX), exsudatos moles (SE) e hemorragias (HE). As imagens têm alta resolução e tamanhos variáveis (da ordem de 1088×1920 a 3456×5184 *pixels*), enquanto as lesões ocupam regiões diminutas, o que constitui a principal motivação para investigar o *slicing*. As anotações são bastante desbalanceadas, com SE presente em apenas 239 imagens e 1.293 instâncias, contra 23.659 instâncias de EX, conforme resumido na Tabela I. A densidade das microlesões e a grade de *tiles* do SAHI são ilustradas, sobre uma imagem real do DDR, na Fig. 2.

Tabela I
Distribuição das anotações de detecção do DDR (subconjunto de 757 imagens anotadas), após a deduplicação descrita na Seção IV-C.

Lesão	Imagens com a lesão	Instâncias	% instâncias
MA (microaneurismas)	570	10.380	21,7%
EX (exsudatos duros)	486	23.659	49,4%
SE (exsudatos moles)	239	1.293	2,7%
HE (hemorragias)	601	12.538	26,2%
Total	757	47.870	100%

Tabela II
Configurações experimentais avaliadas.

Config.	Treino	Inferência	Propósito
A	imagem cheia	imagem cheia	*baseline* sem *slicing*
B	imagem cheia	*sliced* (SAHI)	efeito do *slicing* só na inferência
C	*tiles* (*slicing-aided FT*)	*sliced* (SAHI)	regime completo de *slicing*

C. Conversão de anotações para o formato YOLO

O DDR fornece as *bounding boxes* oficiais em arquivos Pascal VOC (XML), organizadas nos *splits* `train`/`valid`/`test`. A conversão adotada parseia esses XML e escreve as caixas no formato YOLO (`classe cx cy w h`, com coordenadas normalizadas em $[0, 1]$), unindo os três *splits* em um único *pool* de 757 imagens, de modo que a divisão entre treino, validação e teste passa a ser feita pela validação cruzada (Seção IV-E). Verificou-se que os XML contêm caixas duplicadas exatas (fator próximo de $1{,}7\times$); aplica-se, portanto, deduplicação por caixa, resultando nas 47.870 instâncias da Tabela I. Após a conversão, as caixas foram validadas visualmente sobre uma amostra de imagens, para descartar erros de eixo ou de normalização. Na avaliação, adotou-se um lado mínimo de caixa de 2 *pixels*, o que evita áreas nulas no reagrupamento geométrico do SAHI.

D. Arquitetura de experimentos

Para isolar o efeito do *slicing*, três configurações são avaliadas sob o mesmo protocolo, conforme a Tabela II.

A configuração A é o *baseline* (sem *slicing*); a B isola o efeito do SAHI aplicado apenas na inferência, sobre o *mesmo* modelo treinado em imagem completa; e a C corresponde ao regime completo, em que o modelo também é treinado sobre *tiles*. As Configs. A e B derivam de um *único* treino por *fold*, avaliado de duas formas (imagem cheia e SAHI), o que torna a comparação A vs. B um teste exato do efeito da inferência fracionada.

E. Validação cruzada

Adota-se validação cruzada repetida e estratificada, com a imagem como unidade de divisão (as 757 anotadas), de modo que uma mesma imagem nunca apareça em mais de um

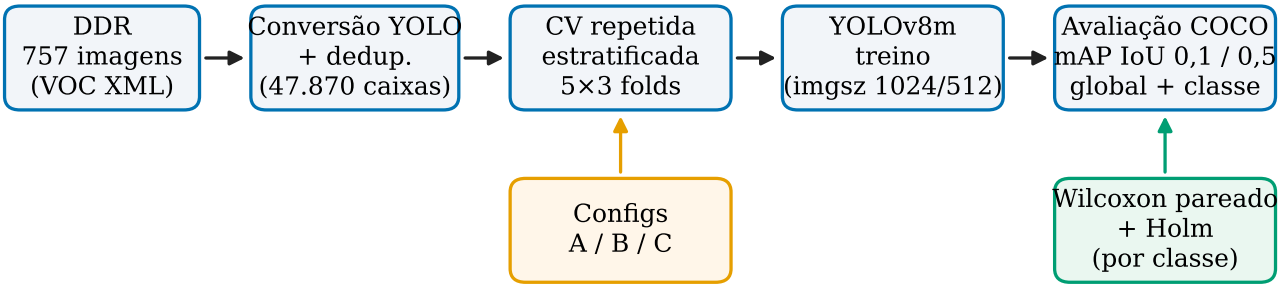

Figura 1. Visão geral do *pipeline* proposto: conversão das anotações VOC do DDR para o formato YOLO (com deduplicação), validação cruzada repetida e estratificada por lesão, treino do YOLOv8m, avaliação COCO (mAP a IoU 0,1 e 0,5, global e por classe) e teste estatístico pareado. As três configurações (A/B/C) compartilham os mesmos *folds*.

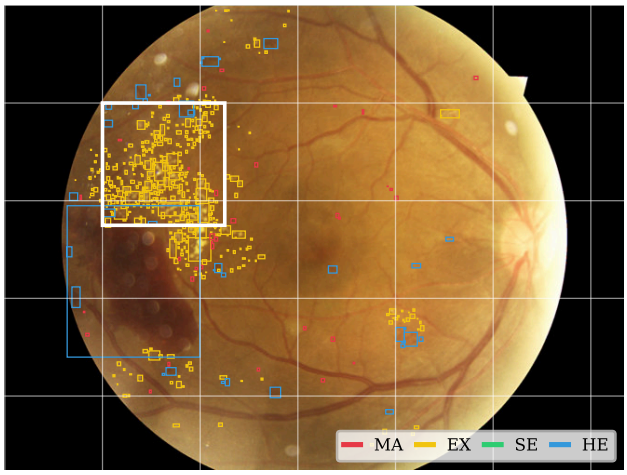

Figura 2. Imagem do DDR com as *bounding boxes* do *Ground Truth* (cores por classe) e a grade de *tiles* do SAHI (512 × 512, sobreposição 0,2); em destaque, um *tile*. A alta densidade de microlesões diminutas, muitas menores que a espessura da linha das caixas, motiva a inferência assistida por fracionamento.

subconjunto, evitando vazamento de dados. Como o DDR não disponibiliza identificadores de paciente para o subconjunto anotado, a partição é por imagem, não por paciente: imagens de um mesmo paciente podem, em princípio, ocorrer em *folds* distintos. Estimativas de partição única são instáveis em conjuntos pequenos, e a repetição reduz essa variância ao promediar múltiplas partições [20], [21]; no próprio DDR, Pereira *et al.* [7] reportam diferença de 0,16 de mAP entre validação e teste para o mesmo modelo, magnitude superior a qualquer efeito que se pretenda medir entre configurações.

Utiliza-se `RepeatedMultilabelStratifiedKFold` (5 *folds* × 3 repetições = 15 avaliações), estratificado pelo vetor binário de presença de lesão (tem MA / tem EX / tem SE / tem HE) de cada imagem [22]. Essa estratégia é essencial dado o desbalanceamento, sobretudo para SE, presente em 239 das 757 imagens: sob partição aleatória, os *folds* teriam contagens díspares dessa classe, inflando a variância de seu AP. Em cada *fold* externo, o conjunto de treino é novamente dividido de forma estratificada, reservando-se 80% para o ajuste dos pesos e 20% para a validação interna do *early-stopping*.

Como detector, hiperparâmetros (Tabela III), *seed*, *folds* e protocolo de avaliação são compartilhados, qualquer diferença entre A, B e C é atribuível ao fracionamento. O desempenho é reportado como média ± desvio-padrão do mAP entre os 15 *folds*.

F. Modelos e hiperparâmetros

O detector YOLOv8m foi implementado com a biblioteca `ultralytics` e o *slicing* com a biblioteca `sahi`, em Python. No *baseline* (Configs. A/B), as imagens são processadas em resolução elevada (lado maior redimensionado para 1024), a fim de preservar as lesões pequenas; nas inferências com SAHI, utilizam-se *tiles* de 512 × 512 com sobreposição de 0,2. Na Config. C, o modelo é treinado diretamente sobre *tiles* de 512 *px*, com *batch* maior, dado o menor consumo de memória por *tile*; treino e validação interna operam no domínio de *tiles*, para que o *early-stopping* reflita o mesmo domínio da inferência SAHI. Para preservar a morfologia das microlesões, emprega-se aumento de dados moderado e desativa-se o *mosaic*, que tende a prejudicar objetos minúsculos. A Tabela III lista os hiperparâmetros finais.

G. Métricas e protocolo de avaliação

Para comparar os modelos utiliza-se a *Intersection over Union* (IoU), que mede a sobreposição entre a *bounding box* predita e a do *Ground Truth*, conforme a Eq. (1):

$$\mathrm{IoU} = \frac{\mathrm{Area}\,(gt \cap pd)}{\mathrm{Area}\,(gt \cup pd)}, \tag{1}$$

em que gt é a caixa do *Ground Truth* e pd a caixa predita. A *Average Precision* (AP) é a área sob a curva de Precisão×Revocação de cada classe, e o *mean Average Precision* (mAP), a média das AP entre as classes, conforme a Eq. (2):

Tabela III
HIPERPARÂMETROS FIXOS (IDÊNTICOS ENTRE CONFIGURAÇÕES, SALVO OS *overrides* DE TREINO DA CONFIG. C).

Parâmetro	**Valor**
Detector / variante	YOLOv8m (`ultralytics`)
Otimizador / lr_0	SGD / 0,01
Resolução de treino (A/B)	1024 (lado maior)
Resolução de treino (C)	*tiles* 512
Batch (A/B | C)	8 | 16
Épocas (teto) / *patience*	100 / 20 (*early-stopping*)
Mosaic	desativado
SAHI *tile* / *overlap*	512×512 / 0,2
SAHI pós-proc. / *conf*	*GREEDYNMM* / 0,1
Seed	42

Tabela IV
DESEMPENHO GLOBAL (MAP, MÉDIA $\pm$ DESVIO ENTRE OS 15 *folds*) E TESTES PAREADOS. p_{Holm}: WILCOXON COM CORREÇÃO DE HOLM; r: TAMANHO DE EFEITO; p_{NB}: TESTE-T CORRIGIDO DE NADEAU–BENGIO. MELHOR VALOR EM **NEGRITO**.

Config.	**mAP@0,1**	**mAP@0,5**
A (*baseline*)	**0,300 $\pm$ 0,019**	**0,189 $\pm$ 0,015**
B (SAHI na inferência)	0,245 $\pm$ 0,033	0,095 $\pm$ 0,019
C (SAHI + *fine-tuning*)	0,290 $\pm$ 0,016	0,159 $\pm$ 0,012
Comparações pareadas (mAP@0,1):		
A vs. B	A>B; p_{Holm}=0,002, r=0,88, p_{NB}=0,001	
A vs. C	A>C; p_{Holm}=0,005, r=0,72, p_{NB}=0,125	
B vs. C	C>B; p_{Holm}=0,002, r=0,87, p_{NB}=0,013	

$$\mathrm{mAP} = \frac{1}{N}\sum_{i=1}^{N} \mathrm{AP}_i. \tag{2}$$

O mAP é calculado com o avaliador COCO (`pycocotools`) a IoU 0,1, compatível com o protocolo de Li *et al.* [1], e também a IoU 0,5, de forma global e por classe, sempre sobre o mesmo conjunto de teste de cada *fold*; dado o grande número de lesões por imagem, o limite de detecções por imagem foi ampliado (*maxDets* até 1000). Classes ausentes do *Ground Truth* de um *fold* são excluídas da média daquele *fold*, seguindo o padrão COCO.

H. Análise estatística

As três configurações são comparadas duas a duas, nos pares A vs. B, A vs. C e B vs. C, sob a hipótese nula bilateral de ausência de diferença de desempenho. A unidade de observação é o *fold*: como as três configurações são avaliadas exatamente sobre os mesmos 15 conjuntos de teste, cada uma produz um vetor de 15 valores, pareados elemento a elemento. Para um par (X, Y), define-se o vetor de diferenças

$$d_i = m_i^X - m_i^Y, \qquad i = 1, \ldots, 15, \tag{3}$$

em que m_i é a métrica obtida no *fold* i. O pareamento elimina a variabilidade atribuível à partição, isolando o efeito do *slicing*. O procedimento é aplicado ao mAP global (três comparações) e ao AP de cada lesão (doze comparações: 3 pares $\times$ 4 classes), sempre sobre o desempenho a IoU 0,1.

Cada vetor de diferenças é submetido a dois testes complementares. O primeiro é o de Wilcoxon pareado (*signed-rank*) [23], escolhido por não pressupor normalidade das diferenças, suposição pouco verificável com apenas 15 observações; dele se reporta o valor-p e o tamanho de efeito $r = |Z|/\sqrt{N}$, com $N = 15$. Esse teste, contudo, pressupõe observações independentes, condição que a validação cruzada repetida não satisfaz, pois *folds* de repetições distintas compartilham as mesmas imagens. Tal dependência subestima a variância das diferenças e tende a produzir valores-p artificialmente baixos, e não existe variante de Wilcoxon que a corrija. Aplica-se, por isso, um segundo teste: o teste-t pareado com a correção de variância de Nadeau–Bengio [24], que adiciona ao erro-padrão um termo proporcional à razão $n_{\mathrm{teste}}/n_{\mathrm{treino}} = 0{,}25$ de cada *fold*.

Os testes cumprem papéis distintos: Wilcoxon dispensa a normalidade, mas ignora a dependência entre *folds*; Nadeau–Bengio corrige essa dependência, ao custo de assumir diferenças aproximadamente normais. Considera-se robusta apenas a diferença em que ambos concordam; quando divergem, adota-se a conclusão do teste mais conservador, situação que ocorre em A vs. C (Seção V-A). Como análise complementar, dado o poder estatístico limitado de $n = 15$, a comparação é repetida tendo a imagem como unidade de observação: o AP é calculado por imagem e, como cada uma das 757 compõe o conjunto de teste exatamente uma vez por repetição, obtêm-se 757 observações pareadas, submetidas ao mesmo teste de Wilcoxon. Por fim, aplica-se a correção de Holm–Bonferroni separadamente em cada família de hipóteses, com $\alpha = 0{,}05$, denotando-se por p_{Holm} o valor-p corrigido.

V. RESULTADOS E DISCUSSÃO

A. Desempenho global

O desempenho global das três configurações, expresso pelo mAP médio entre os 15 *folds*, é apresentado na Tabela IV e na Fig. 3. O *baseline* em imagem completa (Config. A) obteve os maiores valores em ambos os limiares. A aplicação do SAHI restrita à inferência (Config. B) resultou em desempenho inferior, contrariando os ganhos reportados na literatura para arquiteturas anteriores [7], [12]. O regime completo, com ajuste fino no domínio de *tiles* (Config. C), atenuou essa degradação e aproximou-se do *baseline* a IoU 0,1, embora permanecesse abaixo dele a IoU 0,5.

Os testes pareados sustentam essa leitura. A diferença entre as Configs. A e B é significativa e com tamanho de efeito elevado ($p_{\mathrm{Holm}} = 0{,}002$; $r = 0{,}88$), resultado corroborado pela análise complementar por imagem ($p_{\mathrm{Holm}} = 0{,}003$) e pelo teste de Nadeau–Bengio ($p_{\mathrm{NB}} = 0{,}001$): a inferência fracionada, aplicada isoladamente sobre um modelo treinado em imagem completa, degrada o desempenho global. A diferença entre as Configs. B e C também é significativa ($p_{\mathrm{Holm}} = 0{,}002$; $p_{\mathrm{NB}} = 0{,}013$), o que evidencia que o ajuste fino no domínio de *tiles* é condição necessária para compensar essa perda.

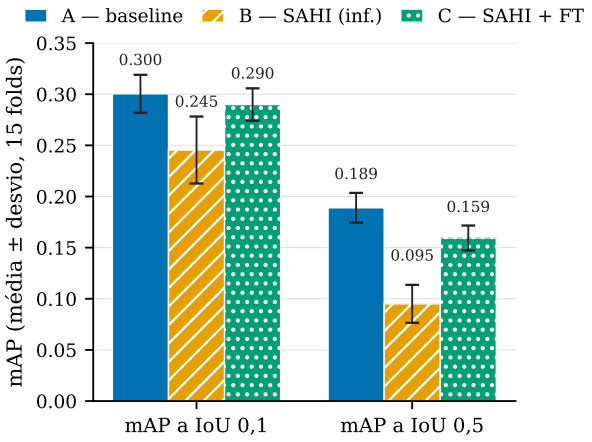

Figura 3. mAP global por configuração a IoU 0,1 e 0,5 (média ± desvio entre os 15 *folds*).

Já a comparação entre as Configs. A e C depende do teste adotado: a diferença é significativa sob Wilcoxon ($p_{\text{Holm}} = 0{,}005$), mas não sob Nadeau–Bengio ($p_{\text{NB}} = 0{,}125$), que ajusta a variância para a não-independência entre os *folds*. Pelo critério mais conservador, não há evidência suficiente para rejeitar a hipótese de ausência de diferença de mAP global entre elas. O *slicing* não produziu, portanto, nesta configuração experimental, o ganho global descrito em trabalhos com gerações anteriores de YOLO [5], [7].

B. Desempenho por classe

A estratificação por tipo de lesão revela comportamento distinto do agregado: os efeitos do *slicing* têm sinal e magnitude dependentes da classe, sendo positivos nas lesões de menor extensão espacial, conforme a Tabela V e as Figs. 4 e 5.

Os microaneurismas constituem a única classe em que uma configuração com *slicing* supera o *baseline* de forma estatisticamente significativa. A Config. C elevou o AP@0,1 de 0,177 para 0,216, incremento absoluto de 0,039 e relativo de 22% ($p_{\text{Holm}} = 0{,}009$; $r = 0{,}82$), e, a IoU 0,5, de 0,059 para 0,111. A Config. B também superou o *baseline* nessa classe (0,189 a IoU 0,1), sem atingir significância após a correção de Holm–Bonferroni. O efeito é consistente entre partições: a Config. C supera o *baseline* em 13 dos 15 *folds* (Fig. 6).

Nos exsudatos duros, o maior AP@0,1 coube à Config. B (0,404 contra 0,348 do *baseline*; $p_{\text{Holm}} = 0{,}008$); a IoU 0,5, porém, o *baseline* mantém-se superior (0,181 contra 0,108), o que sugere que o fracionamento aumenta a taxa de detecção dessa classe em detrimento da precisão de localização das caixas. Exsudatos moles e hemorragias apresentaram redução de AP sob ambas as configurações com *slicing*, comportamento analisado na Seção V-C.

C. O trade-off do slicing

A contrapartida do ganho nos microaneurismas é a perda nas lesões maiores e difusas. Exsudatos moles (SE) e hemorragias (HE), que frequentemente excedem ou cruzam as dimensões de um *tile* de 512 *px*, são fragmentados, e o reagrupamento por pós-processamento não os reconstrói integralmente. A inspeção qualitativa das predições corrobora o mecanismo, com caixas espúrias e fragmentadas concentradas nas junções dos *tiles*. O efeito é acentuado na Config. B: o AP@0,1 de SE cai de 0,354 para 0,178 ($\Delta = -0{,}176$) e o de HE cai 0,112, o que explica isoladamente a queda do mAP global dessa configuração. O ajuste fino da Config. C atenua o dano (SE recupera para 0,329; HE para 0,255), pois o modelo aprende a operar no domínio de *tiles*, mas ainda não iguala o *baseline* nessas classes (Fig. 5).

Esse *trade-off* explica por que o SAHI não melhora o mAP *global*: sendo uma média entre classes, o mAP dilui o ganho nos microaneurismas na perda em SE e HE. Na prática, o valor do *slicing* depende da métrica priorizada: quando o AP de microaneurismas é o critério de interesse, a Config. C supera o *baseline*; para uma detecção equilibrada das quatro classes, o *baseline* em alta resolução é mais robusto, um achado metodológico, não uma recomendação clínica, que exigiria validação adicional.

Em análise exploratória *post-hoc* (fora do protocolo predefinido e sem teste estatístico), a reavaliação dos pesos da Config. C com fusão IOU (em vez da IOS, padrão do SAHI) no *GREEDYNMM* eleva o mAP@0,5 de 0,159 para 0,183, próximo do *baseline* (0,189), preservando o AP@0,5 de MA ($\approx$ 0,11), indício de que a fusão imperfeita de caixas nas junções, mais que erros de detecção, responde por parte da perda a IoU alto.

O *slicing* também tem custo de inferência: cronometrado o teste de um *fold* (145 imagens; em média 34,9 *tiles* por imagem a 512/0,2), a Config. B custa 11,4× e a C 5,0× o *baseline*; a diferença entre ambas decorre da resolução de entrada herdada do treino (1024 vs. 512 *px*). Como tempos absolutos dependem do *hardware*, importam as razões: um sobrecusto de cerca de uma ordem de grandeza, a ponderar na viabilidade de rastreamento em larga escala.

D. Comparação com a literatura

Os resultados são posicionados frente à literatura do DDR na Tabela VI, com todos os valores a IoU 0,5. A comparação direta exige cautela: os trabalhos anteriores reportam um único

Tabela V
AP POR CLASSE (MÉDIA ENTRE OS 15 *folds*), A IOU 0,1 E 0,5. EM **NEGRITO**, O MELHOR VALOR POR CLASSE/IOU. †: DIFERENÇA SIGNIFICATIVA VS. A ($p_{\text{Holm}} < 0{,}05$, WILCOXON NA FAMÍLIA POR CLASSE). OS TESTES DE SIGNIFICÂNCIA FORAM CONDUZIDOS SOBRE O AP A IOU 0,1.

IoU	Config.	MA	EX	SE	HE
0,1	A	0,177	0,348	**0,354**	**0,323**
	B	0,189	**0,404**†	0,178†	0,210†
	C	**0,216**†	0,360	0,329†	0,255†
0,5	A	0,059	**0,181**	**0,308**	**0,208**
	B	0,032	0,108	0,150	0,091
	C	**0,111**	0,132	0,258	0,137

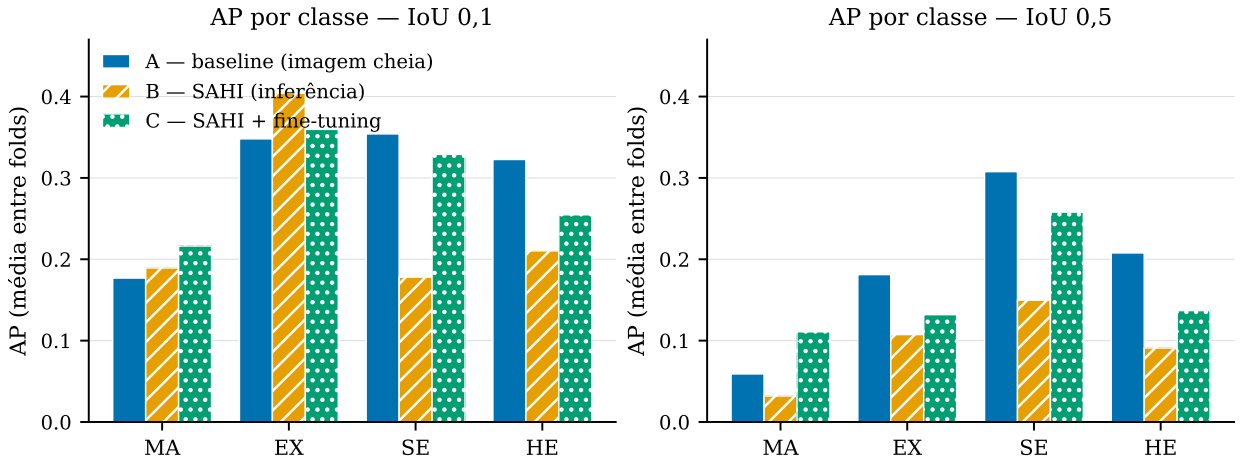

Figura 4. AP por classe de lesão (média entre os 15 *folds*), a IoU 0,1 (esquerda) e 0,5 (direita). O *slicing* beneficia os microaneurismas (MA) e, na inferência, os exsudatos duros (EX), mas prejudica os exsudatos moles (SE) e as hemorragias (HE), que são lesões maiores e mais difusas.

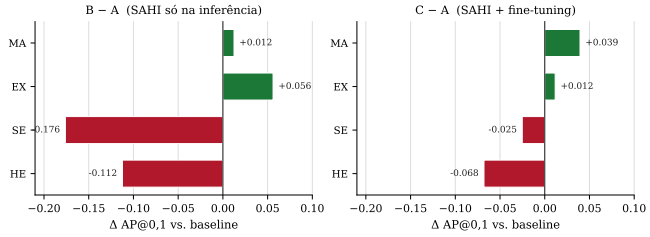

Figura 5. Ganho de AP@0,1 de cada configuração de *slicing* em relação ao *baseline* (A), por classe. Verde: ganho; vermelho: perda.

Tabela VI
COMPARAÇÃO COM A LITERATURA NO DDR (MAP A IOU 0,5). "VAL."/"TESTE" INDICAM O SUBCONJUNTO; "CV" INDICA VALIDAÇÃO CRUZADA REPETIDA (MÉDIA DE 15 *folds*). PROTOCOLOS, RESOLUÇÕES E ARTIFÍCIOS DE TREINO DIFEREM ENTRE ESTUDOS E NÃO SÃO DIRETAMENTE COMPARÁVEIS.

Trabalho / método	**Protocolo**	**mAP@0,5**
Li *et al.* [1] (SSD/YOLO)	teste	$< 0{,}01$
Alyoubi *et al.* [18] (CNN512+YOLOv3)	n. i.	0,216
Santos *et al.* [5] (YOLOv5+*Tiling*)	val.	0,263
Santos *et al.* [5] (YOLOv5+*Tiling*)	teste	0,154
Pereira *et al.* [7] (YOLOR-CSP+SAHI)	val.	0,381
Pereira *et al.* [7] (YOLOR-CSP+SAHI)	teste	0,222
Este trabalho, A (*baseline*)	CV	0,189
Este trabalho, C (SAHI+FT)	CV	0,159
Este trabalho, A (*split* oficial)	teste	0,113

split (tipicamente a *validação*), enquanto aqui se reporta a média de uma validação cruzada repetida, protocolo mais conservador. Para uma comparação justa, avaliou-se também a Config. A no *split* oficial do DDR (383/149/225), o mesmo usado por [5], [7]: nele o *baseline* obtém mAP@0,5 de 0,113, valor coerente com a faixa de teste dos trabalhos correlatos (0,154 e 0,222).

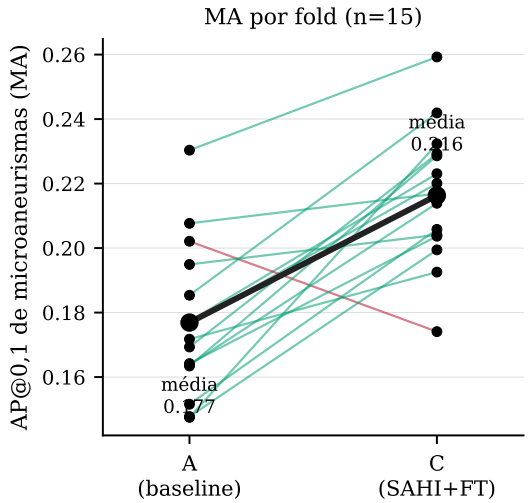

Figura 6. AP@0,1 de microaneurismas (MA), por *fold* ($n = 15$): *baseline* (A) vs. Config. C. As linhas verdes indicam *folds* em que a Config. C supera o *baseline* (13 de 15); a linha preta liga as médias (0,177 → 0,216).

Não se pretende, aqui, competir por desempenho absoluto: os métodos da literatura empregam artifícios adicionais (recorte do fundo, pré-treino em COCO, milhares de épocas, ajuste de âncoras, aumento de dados agressivo) que este estudo deliberadamente evita para *isolar* o efeito do *slicing*. O ponto é metodológico: a diferença entre validação e teste observada em [7] (0,381 vs. 0,222) reforça que números de *split* único devem ser lidos com cautela, e que a validação cruzada oferece estimativa mais fiel do desempenho esperado.

E. Limitações

Este estudo apresenta limitações. Primeiro, os hiperparâmetros foram fixados (sem busca), privilegiando a comparabilidade sobre o desempenho absoluto; uma busca dedicada poderia alterar as magnitudes, mas dificilmente inverteria o

trade-off por classe, de natureza geométrica. Segundo, avaliou-se um único detector (YOLOv8m) e uma única configuração de fracionamento (512/0,2); *tiles* menores poderiam favorecer os microaneurismas ao custo de agravar a fragmentação, e a extensão do *trade-off* a outras arquiteturas (YOLO recentes, *Transformers*) permanece em aberto. Terceiro, a avaliação restringe-se ao DDR, com generalização a outras bases, equipamentos e populações (por exemplo, IDRiD [25]) a verificar; e, sem identificadores de paciente, a partição é por imagem (Seção IV-E). Por fim, o escopo é a acurácia de detecção: desfechos em nível de paciente (graduação de RD, sensibilidade de triagem) não foram avaliados.

VI. Considerações Finais

Este trabalho avaliou, de forma controlada e estratificada por lesão, se a inferência assistida por SAHI melhora a detecção de lesões de RD no DDR quando aplicada a um detector YOLO moderno (YOLOv8m). A resposta é matizada. *Globalmente*, o SAHI não melhora o mAP: a inferência fracionada sobre um modelo treinado em imagem cheia (Config. B) degrada significativamente o desempenho, e mesmo o regime completo com ajuste fino (Config. C) não apresenta diferença detectável em relação ao *baseline*. *Por classe*, entretanto, o *slicing* cumpre sua promessa exatamente na lesão mais precoce e crítica: a Config. C melhora de forma significativa e consistente a detecção de microaneurismas, ao custo de piora nos exsudatos moles e nas hemorragias, que o fracionamento tende a fragmentar, *trade-off* que o mAP, por ser uma média entre classes, oculta.

A principal mensagem é que, em detectores YOLO modernos operando em alta resolução, o benefício do SAHI é *condicional*: localizado nas menores lesões e dependente de ajuste fino em *tiles*, e não o ganho global sugerido por trabalhos com arquiteturas anteriores. O resultado deve ser lido como evidência metodológica sobre o detector no DDR; uma recomendação clínica exigiria validação externa e desfechos em nível de paciente, fora do escopo deste estudo.

Como trabalhos futuros, pretende-se: (i) varrer o tamanho de *tile* e a sobreposição, buscando o equilíbrio do *trade-off*; (ii) explorar estratégias de fusão de caixas nas bordas dos *tiles* para reduzir a perda em lesões grandes; (iii) validar *cross-dataset*, treinando no DDR e avaliando em IDRiD [25] e em bases brasileiras; (iv) contrastar o *slicing* com arquiteturas mais recentes de YOLO e com *Transformers* de detecção; (v) aprofundar a análise dos modos de falha com técnicas de explicabilidade; e (vi) integrar a detecção a um *pipeline* de triagem com desfechos em nível de paciente.

***Abstract*—Robotic devices, such as exoskeletons and robotic arms, have proven instrumental in upper limb rehabilitation and assistance in activities of daily living. These devices can be controlled by electroencephalographic (EEG) signals that detect the user's movement intention. However, EEG signals are susceptible to noise, positioning artifacts, and interference, posing significant challenges for real-time classification. This work presents the development and validation of an EEG-based classification pipeline for bidirectional (left and right) movement intention detection in robotic arm reaching tasks. The proposed system employs Riemannian geometry-based feature extraction combined with Principal Component Analysis (PCA) and Linear Discriminant Analysis (LDA) to process and classify EEG signals into left and right movement intentions. The pipeline was trained and validated on data acquired from five subjects using cross-validation, achieving a mean accuracy of approximately 79% over all subjects, with high stability between classes. These results show a performance comparable to existing literature while requiring fewer computational resources and EEG channels. Future work will focus on expanding the subject pool, increasing the number of movement classes, integrating complementary sensing modalities such as electromyography (EMG) and Inertial Measurement Units (IMUs), and validating the system under true real-time conditions.**

***Index Terms*—Robotic devices, Electroencephalography, BCI, Machine learning**

I. Introduction

Robotic devices, such as exoskeletons and robotic arms, have been proven to be useful in upper limb rehabilitation and assistance in activities of daily living (ADL) [1]. A significant advantage of these systems is the ability to monitor user electrophysiological and biomechanical variables that can be used to infer motor intentions. Detecting the user's intention is paramount for the robot to assist the movement seamlessly and smoothly. In this context, electroencephalographic (EEG) signals are widely used, as they capture the electrical brain activity preceding physical movement [2], [3].

However, the interfaces between the human body and assistive devices still present challenges. The major obstacle facing assistive robotic devices (ARDs) is how to control these devices without cognitively overloading the user. The control interface must be intuitive, allowing users to operate ARDs naturally [4]. For robotic arms, which are versatile machines capable of assisting individuals lacking motor control, achieving seamless coordination requires robust control and real-time classification algorithms.

One of the most frequently performed ADLs is the task of grasping an object. This task requires coordination among multiple joints, along with anticipatory planning by the central nervous system [5]. This complexity becomes a problem in exoskeleton control, as signals from several different channels must be processed simultaneously [6]. Therefore, a solid technique for validating control algorithms is the use of reaching tasks, where the robotic arm must be moved to a certain target within a defined space, with its precision and speed serving as performance metrics. These tasks challenge the algorithm's ability to process multiple sources of information at the same time and produce a real-time response [7].

Although EEG-based human movement intention prediction

(MIP) is promising, its practical application is still limited by the intrinsic variability of the electroencephalographic signal and the need for complex and time-consuming calibration for each user [8], leading to challenges in real-time acquisition, detection and classification. Furthermore, the movement of electrodes during use and the susceptibility to biological artifacts can alter the characteristics of the recorded signal and negatively impact classification [9], while practical barriers — such as comfort and setup difficulty — continue to hinder continuous signal acquisition and the daily adoption of these technologies [10].

A number of systems capable of real-time EEG interpretation have been reported in the literature. For instance, Meng et al. [11] developed a non-invasive Brain-Machine Interface system that enabled individuals to control a robotic arm in three dimensions in real time, allowing the user to perform complex target-reaching tasks. Ding et al. [12] trained a neural network model capable of controlling finger movements in robotic arms, achieving an accuracy of 80% in two-finger movements, and 60% in three-finger movements.

Given the existing challenges in EEG signal processing, the present work develops a classification pipeline for bidirectional movement intention in complex target-reaching tasks. We implemented processing routines to extract key features, trained machine learning models to classify bidirectional movement intention, and validated the trained model using pre-recorded signals.

II. Methodology

A. Data Generation

The data were obtained from five subjects performing an experimental task that used a robotic arm to reach specific targets. To control the arm movement, we used a methodology developed at the University of São Paulo (USP) that employs two Inertial Measurement Units (IMUs)—one attached to the subject's forearm and another to their wrist. The IMUs were calibrated and operated by sending the real-time position of the user's arm and hand to the robotic arm, which replicated the movement. Before each task, the subject maintained a resting state for 60 seconds with their eyes open to establish a baseline, though these data were not used in the present analysis and is reserved for future work. The experiment is shown in Figure 1 and is structured as follows: The subject started in the center, and a target was shown on the monitor, the subject had to then move the arm and stop at the correct target, repeated 96 times.

The raw signal was saved in a .poly5 file - a binary data format developed by the company TMSi, for use with the REFA amplifier - which contained the data for 32 EEG channels as well as 4 EMG channels, and sampled signals at 2048 Hz. For each experiment, the data from the first 24 EEG channels according to the 10-20 system (Fp1, Fp2, Fz, FC5, FC3, FC1, FCz, FC2, FC4, FC6, C5, C3, C1, Cz, C2, C4, C6, CP5, CP3, CP1, CPz, CP2, CP4, CP6) were used. Data from 5 healthy adult subjects were obtained, each participating in one session. The protocol was approved by the university

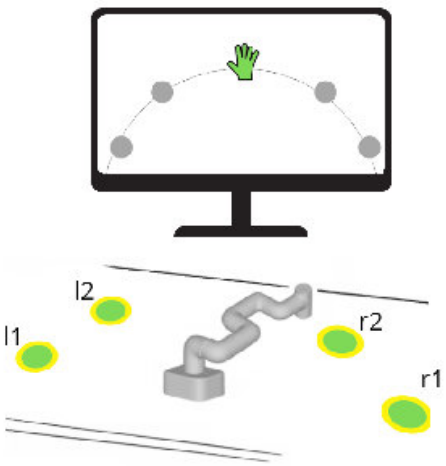

Fig. 1: Diagram of the task used in the project

Hospital Ethics Committee (CAAE: 90632625.7.0000.0076), and all participants provided written informed consent before entering the study.

B. Algorithm Development

The classification algorithm was developed in Python, using primarily Numpy, Pandas, Scikit-learn, Pyriemann, and MNE. The code can be divided into two parts: Processing and classification. The processing stage was based on extracting and cleaning the raw signal from the EEG, as well as extracting discriminative features for the classifier. The classification stage involved training the classifier on the extracted features, and evaluating its accuracy.

For noise removal, a notch filter was used to remove powerline (60 Hz) noise, in addition to a fourth-order Butterworth bandpass filter to retain frequencies in EEG range (0.5-100 Hz). Lastly, the DC component of the original signal was removed using mean subtraction, where the per-channel temporal mean was computed and subtracted from each channel independently. The filters were applied both forwards and backwards, eliminating lag. It's worth noting that for real-time implementations, causal variants of those filters will have to be used. To simplify the implementation, the preprocessing utilities provided by SciPy were used. Once the data was cleaned, the algorithm aligned the trigger onset time with the EEG capture time and the description of the cue provided to the subject. From the alignment, the algorithm extracted two-second windows, starting 0.5 seconds after the trigger, to extract the features.

With the data prepared, the Floating Sequential Forward Feature Selector (FSFFS) technique was applied to select the most important channels for the model. This technique evaluates the full feature extraction and classification pipeline on each channel individually, selecting the one that yields the highest accuracy. Next, it tests the combination of this channel with all the others in the same manner and selects the most accurate combination. After each addition, the algorithm

tries removing previously selected channels, and evaluating the cross-validated accuracy. This process is repeated until the channel selection threshold is reached, which in this project was set to 10.

The processing pipeline involved calculating the covariance matrix across the selected channels, followed by a projection of this matrix onto a tangent space on the Riemannian manifold. With the Riemannian vectors, PCA was performed to reduce its dimensions to 15, followed by a Linear Discriminant Analysis (LDA) classifier.

C. Validation

The trained models were validated using techniques such as cross-validation, with performance assessed through accuracy, recall, precision, F1 score, and confusion matrices. Cross-validation involved dividing the dataset for each subject into k equal-sized subsets using k-fold cross-validation with k = 5. The model was iteratively trained on all but one of these subsets and tested on the remaining subset. This approach allows assessment of how well the model generalizes unseen data.

To measure classification performance, the project focused on four key metrics. Accuracy represents the overall proportion of correct predictions made by the model. Recall measures the proportion of actual positive cases the model correctly identified. Precision evaluates the proportion of positive predictions the model made that were actually correct. Finally, the F1 Score serves as the harmonic mean of Precision and Recall, providing a balanced metric for the model's performance.

In order to display these metrics, a confusion matrix was used. A confusion matrix divides the data points into four cells, according to the correspondence between their true and predicted labels, creating True Positives (TP), True Negatives (TN), False Positives (FP), and False Negatives (FN). These metrics are formally defined as follows:

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN}$$

$$Recall = \frac{TP}{TP + FN}$$

$$Precision = \frac{TP}{TP + FP}$$

$$F1Score = 2 * \frac{Precision * Recall}{Precision + Recall}$$

In addition to per-class metrics, statistical methods were also employed in order to ascertain that the models were truly performing better than just chance. To evaluate whether or not the model would produce correct predictions, the binomial test was used to determine whether or not the models were predicting with an accuracy greater than chance. A model was considered above chance if the calculated p-value was below the threshold of $\alpha = 0.05$. The hypotheses considered for the binomial test were as follows, following a one-sided approach:

H_0 : $\pi \leq 0.5$:The model predicts at or below chance.

H_1 : $\pi > 0.5$:The model predicts above chance.

Because a finite number of trials allows the classifier to exceed the chance level by luck, an adjusted chance level was computed as the upper 95% confidence bound on the accuracy of a random classifier over n trials:

$$\text{Adj. Chance} = p_0 + z_{0.95}\sqrt{\frac{p_0(1-p_0)}{n}}$$

where $p_0 = 0.5$ is the chance rate and $z_{0.95} = 1.645$ is the one-sided 95% normal quantile.

Alongside the binomial test, the Wilcoxon signed-rank test was used to determine whether subjects as a group performed above chance. A one-sample Student's t-test was not chosen because the small sample size does not allow the assumption of normally distributed accuracies. The hypotheses for the Wilcoxon test were as follows, also following a one-sided approach:

H_0 : The distribution of the subject accuracies are centered at chance: Subject accuracies are symmetric around chance.

H_1 : The distribution of the subject accuracies are shifted toward positive values: subjects as a group perform above chance.

III. Results

Having processed data from 5 different subjects, the results from their respective models are as follows: Figures 2 to 6 contain the confusion matrices for subjects 1 through 5, respectively. Table I complements that with the computed metrics for all subjects, as well as averages for each metric. Table II and figure 7 contain data on which of the 24 available channels the classifier selected for each subject, according to the 10-20 system.

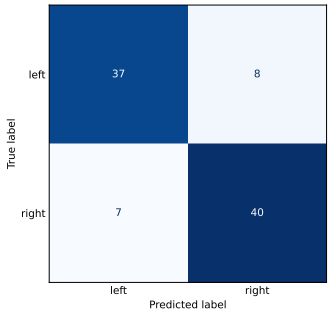

Fig. 2: Confusion Matrix for Subject 1

TABLE I: Classification Reports for All Subjects

		Left			Right		
Subject	**Acc.**	**P**	**R**	**F1**	**P**	**R**	**F1**
Subject 1	0.8370	0.8409	0.8222	0.8315	0.8333	0.8511	0.8421
Subject 2	0.8018	0.8200	0.7593	0.7885	0.7869	0.8421	0.8136
Subject 3	0.7789	0.7955	0.7447	0.7692	0.7647	0.8125	0.7879
Subject 4	0.7553	0.7556	0.7391	0.7473	0.7551	0.7708	0.7629
Subject 5	0.7849	0.7500	0.8478	0.7959	0.8293	0.7234	0.7727
Average	**0.7916**	**0.7924**	**0.7826**	**0.7865**	**0.7939**	**0.8000**	**0.7958**

P: Precision; R: Recall; F1: F1-Score; Acc.: Accuracy

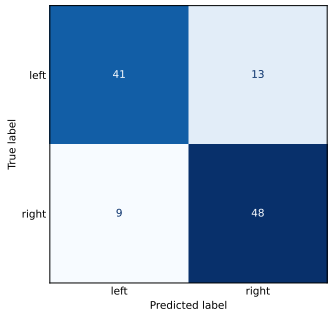

Fig. 3: Confusion Matrix for Subject 2

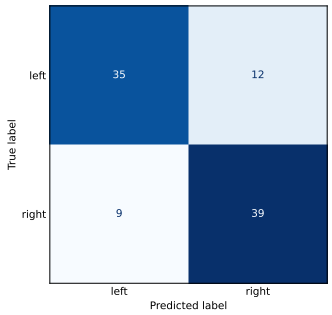

Fig. 4: Confusion Matrix for Subject 3

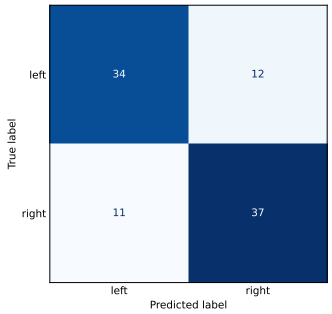

Fig. 5: Confusion Matrix for Subject 4

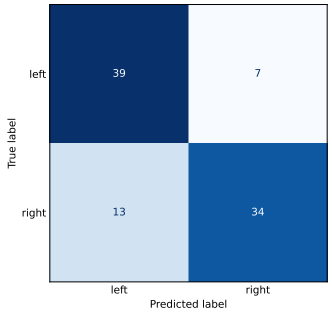

Fig. 6: Confusion Matrix for Subject 5

The matrices and Table I show that the models from all subjects behaved similarly, achieving similar levels of accuracy, precision and recall for both left and right classes, with a mean accuracy of 79%. This is also supported by the matrices themselves, which show a clear line along the main diagonal, indicating that the model made more correct predictions than incorrect ones. The one small exception is Subject 5 (Figure 6), which shows a notable spike of erroneous left predictions, resulting in the lowest left precision of all models (75%). The best performing model, Subject 1 (Figure 2), made only 15 incorrect predictions, having the highest-performing metrics out of all tested models.

TABLE II: FSFFS-Selected EEG Channels per Subject

Subject	**Selected Channels**
Subject 1	FC6, C2, CP5, Fp1, FC3, C3, FCz, FC4, CP1, C6
Subject 2	FC5, C2, C6, FC3, Fp1, CP4, Fp2, FC4, FC6, CP6
Subject 3	FC6, FC4, FC3, FC5, FC1, FCz, Cz, Fz, C1, CP1
Subject 4	CP3, FC5, C2, Fp1, Cz, FC2, C3, FC4, Fp2, FC6
Subject 5	Fz, FC6, FC5, C1, CP5, FCz, CPz, FC3, CP4, Cz

Channels listed in FSFFS selection order. All 24 available electrodes spanned Fp1–CP6 in the 10–20 system.

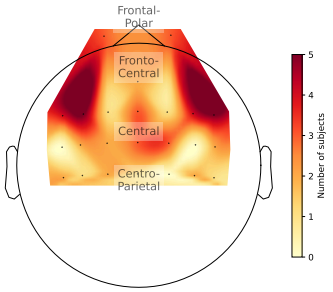

Fig. 7: Channel Selection Frequency Across Subjects

Table II shows that most models selected similar channels. Channel FC6 appears across all subjects and is frequently the first channel FSFFS selected, with recurring presence of channels C2, C3, and CP1. Figure 7 supports this, showing strong selection in the frontocentral region, with some centroparietal activity. Pre-frontal channels also show moderate selection. Temporal and occipital electrodes were not included in the 24-channel setup and thus are absent from the map.

TABLE III: Per subject adjusted chance level and binomial test p-value.

Subject	n	Adj. chance	p
Subject 1	92	0.5857	1.6×10^{-11}
Subject 2	111	0.5781	4.8×10^{-11}
Subject 3	95	0.5844	2.1×10^{-8}
Subject 4	94	0.5848	3.6×10^{-7}
Subject 5	93	0.5853	1.5×10^{-8}
Average	**97**	**0.58366**	

TABLE IV: Inter-subject summary of cross-validated accuracy.

Statistic	Value
Subjects (N)	5
Mean accuracy	0.7916
SD	0.0303
SEM	0.0136
95% CI	[0.7539, 0.8293]
Median accuracy	0.7849
Range	0.7553–0.8370
Wilcoxon W	15
Wilcoxon p (one-sided)	0.031

Table III shows the results of the binomial tests applied to the models, in which they all perform above chance ($p < 0.05$). Table III also shows the adjusted chance threshold for a given subject's model, showing that all models reach accuracies higher than those adjusted by the sample sizes. Table IV shows the per-subject variation, with a standard deviation of 3.0% and standard error of the mean of 1.4%. Table IV also shows the results of the Wilcoxon test, which returned the smallest possible p value for 5 subjects: 0.031, meaning that the group performs above chance.

IV. Discussion

The results demonstrate that the models have a classification precision and stability between classes consistent with what would be required for user intention and control of assistive devices. The models were able to correctly classify a movement across most trials, with little bias towards any given class. Furthermore, the results indicate that it is possible to attain high precision in EEG processing without relying on resource-intensive filtering like Laplacian filters or Independent Component Analysis (ICA).

In addition, the statistical reports also confirm the results shown by Table I. The low probabilities calculated by the binomial test show that the chance of models reaching those accuracies by luck is extremely low, which means that there must be some pattern that the model is correctly picking up on, and predicting. This is further reinforced by the adjusted chance values, which show that every model still performs above chance against the upper 95% bound.

The inter-subject metrics tell a similar story. A low standard deviation alongside a low standard error of the mean show the models don't diverge too much from the mean, and stay consistent in their predictions. The Wilcoxon test also helped prove this, as all 5 subjects had positive signed differences, resulting in a W value of 15, and the lowest possible value for p: 0.031. This means that there is significant evidence at $\alpha = 0.05$ against the per-subject accuracies being symmetrically distributed about the chance level.

Furthermore, the channels selected by the models align with previous results reported in the literature. The frontocentral and central regions are established as sites for motor-related cortical activity [13], and the channels chosen by the models were, for the most part, all part of these areas. The exceptions are part of the centro-parietal region and the frontal polar, in which the former helps to integrate somatosensory stimuli with motor signals [14], and the latter related to visual processing [15]. It's worth noting that frontal polar channels have also been related to eye blinking artifacts, which could be impacting the model's performance.

The classification accuracies achieved are also consistent with comparable work in the literature. For instance, Ding et al. [12] also developed a model capable of decoding movements using EEG signals. Their model was also capable of decoding more precise movements, such as individual fingers, in real time. However, their model differed significantly from ours. They used a deep neural network as their classifier, trained on a larger cohort of 21 healthy adult subjects. Our model achieved similar results, using a less computationally expensive approach and fewer subjects, albeit for less precise intention monitoring.

Meng et al. [11] also developed an EEG classifier for a robotic arm, employing an autoregressive model trained on data from 13 healthy individuals across 62 channels. They were also successful in using their model to drive the arm in reaching tasks, achieving accuracies of around 80%. Our model uses far fewer channels to classify movements, while still maintaining comparable accuracy.

However, this processing pipeline was only tested with 5 different subjects, all with comparable characteristics, in a controlled environment. This means that while our model performs well under controlled testing conditions, it might not achieve similar results when deployed in real-time conditions. This could be attributed to several factors inherent to real-time use — such as signal latency, data loss, subject movement, and environmental noise — that do not affect pre-recorded signals.

Furthermore, the small sample size means that this pipeline was not tested on a sufficiently diverse population. While the model performed well on the limited subset evaluated, it might not generalize well to people of a different ethnicity, geographical location, or age. Additionally, the model's classification was binary, limited to distinguishing left and right movements.

The models proposed by Meng et al. [11] and Ding et al. [12] incorporated a greater number of movement classes, making them more useful in real-world applications. While binary classification served as a strong proof of concept, expanding the number of classes is necessary for broader clinical applicability.

Therefore, the next steps of this research project are to increase the number of movement classes, to broaden the range of movements the classifier can analyze, and to move toward a model capable of continuous movement decoding. This will create a more robust model and increase its usefulness in real-world scenarios.

Real-time deployment remains the most immediate challenge. This will require measuring the latency and response time in each step of the pipeline and developing functionality for real-time monitoring and data delivery. This would allow the pipeline to use EEG signals to control devices like robotic arms, expanding its applicability in clinical settings.

Furthermore, to increase the reliability of the model, the subject pool would be expanded, testing the model by incorporating more diverse datasets encompassing subjects of varying ages and neurological profiles. This will assess whether our classifier can accurately and consistently detect movement patterns from a broader and more diverse population, rather than a narrow, homogeneous subgroup.

Lastly, the signals from complementary modalities such as EMG and inertial sensors could be merged with the EEG data and integrated into the model, providing the model with richer, multimodal input. While EEG captures neural activity from cortical sources, EMG captures peripheral muscle activation, providing richer contextual information than cortical signals alone. Inertial sensors would further complement both modalities by capturing kinematic data that reflects the physical execution of the intended movement, thereby enriching the spatiotemporal patterns available for model training.

V. Conclusion

This work presented a pipeline for the processing and classification of EEG signals for bidirectional movement intention detection in robotic arm reaching tasks. Using a Riemannian geometry-based feature extraction approach combined with Linear Discriminant Analysis, the proposed system achieved a mean accuracy of 79.2% across five subjects, with high stability between classes. These results can be compared with those reported in the literature [12] [11], while requiring significantly fewer computational resources, fewer EEG channels, and a smaller subject cohort for training.

Nevertheless, several limitations remain to be addressed before this pipeline can be considered for real-world deployment. The model was validated exclusively on pre-recorded data from a small, homogeneous subject pool, and its performance under true real-time conditions, where signal latency, noise, and subject movement are unavoidable, remains to be evaluated. Additionally, the binary nature of the classifier restricts its utility across broader assistive robotics scenarios.

Future work will focus on expanding the number of movement classes, implementing and benchmarking real-time signal acquisition and classification, broadening the subject pool to improve generalizability, and incorporating complementary sensing modalities such as EMG and inertial sensors. Taken together, the results presented here establish a promising foundation to help improve the efficiency of real-time EEG-based robotic control systems.

***Abstract*— Cardiovascular diseases (CVDs) remain the leading cause of death worldwide in both developed and developing countries. A significant portion of these deaths is associated with sudden cardiac death (SCD), an unexpected event frequently triggered by cardiac arrhythmias that compromise the heart's ability to pump blood effectively. The electrocardiogram (ECG) is the most widely used non-invasive tool to evaluate the functional status of the heart, as it records the electrical activity generated by the depolarization and repolarization of the cardiac chambers. The objective of this work is to propose and evaluate a parameter-optimized 1D-CNN, seeking to enable classification with reduced patient-dependency bias. To measure its true efficiency and generalization capacity, the model is contrasted with established approaches in literature. Data from 19 patients from the same database were used, with 15 assigned for training and 4 for validation. The data were digitally processed using a digital filter, subsequently segmented into 5-second intervals, and normalized. Intervals considered normal and high-risk were separated based on database annotations. The data was used to train a one-dimensional convolutional neural network with four convolutional layers, a Global Average Pooling (GAP) layer, a dense layer, and an output layer. The results yielded an overall accuracy of 96.69%, sensitivity for high-risk findings of 94.31%, sensitivity for normal findings of 97.91%, specificity of 97.39%, and an Area Under the Curve (AUC) of 0.9894. The results demonstrate the system's applicability for sudden death risk detection, serving as a potential auxiliary tool in clinical diagnosis.**

Keywords*— *One-dimensional convolutional neural networks, 1D CNN, sudden cardiac death, classification

I. Introduction

Cardiovascular diseases (CVDs) remain the leading cause of death worldwide in both developed and developing countries. Projections indicate that the global number of deaths associated with CVDs will continue to increase significantly over the coming decades, representing a critical challenge for public healthcare systems [1], [2]. A relevant portion of these deaths is associated with sudden cardiac death (SCD), an unexpected event often triggered by cardiac arrhythmias that compromise the heart's ability to pump blood effectively [3], [4]. In this scenario, early identification of abnormal cardiac rhythms is essential, not only to support clinical decision-making but also to enable preventive strategies in high-risk patients. Therefore, continuous and non-invasive monitoring of cardiac activity plays a central role in modern cardiology and biomedical engineering [5].

The electrocardiogram (ECG) is the most widely used non-invasive tool to evaluate the functional status of the heart, as it records the electrical activity generated by the depolarization and repolarization of the cardiac chambers [5], [6]. The ECG signal is quasi-periodic, and each heartbeat is characterized by a sequence of distinct waveforms — the P wave, the QRS complex, and the T wave — whose morphology, amplitude, and timing contain diagnostic information about the underlying cardiac condition [6], [7]. However, reliable identification of abnormal cardiac rhythms is challenging due to the variety of noise sources and high morphological variability of the ECG across different individuals [8], [9]. Although clinical multi-lead ECG systems provide comprehensive spatial data, single-lead ECG configurations offer a low-cost, broadly accessible alternative suitable for long-term monitoring and wearable device applications [10].

A wide range of techniques has been proposed in the literature for ECG wave delineation, feature extraction, and arrhythmia classification. Traditional approaches frequently utilize the Pan-Tompkins algorithm [11] for QRS complex detection, wavelet-based transforms for joint time-frequency representation [12],[13],[14], or classical machine learning classifiers (such as Support Vector Machines) [15]. However, these traditional processing pipelines are highly sensitive to noise and rely heavily on the precise detection of fiducial points, which often fails in real clinical environments due to inter- and intra-patient variability [8]. Recently, Deep Learning models, particularly 1D Convolutional Neural Networks (1D-CNNs), have emerged as a powerful alternative by performing automated end-to-end feature extraction directly from raw or filtered signals, bypassing the need for manual wave segmentation [16].

Wang et al. [17] proposed an early prediction method for sudden cardiac death risk using a Nested LSTM combined with wavelet denoising and phase space reconstruction to predict the continuous temporal trajectory of ECG signals. The work of Telangore et al. [18] proposed a multimodal framework for early SCD prediction, using a fusion of 1D-CNN networks combined with LSTM for raw ECG data extraction, 2D-CNN networks to analyze Hilbert-Huang spectra (HHT), and Vision Transformer (ViT) models with

self-attention applied to 2D wavelet scalograms. The same study validated its model through a 4-fold cross-validation scheme. In a recent study within time-series processing, Khan et al. [19] demonstrated the feasibility of using 1D Convolutional Neural Networks operating directly on raw ECG signals. The authors proposed a deep residual architecture (ResNet) focused on multi-class classification of five arrhythmia types from the MIT-BIH database.

In this context, the objective of this work is to develop and evaluate a highly regularized, parameter-efficient 1D-CNN for patient-independent classification of sudden cardiac death (SCD) risk using single-lead, low-resolution ECG signals. Unlike conventional deep learning approaches that suffer from overfitting or evaluate performance using patient-overlapping data splits, the proposed methodology focuses on rigorous patient-independent validation to ensure true clinical generalization. The network architecture incorporates Global Average Pooling (GAP) and biologically aligned data handling to mitigate overfitting. Signals from a public database are used to validate the proposed model, demonstrating high classification accuracy on previously unseen patients while maintaining minimal computational load, suitable for resource-constrained devices.

II. BACKGROUND

A. Electrocardiogram

While the cardiac impulse travels through the heart, electrical currents propagate to the surrounding tissues, and a small portion reaches the body surface [20]. The electrocardiogram (ECG) signal results from the polarization and depolarization of the internal cardiac chambers. Its acquisition is performed via electrodes placed on the skin surface. The ECG is an essential tool for providing information on the functional status of the heart.

Through the electrocardiogram, it is possible to identify how the cardiac impulse circulates across the muscle surface and whether contractions (systoles) and relaxations (diastoles) were performed properly. The ECG examination can inform on the physical condition of the heart muscle simply by capturing the signal via surface electrodes. The simplicity of the examination and the depth of information it provides reinforce its importance in cardiological diagnosis [22].

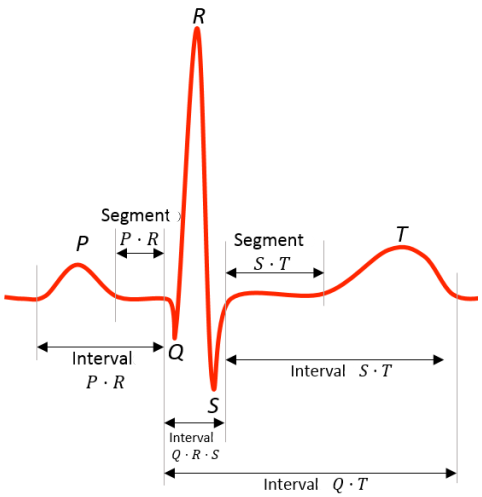

Fig. 1. Hearth waves and segments. Source: Adapted from [21].

The electrocardiogram (ECG) graphically translates the mechanical movements of the heart through three main phases (Fig. 1): the P wave records the electrical activation that causes the atria (upper chambers) to contract to expel blood; the QRS complex signals the rapid and vigorous contraction of the ventricles (lower chambers) combined with atrial relaxation; and the T wave represents the relaxation and recovery period of the ventricles. Thus, each oscillation on the graph acts as a continuous visual map of cardiac muscle exertion and rest [5].

B. Sudden Cardiac Death

Maintaining a healthy individual also requires a healthy heart. It is the electrical activity of the heart that provides a normal cardiac rhythm. Irregular electrical activities or arrhythmias are caused by cardiovascular system problems, which can accelerate the heart (tachycardia) or cause it to beat too slowly (bradycardia). Additionally, another type of arrhythmia is fibrillation, caused by a chaotic and irregular cardiac rhythm. Ventricular fibrillation and ventricular tachycardia are the main causes of sudden cardiac death, requiring immediate medical attention [23].

Sudden cardiac death refers to an abrupt loss of heart function, leading to loss of consciousness and cessation of breathing. SCD is one of the leading causes of natural death worldwide [24]. The patient must be diagnosed before reaching states requiring emergency intervention, which is possible through cardiac signal monitoring and patient risk classification.

C. Limitations of Traditional Clinical Assessment

As mentioned earlier, immediate medical intervention is required for a patient to have a chance of survival. The problem is that physicians currently attempt to predict this by measuring static intervals (such as QRS duration or QT interval). Manual measurements are accurate considering the professional's level of expertise; however, arrhythmic conditions appear silently and unexpectedly [25]. Diagnosis may be straightforward for healthcare professionals, but static measurements fail to capture the short-term dynamics of the heart. Traditional clinical assessment requires constant evaluation depending on the patient. Therefore, equipment such as a low-cost Holter monitor, which uses processing to inform physicians of cardiac events and provide quantified data along with a high SCD risk diagnosis, could assist and streamline medical practice.

D. Deep Learning Approach

A CNN, or Convolutional Neural Network, is a deep neural network model with multiple stacked layers designed to mimic neuronal activity in the human brain [26]. The CNN feature extraction process involves several hidden layers, including convolutional layers, Rectified Linear Unit (ReLU) activation functions, and pooling layers [27]. The CNN classification process includes a fully connected layer and an activation function that produces the classification output.

The typical structure of a 1D CNN is shown in Fig. 2, and it is composed of three important layers: 1D convolutional layers, pooling layers, and fully connected layers [28].

A one-dimensional convolutional neural network (1D-CNN) analyzes the signal continuously from start to finish. It does not need to measure where a wave starts or ends; the training process adjusts the weights so that the output layer correctly classifies the signal, thereby learning to correlate

subtle, dynamic morphological variations that go unnoticed by the human eye.

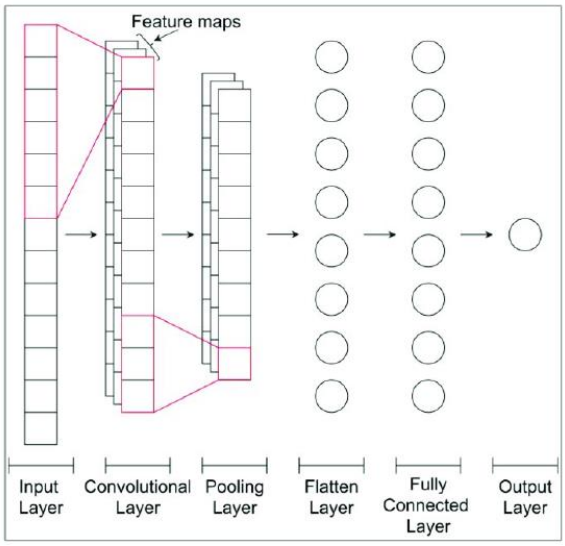

Fig. 2. One-dimensional convolutional neural network (1D CNN) architecture. Source: Guessoum at al. [28].

III. Methodology

The proposed system architecture for early sudden cardiac death risk detection was divided into digital signal preprocessing, neural network construction and training, and structural validation. For the development of this work, the Python programming language was used, along with essential libraries for algorithm development, such as PyTorch (an open-source machine learning framework) and NumPy (focused on array and matrix operations) [29].

A. Database

For algorithm development, training, and validation, the Sudden Cardiac Death Holter Database from the PhysioNet platform was used [30], [31]. The database consists of 23 long-term Holter recordings corresponding to 23 patients who exhibited sustained ventricular tachyarrhythmias, most of whom progressed to cardiac arrest during monitoring. ECG signals were acquired via two leads at a sampling rate of 250 Hz and 12-bit resolution, covering a dynamic range of ±10 mV. Recordings vary in duration between approximately 4 and 25 hours, with a predominance of recordings close to 24 hours. In this study, only one ECG lead was used — the Modified Lead II with electrodes positioned on the chest in areas of lower muscle movement — characterizing a single-lead ECG approach.

Nineteen patients were selected from the database. To prevent data leakage, a inter-patient splitting protocol was implemented. Of the 19 patients, 12 were assigned to neural network training, 3 were isolated for the validation set, used for early stopping monitoring and hyperparameter tuning during the training phase. Four patients were completely held out to form the final testing set.

Segmentation into 5-second windows was based on the annotation files (.atr and .ari) provided by the PhysioNet platform [30][31]. Segments displaying baseline sinus rhythm without tachyarrhythmias (annotation N) were labeled as normal rhythm (control). The high-risk class comprised windows containing confirmed episodes of Ventricular Tachycardia (VT), and Ventricular Fibrillation (VF), as well as ECG time windows corresponding to the 5-minute interval immediately preceding the onset of these fatal events. This formulation allows evaluating the network's capacity to recognize pre-arrhythmic and acute arrhythmic electrocardiographic alterations associated with Sudden Cardiac Death (SCD).

B. Signal preprocessing

To ensure ECG signal quality and eliminate noise that could compromise network learning, raw data underwent preprocessing. A 4th-order Butterworth bandpass filter was applied to the signal, constraining it between cutoff frequencies of 0.5 Hz and 100 Hz. This removed electromyographic noise and respiration baseline wander, making the signal suitable for the neural network.

Following filtering, the signal was segmented into 5-second time windows, totaling 360 normal time windows and 180 high-SCD-risk windows per patient.

Finally, to homogenize signal amplitudes across different patients and electrodes, segment normalization was performed using Z-score standardization, adjusting values based on standard deviations from the mean to contain input data within a uniform distribution scale.

C. Proposed 1D-CNN Architecture

The use of convolutional neural networks (CNNs) has demonstrated effectiveness in both image and signal processing, transforming biomedical signal processing. CNNs have achieved success ranging from X-ray and MRI image processing to ECG signal classification [32].

Classification of ECG segments was performed via a 1D Convolutional Neural Network (1D-CNN) architecture. Choosing 1D convolutions is justified by their intrinsic ability to process time series, extracting local morphological patterns directly from the signal without requiring manual feature engineering [33].

The model in Fig. 3 adopts an end-to-end learning approach structured into three stages: feature extraction, temporal aggregation, and classification. The first stage consists of four sequential convolutional blocks in a hierarchical structure. The initial layers use larger receptive fields (wider kernels) combined with Max-Pooling to capture general heart rhythm shapes and reduce temporal dimensionality. As the signal progresses through the network, kernel sizes decrease while channel depth increases, allowing representation of more complex and refined morphological features. All blocks share Batch Normalization for training stability and ReLU non-linear activation.

Next, a Global Average Pooling (GAP) layer is applied to synthesize feature maps into a single-dimensional vector, drastically mitigating the risk of overfitting. Finally, this vector is processed by a densely connected layer — regularized by Dropout — which directs learned representations to the linear output layer for binary classification between Normal Rhythm and High Risk.

It is worth noting that simpler structures were attempted prior to this final architecture; however, modifications were required to improve final classification performance and accuracy.

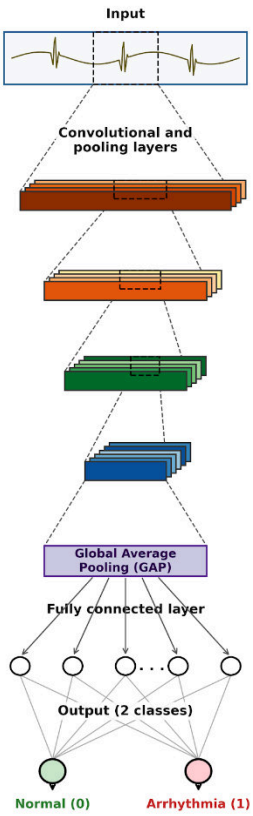

Fig. 3. Structure of the 1D-CNN used. Source: the authors (2025).

D. *Training and Evaluation Protocol*

1D-CNN training was conducted using the Categorical Cross-Entropy loss function from the PyTorch library, ideal for the proposed classification scenario. Network weights were updated using the Adam optimizer with an initial learning rate of 0.001 and batch size set to 32. The learning process extended over 80 epochs, incorporating early stopping monitored via validation loss to prevent overfitting. To measure predictive performance on the independent test set (4 patients unseen during training), Accuracy, Sensitivity (Recall), Specificity, F1-Score, and Area Under the ROC Curve (AUC-ROC) were calculated, ensuring a multidimensional and statistically solid evaluation.

To evaluate the impact of inter-patient variability and address the temporal dependence between multiple segments extracted from the same subject, the model performance was analyzed both in aggregate and on a per-patient basis. For this analysis, the following parameters were calculated for each patient: total segments, sensitivity for sudden death, specificity for normal status, and accuracy.

IV. Results

Performance of the proposed 1D-CNN architecture was evaluated using the independent test set comprising ECG recordings from 4 patients not presented to the network during training. This set generated a total of 2,208 continuous 5-second time windows (1,452 normal and 756 high-risk). It should be noted that although the primary evaluation unit is the time segment to enable continuous signal analysis, these samples correspond to clustered observations originating from the 4 tested individuals. Figure 4 displays the signal from Record No. 30, containing segments considered normal and high risk.

The architecture achieved an overall accuracy of 96.69%, with a sensitivity of 94.31% for the high-risk class and a specificity of 97.93% for the normal class. For a robust, clinically relevant analysis, performance was measured across multiple metrics, consolidated in Table I.

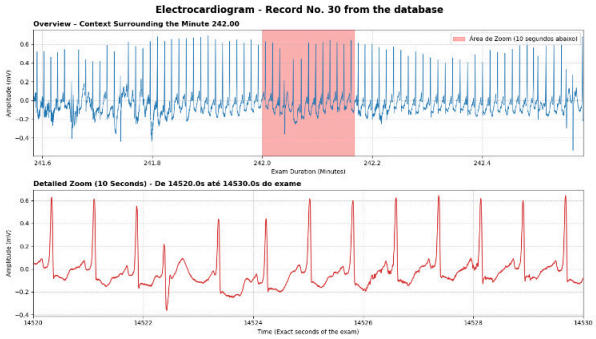

Fig. 4. Structure of the 1D-CNN used. Source: the authors (2025).

The sensitivity achieved by the model was 94.31% and minimizes false negatives, an extremely dangerous occurrence during screening of patients at risk for sudden death. The specificity of 97.93% demonstrates that the model is robust against false alarms, correctly identifying periods of stable normal rhythm.

TABLE I. Quantitative performance of the proposed 1D-CNN on the independent test set.

	Precision	Recall	F1-score	support
Normal	0.9706	0.9793	0.9750	1452
Risk/Arrythmia	0.9596	0.9431	0.9513	756
Acuracy			0.9669	2208
Macro avg	0.9651	0.9612	0.9631	2208
Weighted avg	0.9669	0.9669	0.9669	2208
Sensitivity (Risk Detection): 94.31%				
Specificity (Normal Detection Rate): 97.93%				

Source: the authors (2025).

ROC curve analysis (Fig. 5) revealed an Area Under the Curve (AUC) of 0.9894, indicating that the network maintains a highly stable and reliable decision threshold regardless of individual morphological variations. Model convergence occurred stably during training, reaching early stopping at epoch 70 without signs of overfitting.

Detailed breakdowns of correct and incorrect classifications can be observed in Table II, expressing the data for each test patient. In addition, Figure 6 represents the confusion matrix showing the total distribution regarding the patients as a test set. The model correctly classified 1,422 normal rhythm segments as control, with only 30 false positives. For the high-risk class, the network accurately identified 713 pathological segments. Notably, only 43 false negatives occurred (risk cases misclassified as normal), reinforcing the clinical safety of the proposed methodology for automated SCD screening. With these findings, sensitivity reaches 94.31% for high-risk findings and 97.91% for normal findings.

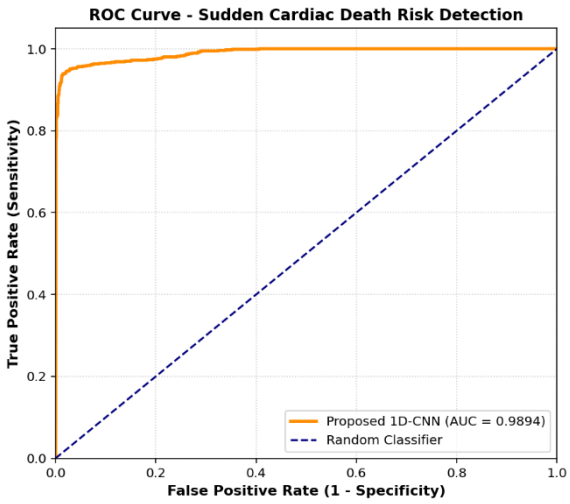

Fig. 5. ROC Curve. Source: the authors (2025)

TABLE II. INDIVIDUAL CLASSIFICATION PERFORMANCE ACROSS INDEPENDENT TEST PATIENTS EVALUATED.

Patient ID	Total segments	Sensitivity	Specificity	Accuracy
P01	540	96.00%	96.47%	96.30%
P02	576	89.77%	99.00%	96.18%
P03	552	97.03%	97.43%	97.28%
P04	540	93.82%	98.62%	97.04%
Total / Overall	2,208	94.31%	97.93%	96.69%

Although overall accuracy reached 96.69%, this was obtained under an independent patient-wise validation protocol, which is more rigorous than random segment splitting. Thus, reported performance reflects the model's ability to generalize to unobserved individuals, aligning experimental setup with real clinical application.

V. DISCUSSION

This study aims to construct an artificial neural network for identifying high risk of sudden cardiac death. The use of ECG for identifying SCD parameters is well documented in the literature [18], [19].

Electrocardiogram monitoring has increased substantially in recent years due to its ability to provide an overview of mechanical heart function using low-cost portable devices outside hospital settings. However, its application for sudden death risk detection remains limited due to the wide variety of cardiac alterations indicating sudden death, such as T-wave alternans, ST-segment duration, and late potentials [34].

Findings from this study align with Wang et al. [17], who predicted sudden death on the same database using a Nested LSTM combined with wavelet denoising. Similarly, Telangore et al. [18] proposed a fusion of 1D-CNN and LSTM networks for raw ECG extraction and SCD prediction. Collectively, these studies and our findings reinforce the growing trend toward artificial neural networks for sudden cardiac death prediction, serving as diagnostic support.

When comparing the findings with the literature is not simple, because there are differences in protocols, tasks and architectures. Khan et al. [19] reported a sensitivity of 92,41% using a 1D-CNNs directly on raw ECG signals using a deep residual architecture (ResNet) for multi-class classification of five arrhythmia types from the MIT-BIH database. His sensitivity is lower than the related in this work, but his evaluation is more complex because of the arrythmia classification. The performance achieved in this work highlights the efficacy of the proposed 1D-CNN for the specific binary screening task of SCD risk within the Sudden Cardiac Death Holter Database.

Some limitations should be acknowledged. First, the dataset used is restricted to 19 patients available on a public database and four patients were used to the blind test. Future work will focus on incorporating Group K-fold cross-validation and evaluating the architecture on external ECG databases with different recording equipment to ensure broader clinical generalization.

Increasing the number of patients and databases would add robustness to the neural network. This study focuses primarily on binary classification between "normal" and "high risk", limiting classification regarding specific cardiac arrhythmias. Besides thar, future studies should expand validation to different databases and analyze the model's predictive capacity at time windows progressively further removed from the fatal event (e.g., 60, 30, and 5 minutes before cardiac arrest).

In summary, findings demonstrate that the proposed neural network represents a promising alternative for detecting high-risk SCD ECG signals, serving as a potential auxiliary tool in clinical diagnosis.

VI. CONCLUSIONS

This work presented a robust and computationally efficient approach based on One-Dimensional Convolutional Neural Networks (1D-CNN) for early detection and risk classification of Sudden Cardiac Death (SCD) using single-lead ECG signals. Unlike traditional clinical approaches based on manual static metrics, the proposed model performs end-to-end learning, capturing complex dynamic morphological variations directly from filtered signals.

By adopting a rigorous inter-patient split validation protocol, the system was validated on individuals completely unseen by the network, overcoming common data leakage bias and accurately simulating a real hospital screening scenario.

On the independent test set, the architecture achieved an overall accuracy of 96.69%, with a sensitivity of 94.31% (a critical factor in mitigating false negatives in high-risk conditions), a specificity of 97.93%, and an AUC-ROC of 0.9894.

Future work includes validating architecture generalization on larger and more diverse clinical databases, including different heart disease etiologies. Additionally, an artificial intelligence model will be developed to indicate the probability of a patient being high-risk while specifying heart rhythm characteristics. In parallel, a low-cost Holter device will be developed to transmit captured signals to an online portal.

***Abstract*—The widespread adoption of myoelectric upper-limb prostheses is limited by the complexity, accessibility, and control requirements of commercially available devices, factors that contribute to prosthesis abandonment. This work presents an accessible myoelectric prosthesis prototype built by 3D printing from an open-source design, using readily available materials and electronic components, and conceived as an experimental platform for the development of prosthetic systems for individuals with upper-limb amputation. The control strategy accommodates different muscle groups, including residual musculature, provided that training enables the generation of distinguishable electromyographic activation patterns, with preference given to residual muscles naturally associated with the movements previously performed by the amputated limb. Surface electromyographic (EMG) signals were collected from four volunteers to investigate the identification of muscle activation patterns associated with prosthetic hand opening and closing. A real-time acquisition, processing, and classification framework was developed based on time-domain EMG features and Linear Discriminant Analysis (LDA), with performance evaluated through Leave-One-File-Out (LOFO) and Leave-One-Subject-Out (LOSO) validation. LOFO achieved an overall accuracy of 89.9%, with recall of 81.4%, precision of 81.9%, and an F1-score of 81.7%, whereas LOSO resulted in an overall accuracy of 89.4%, with recall of 79.0%, precision of 82.1%, and an F1-score of 80.5%. The proposed control methodology was experimentally integrated with a 3D-printed, servomotor-actuated robotic hand, which reproduced the opening and closing commands identified from the EMG signals. Although the results in able-bodied volunteers were promising, validation with amputee participants, assessment of residual muscle recruitment under realistic prosthetic conditions, and embedded implementations of the control system remain as future work.**

I. Introduction

Over the past decades, upper-limb prostheses have become an important resource for the rehabilitation of individuals with limb loss, contributing to the recovery of functional independence in activities of daily living. In Brazil, the demand for this type of assistive technology is substantial: according to the 2010 Demographic Census, more than 470,000 Brazilians reported some form of amputation, of whom approximately 94,000 had upper-limb amputations [1]. Despite this demand, access to functional upper-limb prosthetic devices remains limited. Within the Brazilian Unified Health System (SUS), prosthetic care is provided through national policies addressing orthoses, prostheses, and mobility aids [2]. Nevertheless, limitations related to availability, technological complexity, maintenance, adaptation, and access to more advanced prosthetic systems still restrict their use [3], [4]. Prosthesis abandonment is also an important challenge, and previous studies have associated device discontinuation with discomfort, excessive weight, limited functionality, muscle fatigue, and difficulties in prosthesis control [5], [6]. Myoelectric prostheses use electromyographic (EMG) signals generated by muscle contractions to produce commands for prosthetic movements, potentially providing a more direct relationship between muscle activation and device operation than passive or purely mechanical systems [7], [8]. However, this control approach depends on the availability of muscles capable of producing distinguishable EMG patterns and on the user's ability to activate them consistently, requirements that are particularly relevant in individuals with upper-limb amputation, whose remaining musculature may vary considerably in anatomical and functional characteristics. In this context, the present study focuses on the development of a myoelectric prosthesis prototype based on an open-source robotic hand manufactured by 3D printing. The open-source design, readily available electronic components, and relatively simple actuation architecture were adopted to reduce the technological and manufacturing complexity of the prototype while increasing its accessibility and reproducibility. EMG signals were acquired from two antagonistic forearm muscles involved in finger movements: the flexor digitorum superficialis (FDS), associated with finger flexion, and the extensor digitorum (ED), associated with finger extension. These muscles served as a methodological model for investigating whether antagonistic activation patterns could be identified and classified to control the opening and closing commands of the robotic

hand; in future applications with amputee participants, the same strategy is intended to be applied to functional residual muscles associated with the original movements of the missing hand. Therefore, the objective of this study was to develop a myoelectric upper-limb prosthesis prototype by fabricating a 3D-printed robotic hand based on an open-source design, developing a system for the acquisition and conditioning of surface EMG signals, and implementing real-time EMG signal processing and classification to identify muscle activation patterns associated with hand opening and closing commands. Classification performance and robotic prototype operation were experimentally assessed in four non-amputee volunteers as an initial investigation of the proposed strategy, which does not constitute clinical validation of the prosthetic system. Future studies involving individuals with upper-limb amputation are required to determine its applicability under real-world prosthetic-use conditions.

II. Methodology

The development of the prototype followed sequential stages: mechanical fabrication, signal acquisition hardware, experimental data collection, signal processing, classification, and robotic actuation. Four healthy volunteers without upper-limb amputation were recruited, and surface EMG signals were acquired from the FDS and ED muscles while participants performed predefined hand opening and closing tasks. The acquired signals were represented by time-domain features and classified using an LDA classifier, whose performance and generalization were assessed using LOFO and LOSO cross-validation, and the classification output was applied to the robotic hand to convert the detected EMG patterns into opening and closing commands of the prototype.

A. Development of the EMG acquisition circuit

An analog electronic circuit dedicated to the acquisition and conditioning of electromyographic signals was designed and implemented using a modular architecture composed of three printed circuit boards (PCBs): a motherboard, which incorporates the active reference circuit shared by the system, and two identical daughterboards, each responsible for the complete signal-conditioning chain of one independent acquisition channel. This architecture enables the simultaneous acquisition of EMG signals from two forearm muscles, providing complementary information on muscle activation and improving the discrimination between rest and contraction states. Each

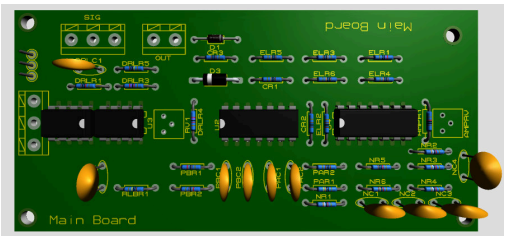

Figure 1. EMG printed circuit board.

acquisition channel incorporates an AD620 instrumentation amplifier, selected for its high input impedance and high common-mode rejection ratio (CMRR), which are particularly important for acquiring low-amplitude biopotentials while minimizing external electromagnetic interference. Gain adjustments based on a fixed resistor and a trimmer accommodate the variability of the EMG signal amplitude across subjects and electrode–skin contact impedances, and a Driven Right Leg (DRL) active feedback circuit feeds the inverted common-mode component back to the subject through a dedicated reference electrode, actively attenuating 60 Hz power-line interference [**?**]. Following the initial amplification stage, the signal passes through a second-order Butterworth band-pass filter with cutoff frequencies of 20 Hz and 250 Hz, which preserves the spectral content of interest of the EMG signal while attenuating motion artifacts and high-frequency noise; the 250 Hz low-pass cutoff also serves as the antialiasing filter for the subsequent analog-to-digital conversion. A second amplification stage is subsequently applied to maximize the effective resolution of the analog-to-digital converter (ADC). Since the EMG signal is bipolar, whereas the ESP32 ADC operates exclusively with positive input voltages, a level-shifting circuit was incorporated to adjust the signal to the ADC input range, establishing a 1.5 V reference around which the conditioned signal oscillates. The conditioned signals were then digitized by the ESP32 internal 12-bit ADC, providing 4096 quantization levels, at a sampling frequency of 1000 Hz for each EMG channel, and a protection circuit prevents overvoltage at the ESP32 analog inputs.

B. Construction and assembly of the robotic prosthesis

The mechanical prototype consisted of a humanoid robotic hand fabricated by additive manufacturing (3D printing) from an open-source design [9]. This choice enables unrestricted reproduction of the mechanical structure, facilitating its use in research and in the development of accessible assistive technologies, while additive manufacturing reduces fabrication complexity, enables device customization, and allows the production of lightweight prosthetic structures at lower manufacturing cost. The assembly process included the installation of the phalanges, the articulation of the interphalangeal joints, and the routing of the actuation tendons through the internal channels provided in the original mechanical design. Finger actuation follows a tendon-driven mechanism that reproduces the operating principle of the extrinsic musculature of the human hand. Each finger is actuated by a 0.40 mm diameter nylon tendon routed through the internal channels of the phalanges and connected to its corresponding actuator, while finger extension is achieved passively by elastic elements positioned on the opposite side of each finger, which act as restoring springs. This antagonistic configuration enables bidirectional finger motion—active flexion and passive extension—using a single actuator per finger. Actuation was performed by five SG90 servomotors, one assigned to each finger, selected for their compact dimensions, affordability, and pulse-width modulation (PWM) control interface, which is directly compatible with the digital outputs of the ESP32. To transmit motion from each

servomotor to its corresponding tendon, a smooth pulley was designed in Autodesk Fusion and fabricated by 3D printing: mounted on the servomotor shaft, it secures the tendon end and converts the servo angular displacement into linear tendon traction, producing finger flexion during rotation in the closing direction, whereas rotation in the opposite direction releases the tendon and allows the elastic element to restore finger extension.

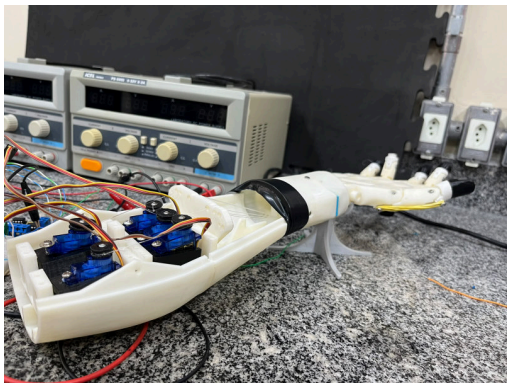

Figure 2. Assembled humanoid robotic prosthesis.

C. Power supply and servomotor actuation

The electrical architecture used for powering and controlling the prototype is shown in Fig. 3. The signals from the two EMG acquisition channels were connected to the ESP32 analog inputs, while the microcontroller communicated with the computer through the USB interface and generated the PWM signals responsible for controlling the five servomotors, configured at a frequency of 50 Hz with pulse widths ranging from 500 μs to 2400 μs. An angular position of 180° corresponded to the fully open hand, whereas 0° corresponded to the fully closed hand. The same angular command was sent to all servomotors, producing synchronized opening and closing movements according to the state identified by the classification system. The servomotors were powered independently from the ESP32 by a regulated 5 V supply capable of providing at least 3 A, since preliminary tests showed that the power supplied through the development board was insufficient for the simultaneous actuation of all five servomotors, resulting in unstable system operation. A 1000 μF electrolytic capacitor was connected in parallel with this supply to reduce voltage fluctuations during transient current demands. The EMG acquisition boards were powered by a separate 9 V supply, while the ESP32 was powered through the USB connection, and the grounds of all supplies were connected to a common point in a star-ground configuration, as illustrated in Fig. 3.

D. EMG acquisition protocol and electrode placement

The data collection procedures were conducted after approval by the Human Research Ethics Committee of the João de Barros Barreto University Hospital Complex at the Federal University of Pará, and the experiments were carried out at eBio, the Biomedical Engineering Laboratory Complex of

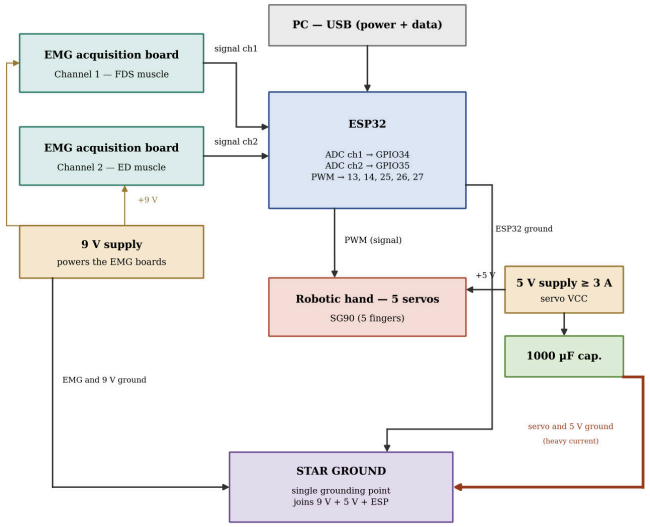

Figure 3. Electrical architecture of the EMG-controlled robotic hand system.

the School of Electrical and Biomedical Engineering at the Federal University of Pará. Four healthy adult volunteers over 18 years of age, without upper-limb amputation and without self-reported conditions that could interfere with the execution of the proposed motor tasks, were recruited for the study. Before data collection, each participant received information about the objectives of the study and the procedures involved in the experimental protocol, and those who agreed to participate voluntarily signed the Informed Consent Form prior to the beginning of the experiments. During data acquisition, participants were seated in a comfortable chair in an environment with controlled temperature and were instructed to remain as relaxed as possible between the proposed tasks. Personal information and the identity of all volunteers were kept confidential throughout the study, and the collected data were handled in a manner that preserved participant anonymity. The first acquisition channel was positioned over the FDS, on the anterior aspect of the forearm, whereas the second channel was positioned over the ED, on the posterior aspect. Because these muscles perform antagonistic functions in finger flexion and extension, respectively, they produce distinct activation patterns, which favors discrimination between hand opening and closing movements [10]. The surface electrodes were positioned over the muscle bellies, aligned parallel to the orientation of the muscle fibers; before electrode placement, the skin was cleaned to reduce electrode–skin contact impedance, and disposable electrodes were replaced at each acquisition session. Electromyographic signals were acquired at a sampling frequency of 1000 Hz, selected according to the Nyquist criterion to ensure a sampling rate greater than twice the highest frequency of interest, defined as 250 Hz by the analog low-pass filter cutoff, providing an adequate representation of the EMG spectral content while reducing the risk of aliasing

during analog-to-digital conversion. In addition to the two EMG acquisition channels, a third channel recorded the state of a light-emitting diode (LED) used as a synchronization signal: LED activation indicated the period during which the volunteer was instructed to perform the muscle contraction, allowing contraction and rest intervals to be automatically identified during subsequent signal processing. The experimental protocol began with a 30 s resting period for signal stabilization and baseline EMG recording, followed by 10 acquisition cycles, each consisting of 5 s of voluntary muscle contraction, indicated by LED activation, and 10 s of rest, during which the LED remained off, as illustrated in Fig. 4.

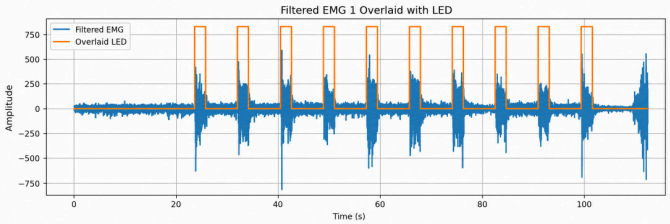

Figure 4. EMG acquisition protocol showing the initial 30 s baseline followed by 10 cycles of 5 s contraction and 10 s rest, synchronized by the LED signal.

E. Preprocessing of the electromyographic signals

Signal preprocessing began with the removal of the direct current (DC) component through subtraction of the mean value of each signal, centering the waveform around zero. A fourth-order Butterworth digital band-pass filter with cutoff frequencies of 20 Hz and 200 Hz was then applied to restrict the analysis to the frequency band most relevant for the discrimination of contraction patterns, followed by notch filters centered at 60 Hz, 120 Hz, and 180 Hz, each with a quality factor of 30, to attenuate power-line interference and its harmonics. The filtered signals were segmented into sliding windows of 250 ms (250 samples), with a window shift of 50 ms (50 samples) and an overlap of 80%. This configuration provides improved temporal resolution while preserving a sufficient number of samples for reliable feature extraction. The LED channel was used exclusively as a temporal synchronization marker for the automatic labeling of the EMG windows. For each window, the mean value of the LED signal was computed: windows with a mean value greater than or equal to 0.8 were labeled as muscle contraction, indicating that the LED remained active during nearly the entire window, whereas windows with a mean value lower than or equal to 0.2 were labeled as rest, corresponding to periods in which the LED remained off. Windows with intermediate mean values were discarded because they contained transitions between the rest and contraction states.

F. Feature extraction and classification

Six time-domain features were extracted from each EMG window: root mean square (RMS), mean absolute value (MAV), variance (VAR), waveform length (WL), zero crossings (ZC), and slope sign changes (SSC), as defined in [10]. Since two EMG acquisition channels were employed, each window was represented by a 12-dimensional feature vector. To reduce the influence of residual noise, the thresholds for the computation of ZC and SSC were defined adaptively for each acquisition channel as three times the standard deviation of the corresponding filtered signal. The features from both channels were then concatenated into a single feature vector and standardized using the mean and standard deviation computed exclusively from the training set. Classification between the rest and muscle contraction classes was performed using LDA, which determines a linear projection that maximizes class separability, with the decision function given by

$$s(\mathbf{z}) = \mathbf{w}^T \mathbf{z} + b. \tag{1}$$

Because of the class imbalance, balanced prior probabilities were adopted to reduce the tendency of the classifier to favor the majority class. Two cross-validation strategies were employed. In LOFO validation, one complete acquisition file was held out for testing at each iteration, while the remaining files were used for training, allowing the classifier performance to be assessed on recordings or acquisition sessions that did not participate in the respective training. In LOSO validation, all records belonging to one participant were completely excluded from training and used as the test set at each iteration, with the process repeated until each participant had been used once as the test set, directly evaluating the ability of the model to recognize the rest and contraction states in an individual whose data were not used during training. In both strategies, feature standardization and LDA training were performed again at each iteration, using exclusively the data belonging to the training set. Performance was quantified by means of accuracy, recall, precision, F1-score, and the confusion matrix.

G. Real-time classification and control

To further assess the real-time behavior of the classification system, additional tests were performed using an acquisition file held out from training, following the LOFO strategy. The recorded EMG signals were processed as a simulated data stream using 250 ms windows updated every 50 ms, with classification stability improved through majority voting over five consecutive predictions. Processing latency was measured for each classification window as the interval between the start of signal processing and completion of the LDA prediction, using a high-resolution timer. Mean, median, standard deviation, minimum, maximum, and 95th and 99th percentile latency values were subsequently calculated. Classification errors and correct detections were evaluated by comparing the classifier output with the LED synchronization channel, used as the reference signal. Predictions were categorized as true positive, true negative, false positive, or false negative. In addition, contraction and rest transitions were analyzed as events, allowing the calculation of the detection rate, missed events, and isolated false-positive activations.

III. Results

A. Analysis of the RMS of the EMG channels

The RMS quantifies the signal energy within each analysis window and is widely used to estimate the level of muscle activation, with lower values typically associated with resting conditions and pronounced increases indicating voluntary muscle contractions. The EMG1 channel exhibits higher activation peaks and greater dynamic variation during contraction periods, reaching values close to 200, whereas EMG2 also presents clear increases during muscle activation, although with lower amplitudes, reaching approximately 120. These differences are expected and may be attributed to factors such as electrode placement, the anatomical characteristics of the monitored muscles, and variations in muscle recruitment between the two acquisition sites. During resting periods, the RMS of EMG1 remains predominantly between 10 and 25, whereas EMG2 exhibits slightly higher baseline values, generally ranging from 20 to 40, a behavior that may be associated with residual electronic noise, low-level involuntary muscle activity, or differences in the baseline activation of the monitored muscles. Despite these differences, both channels exhibit synchronous increases during the contraction intervals, demonstrating a clear temporal correspondence between muscle activation and the increase in RMS, which provides a reliable representation of muscle activation and contributes to the discrimination between rest and contraction states.

B. Classification performance under LOFO and LOSO validation

The ability of the classifier to maintain its performance across acquisition records not used during training was evaluated using the LOFO strategy, in which each complete recording was used once as the test set while the remaining recordings were used for training. Across nine valid folds, the classifier achieved an overall accuracy of 89.9%, recall of 81.4%, precision of 81.9%, and an F1-score of 81.7%. The accumulated confusion matrix showed 37,611 rest windows and 12,546 contraction windows correctly classified, whereas 2,765 rest windows were incorrectly classified as contraction and 2,870 contraction windows were classified as rest. Inter-subject generalization was evaluated using the LOSO strategy, in which the recordings associated with one participant were used exclusively for testing while the remaining data were used for training. The LOSO evaluation achieved an overall accuracy of 89.4%, recall of 79.0%, precision of 82.1%, and an F1-score of 80.5%. The accuracies obtained in the three validation folds were 86.6%, 93.0%, and 88.8%, indicating relatively consistent performance across the evaluated subjects. The accumulated confusion matrix contained 37,722 correctly classified rest windows and 12,176 correctly identified contraction windows, with 2,654 false-positive and 3,240 false-negative classifications. The results of both validation strategies are summarized in Table I.

Table I
Classification performance under LOFO and LOSO validation.

Metric	LOFO	LOSO
Accuracy	0.899	0.894
Recall	0.814	0.790
Precision	0.819	0.821
F1-score	0.817	0.805

C. Temporal Evaluation of Contraction and Rest Commands

The temporal performance of the system was further evaluated at the event level, using the LED signal as a reference to determine the onset and end of each contraction period. A total of 30 contraction-onset events (ON) and 30 return-to-rest events (OFF) were analyzed, resulting in 60 expected transitions. All 30 ON events were correctly identified, corresponding to a detection rate of 100% with no missed contraction events, which indicates high sensitivity of the system in detecting the onset of muscle activation. For the OFF events, corresponding to the transition from contraction to rest, 12 of the 30 events were correctly detected, whereas 18 were not recognized according to the adopted temporal criterion, resulting in a detection rate of 40%. Considering the ON and OFF transitions together, 42 of the 60 expected events were correctly identified, corresponding to an overall detection rate of 70%. No isolated false activations were observed during the analyzed period, resulting in a rate of 0 false positives per minute. The results reveal an asymmetric behavior of the system in identifying state transitions: while contraction-onset detection showed consistent performance, recognition of the transition back to rest was less effective, indicating the need to optimize the logic used to confirm the OFF state.

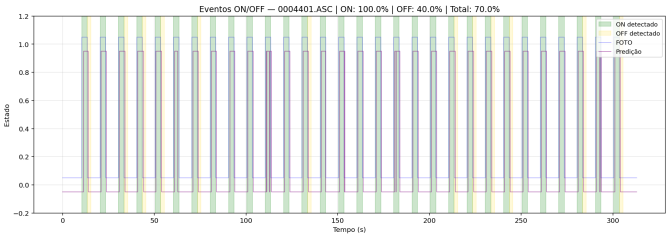

Figure 5. ON/OFF event detection during the temporal evaluation of contraction and rest commands.

D. Computational Latency of Real-Time Processing

The computational latency of the processing and classification pipeline was evaluated over 6,255 consecutive windows, yielding a mean processing time of 3.3 ms, a median of 2.8 ms, and a standard deviation of 1.4 ms, with minimum and maximum recorded times of 2.4 ms and 45.1 ms, respectively, and 95th and 99th percentiles of 5.5 ms and 7.6 ms. The distribution of the latency values is illustrated in Fig. 6. The proximity between the mean and median values, together with the 95th percentile of 5.5 ms, indicates that the vast majority of windows were processed within a few milliseconds, despite

the occurrence of isolated higher-latency peaks. Considering that each analysis window had a duration of 250 ms, the computational processing time was substantially shorter than the duration of the window itself, indicating that the feature extraction, standardization, and LDA classification stages impose a computational burden compatible with real-time operation. However, the reported values correspond specifically to the computational latency of the algorithm and not to the total delay between the onset of muscle contraction and the complete execution of the prosthetic movement, which also depends on acquisition-window filling, temporal confirmation logic, serial communication, and servomotor actuation time.

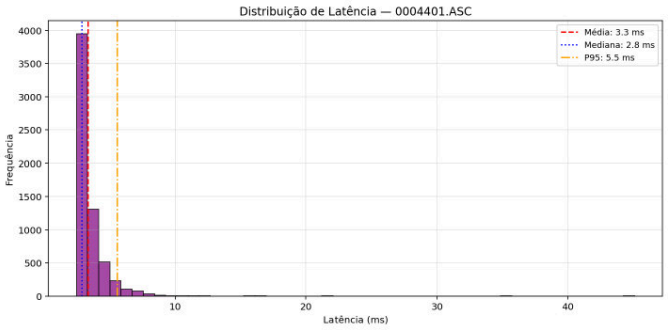

Figure 6. Distribution of computational latency during real-time processing.

E. Validation on the Humanoid Prosthesis

As the final experimental validation stage, the proposed control system was implemented on the humanoid robotic prosthesis, which was operated in real time using the electromyographic signals acquired from the user. During the experiments, the prosthesis consistently executed the opening and closing movements corresponding to the muscle activation patterns identified by the classifier, demonstrating the practical applicability of the proposed methodology. A short delay was observed between the user's voluntary muscle contraction and the execution of the corresponding prosthetic movement, primarily associated with the cumulative processing time required for signal acquisition, preprocessing, feature extraction, classification, temporal confirmation, serial communication, and servomotor actuation. Despite this delay, the system operated reliably throughout the experiments, with stable command recognition and consistent prosthesis actuation, experimentally demonstrating the feasibility of the proposed approach for real-time control of humanoid myoelectric prostheses.

IV. Discussion

A. Classification performance and inter-subject generalization

The results obtained in this study indicate that a relatively compact myoelectric control architecture, based on two EMG channels, time-domain features, and LDA, can discriminate between rest and muscle contraction while maintaining relatively low computational complexity. The use of time-domain descriptors for myoelectric pattern recognition is well established in the literature: features related to signal amplitude, temporal variability, zero crossings, and changes in signal slope provide useful representations of muscle activation while requiring limited computational resources [10], [11], characteristics that make them particularly suitable for real-time prosthetic control systems and future embedded implementations [7], [12]. The LOFO and LOSO evaluations (Table I) achieved overall accuracies of 89.9% and 89.4%, respectively, indicating that the classifier maintained its ability to distinguish between contraction and rest across complete acquisition records and subjects not included during training. The small difference between the two validation strategies suggests that relevant characteristics of the EMG activation patterns were preserved under inter-subject evaluation, although the reduction in recall relative to overall accuracy indicates that identifying the contraction class remains more challenging than identifying rest. This behavior may be related to inter-individual differences in anatomy, muscle recruitment strategies, electrode positioning, contraction intensity, subcutaneous tissue characteristics, and physiological variability [6], [7], and Fougner et al. [13] demonstrated that variations in limb position can substantially affect EMG classification performance. Therefore, although the LOSO results are promising, future applications may benefit from short subject-specific calibration procedures or adaptive strategies capable of compensating for differences in EMG feature distributions between users. These values are within the range reported in previous studies employing time-domain features and linear classification methods, although direct comparisons should be made cautiously because of differences in acquisition protocols, number of channels, movement classes, participant characteristics, and validation strategies. Wang et al. [14], for example, employed time-domain EMG features and LDA and reported classification accuracies between approximately 96.9% and 98.4%, depending on the feature combination, whereas Koppolu and Chemmangat [15] reported an LDA accuracy of 93.63% after artifact reduction in a multiclass protocol involving three acquisition channels. The lower accuracy observed in the present study compared with some highly controlled offline investigations should not necessarily be interpreted as inadequate classifier performance, since evaluations in which training and test windows originate from the same acquisition session generally represent a less demanding condition than evaluations involving complete independent recordings or previously unseen subjects [6], [12]. Therefore, the LOFO and LOSO results provide a more informative estimate of the generalization capability of the proposed classifier.

B. Decision threshold and number of channels

An additional analysis investigated the influence of the LDA decision threshold on the balance between contraction detection and false-positive classifications. Increasing the decision offset progressively increased the recall of the contraction class, although this was accompanied by a reduction in precision. The highest F1-score was obtained using an offset of +1.00, at which recall increased to 88.9%, with a precision of 77.6%, an F1-score of 82.9%, and an accuracy of 89.9%. For prosthetic

control, this balance is particularly relevant because failing to detect an intended contraction and generating an unintended command may have different functional consequences; the selected operating point favored increased sensitivity to muscle activation while maintaining an overall accuracy close to 90%, although the optimal decision threshold may depend on the intended prosthetic application and should be further investigated under real-time functional conditions. Another relevant aspect of the proposed architecture is that classification was performed using only two EMG acquisition channels. Classical multifunction myoelectric control approaches frequently employ four or more recording channels [11], and although high-density EMG systems can provide additional spatial information, they require more electrodes, processing resources, and more complex electrode placement procedures. Daley et al. [16], for example, reported high-density EMG classification accuracies ranging from approximately 85% to 98% in normally limbed and transradial amputee participants, also suggesting that useful performance could be maintained with a reduced number of appropriately positioned electrodes, and Li and Kuiken [17] similarly demonstrated that residual forearm EMG contains relevant information for recognizing basic wrist and hand movements. In the present study, the use of two acquisition channels represents a deliberate compromise between classification performance and system complexity, consistent with the objective of developing a more accessible prototype. The choice of LDA follows the same principle: linear classifiers remain attractive for prosthetic applications because of their relatively low memory requirements, rapid inference, and straightforward implementation [11], [12], making the method suitable for future investigation in embedded platforms.

C. Real-time processing and event-based evaluation

The computational latency measurements indicate that the processing and classification stages impose a relatively small computational burden, as reported in the Results section. Previous studies have emphasized that real-time myoelectric control requires a compromise between classification performance and controller response time: Smith et al. [18] identified window durations between approximately 150 and 250 ms as an appropriate compromise for pattern-recognition-based myoelectric control. However, the mean computational latency of 3.3 ms should not be interpreted as the complete response time of the prosthetic system, since the total delay between muscle activation and mechanical movement also includes the time required to fill the analysis window, temporal confirmation of successive classifications, serial communication, and servomotor actuation [12], [19]. The event-based analysis provided complementary information regarding the temporal behavior of the classifier, revealing that the system was more effective in identifying the onset of muscle activation (100% ON detection) than the subsequent return to rest (40% OFF detection). One possible explanation is the temporal decision strategy adopted to increase command stability: strategies based on repeated classifications or majority voting can reduce isolated misclassifications, but may also delay state transitions when muscle relaxation occurs gradually, a trade-off between stability and responsiveness also described in previous studies of myoelectric control [20]. Importantly, no isolated false-positive activation was observed during the analyzed experiment, corresponding to 0 false-positive events per minute; although encouraging, this result should be interpreted as preliminary, and longer experiments involving more diverse motor tasks will be required to determine the frequency of unintended activations under conditions closer to actual prosthetic use. The lower performance observed for OFF transitions indicates that the decision logic used to identify the return-to-rest state should be further optimized, and independent confirmation criteria for contraction onset and relaxation may represent a useful strategy for future implementations.

D. Limitations and future application in individuals with amputation

An important limitation of the present study is that the experimental data were obtained from participants without upper-limb amputation. Although the prototype was conceived for future application in individuals with transradial limb loss, residual musculature may differ from intact musculature in terms of anatomy, available muscle volume, recruitment patterns, signal amplitude, and possible electrode positions. Maintaining a correspondence between the muscle activation used to generate a command and the intended prosthetic movement is conceptually relevant because it may reduce the need to associate an unrelated muscular contraction with a specific prosthetic action, and previous studies have demonstrated that residual forearm musculature can provide useful information for pattern-recognition-based prosthetic control [16], [17]; however, the present results do not demonstrate that the same electrode positions or activation patterns will be directly transferable to individuals with transradial amputation, and potential benefits such as reduced muscle fatigue, lower cognitive demand, or shorter training time should be considered hypotheses for future investigation rather than demonstrated advantages of the current prototype. Consequently, the current results should be interpreted as a preliminary assessment of the technical feasibility of the proposed acquisition and classification architecture rather than as clinical validation of a prosthetic system. Additional limitations include the relatively small participant sample, the binary classification between contraction and rest, and the controlled conditions under which the signals were acquired, since real-world prosthetic use introduces additional sources of variability, including changes in limb position, electrode displacement, muscle fatigue, changes in contraction intensity, and long-term physiological adaptation [6], [13]. Future studies should therefore include participants with upper-limb amputation, evaluate residual-muscle training and subject-specific calibration, investigate the system under different limb positions and electrode-placement conditions, optimize the detection of transitions from contraction to rest, and subsequently evaluate the implementation of the classification architecture in embedded systems.

V. Conclusion

This work presented the development and experimental assessment of an accessible myoelectric upper-limb prosthesis prototype based on a 3D-printed open-source robotic hand, integrating two-channel EMG acquisition and conditioning, time-domain feature extraction, LDA classification, and real-time robotic actuation. Overall accuracies of 89.9% and 89.4% were achieved under LOFO and LOSO validation, respectively (Table I), with decision-threshold adjustment further improving contraction detection (F1-score of 82.9% at an offset of +1.00). The event-based analysis showed reliable detection of contraction onset (100% of ON events), whereas the detection of the return to rest (40%) indicates that the transition logic should be further optimized. The computational processing stage presented a mean latency of 3.3 ms over 6,255 evaluated windows, compatible with real-time operation, although these values represent only the algorithmic latency and not the complete response time between muscle activation and prosthetic movement. Future studies should evaluate the prototype in individuals with upper-limb amputation, particularly by identifying and training residual muscles associated, whenever possible, with the original movements of the missing hand. Further investigations should also include a larger participant sample, optimization of contraction-to-rest detection, evaluation under different limb positions and electrode-placement conditions, and subsequent implementation of the control architecture in embedded systems.

***Resumo*—A segmentação automática de cárie em radiografias panorâmicas é dificultada pelo baixo contraste e pelo tamanho diminuto das lesões: em média uma cárie ocupa cerca de 1,5‰ da imagem, e a cárie superficial menos de 0,5‰. O *benchmark* público do conjunto DC1000 trata a cárie como tarefa binária, ignorando a severidade — dimensão codificada no próprio dataset e clinicamente decisiva (esmalte → dentina → polpa). Este trabalho avalia se o fatiamento (*Slicing-Aided Fine-Tuning*, SF, e *Slicing Aided Hyper Inference*, SAHI) melhora a segmentação *por severidade* (superficial/média/profunda) com YOLO11n-seg, e se o ganho é maior na cárie superficial. Na validação cruzada de 5 *folds*, o SF+SAHI com *tiles* de 384 px elevou o Dice macro de 0,308 para 0,415 ($\Delta = +0{,}108$) e, na cárie superficial, de 0,092 para 0,265 ($\Delta = +0{,}173$; *recall* de 0,097 para 0,323). Os cinco *folds* melhoraram em todas as classes (Wilcoxon unilateral exato, $p = 0{,}031$; indicador descritivo de consistência direcional). A ablação indica que o ganho depende da combinação (SAHI só na inferência: 0,152; SF sem fatiar a inferência: 0,291). O ganho de sensibilidade veio acompanhado de mais falsos positivos superficiais (0,526→1,591 instâncias/imagem), o que restringe o sistema a apoio ao especialista, e não a uso autônomo.**

I. Introdução

A CÁRIE dentária é uma das doenças crônicas mais prevalentes do mundo. Estima-se que a cárie não tratada afete mais de um terço da população global e que, em crianças, seja a condição crônica mais comum, atingindo cerca de 514 milhões de indivíduos [1]–[3]. Trata-se de um processo progressivo: iniciando-se como desmineralização do esmalte, a lesão avança para a dentina e, se não interrompida, atinge a polpa, podendo causar dor, infecção e perda do dente [3], [4]. Por isso, a detecção precoce e o estadiamento corretos são decisivos: o estágio da lesão determina a conduta, da remineralização não invasiva, nas lesões de esmalte, à intervenção restauradora ou endodôntica, nas lesões profundas [5], [6].

O diagnóstico convencional, baseado em inspeção visual-tátil e leitura radiográfica, é limitado por interpretação subjetiva, variabilidade entre examinadores e baixa sensibilidade às lesões iniciais de esmalte [1], [4], [7]. Esse cenário motivou a adoção de aprendizado profundo em odontologia, com redes convolucionais aplicadas à detecção e ao diagnóstico de cárie em diferentes modalidades [7], [8]. Entre elas, a radiografia **panorâmica** destaca-se como método extraoral pela baixa dose de radiação, rapidez, conforto e cobertura de toda a arcada, sendo especialmente útil em pacientes pediátricos [4].

A automação em panorâmicas, contudo, é desafiadora. A região cariada cobre apenas uma fração minúscula da imagem — em média $\sim$1,5‰ da área, e a cárie superficial menos de 0,5‰ [9] — o que aproxima a tarefa do problema de *detecção de objetos pequenos*. Soma-se o baixo contraste: a sensibilidade da leitura manual para cárie inicial varia de apenas 0,37 a 0,69 [10], com elevada taxa de falsos-negativos nas lesões incipientes — justamente o regime em que a automação poderia agregar mais valor clínico.

No conjunto público **DC1000** [9], [11], o *benchmark* mais recente avaliou doze arquiteturas de ponta (CNNs, *Transformers* e modelos *Mamba*) sob protocolo uniforme e concluiu que arquiteturas convolucionais superam as demais, com a DoubleU-Net [12] atingindo Dice de 0,7345 [1]. Esse e os demais trabalhos no DC1000, entretanto, tratam a cárie como tarefa *binária* (lesão *vs.* fundo), ignorando a *severidade* — apesar de o próprio dataset codificá-la nas máscaras. Persiste, assim, uma lacuna: avaliar a segmentação *por severidade* no DC1000, atacando o gargalo das lesões pequenas e de baixo contraste apontado por [1] como limite de desempenho.

Este estudo contribui ao formular a severidade como segmentação por instância no DC1000 e ao isolar, por ablação, a interação entre treino fatiado e inferência SAHI.

II. Objetivos e Hipótese

A. Objetivo geral

Avaliar o impacto do fatiamento (*Slicing-Aided Fine-Tuning* e *Slicing Aided Hyper Inference*) na segmentação de cárie dentária *por severidade* com YOLO11n-seg sobre o conjunto DC1000, sob validação cruzada e análise estatística.

B. Objetivos específicos

- Converter as máscaras de severidade do DC1000 para o formato de segmentação por instância e treinar um *baseline* YOLO11n-seg sobre a imagem inteira;
- Implementar o *Slicing-Aided Fine-Tuning* e a inferência fatiada (SAHI), variando o tamanho do *tile* em $\{640, 512, 384\}$ px;
- Decompor, no *tile* selecionado, os efeitos de SF e SAHI em quatro braços: *baseline*, *baseline*+SAHI, SF com inferência inteira e SF+SAHI;
- Avaliar a segmentação *por classe de severidade* com **Dice** (por classe, macro e binário), **precisão**, ***recall*** e $\mathbf{F_2}$ da superficial, **mIoU** binário e falsos positivos por imagem;
- Comparar *baseline* e configurações SF+SAHI por validação cruzada de 5 *folds* e teste de Wilcoxon pareado;
- Posicionar o resultado frente à literatura do DC1000 em colapso binário.

C. Hipótese

O fatiamento, ao recortar e reescalar *tiles*, amplia a área relativa de pixels das lesões e, portanto, beneficia *mais* a cárie superficial (pequena, baixo contraste) do que a profunda (maior em área), reduzindo o *gap* de desempenho entre as classes de severidade.

III. Fundamentação Teórica

Em visão computacional, o **aprendizado profundo** [13] domina a segmentação. A **segmentação por instância** distingue objetos individuais da mesma classe, ao contrário da semântica, que apenas rotula pixels [14]; para cárie por severidade isso é natural, pois cada lesão é um objeto cujo rótulo é o grau. Entre os detectores, os de **estágio único** (família **YOLO** [15]–[17]) predizem caixas e classes em uma passagem, com melhor relação velocidade/precisão que os de dois estágios (ex. Faster R-CNN [18]); a variante YOLO-seg acrescenta um ramo de protótipos de máscara à cabeça.

Detectores treinados em baixa resolução só reconhecem objetos acima de uma fração mínima da imagem (critérios tipo DORI, $\sim$10% da altura). Em panorâmicas de alta resolução com lesões diminutas, o **fatiamento** (*slicing*) recorta a imagem em *tiles* reescalados, elevando a área relativa do alvo e recuperando a detectabilidade, ao custo de processar múltiplas fatias [19].

IV. Trabalhos Relacionados

Segmentação binária no DC1000. O DC1000 foi introduzido por [9] e detalhado por [11]; o método que o acompanha, MLUA, é semissupervisionado: combina um esquema *teacher–student* com estimativa de incerteza em múltiplos níveis para aproveitar imagens não rotuladas e recorta o treino em quadrados de 384 px para ampliar a área de *foreground*, reportando Dice entre 0,614 (265 *slices*) e 0,711 (530 *slices*) [9]. Posteriormente, [1] estabeleceram o *benchmark* de referência, treinando doze arquiteturas (CNNs, *Transformers* e modelos *Mamba*) sob protocolo idêntico; a CNN DoubleU-Net [12] venceu (Dice 0,7345; mIoU 0,5978), e os autores observaram que a maior complexidade arquitetural não superou as redes convolucionais — um alto poder discriminativo não se traduzindo necessariamente em boa delimitação de máscara — atribuindo o teto de desempenho ao dataset pequeno, ao desbalanceamento de classes e às lesões sutis de baixo contraste. Ambos os trabalhos, contudo, colapsam a cárie em uma única classe.

Cárie multiestágio. O CariesNet [6] segmenta cárie em três estágios com um decodificador parcial e um módulo de atenção axial em escala completa para refinar lesões pequenas, atingindo Dice de 0,936 — porém em *dataset próprio* de lesões mais salientes, o que torna o valor não comparável ao DC1000. [20] combinam YOLOv5 e *Attention* U-Net [22] para detecção e segmentação por esmalte/dentina/polpa. [21] graduam cárie superficial/média/profunda em panorâmicas segmentando esmalte, dentina e polpa e intersectando essas regiões anatômicas com a lesão, porém em base própria. Na vertente de *detecção*, [10] propõem um *Transformer* para cárie inicial (graus D1–D4, *mAP* 0,873). Tais trabalhos confirmam a relevância da severidade, mas não a avaliam no DC1000.

Fatiamento para objetos pequenos. O SAHI [19] melhora a detecção de objetos pequenos sem alterar a arquitetura, atuando no treino (SF) e na inferência. O próprio MLUA recorta o treino em quadrados de 384 px para elevar a área de *foreground* de $\sim$1,5‰ para 11,79% [9] — evidência de que o

fatiamento ataca o núcleo do problema. A Tabela I resume a lacuna operacional avaliada aqui: combinar, no DC1000, severidade, validação cruzada e fatiamento.

V. Materiais e Métodos

A Figura 1 resume o *pipeline*. As subseções a seguir detalham o conjunto de dados, a conversão das anotações, o modelo YOLO11n-seg, o fatiamento SF/SAHI, as métricas, a validação cruzada, o teste de Wilcoxon e os hiperparâmetros.

O experimento segue quatro etapas encadeadas: (1) treina-se um *baseline* sobre a imagem inteira; (2) aplica-se o *Slicing-Aided Fine-Tuning*, varrendo os tamanhos de *tile* $\{640, 512, 384\}$ px com inferência SAHI, para identificar a escala mais promissora; (3) no *tile* selecionado, avaliam-se os quatro braços *baseline*, *baseline*+SAHI, SF com inferência inteira e SF+SAHI; e (4) submete-se cada configuração à validação cruzada de 5 *folds*, registrando as métricas por classe e por imagem. As comparações pareadas quantificam a consistência direcional entre *folds*. A grade de *tiles* permanece exploratória; a ablação evita atribuir ao pacote completo um efeito que pertença exclusivamente ao treino ou à inferência.

A. Conjunto de dados DC1000

O DC1000 [9], [11] deriva do *Children's Dental Panoramic Radiographs Dataset* e é um dos poucos conjuntos públicos de panorâmicas com máscaras de cárie — e o primeiro amplamente utilizado para a tarefa. A base-mãe agrega subconjuntos de segmentação de estrutura dentária e de detecção de doenças, com pares imagem/máscara; o recorte de interesse aqui é o de cárie anotada por grau de severidade, em nível de pixel por dentistas experientes [11]; o nome DC1000 provém do *benchmark* de [9]. Do release ($\sim$597 panorâmicas), pareamos 593 imagens com máscara de cárie válida em escala de cinza (2943×1435 px), das quais 2 sem lesão. Cada lesão recebe rótulo de severidade, codificado nas máscaras pelos tons de cinza $\{102, 153, 255\}$, correspondentes a *superficial*, *média* e *profunda*. A Tabela II resume a distribuição das instâncias.

A análise de tamanho fundamenta a hipótese: pela convenção COCO de objeto pequeno (área $< (32\,\text{px})^2$), **99,2%** das lesões superficiais e 90,3% das médias são "pequenas", contra apenas 36,9% das profundas — estas predominantemente médias/grandes. É esse predomínio de lesões diminutas nas classes superficial e média que o fatiamento procura mitigar.

B. Pré-processamento e conversão para YOLO-seg

O pré-processamento segue: (i) leitura da máscara de severidade e mapeamento de cada tom de cinza à sua classe; (ii) extração de componentes conexos por classe, descartando-se os de área inferior a 10 px como ruído; (iii) aproximação poligonal dos contornos; e (iv) escrita no formato de segmentação por instância do YOLO (uma linha por instância: classe seguida dos vértices normalizados do polígono). O *split* é estratificado por classe, preservando a proporção de severidades em treino e validação — cuidado relevante dado o desbalanceamento de área entre as classes. O descarte de componentes com área $<$10 px removeu apenas 20 anotações (0,44%; 17 na superficial, todas $\leq$9 px) — componentes extremamente pequenos, de impacto quantitativamente limitado sobre o conjunto de anotações.

C. Modelo base: YOLO11n-seg

Adotamos a **YOLO11n-seg** [16], [17], variante de segmentação por instância da família YOLO, na configuração *nano* (a mais leve). Diferentemente da segmentação semântica, que apenas rotula cada pixel, a segmentação *por instância* distingue objetos individuais — aqui, cada lesão é uma instância cuja classe é o seu grau de severidade. A rede é composta por: (i) um *backbone* convolucional com blocos *C3k2* (variante eficiente de CSP), agregação multiescala por *SPPF* e atenção espacial *C2PSA*; (ii) um *neck* do tipo *PAN-FPN* [23] que funde características em múltiplas escalas; e (iii) uma cabeça desacoplada, *anchor-free*, que prediz caixas (via *Distribution Focal Loss*) e classes, acrescida de um ramo de *protótipos de máscara* no estilo YOLACT [14]: a máscara de cada instância resulta da combinação linear de k protótipos ponderados pelos coeficientes preditos. A função de perda combina termos de caixa (*CIoU* + DFL), de classificação (entropia cruzada binária) e de máscara. A escolha do *backbone nano* privilegia custo computacional, adequado a um cenário de apoio ao diagnóstico.

D. Slicing-Aided Fine-Tuning *e SAHI*

O **SAHI** [19], [24] ataca o problema de objetos pequenos em duas frentes independentes e combináveis. No **treino** (*Slicing-Aided Fine-Tuning*), as imagens são recortadas em *tiles* sobrepostos de $S \times S$ px, com $S \in \{384, 512, 640\}$ e sobreposição de 20% entre *tiles* adjacentes; cada *tile* é reescalado para a resolução de entrada da rede, de modo que a área relativa de pixels de uma lesão pequena cresce substancialmente. *Tiles* positivos (com lesão) são mantidos e uma amostra de *tiles* vazios é incluída para regular falsos-positivos. Na **inferência** (*Slicing Aided Hyper Inference*), a imagem completa é fatiada com o mesmo S e sobreposição; cada *tile* é processado independentemente; e as predições são remapeadas para as coordenadas originais e fundidas por *Non-Maximum Suppression* (NMS) com casamento por IoU e limiar de casamento 0,5 (no ponto de operação conf $=$ 0,25). A biblioteca SAHI oferece ainda a fusão por *merging* (NMM e sua variante gulosa GREEDYNMM), que combina — em vez de descartar — detecções sobrepostas; adotamos o NMS por casamento de IoU, mais conservador. A ablação usa o *tile* de 384 px e a sobreposição de 0,20, mantendo o mesmo ponto de operação em todos os braços (Tabela III). Ela é operacional: o SF altera tanto a escala quanto a distribuição de exemplos de treino; por isso a interpretação do efeito de treino fatiado deve considerar também o orçamento adicional de *fine-tuning*.

A sobreposição de 20% entre *tiles* reduz o risco de uma lesão ser cortada na borda de uma fatia e, com isso, perdida ou fragmentada. O mecanismo explica por que o fatiamento favorece justamente a cárie pequena: detectores treinados em baixa resolução só reconhecem objetos acima de uma fração

mínima da imagem, e o reescalonamento do *tile* eleva a lesão a essa faixa. As configurações são denotadas `sf`S`_o0.2`.

E. Métricas de avaliação

A avaliação é *pixel-level*, calculada *por classe de severidade* e também em macro-média e na variante *binária* (cárie *vs.* fundo). Sejam, por classe, TP, FP e FN o número de pixels verdadeiros-positivos, falsos-positivos e falsos-negativos. Reportamos [6], [9]:

$$\mathrm{Dice} = \frac{2\,\mathrm{TP}}{2\,\mathrm{TP} + \mathrm{FP} + \mathrm{FN}}, \quad \mathrm{IoU} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FP} + \mathrm{FN}}, \tag{1}$$

$$P = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FP}}, \quad R = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FN}}, \tag{2}$$

$$F_2 = \frac{5\,P \cdot R}{4\,P + R}. \tag{3}$$

O Dice (equivalente ao F_1 na segmentação) mede a sobreposição com a referência; a IoU é mais severa, penalizando mais as diferenças de borda. Adotamos o Dice como métrica primária e destacamos o *recall* (sensibilidade): em cárie incipiente, o falso-negativo é clinicamente mais grave que o falso-positivo, lógica que o F_2 formaliza ao ponderar R acima de P. Deliberadamente não reportamos acurácia e especificidade: como o fundo domina a imagem (a cárie ocupa ∼1,5‰), ambas excedem 99% mesmo para predições pobres, sendo pouco informativas. As métricas são calculadas *por classe* e agregadas por macro-média (média simples entre as três severidades), de modo que a classe profunda — maior em área — não domine o indicador global. As contagens de TP, FP e FN são acumuladas no nível de pixel, e a métrica de cada radiografia é calculada antes da média sobre o conjunto de validação (convenção por imagem), evitando que imagens com lesões extensas dominem o valor agregado. No corpo reportamos Dice (por classe, macro e binário), precisão/*recall*/F_2 da superficial e mIoU binário; não usamos *mAP* de máscara, mantendo o foco *pixel-level*. Além de FP em pixels, contabilizamos componentes preditos sem casamento um-para-um com componente de referência a IoU de máscara $\geq 0{,}5$. Reportamos esses falsos positivos

por imagem, juntamente com precisão e *recall* da superficial. Quanto a classes ausentes: a média *por classe* inclui apenas as radiografias que contêm aquela severidade (convenção *m*); imagens sem a classe não entram em sua média. No binário, todas as radiografias contam — uma imagem sem cárie e sem predição recebe Dice $= 1$, sendo penalizada apenas na presença de falso-positivo. Para os indicadores de FP por imagem, contudo, todas as radiografias entram no denominador, inclusive as sem a severidade em questão.

F. Validação cruzada k-fold

Empregamos validação cruzada estratificada de $k = 5$ ***folds***. O conjunto é dividido em k subconjuntos mutuamente exclusivos de tamanho aproximadamente igual; em cada uma das k iterações, um *fold* serve de validação e os $k-1$ restantes, de treino, até que cada *fold* tenha sido validado exatamente uma vez. A divisão é feita **por radiografia**, não por *tile*: os *folds* são formados a partir das imagens inteiras e, *somente depois*, os *tiles* de cada imagem são gerados *dentro* do seu *fold*; assim, nenhuma fatia de uma mesma radiografia aparece em treino e validação ao mesmo tempo, evitando **vazamento de dados**. A estratificação usa a **classe de severidade dominante** de cada imagem (a mais frequente, com desempate por área), preservando aproximadamente a proporção de severidades em cada *fold*. De fato, a distribuição da classe dominante no conjunto de validação é praticamente idêntica entre os cinco *folds* (≈64 imagens superficiais, 27 médias e 27 profundas por *fold*), confirmando que a estratificação funcionou. As duas radiografias sem lesão não formam um estrato de cinco partes; elas são distribuídas deterministicamente em dois *folds* de validação, e essa assimetria é registrada nos manifestos das partições. O desempenho é agregado pela média e desvio-padrão entre *folds*,

$$\mu = \frac{1}{k}\sum_{i=1}^{k} x_i, \qquad \sigma = \sqrt{\frac{1}{k-1}\sum_{i=1}^{k}(x_i-\mu)^2}, \tag{4}$$

onde x_i é a métrica no *fold* i. A escolha $k = 5$ equilibra viés e variância da estimativa [25] em um conjunto pequeno e de centro único, mantendo tratável o custo da grade principal (20 treinamentos: 5 *folds* × *baseline* mais três modelos SF). A ablação acrescenta inferências, mas não novos treinamentos. A configuração recomendada é aquela com o maior ganho médio de Dice na cárie superficial *sem* deteriorar as demais classes, entre as consistentes. Esta varredura de *tile* é **exploratória**: como as três escalas são comparadas e a melhor é destacada no *mesmo* esquema de *folds*, há viés de seleção, que um conjunto de teste externo deveria confirmar.

G. Teste estatístico de Wilcoxon

Para comparar cada braço da ablação e cada configuração SF+SAHI com o *baseline* usamos o teste de **Wilcoxon de postos sinalizados**, não paramétrico e adequado a amostras pareadas que não pressupõem normalidade — caso das métricas obtidas sobre os *mesmos folds*. Para cada *fold* i calcula-se a diferença d_i entre a métrica das duas configurações; ordenam-se as diferenças por $|d_i|$, atribuindo-se postos; somam-se os postos das diferenças positivas (R^+) e negativas (R^-), e a estatística é $T = \min\{R^+, R^-\}$. Adotamos a hipótese nula H_0 de mediana das diferenças igual a zero, alternativa *unilateral* (melhora direcional), método exato e $\alpha = 0{,}05$. Duas ressalvas são tratadas explicitamente. Primeiro, com $n = 5$ o menor valor-p unilateral alcançável é $1/2^5 = 0{,}031$ (todos os *folds* na mesma direção); nesse regime o teste degenera, essencialmente, no *teste de sinais*. Segundo, não aplicamos correção para múltiplas comparações. Além disso, os conjuntos de treino dos *folds* se sobrepõem e não constituem repetições independentes. Por isso tratamos os valores-p como indicadores *descritivos* de consistência direcional e enfatizamos os **tamanhos de efeito** (Δ), a precisão e os falsos positivos por imagem.

H. Hiperparâmetros e ambiente

A Tabela IV resume o protocolo de treino, comum a todas as configurações. A grade principal compreende 20 treinamentos; o controle de imagem inteira em 1920 px acrescenta 5, totalizando 25, cada um executado em subprocesso isolado para controle de memória; o *pipeline* foi implementado em Python com Ultralytics, SAHI e scikit-learn, e executado em GPU. A geração das partições usou semente 42; os treinamentos usaram semente 42+índice do *fold*. Uma auditoria dos *checkpoints* confirmou que a seleção automática do otimizador resolveu para **AdamW** com taxa de aprendizado efetiva $\approx 1{,}43 \times 10^{-3}$ em *todos* os braços, com 85–100 épocas efetivas por treino; o *weight decay* efetivo foi 0,000375 no *baseline* e 0,0015 nos braços SF (escalonamento da biblioteca conforme o *batch*), e as atualizações diferem pela maior contagem de *tiles* — ambos decorrentes da configuração, não da escolha do otimizador. O artefato de execução `fase3_environment.json` registra as versões efetivas de Python, PyTorch/CUDA, Ultralytics, SAHI, scikit-learn e GPU; os manifestos `fase3_fold*_split.json` preservam a lista de validação de cada *fold*. Esses arquivos, os CSVs por *fold* e o código serão depositados em repositório público com DOI após a aceitação.

VI. Resultados

Varredura de *tile*. A Tabela V apresenta o Dice por classe (média de 5 *folds*). Todas as configurações SF+SAHI superam o *baseline* na cárie superficial e em macro-média. O *tile* menor (384 px) é o melhor em superficial, média e macro; na cárie profunda, o *tile* de 512 px leva ligeira vantagem.

Ablação de SF e SAHI. A Tabela VI separa os dois componentes no *tile* de 384 px. SAHI aplicado somente ao *baseline* reduz o Dice macro de 0,308 para 0,152. O SF com inferência inteira não melhora o *baseline* em macro (0,291). Em contraste, SF+SAHI alcança Dice macro de 0,415 e Dice superficial de 0,265. A combinação, portanto, é o elemento associado ao ganho; ela também eleva a precisão e o *recall*, mas aumenta os falsos positivos por imagem.

Tabela IV
PROTOCOLO DE TREINO E INFERÊNCIA.

Parâmetro	Valor
Modelo	YOLO11n-seg
Semente (*splits*)	42

Tabela V
DICE POR CLASSE DE SEVERIDADE (MÉDIA DE 5 *folds*). MELHOR POR COLUNA EM **NEGRITO**.

Configuração	Superf.	Média	Profunda	Macro
Baseline	0,092	0,261	0,571	0,308
`sf640_o0.2`	0,261	0,341	0,556	0,386
`sf512_o0.2`	0,256	0,347	**0,627**	0,410
`sf384_o0.2`	**0,265**	**0,358**	0,623	**0,415**

Controle de resolução. Como o *baseline* reduz a imagem a 1280 px enquanto o SF opera sobre recortes *nativos*, o fatiamento poderia estar confundido com maior resolução efetiva. Treinamos então um *baseline* de imagem inteira em **alta resolução (1920 px)**, mesmos *folds* e protocolo (Tabela VI). A resolução recupera *parte* do ganho (Dice superficial 0,092 → 0,168; *recall* → 0,180; $p = 0{,}031$), mas o SF+SAHI-384 ainda o supera em Dice superficial (+0,098), macro (+0,050) e *recall* (+0,143), cinco *folds* na mesma direção ($p = 0{,}031$); só na profunda empatam ($\Delta = +0{,}004$; $p = 0{,}5$). O ganho, portanto, não é explicado apenas pela resolução efetiva, sugerindo uma contribuição adicional do fatiamento.

Consistência direcional (grade completa). A Tabela VII traz, para cada configuração, o tamanho de efeito (Δ) por métrica. A `sf384_o0.2` é a única que melhora *todas* as classes com os cinco *folds* na mesma direção ($p = 0{,}031$), inclusive na profunda. Em `sf512` também há melhora direcional na profunda, enquanto em `sf640` a profunda chega a piorar ($\Delta = -0{,}015$).

***Baseline vs.* SF+SAHI-384.** A Figura 2 e a Tabela VI detalham a comparação com a vencedora. O Dice superficial quase triplica (0,092 → 0,265), a precisão aumenta de 0,113 para 0,286, o *recall* de 0,097 para 0,323 e o F_2 superficial de 0,092 para 0,283. Em contrapartida, os FP superficiais por imagem aumentam de 0,526 para 1,591.

Estabilidade entre *folds*. A `sf384_o0.2` é também a mais *estável*: o menor desvio-padrão do Dice superficial entre *folds* (0,009, contra 0,032 da `sf512` e 0,014 do *baseline*), combinando maior ganho médio à menor variância — o ganho não depende de um *fold* particularmente favorável.

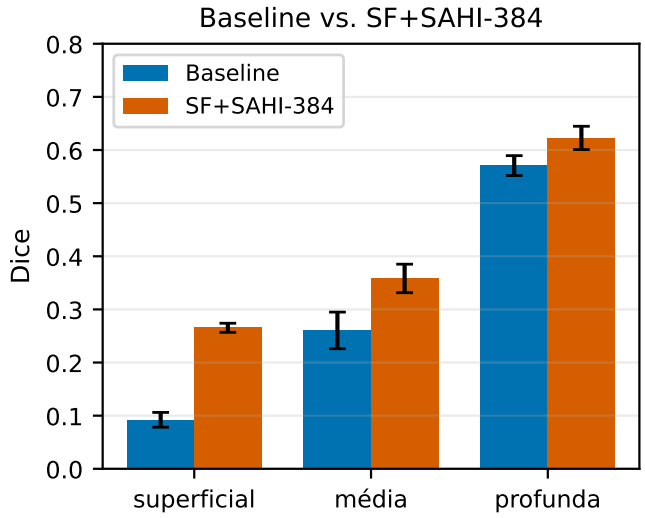

Figura 2. Dice por classe: *baseline vs.* `sf384_o0.2`. Barras de erro = desvio-padrão entre os 5 *folds*.

Posicionamento binário. *Uma ressalva precede a comparação:* o colapso da nossa saída de segmentação por *instância* em uma máscara semântica binária, somado a diferenças de arquitetura, resolução e *split*, faz de qualquer comparação com a literatura um *contexto*, não um confronto direto. Feita a ressalva, a Tabela VIII situa nosso Dice binário (0,608), próximo ao do MLUA em 265 *slices* (0,614) e abaixo da DoubleU-Net (0,735).

Falsos positivos e custo. A Figura 3 e a Tabela VI mostram que o ganho de sensibilidade não é gratuito: os FP superficiais passam de 0,526 para 1,591 instâncias por imagem e os binários de 1,246 para 2,713. Quanto ao custo, a inferência fatiada processa $\lceil W/S \rceil \times \lceil H/S \rceil$ fatias por imagem: *tiles* menores (384 px) implicam mais fatias e maior tempo — *trade-off* entre sensibilidade e custo a considerar em uso clínico.

VII. DISCUSSÃO

A ablação identifica uma interação entre SF e SAHI. O ganho do SF+SAHI-384 concentrou-se na cárie superficial (Δ Dice $= +0{,}173$; Δ recall $= +0{,}226$), acima da profunda (+0,052), e ocorreu na mesma direção nos cinco *folds*. Entretanto, o resultado não pode ser atribuído a qualquer componente isoladamente: SAHI sobre o *baseline* reduz o Dice macro para 0,152, e SF com inferência inteira chega a 0,291, abaixo do *baseline* (0,308). A melhoria requer o alinhamento entre a escala vista no *fine-tuning* e a escala da inferência fatiada. Isso é coerente com o mecanismo proposto para objetos pequenos [19] e com o fato de 99,2% das lesões superficiais serem objetos "pequenos".

O piso baixo do *baseline* não é um artefato. O Dice superficial do *baseline* (0,092) é muito baixo, mas a ablação mostra que não decorre apenas do *fine-tuning* extra (SF-inteira atinge só 0,098) nem apenas da resolução (o *baseline*

Tabela VI
ABLAÇÃO DE SF, SAHI E CONTROLE DE RESOLUÇÃO (*baseline* 1920 PX), MÉDIA DE 5 *folds*. FP: INSTÂNCIAS PREDITAS SEM CASAMENTO POR IOU DE MÁSCARA $\geq 0{,}5$; MENOR É MELHOR.

Configuração	Dice sup.	Precisão sup.	Recall sup.	FP sup./img.	Dice macro	Dice bin.	FP bin./img.
Baseline (1280 px)	0,092	0,113	0,097	0,526	0,308	0,536	1,246
Baseline (1920 px)	0,168	0,205	0,180	0,966	0,366	0,594	1,549
Baseline+SAHI	0,023	0,055	0,017	0,125	0,152	0,284	2,162
SF (inteira)	0,098	0,114	0,107	0,644	0,291	0,520	1,232
SF+SAHI	**0,265**	**0,286**	**0,323**	1,591	**0,415**	**0,608**	2,713

Tabela VII
TAMANHO DE EFEITO (Δ DICE; MÉDIA DE 5 *folds*) DE CADA SF *vs. baseline*. TODA MELHORA DIRECIONAL CONSISTENTE (5/5 *folds*) CORRESPONDE A $p = 0{,}031$ (WILCOXON UNILATERAL, DESCRITIVO — SEÇÃO V-G); $\Delta < 0$ INDICA PIORA. "REC_S": *recall* SUPERFICIAL; "BIN": BINÁRIO.

Config.	Superf.	Média	Profunda	Macro	rec_S	bin

Figura 3. Ablação de SF e SAHI no protocolo de cinco *folds*. (a) Dice, precisão e *recall* da cárie superficial; maior é melhor. (b) falsos positivos por imagem; menor é melhor. O ganho da configuração SF+SAHI vem acompanhado de maior número de falsos positivos.

Tabela VIII
POSICIONAMENTO NO DC1000 (BINÁRIO). **CONTEXTO**, NÃO COMPARAÇÃO DIRETA.

Método	Dice (bin.)	mIoU (bin.)
Baseline (nosso)	0,536	0,406
SF-384+SAHI (nosso)	0,608	0,472
MLUA 265 *slices* [9]	0,614	–
MLUA 530 *slices* [9]	0,711	–
DoubleU-Net [1], [12]	0,735	0,598

a 1920 px chega a 0,168): expressa a dificuldade intrínseca de segmentar lesões diminutas e de baixo contraste. Uma atribuição causal estrita ao treino fatiado ainda exigiria igual orçamento de atualizações em imagem inteira; os valores absolutos permanecem modestos.

O mecanismo, porém, não é estritamente monótono — uma questão em aberto. O *tile* de 384 px maximiza a superficial, a média e o macro, enquanto 512 px leva vantagem na profunda (classe majoritariamente média/grande). Pelo argumento puro de área relativa, espera-se que *tiles* menores ajudem *menos* as classes maiores — o que não se observa de forma limpa. Não temos, com os dados atuais, explicação fechada para essa não-monotonicidade; ela permanece uma questão em aberto, cuja investigação exige isolar a densidade de falsos-positivos por fatia e o efeito da fusão das predições entre *tiles*. Registramos, assim, que o argumento de área relativa explica o ganho dominante na superficial, mas não esgota o comportamento por classe.

***Trade-off* de falsos positivos.** A melhor configuração melhorou todas as severidades em Dice e elevou a precisão superficial (0,113 → 0,286), mas também triplicou os FP superficiais por imagem (0,526 → 1,591) e mais que dobrou os FP binários (1,246 → 2,713). O ganho não decorre, portanto, de uma simples troca de *recall* por precisão; ele vem com maior atividade preditiva, que ainda exige triagem pelo especialista.

Posicionamento. Nosso Dice binário (0,608) é compatível com o MLUA em 265 *slices* (0,614) e inferior à DoubleU-Net (0,735) — esperado, pois colapsamos uma saída por instância em máscara semântica, além de diferenças de arquitetura e *split*. Ademais, nosso próprio *baseline* (0,536) está $\sim$0,20 abaixo da DoubleU-Net, de modo que o $+0{,}072$ do SF+SAHI é melhora *relativa* controlada sobre o mesmo *baseline*, e não aproximação do estado da arte binário — que uma rede-base mais forte provavelmente já alcançaria. A contribuição principal não é superar o *benchmark* binário, mas avaliar a severidade — informação que orienta a conduta [5], [6] e ausente nos trabalhos no DC1000.

Análise estatística. Diferentemente dos trabalhos no DC1000, usamos validação cruzada estratificada, comparação pareada e tamanhos de efeito; reportar os Δ ao lado dos valores-p evita a leitura binária "significativo/não" que o pequeno n tornaria frágil.

Implicações clínicas. Segmentar *por severidade* distingue estágios de conduta distinta — da remineralização, na superficial, à restauração ou endodontia, na profunda. O ganho de *recall* na superficial ($0{,}097 \rightarrow 0{,}323$) é relevante, pois é na fase incipiente que a prevenção é mais eficaz e a leitura manual mais falha [10]. Ainda assim, os valores modestos e o aumento de FP posicionam a ferramenta como *apoio* ao especialista, não substituto.

Limitações. (i) Com $n = 5$ *folds* o poder estatístico é baixo (o teste degenera no de sinais); enfatizamos tamanhos de efeito. (ii) Métricas em um único ponto de operação (conf $= 0{,}25$). (iii) DC1000 é de centro único. (iv) Os valores absolutos de Dice são modestos. (v) As classes derivam da intensidade das máscaras, sem validação histológica. (vi) Usamos o *backbone* mais leve (YOLO11n); variantes maiores podem alterar os absolutos. (vii) A escolha do *tile* e o teste usam o mesmo esquema de *folds*, sem *hold-out* — viés otimista que um conjunto externo deveria confirmar. (viii) O SF recebe *fine-tuning* adicional; um controle de igual orçamento de atualizações em imagem inteira reforçaria a atribuição causal ao treino fatiado.

VIII. Conclusão

Avaliamos a segmentação de cárie *por severidade* no DC1000. No protocolo de cinco *folds*, SF+SAHI com *tiles* de 384 px foi a configuração mais consistente com YOLO11n-seg, elevando o Dice macro de 0,308 para 0,415 e o superficial de 0,092 para 0,265 (*recall* $0{,}097 \rightarrow 0{,}323$). A ablação indica que o ganho depende da combinação entre treino e inferência fatiados, e um controle em alta resolução (1920 px) mostra que ele **não** se reduz à resolução efetiva. O custo foi o aumento dos falsos positivos ($0{,}526 \rightarrow 1{,}591$/imagem), que restringe o uso a apoio ao especialista. Próximas etapas: teste externo, mais centros, validação histológica, varredura do limiar e *backbones* mais robustos.

***Abstract*—Quantitative EEG (qEEG) indices have been proposed as early biomarkers of post-stroke neuroplasticity, on the premise that synaptic reorganization precedes the functional gains captured by clinical scales used in neurorehabilitation. This work proposes and demonstrates a clinimetric sensitivity-analysis framework that jointly evaluates the reliability and responsiveness of candidate qEEG biomarkers against the Fugl-Meyer Assessment, scoring each on four mutually non-redundant, equally weighted core criteria—reliability (ICC), signal above measurement noise (MDC_{95}), responsiveness (SRM), and clinical discrimination (AUC-ROC)—while SEM, paired Cohen's d and clinical coupling (Spearman's ρ) are reported without being scored. To overcome the limited availability of patient-level raw EEG in the source cohort, a hybrid dataset was constructed by pairing published longitudinal clinical scores for proportional and poor recoverers with group-conditioned, physiologically clamped Gaussian Monte Carlo simulations of PSD-derived qEEG trajectories (DAR, DTABR, BSI, pdBSI) at the initial (2 weeks) and final (3 months) post-stroke periods, parameterized from the stroke EEG literature. Applied to two proportional-recovery subgroups with high and low clinical variation, the framework identified DTABR and BSI as the most informative biomarkers, distinguishing statistically significant from clinically meaningful candidates even when clinical improvement was minimal or imperceptible. These results show how the framework separates reliable, responsive signals from measurement noise, motivating its application to neurorehabilitation protocols. By conceptualizing the brain as a dynamic target and therapy as a responsive system, this framework may substantially improve functional recovery.**

***Index Terms*—Clinimetrics, Fugl-Meyer Assessment, Monte Carlo simulation, Post Stroke neurorehabilitation, Quantitative EEG, Sensitivity analysis**

I. Introduction

Sensitivity Analysis (SA), or uncertainty analysis, examines how uncertainty in a model's outputs can be traced back to different sources of variability in its inputs. This field focuses on understanding how uncertainties in the inputs influence the outputs [1]. To tackle this problem, researchers employ a range of methodologies, each bringing distinct assumptions and limitations. These approaches yield conclusions that vary in interpretability and detail, all aimed at answering a central question: How do different sources of uncertainty or variations in model inputs affect output uncertainty? Sensitivity Analysis has been applied in patient-centered neurorehabilitation programs designed to optimize motor and cognitive recovery. Sensitivity Analysis provides a structured framework for assessing how variations in clinical assumptions, patient characteristics, or therapy intensity influence functional outcomes [2]. By assessing the distinct impact of each variable on outcomes, SA reveals which factors most strongly influence patient improvement, rather than presuming a uniform response to standard protocols. This insight is essential for crafting truly personalized rehabilitation strategies, especially for complex conditions like stroke [3], spinal cord injury [4], and multiple sclerosis [2]. As a result, SA stands as a cornerstone of methodological rigor in neurorehabilitation research, particularly as studies frequently shift their focus across diverse metrics and encounter related challenges, including:

- Patient heterogeneity—including differences in severity, chronicity, and lesion location [5]—and high dropout rates;
- The use of multiple clinical outcome scales (e.g., Fugl-Meyer Assessment (FMA), Barthel, ARAT, FIM, WISCI-II) [6];
- Lack of blinding in therapist-delivered interventions [7].

Therefore, SA helps ensure that conclusions remain robust despite these specific challenges [8].

A. Kinds of Sensitivity Analysis in Neurorehabilitation

SA application in neurorehabilitation encompasses a set of complementary methods used to test whether study findings remain robust across parameter values and analytic choices. Some of the principal methods are:

- Reliability, which evaluates how much of the observed score variance is due to true differences between real outcomes vs. measurement error [9];
- Responsiveness Analysis, which evaluates the instrument's ability to detect change over time, particularly clinically important change [10].

Together, these two properties define the clinimetric quality this work evaluates: the ability of a specific metric or instrument to sensitively detect true differences or changes in patients receiving treatment [11]. A third quantity, clinical coupling—the correlation between a quantitative metric and an established clinical scale—is customarily invoked as evidence of concurrent validity and is reported here as a companion

measure, but it is not part of the scored core. Seven statistics are computed in total. Four of them—ICC, MDC_{95}, SRM and AUC-ROC—constitute the scored core of the framework; the remaining three—SEM, paired Cohen's d and Spearman's ρ—are reported for completeness and carry no weight in the composite score, for the scale-invariance and redundancy reasons detailed in Section II-B, item (4). They are defined as follows:

1) Reliability:

- The Intraclass Correlation Coefficient (ICC), defined in Eq.1, quantifies the consistency of repeated measurements within the same individual. A high ICC indicates that a scale can reliably reproduce the same value across repeated assessments, effectively distinguishing true between-subject variance from measurement error [12]. If the ICC falls below the commonly accepted threshold (typically $\geq$ 0.7), distinguishing real signal changes from measurement instability becomes challenging. The closer the ICC is to 1, the more consistently the metric produces reliable results. Interpretation: $|\text{ICC}| \geq 0.90$ = excellent; $|\text{ICC}| \geq 0.70$ = acceptable; $|\text{ICC}| \geq 0.50$ = moderate; $|\text{ICC}| < 0.50$ = poor.
- The Standard Error of Measurement (SEM), defined in Eq.2, quantifies measurement precision by representing the 'noise band' surrounding an individual score [13]. SEM depends on both the standard deviation (SD) of measurements and the reliability (ICC). Higher reliability (ICC approaching 1) or lower SD yields a smaller SEM, indicating greater measurement precision. *Reported, not scored* (Section II-B, item (4)); its information enters the framework through MDC_{95} (Eq.3);
- Minimal Detectable Change (MDC_{95}), defined in Eq.3, is the absolute threshold above which an individual's change in score has a $\leq 5\%$ probability of being due to measurement error. Changes smaller than MDC_{95} are likely the result of measurement error rather than genuine change [14]. Lower MDC_{95} values reflect higher measurement sensitivity.

2) Responsiveness:

- The Standardized Response Mean (SRM), presented in Eq.4, is a widely used measure of internal responsiveness in rehabilitation. SRM captures both the magnitude of change and its consistency across patients in a single index. A higher absolute SRM value ($|\text{SRM}|$) indicates greater ability to detect true changes, effectively distinguishing genuine recovery signals from measurement noise [15]. Interpretation: $|\text{SRM}| \geq 0.8$ = large; ≥ 0.5 = moderate; ≥ 0.2 = small change.
- Paired Cohen's d, described in Eq.5, facilitates comparison of change magnitude across metrics with different scales by expressing changes in units of the baseline standard deviation. The absolute value of Cohen's d ($|d|$) quantifies the change relative to data variability, offering a standardized metric for mean differences [16]. Higher absolute values indicate a greater difference between the initial (T_0) and final (T_n) stages of longitudinal recovery. *Reported, not scored*: d shares its numerator with the SRM, and the MDC_{95} criterion is a strictly more demanding form of the same comparison (Section II-B, item (4)).
- The Area Under the Receiver Operating Characteristic Curve (AUC-ROC), defined in Eq.6, measures the ability of $|\Delta\text{metric}|$ (e.g., changes in a quantitative electroencephalogram metric) to distinguish clinical responders—those with improvement above the median on the clinical scale ($|\Delta\text{FMA}|$)—from non-responders. AUC-ROC translates statistical responsiveness into clinical discriminative utility, providing the essential link between the metric and diagnostic or prognostic decision-making. Interpretation: AUC-ROC = 0.5 indicates random discrimination; ≥ 0.7 is acceptable; ≥ 0.8 is considered good for detecting improvement above the median of ΔFMA [17].

3) Clinical coupling (reported, not scored):

- Spearman's rank correlation coefficient (ρ), described in Eq.7, is a non-parametric statistic that quantifies the strength and direction of a monotonic association between two ranked variables, such as a qEEG metric and a clinical scale [18]. *Reported, not scored*: it enters the composite score with $w_\rho = 0$ (Section II-B, item (4)).

$$\text{ICC} = \frac{\sigma^2_{\text{between}}}{\sigma^2_{\text{between}} + \sigma^2_{\text{within}}} \tag{1}$$

$$\text{SEM} = \text{SD} \times \sqrt{1 - \text{ICC}} \tag{2}$$

$$\text{MDC}_{95} = 1.96 \times \text{SEM} \times \sqrt{2} \tag{3}$$

$$\text{SRM} = \frac{\overline{\Delta}}{\text{SD}(\Delta)} \tag{4}$$

$$\text{Cohen}'\text{s } d = \frac{\overline{\Delta}}{\text{SD}(T_0)} \tag{5}$$

$$\text{AUC} = \frac{U_+}{n_+\, n_-} = \frac{\displaystyle\sum_{i:\, y_i=1} r_i - \frac{n_+(n_+ + 1)}{2}}{n_+\, n_-} \tag{6}$$

$$\rho = 1 - \frac{6 \sum_{i=1}^{n} d_i^2}{n\,(n^2 - 1)} \tag{7}$$

Equations for the evaluation metrics are as follows: ICC (Eq. 1) represents the intraclass correlation coefficient, quantifying the proportion of total variance attributable to between-subject differences, where $\sigma^2_{\text{between}}$ is the between-subject variance and σ^2_{within} is the within-subject (residual) variance. SEM (Eq. 2), MDC_{95} (Eq. 3), SRM (Eq. 4), and paired Cohen's d (Eq. 5) assess measurement error and responsiveness. Here, $\overline{\Delta}$ denotes the mean change between time points, SD(Δ) the standard deviation of that change, SD(T_0) the baseline standard deviation, and SD the relevant sample standard deviation. AUC (Eq. 6) refers to the area under the ROC curve, computed through equivalence to the Mann–Whitney U statistic: r_i is the rank of score x_i among all samples (with ties resolved by midranks), U_+ is the number of correctly ranked positive–negative pairs, and n_+ and n_- are the counts of positive ($y_i = 1$) and negative

samples, respectively. Spearman's ρ (Eq. 7) uses d_i, the difference between paired ranks, to quantify monotonic association.

B. Electroencephalogram in Neurorehabilitation

Quantitative Electroencephalogram (qEEG) metrics offer objective neurophysiological biomarkers for diagnosis, prognosis, and monitoring of recovery in stroke and other neurological disorders [19]. These metrics are increasingly employed to track recovery and guide interventions, providing reliable indicators of neurophysiological change. In many cases, qEEG metrics are more sensitive than traditional clinical scales. Commonly used qEEG metrics include:

- Power Spectral Density (PSD) serves as the basis for most derived qEEG indices, quantifying EEG power within standard frequency bands: delta (δ, 0.5–4 Hz), theta (ϑ, 4–8 Hz), alpha (α, 8–13 Hz), beta (β, 13–30 Hz), and gamma (γ, >30 Hz), as defined in Eq.8. It is treated in this work as the substrate of the candidate biomarkers rather than as a candidate in its own right;
- Delta/Alpha Ratio (DAR), defined in Eq.9, is the ratio of delta (δ) to alpha (α) band power. An elevated DAR is associated with increased cortical dysfunction [20];
- Delta/Theta to Alpha/Beta Ratio (DTABR), defined in Eq.10, is the ratio of combined δ and ϑ band power to combined α and β band power. Higher DTABR reflects a shift toward slow-wave activity and is correlated with greater cortical dysfunction; one of the most robust qEEG markers of impaired Stroke recovery [20].
- Brain Symmetry Index (BSI), defined in Eq.11, quantifies interhemispheric spectral asymmetry and is widely used for acute stroke monitoring [21];
- Pairwise-Derived BSI (pdBSI), defined in Eq. 12, quantifies asymmetry across all symmetric EEG channel pairs and frequency bands. Unlike traditional BSI, pdBSI is computed dynamically over time windows and for each symmetric pair individually, without prior averaging across hemispheres [22].

$$PSD(f) = \frac{1}{N \cdot f_s} \left| \sum_{t=0}^{N-1} x(t)\, w(t)\, e^{-j2\pi f t / f_s} \right|^2 \tag{8}$$

$$\mathrm{DAR} = \frac{\int_{0.5}^{4} PSD(f)\, df}{\int_{8}^{13} PSD(f)\, df} \tag{9}$$

$$\mathrm{DTABR} = \frac{\int_{0.5}^{4} PSD(f)\, df + \int_{4}^{8} PSD(f)\, df}{\int_{8}^{13} PSD(f)\, df + \int_{13}^{30} PSD(f)\, df} \tag{10}$$

$$\mathrm{BSI} = \frac{1}{N \cdot M} \sum_{i=1}^{M} \sum_{j=1}^{N} \left| \frac{R_{ij} - L_{ij}}{R_{ij} + L_{ij}} \right| \tag{11}$$

$$\mathrm{pdBSI} = \frac{1}{N \cdot M} \sum_{i=1}^{M} \sum_{j=1}^{N} \left| \frac{R_{ij}(f) - L_{ij}(f)}{R_{ij}(f) + L_{ij}(f)} \right| \tag{12}$$

qEEG biomarkers are derived from the EEG signal $x(t)$. The Power Spectral Density (PSD, Eq. 8) is computed using a windowed ($w(t)$) discrete Fourier transform over N samples at a sampling frequency f_s, providing the foundation for band-power metrics. The Delta/Alpha Ratio (DAR, Eq. 9) and Delta+Theta/Alpha+Beta Ratio (DTABR, Eq. 10) capture the balance of slow versus fast oscillatory power, with higher values reflecting increased cortical dysfunction. The Brain Symmetry Index (BSI, Eq. 11) and its pairwise-derived spectral variant (pdBSI, Eq. 12) assess average normalized power asymmetry between homologous right (R_{ij}) and left (L_{ij}) hemisphere electrodes across M channel pairs and N frequency bins, where higher values signal greater interhemispheric asymmetry. Collectively, these indices are among the strongest qEEG predictors of stroke recovery.

C. The Importance of Multimodal Integration of qEEG and Clinical Scales in Stroke Neurorehabilitation

In neurorehabilitation, relying solely on either qEEG or clinical scales is insufficient. Clinical scales reflect the end result of motor and cognitive function but frequently overlook subclinical brain reorganization. Conversely, qEEG uncovers the neurophysiological substrates of recovery—such as cortical excitability, interhemispheric balance, and network reorganization [19]—yet lacks direct correspondence to functional outcomes. Integrating these modalities enables earlier and more accurate prognosis, personalized therapy, objective recovery monitoring, and deeper mechanistic understanding [20]. qEEG-derived metrics also reduce operator-dependent variability, converting subjective clinical assessments into reproducible biomarkers ideal for clinical trials and longitudinal studies [23]—mechanistic distinctions that clinical indices alone cannot provide [24]. As neurorehabilitation advances toward greater precision and individualization, the convergence of qEEG biomarkers and clinical scales is shaping the next generation of personalized neurorestoration. In this paradigm, therapy intensity, modality, and timing are continuously tailored to each patient's evolving neurophysiological profile [25]. This work proposes a multimodal assessment framework designed to bridge the gap between neurophysiological mechanisms (what is happening in the brain) and functional outcomes (what the patient can do).

II. Methodology

A. Hybrid Solution: Real and Simulated Data

To illustrate the application of Sensitivity Analysis (SA) in neurorehabilitation, clinical assessment data from [26] were analyzed. This dataset includes longitudinal FMA scores recorded at 2 weeks (T_0) and 3 months (T_1) post-stroke, allowing comparison between proportional (PROP) and poor (POOR) recovery groups in motor rehabilitation programs (see Fig.1). However, only aggregated FMA scores for the overall cohort or specific subgroups were available, and no raw EEG data or channel-wise PSD signals were accessible [26]. This lack of raw data precluded recalculation of qEEG metrics

for individual frequency bands or sensor regions[1]. To address this, Gaussian Monte Carlo simulations were performed to estimate the expected evolution of brain physiological patterns for each subgroup, drawing on established findings from the qEEG literature [27]. Value assignment was guided by theoretical markers of post-stroke cortical slowing: poorer outcomes are typically associated with higher relative energy in slow bands (delta/theta), reduced balance with fast bands (alpha/beta), and greater interhemispheric asymmetry [28]. Informed by this and related studies [29], the simulations enforced separation between groups at T_0 and distinct trajectories through T_1—improvement in PROP patients, and maintenance or worsening in POOR patients. Group-conditioned Gaussian sampling with clamp truncation [30] ensured physiological plausibility and avoided unrealistic outliers. As a result, all longitudinal qEEG variations in the analysis reflect simulated group trajectories rather than direct patient measurements.

$$X_0 \sim \mathcal{N}(\mu_0, \sigma_0^2) \tag{13}$$

$$\tilde{X}_0 = \mathrm{clip}(X_0, L_0, U_0) \tag{14}$$

$$\varepsilon \sim \mathcal{N}(\mu_\Delta, \sigma_\Delta^2) \tag{15}$$

$$\tilde{X}_1 = \mathrm{clip}(\tilde{X}_0 + \varepsilon,\ L_1, U_1) \tag{16}$$

$$\Delta X = \tilde{X}_1 - \tilde{X}_0 \tag{17}$$

Gaussian Monte Carlo simulations with clipping. Baseline values X_0 are drawn from a normal distribution (Eq.13) and clipped to the bounds $[L_0, U_0]$ to obtain $\tilde{X}_0$ (Eq.14). A random increment ε is sampled and added (Eq.15), with the result clipped to $[L_1, U_1]$ to yield the follow-up value $\tilde{X}_1$ (Eq.16). The simulated change is $\Delta X = \tilde{X}_1 - \tilde{X}_0$ (Eq.17).

B. Implementation of the qEEG–FMA Clinimetrics Sensitivity Analysis Framework

In clinical research, significant clinical coupling—most often quantified by Spearman correlation—between a quantitative metric and a validated clinical scale provides evidence of concurrent validity for the quantitative metric [31]. This relationship addresses a central question: Does the metric's signal change alongside the patient's clinical status? Yet, concurrent validity alone is not enough. The metric must also exhibit reliability—consistently yielding stable values when no real change occurs—and responsiveness—the ability to accurately detect true change when it happens. Without these properties, observed clinical coupling may be confounded by measurement noise, ceiling or floor effects (when scales cannot detect further improvement), or random fluctuations between therapeutic sessions [10]. This rigor is particularly crucial in post-stroke recovery. The proportional recovery rule and the ceiling effect of the FMA scale—which can mask subclinical improvements—require that a candidate qEEG biomarker both minimizes measurement error (Is the signal stable when no true change occurs?) and sensitively tracks clinical outcomes (Does the signal change when genuine recovery happens?) — otherwise, the metric risks statistical significance (demonstrating clinical coupling) without actual clinical relevance. In other words, a metric with high correlation may still be noisy, suffer from ceiling or floor effects, or fail to capture meaningful longitudinal change [32].

The proposed pipeline (Fig. 2) systematically evaluates whether candidate qEEG biomarkers are both reliable and responsive indicators of motor recovery, indexed by the FMA.

(1) Inputs: The power spectral density (PSD, Eq. 8) is simulated at two time points (T_0 and T_1), in parallel with the FMA clinical scale, and the four candidate qEEG biomarkers scored by the framework—DAR, DTABR, BSI, and pdBSI (Eqs. 9–12)—are derived from it. The PSD is therefore an input to the pipeline rather than a scored candidate: being a frequency- and channel-resolved function, it admits no scalar summary that is not itself a band-power or asymmetry index already represented among the four derived metrics.

(2) Longitudinal Change: Within-subject change scores ($\Delta = T_1 - T_0$) are calculated for each biomarker. ΔFMA is then used to dichotomize patients into responders and non-responders using a median split.

(3) Reliability, Responsiveness, and Clinical Coupling Metrics: Each biomarker is characterized in three domains, and within each domain a distinction is drawn between the statistics that are *scored* and those that are *reported only* (see item (4)): - Reliability/Measurement Error: ICC (scored); the minimal detectable change at 95% confidence, MDC_{95} (scored, through the comparison $|\overline{\Delta}| \geq \mathrm{MDC}_{95}$); and SEM (reported only). - Responsiveness: the standardized response mean SRM (scored); the AUC-ROC, which discriminates responders from non-responders (scored); and paired Cohen's d (reported only). - Clinical Coupling: Spearman's correlation ρ between each Δ-metric and ΔFMA, reported for descriptive purposes only and entering the framework with a weight of exactly zero ($w_\rho = 0$): *sensitivity is not correlation*, and a static, cross-sectional association must not compensate for a failure in the longitudinal domain the framework interrogates (see item (4)).

(4) Decision Gate / Scoring: Each biomarker earns one point per core criterion met, yielding a composite score $S \in \{0, \ldots, 4\}$ formally defined in Eq. 18, where c_k denotes the k-th criterion and $\mathbf{1}[\cdot]$ the indicator function. The four core criteria carry equal unit weight ($w_k = 1$ for all k) and are deliberately chosen so that each interrogates a distinct property and none is an algebraic consequence of the others: (c_1) $\mathrm{ICC} \geq 0.70$—is the metric stable?; (c_2) $|\overline{\Delta}| \geq \mathrm{MDC}_{95}$—does the observed change exceed the metric's own measurement noise?; (c_3) $|\mathrm{SRM}| \geq 0.80$—is the change large relative to its dispersion across patients?; and (c_4) $\mathrm{AUC\text{-}ROC} \geq 0.70$—does the metric separate responders from non-responders? All four are invariant under a rescaling of the biomarker—in c_1 and c_3 the scale factor cancels between numerator and denominator, in c_2 it multiplies both sides of the inequality, and c_4 is rank-based—so the same thresholds apply to bounded asymmetry indices (BSI, pdBSI) and to unbounded power ratios (DAR, DTABR) alike. The practical import is clearest

[1]A formal data request was sent to the corresponding authors, but no response was received.

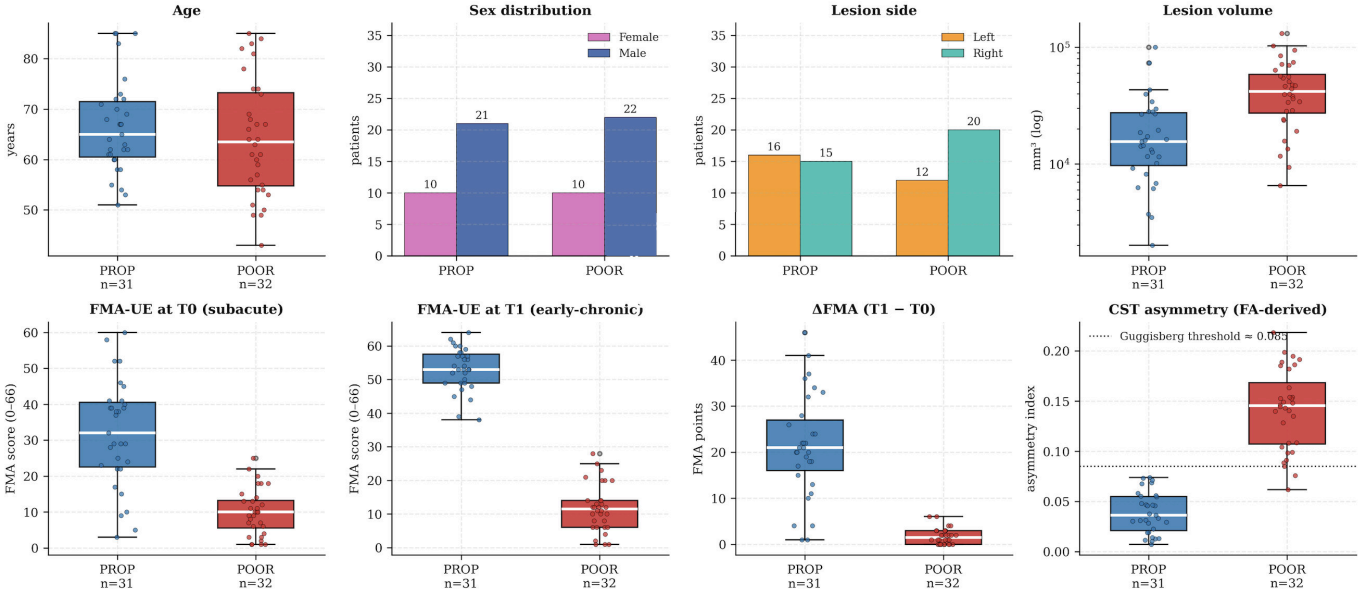

Fig. 1: Based on article [26] metadata of 63 patients. Age 65.3 ∓ 10.4 years (range 43–85y). Sex: 20 females, 43 males. Lesion side: 28 left, 35 right. T_0 = 20 ∓ 4 days post Stroke, T_1 = 89 ∓ 7 days post Stroke. FMA T_0 20.7 ∓ 15.7, FMA T_1 32.1 ∓ 21.7. Corticospinal Tract (CST) asymmetry and lesion volume data were not considered for simulations.

by counterexample: DTABR in Subgroup I (SEM = 0.285) would fail an absolute SEM < 0.05 test, yet expressing the same trajectories in a unit ten times smaller turns that failure into a pass (0.0285) while leaving all four core criteria unchanged—a verdict flipped by a choice of unit measures scale, not precision. The bias is systematic here: the bounded asymmetry indices carry SEMs in the hundredths, the unbounded power ratios in the tenths, so an absolute cutoff would reward the former for being small, not for being reproducible. Two statistics that are commonly reported in clinimetric work are computed here (Tables I and II) but deliberately excluded from S. The SEM is excluded on two grounds: it carries the native units of the biomarker, so an absolute threshold is not comparable across metrics whose scales differ by an order of magnitude; and, by Eq. 2, $\mathrm{SEM} = \mathrm{SD}\sqrt{1-\mathrm{ICC}}$, so at a fixed SD it is a deterministic function of c_1. Paired Cohen's d is excluded for a stronger reason: under the framework's own definitions it is not an independent test at all. Substituting Eq. 2 into Eq. 3 gives $\mathrm{MDC}_{95} = 1.96\sqrt{2}\,\mathrm{SD}\sqrt{1-\mathrm{ICC}}$; dividing both sides of c_2 by the baseline standard deviation $\mathrm{SD}(T_0)$ that normalizes Eq. 5 then yields

$$|\overline{\Delta}| \geq \mathrm{MDC}_{95} \iff \underbrace{\frac{|\overline{\Delta}|}{\mathrm{SD}(T_0)}}_{|d|} \geq 1.96\sqrt{2}\,\sqrt{1-\mathrm{ICC}}\,.$$

Criterion c_2 and a threshold of the form $|d| \geq 0.80$ are therefore two statements about the same quantity, differing only in the threshold—fixed in one case, reliability-adjusted in the other. Since $1.96\sqrt{2}\,\sqrt{1-\mathrm{ICC}} > 0.80$ for every $\mathrm{ICC} < 0.917$, and all reliabilities observed here fall below that value, c_2 is strictly more demanding: satisfying it already guarantees the fixed-threshold form, so scoring both would award two points for a single comparison. (The identity assumes the SD of Eq. 2 is the baseline SD of Eq. 5; with a pooled estimate it is approximate, but the dependence remains.) Spearman's ρ is likewise excluded, entering Eq. 18 with $w_\rho = 0$. A high-scoring biomarker is thus simultaneously reliable, responsive, and clinically discriminative, irrespective of its clinical coupling.

$$S = \sum_{k=1}^{4} w_k\,\mathbf{1}[c_k] \;+\; w_\rho\,|\rho(\Delta\mathrm{qEEG}, \Delta\mathrm{FMA})|\,, \qquad (18)$$

where $w_k = 1$ for all four core criteria $c_1, \ldots, c_4$ and $w_\rho = 0$. The second term is retained in the formulation only to make explicit that clinical coupling is measured and reported, but does not contribute to S.

(5) Output: biomarkers are classified by their composite score S as Strong (4), Good (3), Intermediate (2), or Weak (0–1), and ranked by S alone. Because $w_\rho = 0$, clinical coupling does not act as a tie-breaker: biomarkers sharing the same S are reported as tied and are distinguished qualitatively by which domain—reliability or responsiveness—drives their score.

III. Results

A. Applying the Clinimetrics Sensitivity Analysis Framework to Simulated Data

The results and statistical evaluation of longitudinal changes were analyzed for the following two PROP subgroups:

- Subgroup I with a high clinical variation: 10 patients with $20 \leq \Delta\mathrm{FMA} \leq 25$, 70% right-sided lesions and 80% males;

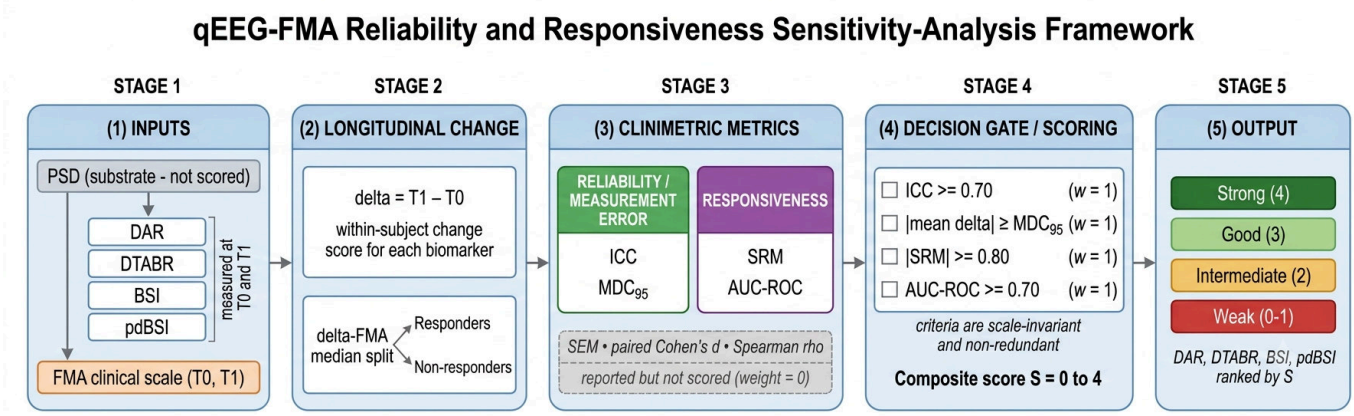

Fig. 2: **Overview of the qEEG–FMA reliability and responsiveness sensitivity-analysis framework.** The pipeline scores candidate qEEG biomarkers according to how reliably and responsively they track motor recovery, indexed by the FMA. **(1) Inputs:** the power spectral density (PSD) is the common substrate of the analysis and is not itself scored; the four candidate biomarkers derived from it—DAR, DTABR, BSI, and pdBSI—are obtained at two time points (T_0 and T_1), in parallel with the FMA clinical scale. **(2) Longitudinal change:** within-subject change scores ($\Delta = T_1 - T_0$) are derived for every biomarker, and ΔFMA is used to dichotomize patients into responders versus non-responders by a median split. **(3) Clinimetric metrics:** the scored statistics are grouped into two domains—reliability/measurement error (ICC and the minimal detectable change at 95% confidence, MDC_{95}) and responsiveness (SRM and the AUC-ROC discriminating responders from non-responders). The dashed box holds the three statistics that are computed and reported but carry no weight in the score—SEM, paired Cohen's d and Spearman's ρ—for the scale-invariance and redundancy reasons detailed in Section II-B, item (4). **(4) Decision gate / scoring:** each biomarker earns one point per criterion met, the four mutually non-redundant criteria carrying equal unit weight ($w_k = 1$): $\mathrm{ICC} \geq 0.70$; $|\overline{\Delta}| \geq \mathrm{MDC}_{95}$; $|\mathrm{SRM}| \geq 0.80$; and $\mathrm{AUC\text{-}ROC} \geq 0.70$, yielding a composite score $S \in \{0, \ldots, 4\}$ as defined in Eq. 18. A strong biomarker must be simultaneously reliable, responsive, and clinically discriminative. **(5) Output:** the four derived qEEG biomarkers are ranked by S alone and color-coded as Strong (4), Good (3), Intermediate (2), or Weak (0–1).

- Subgroup II with a low clinical variation: 7 patients with $0 \leq \Delta\mathrm{FMA} \leq 15$ (low or imperceptible clinical improvement), with 75% left-sided lesions and 50% females.

These subgroups were selected to demonstrate that qEEG metrics can reveal neurophysiological improvements not only in patients with pronounced clinical gains (high clinical variation), but also in those with minimal or imperceptible clinical improvement. In both cases, reliability and responsiveness measures support the sensitivity of qEEG metrics, as shown in Tables I and II.

In the first subgroup, the BSI emerged as the most reliable qEEG metric, exhibiting the highest |ICC| (0.906), lowest |SEM| (0.015), and lowest MDC_{95} (0.044), despite showing negligible clinical coupling (low $|\rho|$ = 0.219). BSI satisfied both reliability criteria (c_1 and c_2) but failed both responsiveness criteria: its |SRM| of 0.144 is an order of magnitude below the 0.80 threshold and its AUC-ROC of 0.60 does not reach 0.70. It therefore met 2 of the 4 core criteria (Score: 2/4), classifying it as Intermediate — reliable, but without a longitudinal signal to be reliable about. DTABR was the most responsive metric, with the highest |SRM| (2.740) and an excellent AUC-ROC (0.96), making it the best qEEG metric for distinguishing patients who improved above the median ΔFMA. It met three of the four core criteria—ICC $\geq$ 0.70 (0.792), |SRM| $\geq$ 0.80 (2.740) and AUC-ROC $\geq$ 0.70 (0.96)—failing only on $|\overline{\Delta}| \geq \mathrm{MDC}_{95}$. DTABR therefore scored 3/4 (Good) in this subgroup: strongly responsive and discriminative, but with a mean change that does not yet clear its own measurement noise at this sample size. The pdBSI matched DTABR at 3/4 (Good) by a complementary route: it combined an excellent ICC (0.865) with a mean change exceeding its MDC_{95} (0.050) and a large SRM (0.927), failing only the discrimination criterion (AUC-ROC 0.64). The two Good biomarkers of this subgroup therefore rest on different evidence—pdBSI on reliability plus change magnitude, DTABR on change magnitude plus discrimination—and neither dominates the other. BSI and DAR both scored 2/4 (Intermediate), Table I. For Subgroup II, BSI once again emerged as the most reliable scale, exhibiting the highest |ICC| (0.899), low |SEM| (0.209), and the lowest MDC_{95} (0.039), along with moderate clinical coupling $|\rho|$ (0.447). BSI also proved to be the most responsive metric, with the highest |SRM| (1.758) and an acceptable AUC-ROC (0.75). These values indicate good discriminatory power and responsiveness within this subgroup. BSI was consequently the only biomarker in the study to satisfy all four core criteria (4/4, Strong), being simultaneously reliable, above its own measurement noise, responsive, and discriminative. DTABR followed at 3/4 (Good), missing only

TABLE I: Sensitivity metrics for the first subgroup with high clinical variation

	Responsiveness			Reliability			Clinical coupling	
Metric	SRM	Cohen's d	AUC-ROC	ICC	SEM	MDC_{95}	$\rho\times\Delta$FMA	Score
pdBSI	-0.927	-0.361	0.64	0.865	0.024	0.050	0.094	3/4
DTABR	-2.740	-0.628	0.96	0.792	0.285	0.292	-0.813	3/4
BSI	-0.144	-0.069	0.60	0.906	0.015	0.044	-0.219	2/4
DAR	-1.118	-0.440	0.64	0.843	0.370	0.731	-0.219	2/4

First PROP subgroup — 10 patients with ΔFMA between 20 and 25. DTABR emerged as the most responsive scale, effectively detecting change between T_0 and T_1 and discriminating patient responses ($|\mathrm{SRM}| = 2.740$, AUC-ROC = 0.96); its clinical coupling was also the strongest of the panel ($\rho = -0.813$), although this does not contribute to its score. BSI proved to be the most reliable metric—demonstrating stability and sensitivity to subtle variations (|ICC| = 0.906, SEM near zero, MDC_{95} = 0.044, the lowest of all metrics)—but failed both responsiveness criteria. Scoring follows the four-criterion core and bands of Section II-B, item (4). In this subgroup: pdBSI and DTABR are Good (3/4) — the former on reliability plus change magnitude, the latter on change magnitude plus discrimination — while BSI and DAR are Intermediate (2/4). The SEM, Cohen's d and $\rho\times\Delta$FMA columns are reported for completeness but are not scored criteria (Section II-B, item (4)); in particular, $w_\rho = 0$.

TABLE II: Sensitivity metrics for the second subgroup with low clinical variation

	Responsiveness			Reliability			Clinical coupling	
Metric	SRM	Cohen's d	AUC-ROC	ICC	SEM	MDC_{95}	$\rho\times\Delta$FMA	Score
BSI	-1.758	-0.534	0.75	0.899	0.209	0.039	-0.447	4/4
DTABR	-1.547	-0.562	0.75	0.846	0.029	0.412	-0.447	3/4
DAR	-0.981	-0.672	0.00	0.756	0.354	1.031	-0.894	2/4
pdBSI	-1.118	-1.215	0.25	0.033	0.024	0.053	0.447	1/4

Second PROP subgroup — 7 patients with ΔFMA between 0 and 15 (imperceptible or low clinical improvement). BSI was the only biomarker to satisfy all four core criteria (4/4, Strong), standing out as both the most responsive (|SRM| = 1.758, AUC-ROC = 0.75) and the most reliable (ICC = 0.899, MDC_{95} = 0.039) metric in this subgroup. DTABR followed at 3/4 (Good), missing only the $|\overline{\Delta}| \geq MDC_{95}$ criterion. DAR was Intermediate (2/4) and pdBSI Weak (1/4), the latter driven by an ICC of 0.033 that places it below the reliability threshold by a wide margin. The SEM, Cohen's d and $\rho\times\Delta$FMA columns are reported for completeness but are not scored criteria (Section II-B, item (4)); in particular, $w_\rho = 0$.

$|\overline{\Delta}| \geq \mathrm{MDC}_{95}$ — the same criterion it missed in Subgroup I. DAR was Intermediate (2/4) and pdBSI Weak (1/4); the latter is a marked reversal from Subgroup I and is driven by an ICC of 0.033, indicating that under low clinical variation the pairwise-derived index carried essentially no reproducible between-subject signal. See Table II.

IV. Discussion

The proposed pipeline offered a robust, systematic framework for identifying the most informative qEEG metrics, thereby enhancing the rigor of biomarker selection and validation. All evaluated metrics performed in agreement with expectations from the literature in our simulations [20, 27, 33]. Both DAR and DTABR—the ratios of slow to fast cortical activity—showed elevated values and power spectra shifted toward slower rhythms, indicating reduced cortical activation, thalamo-cortical deafferentation, and functional disconnection. These patterns mirror those observed in stroke patients with minimal or no recovery. Likewise, BSI and pdBSI, which quantify interhemispheric power asymmetry, also showed higher values, a feature frequently associated with poorer motor recovery. In this study, BSI and DTABR emerged as the most sensitive qEEG metrics for tracking patient progress during neurorehabilitation, independent of gender or lesion laterality. Our findings demonstrate that qEEG scales can reliably detect early progression, contributing to more accurate prognoses. High-reliability measures, such as ICC, consistently distinguished true between-subject variance from measurement error, while responsiveness metrics, such as SRM, captured both the magnitude and consistency of change across patients. Notably, these strengths were established independently of clinical coupling, which by construction carries no weight in the composite score and is reported only as descriptive evidence of concurrent validity. Applying this framework to longitudinal data from stroke and traumatic brain injury cohorts could further demonstrate its utility for personalized treatment. Integrating these qEEG metrics with clinical scales enables early detection and supports individualized, objective monitoring of neuroplastic changes throughout recovery. Ultimately, conceptualizing the brain as a dynamic, adaptable target—and designing therapy as a responsive, stage-adaptive system—offers substantial promise for advancing functional recovery. Future research should explore qEEG metrics beyond traditional spectral densities, such as Functional Connectivity (FC) [34]. By quantifying synchronization between brain regions, FC may offer richer prognostic insights and help guide the development of more tailored therapeutic strategies. Additionally, adopting advanced simulation models—such as neural mass models [35]—that more accurately represent the neurophysiological dynamics of post-stroke patients in neurorehabilitation could uncover further valuable qEEG biomarkers. Beyond that, incorporating additional statistical metrics—such as the Jacobson–Truax index, which identifies individual changes that surpass measurement error, and the Rasch/IRT proxy Z score, an exploratory indicator of signal-to-noise ratio—could also further strengthen sensitivity analyses in neurorehabilitation [36]. Two design choices deserve emphasis: every core criterion is invariant under a rescaling of the biomarker, and the criteria were screened for algebraic dependence before being given equal weight (Section II-B, item (4)); excluding SEM, Cohen's d and ρ from S is what makes the equal weighting defensible. A residual limitation is that c_2 depends on the measurement-error estimate propagated from the ICC, so biomarkers with poorly estimated reliability inherit that uncertainty. It is important to highlight that this work centers on sensitivity analysis as a method for validating biomarkers of post-stroke neural reorganization and recovery. The primary challenge addressed is measurement error—which sensitivity analysis directly quantifies—rather than establishing causal relationships. Responsiveness and reliability are essential prerequisites for subsequent causal modeling, as they ensure a metric reliably captures the relevant signal. Causal modeling should follow as a next step, ideally within a larger, prospectively designed interventional study.

V. Conclusion

This work presented a sensitivity analysis framework that reliably identified DTABR and BSI as the most informative qEEG biomarkers for tracking post-stroke motor recovery: DTABR was the only biomarker to reach Good in both

subgroups, and BSI the only one to satisfy all four core criteria in either. By jointly assessing reliability and responsiveness—with clinical coupling reported as unweighted descriptive evidence—the approach distinguished robust signals from noise and revealed neurophysiological improvements that traditional scales might miss. Although based on simulated data, this framework highlights the importance of reliability and responsiveness in biomarker validation and can be extended to real datasets, connectivity metrics, and more advanced models for personalized neurorehabilitation.

VI. Acknowledgment

We gratefully acknowledge [26] for making the clinical data available, which was essential to the success of this study.

Abstract*—Objective: Electrocardiographic ST-segment analysis is important for the characterization of myocardial ischemia, but amplitude-based measurements provide limited information about the time-frequency organization of repolarization morphology. This study investigates Matching Pursuit (MP) decomposition as a sparse representation of controlled ST-segment modifications in synthetic ECG signals. Methods: Synthetic lead-II ECG signals with ST-segment deviations from −0.8 to +0.8 mV were generated and contaminated with additive white Gaussian noise at multiple signal-to-noise ratio levels. Signals were decomposed using a Gabor-dictionary MP approach, and energy-, frequency-, scale, and sparse-decomposition descriptors were extracted. Kruskal–Wallis testing, regression analysis, two-way ANOVA with interaction effects, effect-size analysis, correlation analysis, and principal component analysis were applied. Results: MP consistently represented QRS morphology using short-scale, higher-frequency atoms, whereas ST morphology was represented by longer-scale, low-frequency atoms. Energy-related descriptors showed strong nonlinear dependence on ST deviation magnitude, with quadratic R^2=0.971 for total ST energy. Mean ST frequency and the number of ST-related atoms within the first ten iterations showed moderate linear relationships with signed ST deviation (R^2=0.354 and 0.223, respectively). For the first ST iteration, the signed linear relationship was negligible (R^2=0.001); however, regression against absolute ST deviation yielded R^2=0.572, indicating a relationship primarily with ST magnitude rather than polarity. Among detected ST atoms, the corresponding timing relationship reached R^2=0.654. The largest noise effect was observed for mean ST scale (η^2=0.133). Conclusion: Under the controlled synthetic conditions investigated, MP provides complementary descriptors of ST morphology beyond a single amplitude measure. The results support further investigation of MP-based sparse descriptors using clinical ECG recordings and systematic comparison with alternative time-frequency methods.

Keywords—electrocardiogram, ST-segment deviation, myocardial ischemia, Matching Pursuit, sparse representation, time–frequency analysis, ECG morphology

I. Introduction

Electrocardiographic (ECG) analysis remains one of the principal non-invasive tools for detection and assessment of myocardial ischemia and acute coronary syndromes [1–4]. In clinical practice, ischemic abnormalities are primarily identified through changes in ST-segment morphology, including ST elevation, ST depression, and repolarization disturbances [1, 3, 5, 6]. Conventional ECG interpretation is largely based on amplitude measurements relative to the isoelectric line and visual assessment of waveform morphology [2, 3, 7]. However, these approaches may provide limited characterization of complex repolarization dynamics, particularly in noisy recordings and subtle ischemic conditions [8-9].

Time–frequency analysis methods offer an attractive alternative for investigation of nonstationary biomedical signals such as ECG, EEG, and MEG [10–13]. Among these approaches, Matching Pursuit (MP) decomposition introduced by Mallat and Zhang [10] enables adaptive sparse representation of signals using abundant time–frequency dictionaries. In MP decomposition, a signal is iteratively approximated using elementary waveforms ("atoms") selected to maximize correlation with the residual signal. This adaptive strategy provides high temporal and spectral resolution while preserving signal interpretability [10, 14].

Matching Pursuit and related sparse decomposition techniques have previously demonstrated utility in biomedical signal analysis, including EEG time–frequency characterization [11–13], ECG compression and QRS detection [15–16], and adaptive decomposition of cardiovascular signals [17]. Recent developments in optimized dictionary structures and GPU-accelerated implementations further improved computational efficiency and representation quality of MP-based approaches [18–19].

Sparse decomposition methods may be particularly suitable for ECG analysis because ventricular depolarization and repolarization exhibit substantially different temporal and spectral characteristics. The QRS complex corresponds to rapid synchronized electrical activation, producing transient high-frequency structures, whereas the ST segment reflects slower plateau-phase ventricular repolarization processes [20]. Consequently, pathological ischemic changes may alter not only ECG amplitudes but also the sparse compressibility structure and spectral organization of repolarization components within adaptive time–frequency space.

Previous studies on ECG morphology modelling have suggested that sparse signal representations may provide complementary information beyond conventional amplitude-based descriptors [21]. However, the application of MP decomposition specifically for characterization of ischemic ST-segment morphology and its robustness under varying noise conditions remains insufficiently explored.

Therefore, the aim of the present study was to investigate sparse time–frequency representation of ischemic ST-segment abnormalities using MP decomposition with Gabor dictionaries. Synthetic ECG signals with controlled ST-segment deviations and additive noise contamination were analysed to evaluate the behaviour of MP-derived descriptors

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

related to energy distribution, spectral organization, temporal scale, and sparse decomposition structure. Particular attention was devoted to the relationship between ischemic morphology, sparse representability, and robustness to additive noise contamination.

II. Materials and Methods

A. ECG Signal Generation

Synthetic ECG signals were generated using the MPS450 biomedical signal simulator (Fluke Biomedical, USA). Lead II ECG recordings were acquired for five-minute intervals at a sampling frequency of 1000 Hz. ST-segment deviations were systematically varied from −0.8 mV to +0.8 mV in steps of 0.1 mV, resulting in 17 distinct ST levels.

To evaluate robustness of the proposed approach under realistic acquisition conditions, additive white Gaussian noise was introduced into the ECG signals. The signal-to-noise ratio (SNR) varied from 0 dB to 20 dB in steps of 2 dB, representing a range from highly noisy to relatively clean signal conditions.

The use of synthetic data allowed precise control over ST amplitude while maintaining consistent waveform morphology. All signals were acquired using the ADS1298 analog front-end (Texas Instruments, USA), ensuring high-resolution digitization suitable for time–frequency analysis.

B. Matching Pursuit Decomposition

Matching Pursuit (MP) decomposes signals into a set of elementary waveforms (atoms) characterized by parameters such as temporal location, energy, amplitude, frequency, phase, and scale, reflecting temporal duration. Gabor atoms are commonly employed due to their optimal time–frequency localization, making them particularly suitable for modelling SCG and ECG components.

In general, a waveform from a time–frequency dictionary can be expressed as a translation (u), dilation (s), and modulation (ω) of a window function g(t):

$$g_{\gamma=(s,u,\omega)}(t) = \frac{1}{\sqrt{s}} g\left(\frac{t-u}{s}\right) \cdot e^{i\omega t} \quad (1)$$

In this study, the dictionary was restricted to Gabor functions of the form:

$$g(t) = A \cdot exp\left(-\frac{(t-t_0)^2}{2s^2}\right) cos(2\pi f(t-t_0) + \varphi) \quad (2)$$

where A denotes amplitude, f frequency, φ phase, t_0 the temporal position of the atom, and s the scale parameter.

The MP decomposition was performed using the SVAROG software environment. Only the first 15 MP iterations were analysed in order to focus on the dominant structures contributing to ECG morphology. The following parameters were extracted: energy, amplitude, frequency, phase, and scale, for each atom.

C. ECG components definition based on atom classification

Following decomposition, atoms were grouped according to their frequency and scale to distinguish between QRS complexes and ST segments. The QRS complex was identified as a high-frequency (8–30 Hz), short-duration (scale ≤ 0.17) component, while the ST segment was associated with low-frequency (< 8 Hz), longer-duration atoms (scale ≥ 0.8).

D. MP-derived descriptors

For each ECG recording, several MP-derived descriptors characterizing ventricular repolarization were extracted. The analysed features included: total ST energy (E_{ST}), total QRS energy (E_{QRS}), ST-to-QRS energy ratio ($R_{ST/QRS}$), iteration number of the first detected ST-related atom, number of ST atoms among the first ten MP iterations, mean ST atom frequency, mean ST atom scale, relative ST energy contribution, i.e., the ratio of the ST energy to the total energy expressed as the sum of the squares of the amplitudes of all atoms. Feature extraction was performed independently for all combinations of ST deviation and noise level. The analysis therefore captured both morphological and noise-related variability of sparse ECG representation.

E. Statistical Analysis

To investigate the joint influence of ischemic morphology and signal quality, a two-factor statistical design was applied. ST-segment deviation level and additive noise level were treated as independent factors in a two-way ANOVA model including interaction effects. Effect sizes were quantified using eta-squared statistics. Since several MP-derived descriptors violated normality assumptions, complementary nonparametric Kruskal–Wallis analysis was additionally performed.

Linear regression analysis was used to quantify directional relationships between MP-derived descriptors and signed ST-segment deviation levels. Because several energy-related descriptors exhibited partially symmetric behaviour for ST elevation and ST depression conditions, additional quadratic regression models were evaluated to investigate potential nonlinear U-shaped dependence on ST deviation.

Robustness to additive noise contamination was assessed using Spearman correlation analysis across SNR conditions.

To investigate multivariate organization of ECG morphology within the MP feature space, principal component analysis (PCA) and correlation analysis were performed using the extracted MP-derived descriptors.

Fig. 1 demonstrates the experimental workflow.

III. Results

A. Sparse Representation of ECG Morphology

Matching Pursuit decomposition produced sparse time-frequency representations across the investigated ST-segment

and noise conditions. Representative examples of synthetic ECG recordings for selected ST levels and additive noise conditions are shown in Fig. 2, whereas the adaptive time–frequency decompositions are presented in Fig. 3. QRS complexes were predominantly represented by short-scale, higher-frequency atoms, whereas ST-segment morphology was represented by multiple longer-scale, low-frequency atoms (Fig. 3).

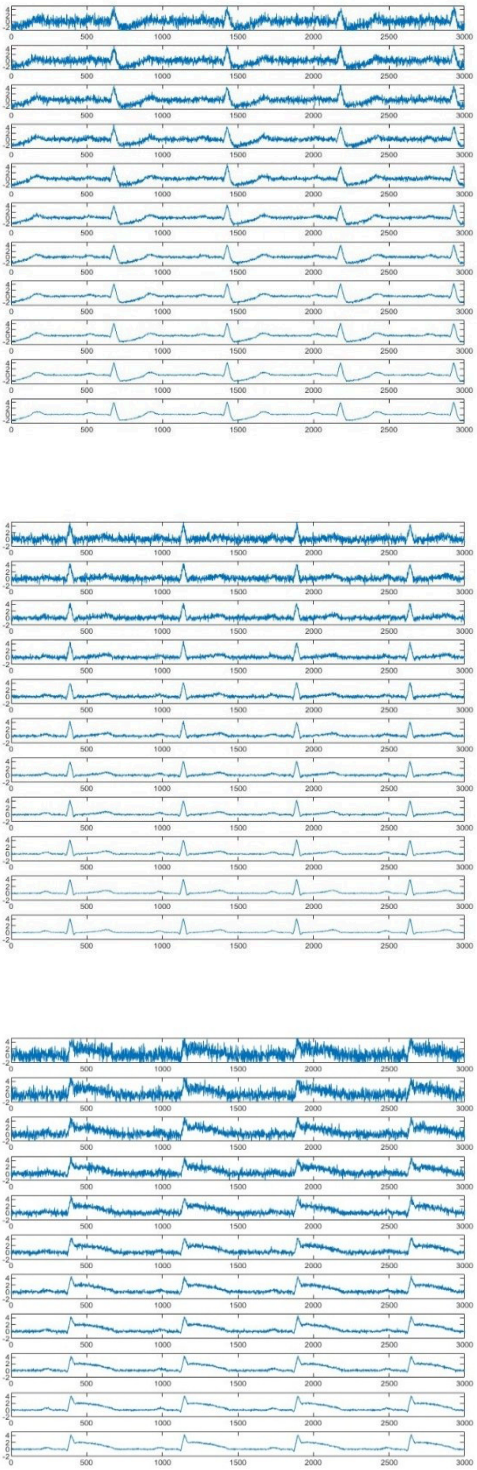

Fig. 2. Representative synthetic ECG recordings for selected ST-segment deviation levels: -0.5 mV, 0 mV, +0.5 mV, and additive noise conditions. Examples illustrate progressive changes in ventricular repolarization morphology under varying signal-to-noise ratios.

According to the atom classification criteria summarized in Table I, QRS-related atoms were typically characterized by frequencies within 8 – 30 Hz and short temporal scales ($\leqslant$ 0.17), while ST-related atoms occupied lower frequency ranges (<8 Hz) with substantially larger scales ($\geqslant$0.8).

This separation was preserved across the investigated noise conditions, supporting the use of the selected frequency- and scale-based criteria for distinguishing QRS- and ST-related components.

The resulting atom-level representation provided complementary information on energy, frequency, temporal scale, and decomposition order. These properties formed the basis for the subsequent ST-morphology descriptors.

TABLE I. DEFINITION OF ECG COMPONENTS.

ECG component	Frequency [Hz]	scale
ST	< 8	≥ 0.8
QRS	8–30	≤ 0.17

B. Statistical Dependence of MP Features on ST Deviation

Kruskal–Wallis analysis demonstrated statistically significant differences among ST levels for all analysed MP-derived descriptors ($p_{KW} < 0.001$; Table II). However, the corresponding regression results demonstrated substantial differences in explanatory strength. This distinction is important because statistical significance indicates that differences among experimental conditions are unlikely to be attributable to random variation alone, whereas R^2 quantifies the proportion of variance explained by a particular regression model.

TABLE II. LINEAR STATISTICAL ANALYSIS OF MP-DERIVED ECG FEATURES (KRUSKAL-WALLIS P-VALUES, NOISE CORRELATIONS, LINEAR REGRESSION R^2).

Feature	p_{KW}	ρ noise	p noise corr	R^2	R^2 adj
E_{ST}	< 0,001	0,016	0,841	0,014	0,008
E_{QRS}	< 0,001	0,004	0,960	0,008	0,002
$R_{ST/QRS}$	< 0,001	0,005	0,949	0,006	0,000
1st ST iteration	< 0,001	-0,037	0,628	0,001	-0,005
$N_{ST\ TOP10}$	< 0,001	0,062	0,421	0,223	0,218
mean ST frequency	< 0,001	0,110	0,154	0,354	0,351
mean ST scale	< 0,001	0,189	0,014	0,147	0,142
ST energy ratio	< 0,001	0,058	0,455	0,046	0,040

For signed ST deviation, the strongest linear relationships were obtained for mean ST atom frequency and the number of ST-related atoms detected within the first ten MP iterations (Table II and Fig. 4). Mean ST frequency achieved R^2=0.354 (adjusted R^2=0.351), whereas $N_{ST\ TOP10}$ achieved R^2=0.223 (adjusted R^2=0.218). These results indicate moderate linear dependence on signed ST deviation.

Energy-related descriptors showed weak linear relationships with signed ST level. For example, total ST energy yielded R^2=0.014 (Table II). However, these descriptors exhibited pronounced nonlinear dependence when elevation and depression were considered together. Quadratic

regression produced R^2=0.971 for total ST energy, R^2=0.686 for the ST energy ratio, and R^2=0.555 for $R_{ST/QRS}$ (Table III, Fig. 4). The nonlinear behaviour therefore reflects the approximately magnitude-dependent response of the sparse energy distribution to both positive and negative ST deviations.

Representative feature trends across ST levels and noise conditions are summarized in Fig. 5, whereas correlations between features are visualized in the heatmap representation shown in Fig. 6.

TABLE III. NONLINEAR DEPENDENCE OF ENERGY-BASED MP DESCRIPTORS ON ST-SEGMENT DEVIATION.

Feature	p-value	p ST^2	R^2	R^2 adj
E_{ST}	< 0,001	< 0,001	0,971	0,971
E_{QRS}	< 0,001	< 0,001	0,629	0,624
$R_{ST/QRS}$	< 0,001	< 0,001	0,555	0,550
ST energy ratio	< 0,001	< 0,001	0,686	0,682

C. First ST-Atom Timing

The first-ST-atom descriptor (Fig. 7) requires more careful interpretation than the other sparsity-related measures.

For the complete dataset, linear regression against signed ST deviation yielded only R^2=0.001 (adjusted R^2=−0.005, p=0.634) (Table IV). Thus, although the descriptor differed significantly among ST conditions in the nonparametric analysis, a simple linear model did not explain a meaningful proportion of its variance.

Additional analysis demonstrated that the descriptor was substantially more closely related to ST deviation magnitude. Regression against absolute ST deviation produced R^2=0.572 (adjusted R^2=0.569, $p=9.62\times10^{-33}$) (Table IV). A quadratic model using signed ST deviation also showed significant nonlinear dependence (R^2=0.371, adjusted R^2=0.363; quadratic term $p=1.80\times10^{-18}$) (Table IV). However, the absolute ST deviation model provided the stronger explanatory relationship.

The first-ST-atom timing was also examined only among recordings in which ST-related atoms were detected. In this subset (N=43), the timing showed a strong linear relationship with signed ST deviation (R^2=0.654, adjusted R^2=0.646, $p=5.29\times10^{-11}$) (Table IV). These findings suggest that first-ST-atom timing should not be interpreted as a universal linear marker of ST polarity. Rather, it appears to reflect the magnitude and detectability of the ST-related morphology, with the relationship becoming more pronounced when ST-related atoms are actually present.

TABLE IV. REGRESSION ANALYSIS OF FIRST ST-ATOM ITERATION.

Model	R^2	R^2 adj	p
Signed ST linear	0.001	−0.005	0.634
Absolute ST linear	0.572	0.569	<0.001
Signed ST quadratic	0.371	0.363	< 0.001
Detected ST atoms only	0.654	0.646	<0.001

D. Effects of Noise Contamination

Two-way ANOVA demonstrated statistically significant effects of ST deviation, noise level, and their interaction for all analysed descriptors (p<0.001; Table V). Nevertheless, the corresponding effect sizes differed substantially.

The largest ST-related effects were observed for total ST energy (η^2 ST = 0.986), first ST iteration (η^2 ST = 0.941), ST energy ratio (η^2 ST = 0.729), and mean ST frequency (η^2 ST = 0.615) (Table V).

The strongest interaction effect was observed for mean ST scale (η^2 interaction = 0.401), followed by $N_{ST\ TOP10}$ (η^2 interaction = 0.370). $R_{ST/QRS}$ and mean ST frequency showed equal interaction effect sizes (η^2 interaction = 0.357) and should therefore be regarded as tied rather than ranked sequentially (Table V).

The largest main effect of noise was observed for mean ST scale (η^2 noise = 0.133). In comparison, the noise effect sizes for total ST energy, first ST iteration, $N_{ST\ TOP10}$, and mean ST frequency were considerably smaller (Table V).

The sensitivity of mean ST scale to noise is consistent with the sequential nature of MP decomposition. Because the next atom is selected from the residual after subtraction of preceding atoms, additive noise can alter the residual structure and consequently affect the balance between shorter- and longer-scale atoms selected to represent low-frequency ST morphology. Mean scale may therefore be more sensitive to noise than descriptors based primarily on the presence or ordering of dominant ST-related atoms.

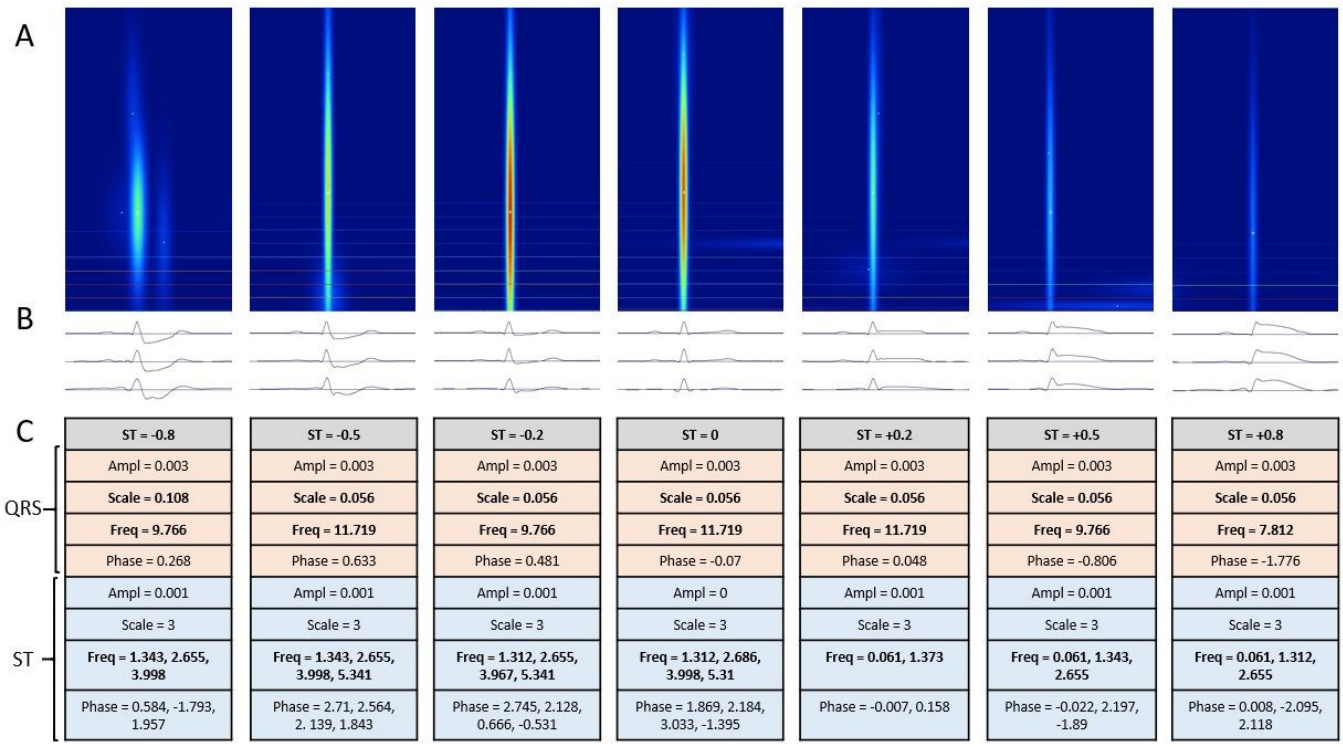

TABLE V. EFFECTS OF ST DEVIATION, NOISE LEVEL, AND THEIR INTERACTION ON MP-DERIVED FEATURES.

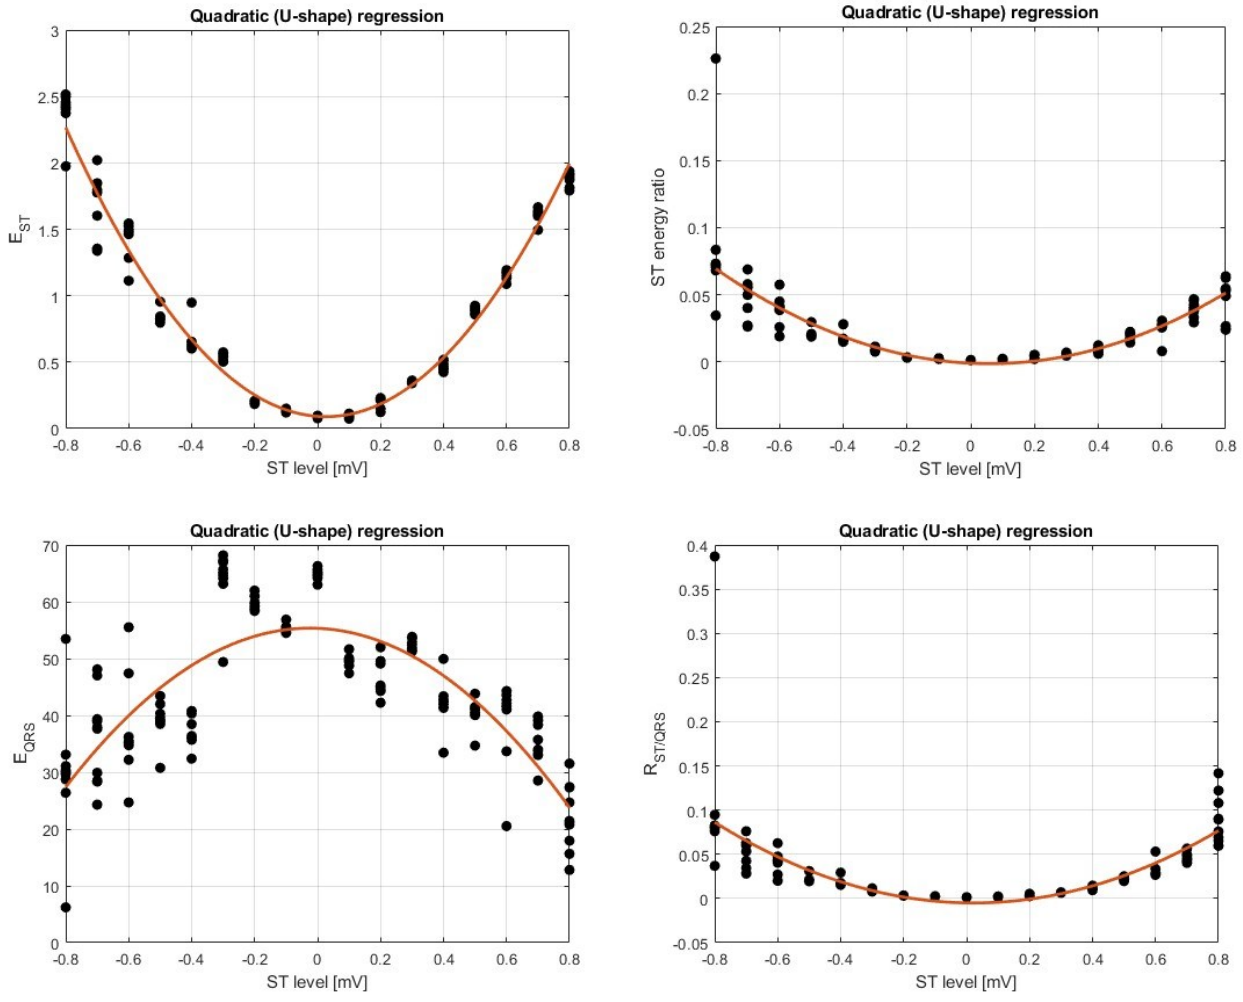
Feature	p ST	p noise	p inter	η^2 ST	η^2 noise	η^2 inter
E_{ST}	< 0,001	< 0,001	< 0,001	0,986	0,000	0,014
E_{QRS}	< 0,001	< 0,001	< 0,001	0,852	0,007	0,141
$R_{ST/QRS}$	< 0,001	< 0,001	< 0,001	0,613	0,030	0,357
1st ST iteration	< 0,001	< 0,001	< 0,001	0,941	0,003	0,056
N_{ST} TOP10	< 0,001	< 0,001	< 0,001	0,605	0,026	0,370
mean ST frequency	< 0,001	< 0,001	< 0,001	0,615	0,027	0,357
mean ST scale	< 0,001	< 0,001	< 0,001	0,466	0,133	0,401
ST energy ratio	< 0,001	< 0,001	< 0,001	0,729	0,013	0,258

E. Multivariate Feature-Space Structure



Principal component analysis demonstrated partial organization of the recordings according to ST condition in the multivariate MP feature space (Fig. 8). Separation between ST conditions remained visible across a range of noise levels, although the organization became less distinct under stronger contamination.

Correlation analysis indicated complementary relationships among energy-, frequency-, scale-, and sparsity-related descriptors (Fig. 6). In particular, the energy-based descriptors captured magnitude-related changes, whereas frequency- and sparsity-related descriptors provided additional information concerning the spectral and temporal organization of the sparse representation.

IV. Discussion

The present study demonstrates that Matching Pursuit provides a sparse and physiologically interpretable representation of controlled ST-segment morphology in synthetic ECG signals. An important observation is that MP does not produce a single descriptor that uniformly represents ST abnormalities. Instead, different descriptors capture different properties of the altered morphology, including energy redistribution, spectral organization, temporal scale, and the order in which ST-related structures become prominent during sparse decomposition. The ability of MP to represent signals through a small number of adaptive time–frequency atoms was originally established by Mallat and Zhang [10], while subsequent biomedical applications demonstrated the usefulness of this representation for resolving transient signal components [11]–[13].

The decomposition showed a consistent distinction between depolarization and repolarization structures. QRS complexes were predominantly represented by short-scale, higher-frequency atoms, whereas ST morphology required multiple longer-scale, low-frequency atoms. This behaviour is compatible with the substantially different temporal characteristics of ventricular depolarization and repolarization. It also illustrates an important property of the MP representation: individual atoms retain explicit information about amplitude, energy, frequency, scale, phase, and temporal location, allowing descriptors to be constructed from several complementary aspects of the decomposition. The use of Gabor-type dictionaries is particularly appropriate for such analysis because they provide joint temporal and spectral localization [10], while previous ECG studies have demonstrated the applicability of MP to QRS detection and ECG decomposition [15], [16]. Sparse ECG decompositions have also previously been investigated for separating cardiac components and representing ventricular and atrial activity [20].

The energy-related descriptors demonstrated the strongest dependence on ST deviation magnitude. Although their linear relationships with signed ST level were weak, quadratic models provided excellent fits, particularly for total ST energy (R^2=0.971). This behaviour is expected for descriptors that quantify the amount of energy assigned to ST-related atoms because both ST elevation and ST depression represent deviations from the reference morphology. Consequently, an energy-based descriptor can respond strongly to the magnitude of the perturbation while remaining relatively insensitive to its sign. The results therefore indicate that energy descriptors should be interpreted primarily as measures of ST-abnormality magnitude, rather than as direct indicators of ST elevation versus depression. This interpretation is consistent with previous work showing that sparse ECG representations can provide information complementary to conventional waveform measurements [20], [23].

Frequency-related descriptors provided complementary information. Mean ST atom frequency demonstrated the strongest linear dependence among the analysed MP descriptors (R^2=0.354), while also showing a relatively small noise effect. This suggests that changes in the spectral organization of the ST-related representation may contain information about the direction or structural characteristics of the imposed ST modification that is not captured by energy alone. Time–frequency analysis is particularly relevant to ECG because the signal contains transient and nonstationary components whose spectral characteristics change over time [10]–[13]. The present findings therefore support the use of MP-derived frequency descriptors as complementary descriptors of ST morphology, rather than as replacements for conventional ST-amplitude measurements.

The interpretation of sparsity-related descriptors requires greater caution. The number of ST-related atoms within the first ten iterations demonstrated a moderate linear relationship with signed ST deviation (R^2=0.223). In contrast, the first-ST-atom timing had essentially no explanatory power in a simple signed linear model (R^2=0.001). Importantly, the additional analysis showed a much stronger relationship with absolute ST deviation (R^2=0.572) and a significant nonlinear quadratic dependence. Furthermore, among recordings in which ST-related atoms were actually detected, the timing relationship reached R^2=0.654. These results indicate that the earlier appearance of ST-related atoms should be interpreted as an observed property of the sparse representation associated mainly with the magnitude and detectability of ST alteration, rather than as evidence of a strong monotonic relationship with signed ST polarity. Previous studies of sparse ECG representations have similarly demonstrated that the ordering and characteristics of selected atoms can provide information about ECG morphology beyond conventional waveform amplitudes [15], [20], [23].

This distinction also illustrates an important statistical issue. All analysed descriptors were statistically significant in the Kruskal–Wallis analysis, but statistical significance did not imply equivalent explanatory strength. The first-ST-atom descriptor provides the clearest example: $p_{KW} < 0.001$ coexisted with a signed linear R^2 of only 0.001. Conversely, total ST energy showed both statistical significance and extremely strong nonlinear explanatory power. Therefore, the interpretation of MP descriptors should consider statistical significance together with effect size and model explanatory power. This distinction is particularly important when developing quantitative ECG descriptors, because a statistically detectable difference between experimental conditions does not necessarily imply clinically or practically useful predictive performance.

The noise analysis further demonstrated that statistical significance should not be interpreted as evidence of large practical sensitivity. Although noise produced statistically significant effects for all descriptors, most noise effect sizes were relatively small. Mean ST scale was the notable

exception, with η^2 noise = 0.133. This sensitivity may arise because scale directly describes the temporal extent of individual atoms. Additive noise modifies the residual signal used by the greedy MP selection process, potentially changing the relative selection of shorter- and longer-scale low-frequency atoms. Mean ST scale should therefore be interpreted cautiously under low-SNR conditions. Future implementations may investigate noise-aware dictionaries or aggregation strategies designed to stabilize scale-related descriptors. The importance of dictionary structure and envelope selection for MP performance has previously been demonstrated by Rozanski [18], providing additional motivation for investigating ECG-specific dictionary configurations.

Advantages and scope of the MP representation

An important advantage of MP for the present application is that it provides a multidimensional sparse representation rather than a single scalar measurement. Conventional ST amplitude primarily quantifies the magnitude of voltage displacement relative to a reference level. In contrast, the MP decomposition provides simultaneous information about energy, frequency, scale, temporal location, phase, and decomposition order. This allows several complementary descriptors of ST morphology to be derived from the same representation. The theoretical basis for such adaptive sparse decomposition was established by Mallat and Zhang [10], while the use of optimized Gabor dictionaries and practical MP implementations has subsequently been developed for biomedical signal analysis [11]–[13], [18], [19].

These properties make MP potentially useful for subsequent automated ECG analysis, particularly when the objective is to characterize morphology rather than simply measure amplitude. Previous studies have demonstrated applications of MP to ECG compression, QRS detection, and sparse representation of cardiac activity [15], [16], [20], [23]. However, the present study does not demonstrate that MP is superior to wavelet transforms, conventional ST-amplitude analysis, or other time-frequency techniques. A direct quantitative benchmark was outside the scope of the present controlled representation study. Such a comparison should be performed under identical signal and noise conditions and should evaluate sensitivity to ST deviation, robustness to noise, temporal localization, feature stability, and computational requirements.

Computational considerations

The MP decomposition used in this study was performed using the SVAROG software environment, and only the first 15 iterations were retained for feature extraction. Because the decomposition was performed externally, a directly comparable execution-time measurement was not obtained within the present MATLAB analysis pipeline. Consequently, no unsupported claim regarding real-time performance is made.

The restriction to the first 15 iterations nevertheless limits the amount of the decomposition required for the analysed descriptors. In addition, recent developments in optimized MP implementations, including the GPU-accelerated empi implementation, provide opportunities for reducing computational burden [18], [19]. A dedicated computational study using the same hardware and implementation for MP and alternative time-frequency methods would be required to establish real-time feasibility quantitatively.

Limitations

Several limitations should be considered. First, the study was performed exclusively using synthetic ECG signals with controlled ST morphology and additive white Gaussian noise. This design provides excellent control over the imposed ST deviation and noise level, but it does not reproduce the nonlinear dynamics, inter-subject variability, anatomical differences, respiration-related modulation, baseline wander, electrode-motion artefacts, conduction abnormalities, or other sources of variability present in clinical recordings. Previous ECG signal-processing literature emphasizes the complexity of real ECG morphology and the importance of robust processing under noisy clinical conditions [21], [24-25]. Second, the analysis was performed using a single ECG lead. Multi-lead recordings may provide additional spatial information about repolarization abnormalities. Third, the present work investigates representation characteristics rather than clinical diagnostic performance. The imposed ST deviation should therefore be regarded as a controlled morphological modification of the simulated ECG waveform, rather than as a direct clinical representation of myocardial ischemia. Studies of subtle ECG changes associated with acute coronary syndromes indicate that clinically relevant repolarization abnormalities can involve features beyond simple ST amplitude [22], but the present experiment was not designed to reproduce such clinical complexity. Fourth, the present study did not quantitatively compare MP with alternative time-frequency or feature-extraction techniques. Such benchmarking, together with validation on clinical databases, is an important direction for future research.

Overall, the findings support the use of MP as a candidate representation for further investigation of ECG repolarization morphology, while the synthetic and controlled nature of the present experiment requires that the results be interpreted as methodological evidence rather than clinical validation.

V. CONCLUSION

This study investigated Matching Pursuit decomposition for sparse characterization of controlled ST-segment modifications in synthetic ECG signals. The results demonstrate that MP provides complementary descriptors of ST morphology, including energy-, frequency-, scale-, and sparse-decomposition characteristics.

Energy-related descriptors primarily reflected the magnitude of ST deviation and showed strong nonlinear relationships, with quadratic R^2 reaching 0.971 for total ST energy. Mean ST frequency and the number of ST-related atoms in the first ten iterations provided complementary information related to the signed ST modification. The first-ST-atom timing required more cautious interpretation: its signed linear relationship was negligible (R^2=0.001), whereas its relationship with absolute ST deviation was considerably stronger (R^2=0.572), and the relationship was stronger when analysis was restricted to conditions in which ST-related atoms were detected.

The analysis also demonstrated that most MP descriptors were relatively insensitive to additive noise in terms of effect size, whereas mean ST scale was the most noise-sensitive descriptor (η^2 noise = 0.133). These findings suggest that different MP descriptors have different levels of robustness and should therefore be selected according to the intended application.

The present results are limited to controlled synthetic ECG signals and should not be interpreted as evidence of clinical diagnostic performance. Quantitative comparison with conventional ST-amplitude and wavelet-based approaches, validation using clinical multi-lead ECG databases, and systematic assessment of computational requirements are important next steps. Nevertheless, the findings demonstrate that MP can provide a physiologically interpretable sparse representation of controlled ST morphology and support further development of ECG-oriented dictionaries and MP-derived descriptors for clinical ECG analysis.

***Abstract*—Atrial fibrillation (AF) is the most prevalent sustained arrhythmia in clinical practice, and characterizing its substrate dynamics remains a central challenge in electrophysiology. This study presents an exploratory framework evaluating recurrence percentage (Rec%) in local atrial electrograms (EGMs) alongside surface electrocardiogram (ECG) complexity. To isolate atrial activity, Adaptive Singular Value Cancellation (ASVC) was applied to remove ventricular components. The pipeline was evaluated on a subset of a publicly accessible Intracardiac Atrial Fibrillation Database ($n = 3$ patients, comprising 12 synchronized mapping points across four anatomical sites: AFW, IVC, SVC, and TVA). Morphological recurrence in EGMs was compared against surface Sample Entropy (SampEn). In this exploratory cohort, an aggregated inverse correlation (Pearson $r = -0.38$, $p < 0.001$, $R^2 = 0.148$) was observed between intracardiac Rec% and surface SampEn. These preliminary findings suggest that surface complexity metrics may reflect intracardiac substrate regularity, as well the potential of pairing both approaches, establishing a reproducible computational baseline for future investigation in larger, clinically stratified cohorts.**

***Index Terms*—Atrial fibrillation, recurrence analysis, biomedical signal processing, electrocardiogram, catheter ablation.**

I. Introduction

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia. It is characterised by chaotic and disorganised atrial activation, which impairs cardiac mechanical function [1]. As well as reducing patients' quality of life, AF is associated with an increased risk of stroke, cardiac insufficiency and mortality [2]. It accounts for a growing number of hospitalisations, particularly in an ageing population [2].

Treatment for AF has evolved from pharmacological therapies towards more invasive interventions, such as catheter ablation (CA), which aims to isolate or eliminate the tissue responsible for sustaining the arrhythmia. However, precisely identifying ablation targets remains a considerable challenge. During electrophysiological mapping, complex fractionated atrial electrograms (CFAEs) are often encountered and may indicate regions of critical slow conduction or re-entrant wave pivots [3]. However, the visual interpretation of these signals is subjective and does not consistently correlate with procedural success.

Conventional mapping techniques using dominant frequency (DF) or CFAE detection often fail to distinguish between potentials representing the arrhythmia's source (e.g. rotor cores) and those resulting from passive conduction or noise [4]. In persistent AF, rotor cores may appear outside the pulmonary veins, which substantially reduces the success rate of conventional ablation procedures.

To overcome these limitations, nonlinear dynamical system analysis offers a promising approach. Recurrence analysis (RA) and recurrence percentage (Rec%) allow visualisation and quantification of state recurrences in a phase-space trajectory. When applied to biomedical signals, these methods can measure the stability and morphological regularity of electrical activations over time, independently of signal complexity in the time or frequency domain [6].

This work presents a reproducible computational framework to quantify local atrial activation regularity using recurrence percentage (Rec$\%$) and assesses its covariation with non-invasive surface ECG complexity (SampEn) following adaptive ventricular cancellation. Rather than claiming definitive clinical guidance, this exploratory study investigates whether localized intracardiac morphological regularity is reflected on the thoracic surface within a preliminary case series ($n = 3$), establishing a baseline methodology for future longitudinal and patient-specific validation.

II. Methodology

A. Dataset

The Intracardiac Atrial Fibrillation Database (IAFDB), publicly available on PhysioNet, was used in this study. To evaluate the feasibility of the proposed signal processing framework, the analysis pipeline was applied to an exploratory subset of $n = 3$ patients (IAF1, IAF2, and IAF3), comprising both paroxysmal and persistent AF subtypes. Each patient possesses recordings acquired from four standard catheter positions: against the atrial free wall (AFW), near the inferior vena cava (IVC), near the superior vena cava (SVC), and near

the tricuspid valve annulus (TVA), totaling 12 synchronized spatial mapping points.

Each record contains simultaneously acquired multi-channel signals sampled at 1 kHz:

- Intracardiac EGM: five bipolar channels from a decapolar catheter (CS12, CS34, CS56, CS78, CS90).
- Surface ECG: four standard leads (I, II, V1, aVF).

Raw data were stored in WFDB format and loaded using the `rdsamp` function from the WFDB MATLAB Toolbox. Table I summarises the main dataset characteristics.

TABLE I
DATASET CHARACTERISTICS

Parameter	Description
Patients	3 (IAF1, IAF2, and IAF3)
AF type	Paroxysmal and persistent
Catheter positions	AFW, IVC, SVC, TVA
EGM channels	CS12, CS34, CS56, CS78, CS90
ECG leads	I, II, V1, aVF
Sampling frequency	1000 Hz
Segment duration	16.77 s

B. EGM Preprocessing

The raw intracardiac EGM signals were bandpass filtered using a 4th-order Butterworth filter with cut-off frequencies of 30 and 300 Hz. This passband enhances local atrial activations while attenuating baseline drift and high-frequency noise. The filtered signals were subsequently divided into non-overlapping segments for recurrence analysis.

C. Ventricular Activity Cancellation (ASVC)

Surface ECG recordings are dominated by ventricular activity (QRST complexes), which must be removed before atrial activity (AA) can be analysed. The Adaptive Singular Value Cancellation (ASVC) method [9] was employed.

Initially, ECG signals were bandpass filtered between 0.5 and 40 Hz using a 3rd-order Butterworth filter. R-peaks were then detected using the Pan–Tompkins algorithm [7], which combines bandpass filtering, derivative filtering, squaring, moving-window integration, and adaptive thresholding. Peak locations were refined through a local maximum search within a ± 50 ms window.

For each detected beat, a QRST segment extending from $-0.3RR_{\min}$ to $+0.7RR_{\min}$ relative to the R-peak was extracted. The resulting beat matrix was decomposed using Singular Value Decomposition (SVD),

$$X = USV^T \tag{1}$$

where the first singular vector represents the dominant ventricular morphology. For each beat k, an adaptive scaling coefficient was estimated according to the minimum mean-square error criterion,

$$\alpha_k = \frac{x_k^T u_1}{u_1^T u_1} \tag{2}$$

and the atrial activity estimate was obtained as

$$\hat{x}_{AA,k} = x_k - \alpha_k u_1. \tag{3}$$

To minimise boundary artefacts, Gaussian windowing and interpolation were applied to the cancelled segments, followed by low-pass filtering and DC removal. Signal quality was verified through Welch power spectral density estimation. A dominant frequency of 4.88 Hz, within the physiological AF range (3–12 Hz), confirmed preservation of atrial dynamics after cancellation.

D. Recurrence Analysis and Rec% Calculation

For each EGM segment, atrial activation peaks were detected using a threshold equal to 1.2 times the signal RMS value and a minimum inter-peak distance of 50 ms. The same procedure was applied to the AA signal extracted from the ECG after ASVC.

For each pair of detected activations (i, j), a 100 ms window centred on each peak was extracted and zero-mean normalised. Morphological similarity was quantified using the maximum normalised cross-correlation over lag,

$$RM(i,j) = \max_{\tau} \left[\frac{(\tilde{x}_i \star \tilde{x}_j)(\tau)}{\|\tilde{x}_i\| \|\tilde{x}_j\|} \right]. \tag{4}$$

The resulting $N \times N$ matrix constitutes the recurrence map (RM). A correlation threshold of 0.8 was applied to define recurrence. The recurrence percentage (Rec%) was computed as

$$\mathrm{Rec}\% = \max_j \left(\frac{1}{N} \sum_{i=1}^{N} \mathbf{1}[RM(i,j) > 0.8] \right) \times 100, \tag{5}$$

where $\mathbf{1}[\cdot]$ denotes the indicator function.

A Rec% close to 100% indicates highly organised and periodic activation patterns, whereas lower values (approximately 35–50%) are characteristic of chaotic atrial fibrillation activity. Intermediate values around 80–90% suggest substantial electrophysiological reorganisation during ablation.

E. Temporal Classification

To enhance the temporal resolution of the dynamics, Rec% was computed continuously over successive non-overlapping 5 s segments, providing a denser time series to track substrate stabilization. The noise level was estimated as

$$\sigma = \mathrm{median}\left(|\mathrm{Rec}\%_{i+1} - \mathrm{Rec}\%_i| \right). \tag{6}$$

A Savitzky–Golay filter with a 9-point window and second-order polynomial approximation was applied to smooth the data. Based on a threshold of 4σ, channels were classified into three patterns:

- Type I (Step): abrupt increase greater than 4σ within a 5-minute interval.
- Type II (Gradual): cumulative increase greater than 4σ from beginning to end without a sudden step.
- Type III (No Response): absence of significant increase in Rec%.

F. Cross-Validation: EGM Rec% vs. ECG SampEn

To evaluate the feasibility of non-invasive monitoring, intracardiac Rec% values were compared with ECG complexity quantified through Sample Entropy (SampEn) across the pooled $n = 12$ synchronized spatial mapping pairs. SampEn was calculated for non-overlapping 1.5-second ECG windows using embedding dimension $m = 2$ and tolerance $r = 0.2\sigma_{\text{segment}}$.

Temporal synchronisation was achieved by averaging all SampEn values contained within each corresponding EGM segment, generating matched pairs $(Rec\%_k, \text{SampEn}_k)$.

The association between both measures was evaluated using Pearson's correlation coefficient (r), Spearman's rank correlation coefficient (ρ), and the coefficient of determination (R^2).

Because this exploratory study evaluates a pilot subset ($n = 3$ subjects, 12 spatial mapping pairs), the pooled correlation analysis serves primarily as an aggregate descriptive assessment of trends across recorded sites. We explicitly acknowledge that pooling intra-subject spatial points across time windows does not satisfy strict sample independence assumptions; therefore, the resulting correlation metrics (r, R^2, p-value) should be interpreted as proof-of-concept indicators of signal covariation rather than population-wide inferential statistics.

III. Results

A. Signal Preprocessing Quality

The bandpass-filtered EGM signal (30–300 Hz) exhibited well-defined atrial activation peaks with stable baseline and low-amplitude background noise, consistent with high-quality intracardiac recordings (Fig. 1). Peak amplitudes ranged between -0.5 mV and $+0.5$ mV, and the morphological consistency of successive activations over the analysed 10-second window suggested moderate-to-high atrial organisation at the selected catheter position (AFW).

For the surface ECG, the ASVC pipeline successfully removed ventricular interference. The dominant frequency (DF) of the extracted atrial activity signal was 4.88 Hz, which falls within the physiological range of AF (3–12 Hz), confirming that the processing preserved the intrinsic atrial dynamics without introducing spectral distortion. The Pan–Tompkins algorithm reliably detected R-peaks across the full 120-second recording, maintaining stable adaptive thresholds even in the presence of baseline variation.

B. Signal and Recurrence Metrics

Table II summarises the acquisition parameters, recurrence metrics, and statistical results obtained for the representative case IAF1-AFW.

C. Rec% Temporal Dynamics

The temporal evolution of Rec% during the ablation procedure showed increasing atrial organisation over time. Although the raw Rec% values exhibited abrupt fluctuations attributable to local tissue dynamics and catheter repositioning between recording segments, the Savitzky–Golay smoothed trend (9-point window, second-order polynomial) revealed a progressive increase in atrial electrical organisation, rising from approximately 55% in the early segments to a final value of 83.87% in the last analysed segment (Fig. 2).

TABLE II
Signal and Recurrence Metrics for Patient IAF1 at Position AFW

Parameter	Value
Catheter position	AFW (atrial free wall)
EGM channels	CS12, CS34, CS56, CS78, CS90
Sampling frequency	1000 Hz
Segment duration	5.0 s
EGM filter	30–300 Hz Butterworth (4th order)
ECG filter	0.5–40 Hz Butterworth (3rd order)
Dominant frequency	4.88 Hz
Recurrence threshold	$r > 0.8$
Final Rec%	83.87%
Pearson r	-0.38
p-value	< 0.001
R^2	0.148
n (position pairs)	12
Classification	Type III (No Response)

According to the 4σ classification criterion, where $\sigma = \text{median}|Rec\%_{i+1} - Rec\%_i|$, this channel was classified as *Type III (No Response)*. Although the increase was physiologically meaningful, it did not reach the abrupt transition threshold required to characterise a Type I response nor the sustained global increase associated with a Type II response. This finding is consistent with a gradual sub-threshold reorganisation of the atrial substrate at the free-wall position, where an arrhythmogenic driver is unlikely to be anchored.

D. Recurrence Map Analysis

The $N \times N$ recurrence map computed for the final segment is shown in Fig. 3. The map is predominantly composed of high-similarity regions (red-orange tones, correlation $r > 0.8$), with symmetric patterns and repetitive blocks along both axes. Low-recurrence regions ($r < 0.5$) are sparse, indicating minimal morphological variability between successive atrial complexes.

The Rec% value of 83.87% reflects a high degree of electrical regularity, approaching the values expected for organised rhythms such as atrial flutter (Rec% $\approx$ 95–100%) and substantially exceeding the recurrence levels typically observed during active AF (Rec% $\approx$ 35–50%). This confirms that the atrial substrate at this position had undergone significant electrophysiological reorganisation by the end of the recording period.

E. EGM vs. ECG Multi-Patient Exploratory Analysis

To assess the potential correspondence between invasive and non-invasive measures, cross-correlation analysis was carried out on the pooled data from the $n = 12$ synchronized spatial mapping points. The aggregate analysis revealed an inverse relationship between both metrics, with a Pearson correlation coefficient $r = -0.38$ ($p < 0.001$), coefficient of determination $R^2 = 0.148$, and Spearman $\rho = -0.35$ (Fig. 4).

The pooled analysis yielded an inverse correlation of $r = -0.38$ with a coefficient of determination $R^2 = 0.148$. This

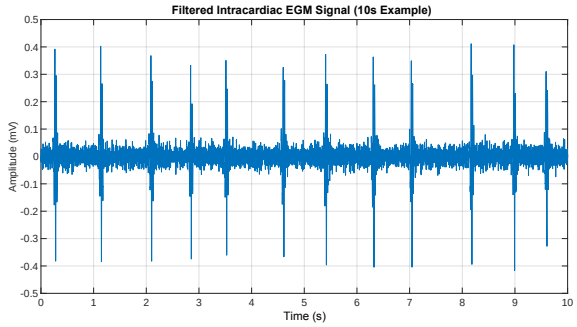

Fig. 1. Bandpass-filtered intracardiac EGM signal (30–300 Hz) for patient IAF1 at the AFW position, showing well-defined atrial activation peaks over a 10-second window.

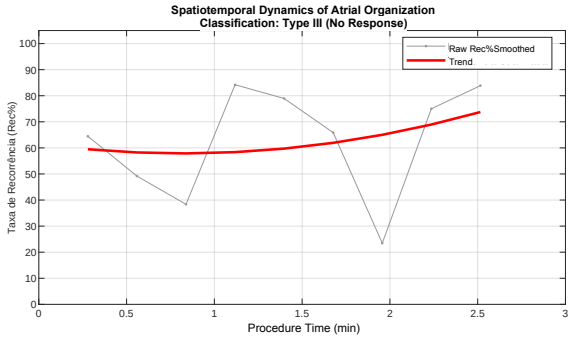

Fig. 2. Temporal evolution of Rec% for the IAF1-AFW channel. Raw values (dashed) and Savitzky–Golay smoothed trend (solid) show a progressive increase from approximately 55% to 83.87%.

indicates that roughly 15% of the variance observed in surface SampEn is linearly associated with local intracardiac Rec%. This moderate strength is physically expected: surface ECG leads integrate electrical wavefronts across the entire atrial syncytium through the thoracic volume conductor, whereas the bipolar EGM captures only highly localized near-field activation. Far from indicating a failure of the metric, this divergence confirms that surface dynamics reflect a global superposition of multiple localized substrate regions.

Although the nominal p-value indicates statistical significance within the pooled data points, these figures reflect an exploratory proof-of-concept across 12 paired recordings from three patients rather than population-wide inference. Patient IAF1-AFW was selected as the representative case because it encompasses the complete analysis pipeline and yields a physiologically interpretable Rec% value of 83.87%, providing a clear contrast with the recurrence levels characteristic of active AF.

IV. Discussion

The results demonstrate that Rec%, derived from recurrence analysis of intracardiac electrograms (EGMs), provides a quantitative and physiologically interpretable measure of atrial substrate organisation during catheter ablation. The progressive increase in Rec% observed in the representative case (IAF1-AFW), from approximately 55% in the initial segments to 83.87% in the final segment, is consistent with the gradual electrophysiological reorganisation expected as ablation modifies the arrhythmogenic substrate.

Physiologically, the inverse correlation between EGM Rec% and ECG SampEn is explained by the physics of volume conduction. During active, chaotic AF, multiple wandering wavelets and unstable rotors propagate randomly through the atria. This localized desynchronization generates highly fractionated electrograms (CFAEs) and, when projected onto the body surface, manifests as highly irregular and complex fibrillatory waves (resulting in low Rec% and high SampEn). Conversely, when catheter ablation successfully terminates or anchors these rapid drivers, the localized atrial tissue undergoes electrophysiological synchronization. The resulting regular, repetitive activation wavefronts are projected through the thoracic volume conductor, translating into highly regular and uniform f-waves on the chest surface, which significantly lowers the SampEn.

It is crucial to clarify that the current framework quantifies local morphological regularity rather than directional activation vectors or driver causality. Consequently, high Rec% values or decreased surface entropy cannot be interpreted as direct identification or spatial localization of rotor cores. A localized increase in Rec% simply reflects that the underlying tissue is undergoing repetitive, morphologically stable activations—which may arise either from proximity to an anchored driver or from regular passive activation by distant sources.

Compared to traditional spectral metrics such as Dominant Frequency (DF) and classical CFAE mean-interval algorithms, the proposed recurrence formulation presents distinct theoretical advantages. While DF mapping relies heavily on Fourier assumptions that are susceptible to harmonic distortion, spectral leakage, and amplitude variations, Rec% relies purely on morphological cross-correlation thresholds, making it robust against amplitude scaling and baseline wander. Unlike subjective CFAE fractionation criteria, Rec% yields a bounded, continuous metric (0–100%) directly grounded in non-linear dynamical stability.

From a computational perspective, the pipeline relies on low-order linear filtering, standard Pan-Tompkins detection, rank-1 SVD projection for ventricular cancellation, and pairwise cross-correlation over short sliding windows (5 s). Given that both SVD truncation and signal correlation have standard polynomial complexities that scale efficiently with window length, the pipeline is well-suited for near real-time execution on standard clinical workstations without requiring high-performance computing clusters.

The temporal classification framework also provides clinically relevant descriptive information. In the representative case, the AFW channel was classified as Type III (No Response), indicating that the observed increase in Rec% did not exceed the 4σ threshold required for a Type I or Type II response. Type I patterns, characterised by abrupt increases in Rec%, are of particular interest as markers of localized

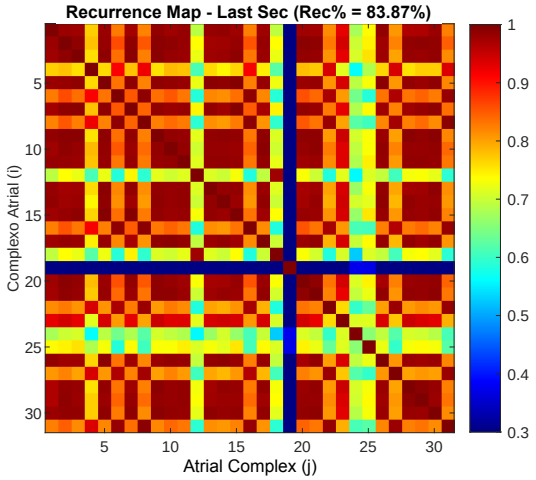

Fig. 3. Recurrence map (RM) computed for the final EGM segment of patient IAF1-AFW. High-similarity regions (warm tones, $r > 0.8$) dominate, indicating a Rec% of 83.87%.

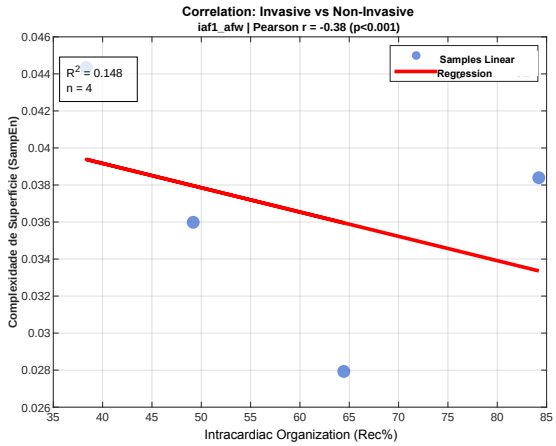

Fig. 4. Scatter plot of intracardiac Rec% versus surface ECG SampEn across 12 exploratory position pairs. Note: Data points represent pooled spatial positions; axes labels correspond to intracardiac recurrence (%) and surface sample entropy.

substrate reorganization, whereas Type II patterns suggest gradual stabilization and Type III patterns indicate persistent irregularity.

Compared with the Granger Causality (GC) framework proposed by Alcaine et al. [8], which evaluates temporal predictability and directional interactions among EGM channels, Rec% quantifies intra-channel morphological consistency. Thus, the two approaches are complementary: combining recurrence-based metrics with directional causality measures represents a logical pathway to capture both morphological morphology and propagation networks.

This study has clear limitations that define its exploratory scope. Foremost is the restricted cohort size ($n = 3$ patients, 12 recording positions), which precludes broad clinical generalizations and prevents patient-stratified hierarchical modeling (e.g., repeated-measures correlation or mixed-effects models). Second, the current dataset does not include long-term clinical ablation outcomes or post-procedure arrhythmia recurrence data, preventing any direct claim of therapeutic prognostic value. Future work will apply this pipeline across the complete 8-patient IAFDB cohort and clinical registries using repeated-measures statistical models to confirm inter-patient robustness.

V. Conclusion

This exploratory case series presented a computational framework for the spatiotemporal characterisation of atrial fibrillation using intracardiac electrograms and surface ECGs. Recurrence percentage (Rec%) proved to be a viable, bounded metric to track local morphological regularity during catheter ablation. An aggregate inverse association between intracardiac Rec% and surface SampEn was documented, physically consistent with thoracic volume conduction phenomena. While the current sample size does not allow for inferring procedural outcomes or pinpointing causal drivers, the proposed pipeline establishes a reproducible baseline for non-invasive substrate evaluation to be substantiated in larger, prospectively designed cohorts.

***Abstract*—Deep learning denoisers have shown promising results for digital mammography, but their effects on noise texture and internal representations remain unclear. By combining local or contextual information, these networks may alter noise texture and introduce spatially structured residuals, potentially affecting image appearance and the visibility of subtle findings. This study investigates how seven pretrained convolutional and transformer-based denoisers modify the spectral properties of denoised images and removed components, while examining their internal representations through feature map analysis. Realistic mammograms were generated using a virtual clinical trial framework and degraded with heteroscedastic noise. Spatial-frequency behavior was assessed using power spectral density (PSD), with mean squared error (MSE) computed over low-, mid-, and high-frequency bands. The denoisers showed different trade-offs between noise suppression and structure preservation. Models with stronger apparent noise suppression produced removed-component spectra with greater low-frequency dominance, whereas less aggressive models preserved more high-frequency content but left more visible noise. Restormer achieved the lowest low- and mid-frequency errors for the denoised-image PSD, while DRUNet achieved the lowest high-frequency error. For the removed-component PSD, DRUNet, SCUNet, and GSDRUNet showed the closest spectral agreement with the inserted noise, depending on the frequency band. Feature maps revealed strategies ranging from image reconstruction through abstract latent representations to direct residual noise modeling. These results suggest that denoising performance and structural preservation are closely related to the representations learned by each network. PSD and feature map analyses provide complementary insights into how pretrained denoisers process mammograms. I. Introduction

Breast cancer remains a major public health concern and is among the most common causes of cancer-related mortality in women worldwide. Excluding non-melanoma skin cancers, it represented the most commonly diagnosed malignancy in 2020, accounting for approximately 11.7% of all newly reported cancer cases [1]. Numerous studies have demonstrated that routine screening programs can substantially decrease breast cancer mortality rates, particularly among women at elevated risk [2]. In this context, medical imaging plays a crucial role in early diagnosis and clinical management.

Digital mammography (DM) is currently one of the most widely adopted imaging modalities for breast cancer screening and detection. Since DM employs ionizing radiation, radiation exposure must be minimized according to the principle of keeping doses as low as reasonably achievable [3]. Nevertheless, reducing the radiation dose generally leads to increased image noise, which may compromise the visibility of subtle lesions, including microcalcifications. Consequently, there is an inherent balance between patient safety and image quality.

To address this challenge, image denoising techniques have been extensively investigated as a means of enhancing DM images while maintaining diagnostically important anatomical information [4]. Recent advances in deep learning (DL) have led to the development of numerous pretrained denoising models that achieve state-of-the-art performance on natural image restoration tasks [5]–[11]. Recently, [12] investigated the pretrained version of these models in mammography denoising within a physics-integrated model-based deep learning framework. Although promising results were obtained in terms of image quality and microcalcification detectability, the impact of spatial correlation in denoised images produced by DL methods remains unexplored. Spatially correlated noise is an important image-quality degradation in digital mammography

because it can reduce radiologists' ability to detect breast lesions, particularly subtle findings such as microcalcifications [13].

Although pretrained deep learning denoisers have recently been investigated for digital mammography, their impact on the spatial-frequency properties of restored images remains insufficiently understood. Since denoising networks combine information from neighboring pixels or broader contextual regions, they may alter noise texture and introduce spatially structured residuals. These changes can affect the visual appearance of mammographic images and may potentially influence the detectability of subtle findings, such as microcalcifications. Moreover, it remains unclear how different denoising architectures modify the spectral characteristics of the removed component and how their internal representations are related to noise suppression and structural preservation. In this work, we address this gap by combining power spectral density analysis of denoised images and removed components with feature map visualization of pretrained convolutional and transformer-based denoisers applied to digital mammography.

II. Materials and Methods

A. Image Dataset

Virtual clinical trials (VCTs) provide a framework for performing in silico experiments in medical imaging. In mammography, these simulations enable the generation of realistic breast images while allowing precise control over anatomical and acquisition parameters. In this study, a synthetic dataset was generated using a breast imaging VCT platform capable of modeling the entire imaging process, including breast anatomy generation, image acquisition, and image formation. Realistic digital mammography (DM) projections were produced using the GPU-based OpenVCT simulation framework [14].

Four anatomical scenarios were considered, each characterized by distinct tissue composition and compression conditions. For each anatomy, ten independent noise realizations were generated, yielding 40 noisy images. The corresponding four noise-free images were retained as ground truth, resulting in a total of 44 images. Since noise was added after the generation of the ideal mammograms, paired noisy and ground-truth images were available for quantitative evaluation. The characteristics of the simulated dataset are summarized in Table I.

Mammograms were synthesized by adding a Gaussian approximation of heteroscedastic Poisson–Gaussian noise to noise-free images, which is valid under high photon statistics [15]. The standard dose for the Selenia Dimensions mammography system (Hologic, Bedford, MA) was adopted. Let $y(i,j)$ denote the ground-truth image and $z(i,j)$ the corresponding noisy observation. The degradation process is described by

$$z(i,j) = y(i,j) + n(i,j), \qquad n(i,j) \sim \mathcal{N}(0, Var(i,j)), \tag{1}$$

where $n(i,j)$ represents the noise term, including quantum and electronic noise, modeled as a Gaussian random variable with zero mean and variance $Var(i,j)$.

TABLE I: Simulated phantom dataset and anatomy details.

Parameter	Value
System	Hologic
Resolution	4096×3328
Volume	450 mL
Percent Dense	25
Skin Thickness	0.15 cm
Deformation Volume	200–400 mL
Number of Anatomies	4
Number of Noise Realizations	10
Number of Ground Truth Images	4
Total Number of Images	44

Although the underlying acquisition noise is Poisson–Gaussian, under high photon statistics it can be approximated as a zero-mean Gaussian noise term with signal-dependent variance. The noise variance depends on both local signal intensity and detector position, capturing the heteroscedastic behavior of mammographic acquisitions. It is expressed as

$$Var(i,j) = y(i,j)\xi_q(i,j) + \xi_e^2, \tag{2}$$

where $\xi_q(i,j)$ represents the spatially varying quantum gain map and ξ_e denotes the standard deviation of the electronic noise component. These parameters were estimated from measurements obtained using a Selenia Dimensions mammography system (Hologic, Bedford, MA) [4]. The spatially varying $\xi_q(i,j)$ map had a mean value of 0.115, whereas ξ_e = 1.15.

B. Deep-Learning Denoisers

Seven deep learning-based (DL) denoising methods were evaluated for the restoration of VCT-generated images corrupted by heteroscedastic Poisson–Gaussian noise. These included four convolutional neural network (CNN)–based models (DRUNet, DnCNN, DSCcP, and GSDRUNet) and three hybrid CNN–Transformer architectures (Restormer, SCUNet, and SwinIR). Table II summarizes the evaluated DL approaches, including each model's architecture, whether it uses an encoder–decoder architecture and the number of channels. The table also presents whether the model requires the noise standard deviation σ as input for denoising. For models requiring a noise-level parameter, a single scalar σ was estimated independently for each input image using the median absolute deviation method and provided to the network during inference. The mean estimated value across the dataset was $\sigma = 8.57$. In this study, all methods were employed in their pretrained, off-the-shelf configurations as implemented in the DeepInv Python library [16]. For models where the grayscale (1-channel) version was not available, the grayscale channel was replicated across all three channels, and the mean was computed over the three channels after denoising. This effectively introduces an additional averaging operation, but it represents the most straightforward strategy for adapting 3-channel architectures to grayscale medical imaging. No variance-stabilizing transformation (VST) was applied before inference, since its impact under similar imaging conditions was previously evaluated in [12].

TABLE II: Denoising methods evaluated in this study.

Model	Ch.	Architecture	Enc.-Dec.	Uses σ	Params.
DRUNet	1	CNN	Yes	Yes	32.7M
Restormer	1	CNN + Transformer	Yes	No	25.31M
SwinIR	1	CNN + Transformer	No	Yes	11.8M
DnCNN	1	CNN	No	No	0.56M
SCUNet	3	CNN + Transformer	Yes	Yes	18M
DSCcP	3	CNN	No	Yes	70K
GSDRUNet	1	CNN	Yes	Yes	17M

C. Spectral Analysis

Let $y(i,j)$ denote the ground-truth image, $z(i,j)$ the corresponding noisy image, and $\hat{y}(i,j)$ the denoised image. Since the inserted noise is known in the simulated dataset, it was defined as

$$n(i,j) = z(i,j) - y(i,j), \tag{3}$$

whereas the image component removed by each denoiser was defined as

$$\hat{n}(i,j) = z(i,j) - \hat{y}(i,j). \tag{4}$$

Thus, $n(i,j)$ represents the noise expected to be removed, while $\hat{n}(i,j)$ represents the component effectively removed by the denoising network.

The two-dimensional power spectral density (PSD) was computed for the denoised images, the inserted noise, and the removed components as

$$PSD(f_x, f_y) = \frac{1}{MN} \left| \mathcal{F}\{x(i,j)\} \right|^2, \tag{5}$$

where $x(i,j)$ represents either $\hat{y}(i,j)$, $n(i,j)$, or $\hat{n}(i,j)$, $\mathcal{F}\{\cdot\}$ denotes the two-dimensional Fourier transform, and M and N are the image dimensions. The resulting PSD was radially averaged as

$$\overline{PSD}(k) = \frac{1}{N_k} \sum_{(f_x,f_y)\in\mathcal{R}_k} PSD(f_x, f_y), \tag{6}$$

where $\mathcal{R}_k$ denotes the set of frequency samples within the k-th radial frequency bin and N_k is the number of samples in that bin. The radial PSDs were then averaged across all L image realizations,

$$\left\langle \overline{PSD}(k) \right\rangle = \frac{1}{L} \sum_{l=1}^{L} \overline{PSD}_l(k), \tag{7}$$

yielding a representative radial spectrum for each denoising method.

Two complementary spectral comparisons were performed. First, the PSD of each denoised image $\hat{y}(i,j)$ was compared with the PSD of the corresponding ground-truth image $y(i,j)$, allowing the preservation of image spatial-frequency content to be assessed. Second, the PSD of the removed component $\hat{n}(i,j)$ was compared with the PSD of the inserted noise $n(i,j)$. This comparison evaluates whether the component removed by each denoiser has spectral characteristics similar to the known noise process. If a denoiser removes little noise, $\hat{n}(i,j)$ is expected to deviate from $n(i,j)$. Conversely, if the denoiser primarily removes the inserted noise, the PSD of $\hat{n}(i,j)$ should be closer to the PSD of $n(i,j)$. Deviations between these spectra may indicate underfiltering, overfiltering, or removal of image structures whose spectral content overlaps with noise.

In addition to the qualitative comparison of the radial PSD curves, the mean squared error (MSE) was computed between reference and estimated radially averaged PSDs. For the denoised-image analysis, the reference spectrum was obtained from the ground-truth image. For the removed-component analysis, the reference spectrum was obtained from the inserted noise. The PSD curves were divided into low- (0–1 mm^{-1}), mid- (1–2 mm^{-1}), and high-frequency (> 2 mm^{-1}) bands to evaluate the frequency-dependent behavior of each denoising method. These bands were selected to summarize the main low-, mid-, and high-frequency trends observed in the PSD curves.

D. Interpretability

To provide insights into the internal representations learned by each denoising network, a feature map visualization analysis was performed. For each pretrained model, all convolutional layers were first identified and ordered according to their position in the network architecture. Since visualizing every feature map from every layer would be impractical in a two-column paper, 16 convolutional layers were uniformly sampled across the network depth, allowing the evolution of learned representations to be inspected from early to late processing stages.

For a given input mammogram, the activations of the selected convolutional layers were extracted using forward hooks during inference. Let $\mathbf{A}^{(l)} \in \mathbb{R}^{C_l \times H_l \times W_l}$ denote the output tensor of the l-th convolutional layer, where C_l is the number of feature channels and $H_l \times W_l$ corresponds to the spatial dimensions of the activation map. The energy associated with the c-th feature map was computed as

$$E_c^{(l)} = \sum_{i=1}^{H_l} \sum_{j=1}^{W_l} \left(A_c^{(l)}(i,j) \right)^2. \tag{8}$$

The feature map with the highest energy was then selected for visualization,

$$c^* = \arg\max_c E_c^{(l)}, \tag{9}$$

and the corresponding activation map

$$F^{(l)} = A_{c^*}^{(l)} \tag{10}$$

was retained as a representative feature map for that layer.

The use of the highest-energy feature map was motivated by the assumption that channels with larger activation energy tend to contain the most prominent responses generated by the network for a given input image. This strategy avoids arbitrary channel selection while providing a compact visualization of the dominant structures being processed throughout the network.

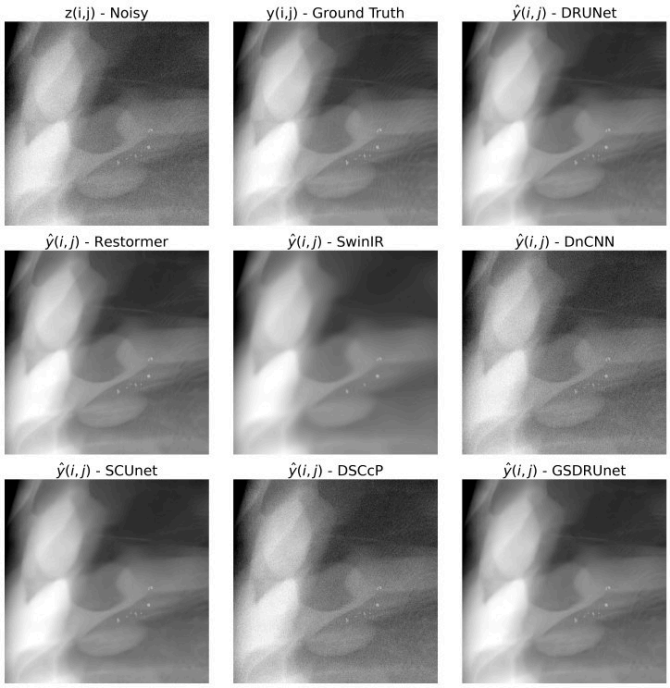

Fig. 1: Representative regions of interest (ROIs) from a synthetic mammogram: noisy (z), ground truth (y), and denoised with the deep learning denoisers, $\hat{y}$. All ROIs are displayed using the same intensity window.

III. Results and Discussion

A. Denoising

Fig. 1 shows the regions of interest in the images denoised by all deep learning denoisers. The images indicate that DnCNN and DSCcP leave more visible residual noise. SwinIR produces a visibly smoother image, whereas the remaining denoisers achieve a better trade-off between noise suppression and image blurring. These differences likely arise, at least in part, from the distinct noise distributions and noise-level parameterizations used during training. SwinIR was trained primarily for higher noise levels ($\sigma > 15$), which may explain its more aggressive denoising behavior. In contrast, DnCNN and DSCcP provide weaker apparent noise suppression under the considered noise conditions.

B. Spectral Analysis

Fig. 2 shows the PSD of the denoised images. In the PSD domain, SwinIR, DRUNet, GSDRUNet, and SCUNet exhibit the strongest attenuation of medium-to-high spatial frequencies, indicating aggressive noise suppression at the expense of fine-texture preservation. DnCNN and DSCcP remain farther from the ground-truth spectrum, suggesting weaker noise suppression and higher residual high-frequency content. Restormer retains the highest high-frequency PSD among the denoisers, consistent with greater preservation of high-frequency content, which may include both anatomical detail and residual noise, compared with the other methods. Thus, the figure reveals a continuum between noise suppression and detail preservation.

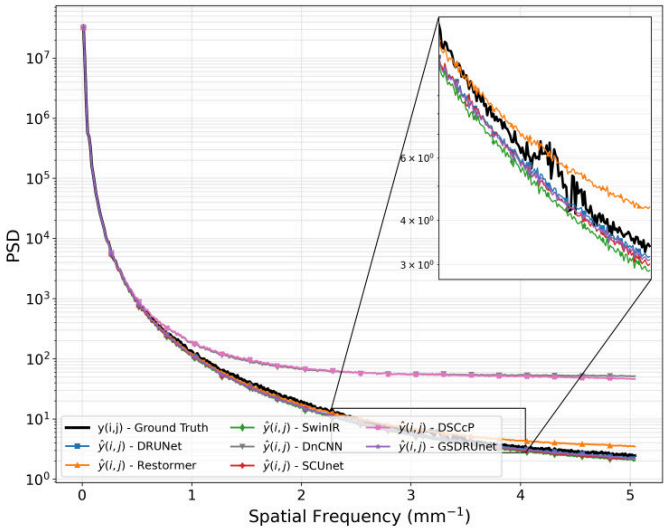

Fig. 2: Power Spectral Density (PSD) for the ground-truth and all the denoised images.

Additionally, Fig. 3 shows the removed-component PSD. For the models with weaker apparent noise suppression, such as DnCNN and DSCcP, the PSD of the removed component remains farther from the reference inserted-noise PSD, indicating that only a limited fraction of the noise was removed. Conversely, the remaining models exhibit smaller deviations from the inserted-noise PSD, suggesting that the removed component is more spectrally similar to the known noise process. However, SwinIR and SCUNet show a stronger low-frequency component in the removed PSD, which may be associated with stronger smoothing and partial removal of low-frequency image structures. DRUNet, Restormer, and GSDRUNet show a more moderate low-frequency deviation, suggesting a different trade-off between noise removal and detail preservation.

This behavior may be related to the spatially structured operations used by denoising networks, including convolutional filtering, attention mechanisms, and reconstruction constraints, which can transform initially white or weakly correlated noise into structured removed components. Consequently, the removed component $\hat{n}(i,j)$ may exhibit spatially structured patterns rather than purely random noise. In the frequency domain, this behavior is reflected by deviations of the removed-component PSD from the reference inserted-noise PSD. Such deviations may indicate underfiltering, overfiltering, or removal of anatomical structures whose spectral content overlaps with that of the inserted noise.

Table III shows the MSE for the low-, mid-, and high-frequency bands of the radial PSD of the denoised images. In the low-frequency band, Restormer exhibited the greatest similarity to the ground-truth PSD, followed by DSCcP and DnCNN. Interestingly, the noisy image exhibited a lower low-frequency PSD error than several denoising methods. This does not indicate superior overall image quality, since the inserted noise contributes predominantly to higher spatial frequencies. DnCNN and DSCcP introduce relatively small mod-

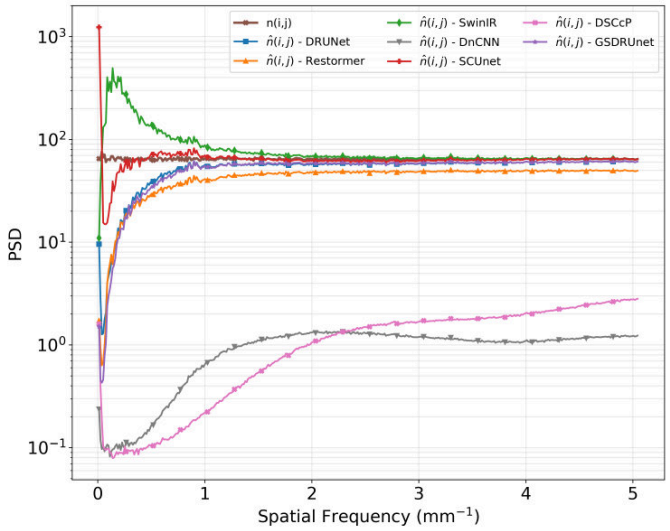

Fig. 3: Power spectral density (PSD) of the inserted noise $n(i,j)$ and of the removed component $\hat{n}(i,j)$ for each denoising method.

ifications in the low-frequency content and therefore remain close to the ground-truth PSD in this band, despite leaving substantial visible noise. Conversely, SwinIR, SCUNet, and DRUNet produce larger low-frequency modifications, resulting in higher errors. Since anatomical signal dominates at low spatial frequencies, these deviations may reflect partial alteration of image structures rather than noise removal alone. Therefore, low-frequency PSD similarity should not be interpreted in isolation as a measure of restoration quality. For the mid-frequency band, Restormer achieved the lowest error, followed by DRUNet, GSDRUNet, and SCUNet. For the high-frequency band, DRUNet achieved the lowest error, followed by SCUNet, GSDRUNet, and SwinIR.

TABLE III: Mean squared error (MSE) computed over the low- (indicated as LF), mid- (indicated as MF), and high-frequency (indicated as HF) ranges of the radial mean PSD of the denoised images. Lower values indicate better agreement with the ground-truth image PSD.

Denoiser	MSE - LF	MSE - MF	MSE - HF
DRUNet	4.20×10^6	60.13	**0.568**
Restormer	$\mathbf{4.43 \times 10^5}$	**26.33**	1.146
SwinIR	1.29×10^7	101.62	1.000
SCUNet	1.92×10^9	73.07	0.658
GSDRUNet	7.14×10^6	65.70	0.676
DSCcP	5.20×10^5	3069.17	1997.59
DnCNN	7.52×10^5	2571.74	2345.50
Noisy	1.57×10^6	4148.38	4121.92

Table IV reports the MSE between the PSD of the inserted noise and the PSD of the component removed by each denoiser. Lower values indicate that the removed component is spectrally closer to the known inserted noise. DRUNet achieved the lowest error in the low-frequency band, whereas SCUNet achieved the lowest errors in the mid- and high-frequency bands. However, Fig. 3 shows that SCUNet and SwinIR remove relatively strong low-frequency components, which is consistent with the smoother appearance observed in Fig. 1. GSDRUNet and DRUNet showed intermediate behavior, suggesting a more balanced trade-off between noise removal and structure preservation. DSCcP and DnCNN showed the highest errors in the mid- and high-frequency bands, consistent with visible residual noise and weaker apparent noise suppression.

TABLE IV: Mean squared error (MSE) computed over the low- (indicated as LF), mid- (indicated as MF), and high-frequency (indicated as HF) ranges between the PSD of the inserted noise and the PSD of the component removed by each denoiser. Lower values indicate greater spectral similarity between the removed component and the known inserted noise.

Denoiser	MSE - LF	MSE - MF	MSE - HF
DRUNet	**1250.99**	59.58	20.12
Restormer	1652.49	375.57	226.14
SwinIR	19574.67	108.90	1.95
SCUNet	18153.65	**3.57**	**1.65**
GSDRUNet	1412.34	53.72	16.66
DSCcP	4107.69	4079.09	3784.47
DnCNN	4095.06	4016.76	3953.37

C. Feature Maps

1) DRUNet: Fig. 4 illustrates representative feature maps extracted from DRUNet, which contains 61 convolutional layers. In the initial layers (0–20), the feature maps closely resemble the input, preserving low-level features such as intensity variations, edges, and anatomical boundaries while retaining visible noise. In the intermediate layers (24–44), the representations become more abstract, emphasizing anatomical structures and spatial patterns while suppressing stochastic noise. In the deeper layers (48–60), the network progressively reconstructs the image, producing smoother feature maps with reduced noise while preserving major anatomical structures and microcalcifications. Overall, DRUNet performs denoising through hierarchical representation learning, progressively extracting low-level features, enhancing structural information, and reconstructing the image while balancing noise suppression and preservation of clinically relevant details. This behavior is consistent with the PSD analysis.

2) Restormer: Fig. 5 illustrates representative feature maps extracted from Restormer, which contains 274 convolutional layers. In the initial layers (0–54), the feature maps preserve low-level features such as intensity variations, edges, and anatomical structures. In the intermediate and deep layers (72–218), the representations become more abstract, emphasizing tissue patterns, microcalcifications, and structural information while suppressing stochastic noise. Unlike DRUNet, Restormer maintains abstract and texture-like representations throughout its deeper layers. Even in the final stages (236–254), anatomical structures remain embedded within textured activations, while the last feature map (273) still exhibits noise-like patterns. Overall, these feature maps suggest that Restormer combines local feature extraction with broader contextual modeling, maintaining rich intermediate

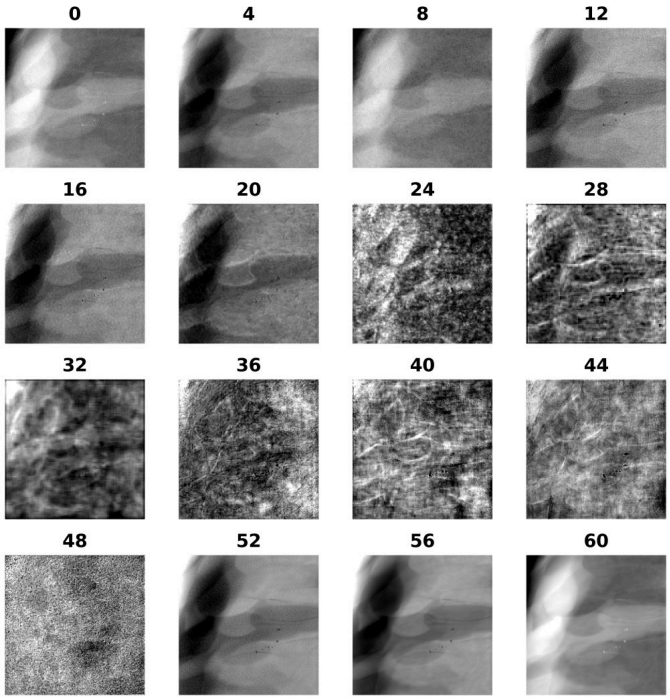

Fig. 4: DRUNet feature maps along its convolutional layers.

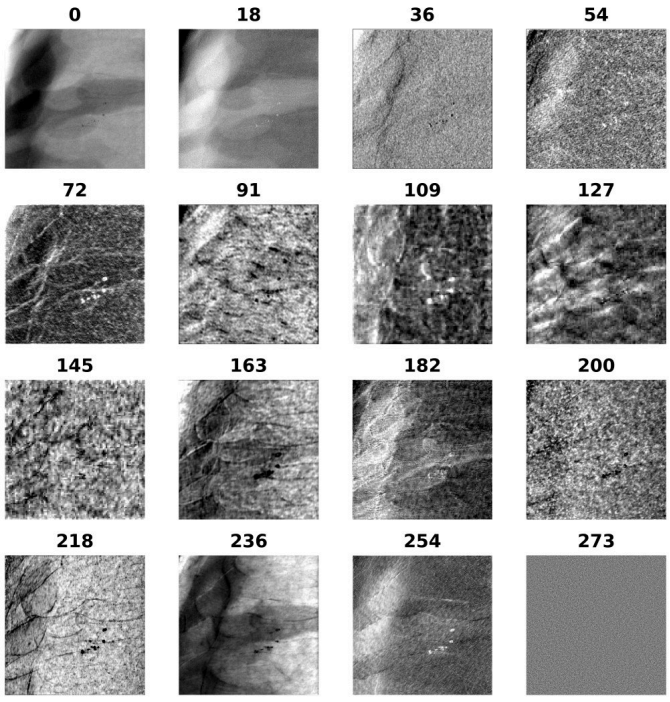

Fig. 5: Restormer feature maps along its convolutional layers.

representations that may contribute to the preservation of fine anatomical details and textures.

3) SCUNet: SCUNet contains 117 convolutional layers, and the representative feature maps in Fig. 6 show a progressive transformation of the mammographic image. In the initial layers (0–23), the feature maps closely resemble the input, preserving anatomical structures, intensity distributions,

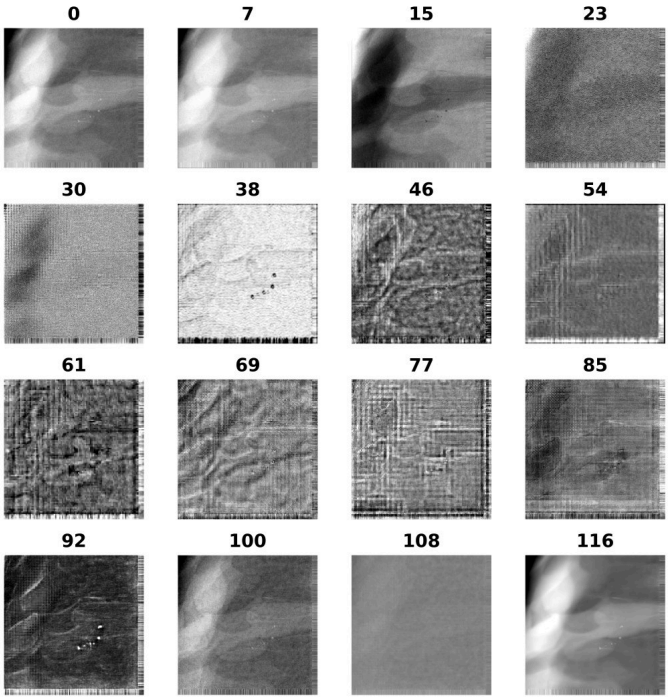

Fig. 6: SCUNet feature maps along its convolutional layers.

and visible noise, indicating low-level feature extraction. In the intermediate layers (30–85), the representations become more abstract, with texture-like patterns, enhanced edges, and high-frequency responses, while emphasizing tissue boundaries and microcalcifications. In the final layers (100–116), the feature maps gradually recover image-like representations while suppressing the previously observed abstract patterns. The final layer (116) reconstructs a smooth image while preserving major anatomical structures and microcalcifications. Overall, SCUNet follows an encoder–decoder-like strategy, progressively transforming low-level features into abstract representations and reconstructing them into a denoised output.

4) SwinIR: SwinIR contains only 9 convolutional layers, with most of its representational capacity concentrated in transformer-based self-attention blocks. The feature maps in Fig. 7 show a markedly different behavior from conventional CNN denoisers. Only layers 0 and 7 retain an image-like appearance, preserving anatomical structures such as tissue boundaries and microcalcifications, whereas the remaining maps (1–6 and 8) exhibit abstract texture patterns, edge responses, and high-frequency activations. This suggests that denoising is primarily performed through contextual representations learned by the attention modules rather than progressive convolutional filtering. The image-like representation at layer 7 indicates the reconstruction stage, where transformer features are projected back into the image domain. Overall, SwinIR relies predominantly on attention-based latent representations, with its convolutional layers mainly supporting feature embedding and image reconstruction.

5) DnCNN: DnCNN contains 20 convolutional layers, and its feature maps reveal a representation strategy distinct from encoder–decoder and transformer-based denoisers. Rather than

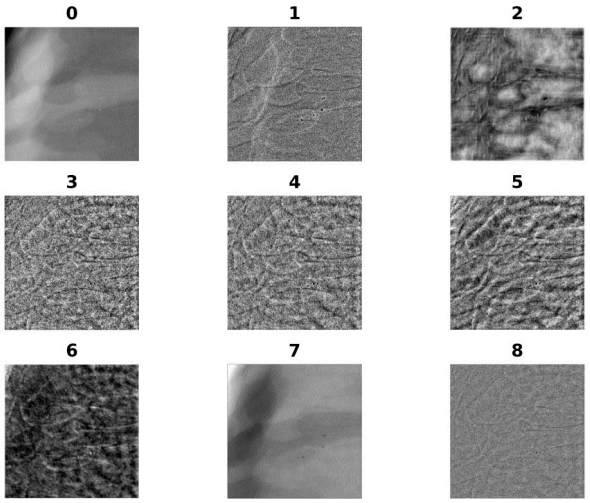

Fig. 7: SwinIR feature maps along its convolutional layers.

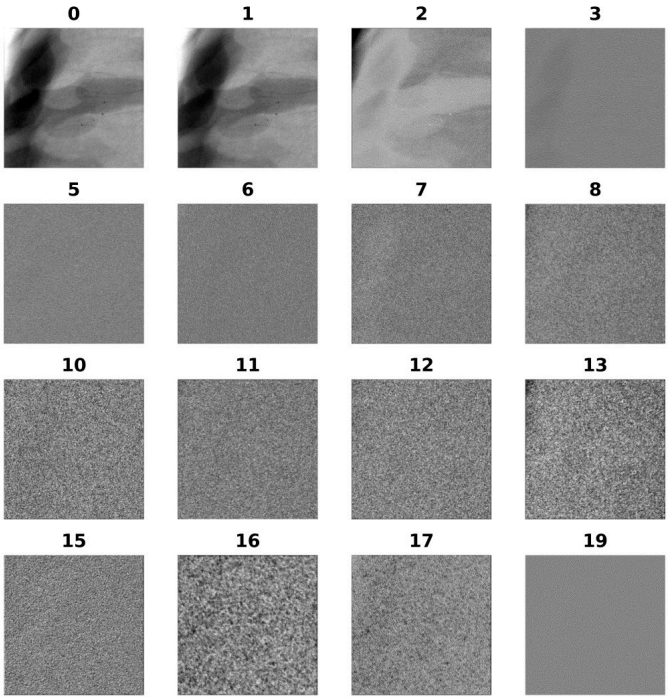

Fig. 8: DnCNN feature maps along its convolutional layers.

progressively encoding and reconstructing the image, DnCNN is explicitly trained to estimate the noise residual. As shown in Fig. 8, the first layers (0–2) preserve image-like representations containing anatomical structures and microcalcifications, while the subsequent layers rapidly suppress image content and become dominated by noise-related patterns. In the intermediate layers (3–17), the feature maps mainly exhibit stochastic textures with little anatomical information, indicating that the network focuses on modeling noise characteristics. In the final layers (17–19), the residual noise is estimated and subsequently subtracted from the noisy input to produce the denoised image. Overall, the feature maps are consistent with DnCNN's residual-learning strategy, in which denoising is performed through noise estimation rather than direct image reconstruction.

6) DSCcP: Fig. 9 shows the feature maps extracted from DSCcP, which contains 20 convolutional layers. Unlike encoder–decoder architectures, DSCcP preserves the same spatial resolution throughout its layers. The early and intermediate layers (0–13) show low-level representations of the noisy input image, including contrast-inverted patterns and texture-like responses. Layer 2 appears to emphasize dense breast structures and the microcalcification cluster. In the final convolutional layers (15–19), the network shows both nearly uniform responses and low-level noise-like textures. Overall, these feature maps suggest that DSCcP performs denoising mainly through low-level texture representations rather than through a hierarchical reconstruction process.

7) GSDRUNet: Fig. 10 illustrates representative feature maps extracted from GSDRUNet, which contains a total of 33 convolutional layers. In the initial layers (0–6), the feature maps correspond to noisy low-level representations of the input image. In the intermediate layers (8–29), the

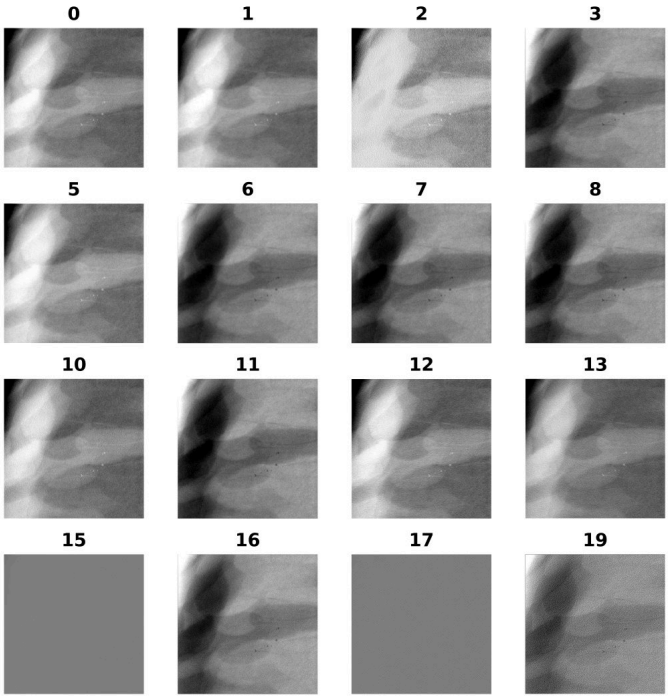

Fig. 9: DSCcP feature maps along its convolutional layers.

representations become increasingly abstract and are dominated by texture-like and noise-related patterns. In the final layer (32), an image-like denoised representation is recovered. Overall, the feature maps suggest that GSDRUNet follows a hierarchical representation strategy similar to DRUNet, progressively transforming low-level image features into abstract representations before reconstructing the denoised output.

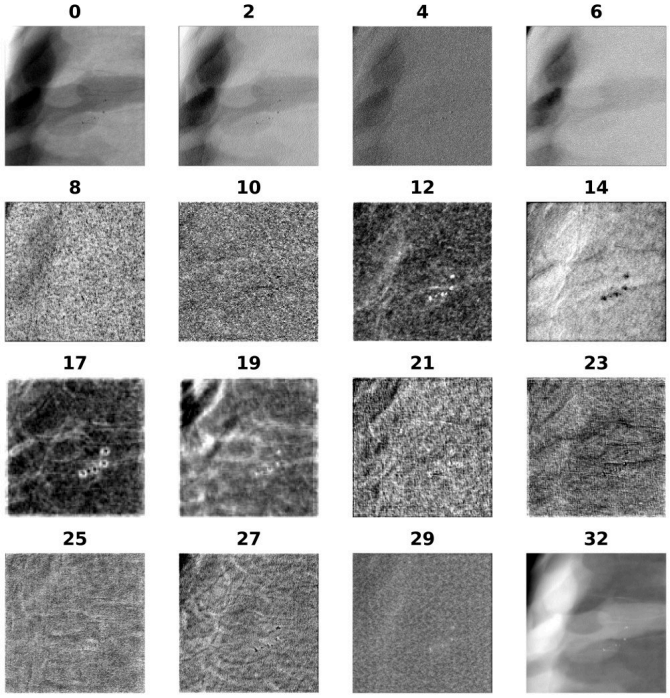

Fig. 10: GSDRUNet feature maps along its convolutional layers.

IV. Conclusion

This work investigated how pretrained deep learning denoisers affect the spectral properties of denoised images and removed components in digital mammography through PSD and feature map analyses. The results showed that some models removed more low-frequency content, whereas others provided weaker suppression in these frequency ranges, highlighting a trade-off between noise removal and mammographic detail preservation. Feature map analysis further suggested that different architectures adopt distinct denoising strategies: encoder–decoder networks progressively transform and reconstruct image representations, transformer-based models rely on attention-driven latent texture representations, and residual-learning networks primarily model noise-like components. These findings indicate that denoising behavior is closely related to the internal representations learned by each architecture and that PSD and feature map analyses provide complementary tools for understanding how deep learning denoisers process mammographic images.

V. Limitations and Future Work

The limitations of this study are outlined as follows. The experiments were conducted using simulated images, which may not fully represent the anatomical variability, acquisition conditions, and noise characteristics of real clinical mammograms. Furthermore, the evaluated denoisers were used in their pretrained, off-the-shelf configurations and were not specifically trained for mammography, while the DeepInverse implementations may differ from the original models. Although PSD analysis provides valuable insights into the frequency-domain behavior, it does not directly assess diagnostic performance or distinguish noise removal from the inadvertent removal of anatomical structures. Finally, the feature map analysis was qualitative and limited to the highest-energy feature map from each sampled layer. Future work should include evaluations on clinical datasets, task-based observer studies, and quantitative explainability methods.

***Abstract*—Microstate analysis has emerged as a useful framework for characterizing the spatiotemporal structure of resting-state electroencephalography, yet the computational choices involved in microstate extraction remain a major source of methodological variability. This work presents a systematic evaluation of how preprocessing decisions, clustering algorithms, and model-order selection influence both the stability of microstate representations and the performance of machine learning models. Using a reproducible pipeline applied to a large clinically annotated EEG dataset, we compare multiple clustering approaches and vary the number of microstates to quantify their effects on cluster validity, temporal descriptors, and classification accuracy. The results show that moderate model orders produce more coherent and reliable microstate features, whereas excessively low or high values lead to fragmentation and reduced discriminability. Among clustering methods, hierarchical and centroid-based algorithms yield the most stable topographic maps, which translate into improved performance for ensemble and kernel-based classifiers. Overall, the study demonstrates that methodological rigor in microstate extraction is essential for achieving robust EEG classification and provides practical guidelines for designing reproducible pipelines in computational neurodiagnostics.**

***Index Terms*—Electroencephalography (EEG), microstates, clustering algorithms, machine learning, neurological disorder detection**

I. Introduction

Neurological disorders affect nearly 3 billion people ($\sim$1 in 3) and have driven an increase of $\approx 18\%$ in combined disability and premature mortality in recent assessments [1]. According to the World Health Organization (WHO), nearly 70% of cases occur in low- and middle-income countries and account for around nine million deaths each year; the leading contributors to disability-adjusted life years (DALYs) are stroke (42.2%), migraine (16.3%), dementia (10.4%), meningitis (7.9%), and epilepsy (5.0%) [2]. In the Region of the Americas, 2019 estimates indicate on the order of 533,000 deaths (about 60% among women) and marked between-country heterogeneity in mortality and disability, Brazil ranks highest in years lived with disability (YLDs), while age-standardized mortality ranges from 47.4 per 100,000 (United States) down to 6.6 per 100,000 (Venezuela) [3].

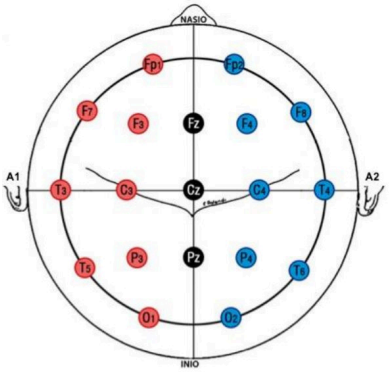

Fig. 1. Illustration of a standard EEG cap with electrodes placed according to the 10–20 international system. The montage highlights the spatial distribution used for recording scalp electrical activity.

A. Electroencephalogram and Microstates

Electroencephalography (EEG) is a noninvasive technique that measures voltage fluctuations on the scalp arising from synchronized postsynaptic activity of cortical pyramidal neurons (Fig. 1). Its millisecond-scale temporal resolution enables direct observation of fast neural dynamics that are not captured by structural or hemodynamic imaging modalities, making EEG particularly useful for studying fast neural processes and large-scale functional organization. Despite its advantages, routine EEG interpretation is often hindered by low signal-to-noise ratios, nonstationarity, inter-subject variability, and contamination from ocular, muscular, and environmental sources, which complicate the reliable extraction of physiologically meaningful features [2].

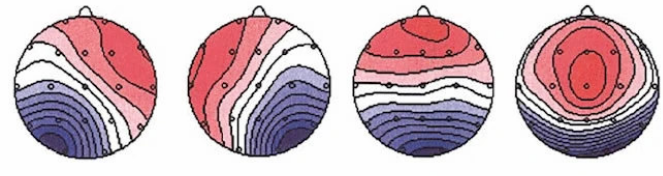

Fig. 2. Canonical EEG microstate maps (A–D).

EEG microstate analysis provides a compact representation of these large-scale neural dynamics by segmenting the continuous signal into brief, quasi-stable topographies that recur over time. These microstates, typically lasting 50–120 ms, are frequently interpreted as elementary building blocks of spontaneous cognitive processing, and their temporal characteristics (duration, occurrence rate, fractional occupancy, and transition structure) are known to exhibit characteristic differences across a range of physiological and pathological conditions [4]. However, microstate-based inference remains highly sensitive to methodological decisions involving preprocessing pipelines, referencing approaches, artifact handling, map normalization, clustering algorithms, and, critically, the choice of the number of microstates. Although the canonical four-class solution (A-D, Fig. 2) is widely used, empirical evidence consistently demonstrates that the optimal model order depends on cohort characteristics, recording conditions, and preprocessing strategies [5]. Common selection criteria, including global explained variance, cross-validation, information-theoretic measures, and cluster-validity indices, often yield divergent estimates, highlighting the need for principled, data-driven approaches rather than fixed heuristic conventions [6], [7].

B. Machine Learning Techniques for EEG Microstates

Machine learning has become increasingly central to EEG analysis and has gained particular relevance in microstate research, where models must capture complex spatiotemporal patterns, offering tools capable of modeling nonlinear relationships, extracting high-dimensional structure, and improving diagnostic accuracy beyond handcrafted descriptors. Supervised approaches, including artificial neural networks, convolutional neural networks, support vector machines, and ensemble-based classifiers, have demonstrated strong performance in differentiating healthy from pathological EEG patterns, detecting epileptiform discharges, and identifying candidate biomarkers for neurological and psychiatric disorders [8], [9]. Their ability to learn discriminative representations directly from raw or minimally processed signals makes them particularly attractive in settings where subtle spatiotemporal signatures carry diagnostic relevance.

Unsupervised methods provide complementary advantages by uncovering organization within EEG activity without requiring labeled data, a property that aligns naturally with the principles of microstate analysis. Algorithms such as k-means, DBSCAN, and graph-based clustering have been used to infer latent state structure, segment recurring topographies, and characterize cohort heterogeneity [10], [11]. Yet, these methods remain sensitive to preprocessing choices, noise levels, and, critically, assumptions about the number of clusters or density structure, limitations shared with traditional microstate pipelines. These considerations mean that the value of machine learning in microstate research is determined as much by the surrounding methodology as by the algorithms themselves. Careful choices in preprocessing, feature construction, and model-order selection are often what separate stable, interpretable findings from results that fail to generalize. When these elements are handled consistently and transparently, machine learning and microstate analysis complement each other well, offering a flexible framework for probing large-scale neural dynamics. Without such methodological discipline, however, the apparent power of these tools can be misleading, underscoring the importance of reproducible and well-justified analytical pipelines.

C. Motivation

Although EEG microstates and modern machine learning techniques offer promising avenues for characterizing large-scale brain dynamics, their practical use remains limited by methodological instability and lack of consensus. A key unresolved issue is the determination of the optimal number of microstates: the choice of model order substantially alters temporal metrics, transition structure, and classification performance, yet commonly adopted heuristics often yield inconsistent or contradictory results across datasets, cohorts, and preprocessing pipelines [12]. This variability hampers interpretability, reduces reproducibility, and complicates clinical translation, especially in heterogeneous populations where neural patterns may deviate from canonical assumptions.

At the same time, machine learning classifiers and clustering algorithms many of the same sensitivities. Their outputs depend strongly on data normalization, artifact removal, feature scaling, and initialization strategies, as well as on the quality of the microstate representations they consume [13]. Without systematic evaluation, it becomes unclear whether observed improvements stem from genuine neurophysiological differences or from arbitrary modeling choices. These challenges highlight a critical gap in the literature: the need for an integrated, data-driven framework that (i) rigorously estimates the optimal number of microstates, (ii) evaluates how this choice propagates through clustering and classification pipelines, and (iii) establishes methodological guidelines to support reproducible EEG microstate research.

D. Contributions

This work addresses the methodological instability surrounding EEG microstate extraction and its impact on machine

learning analysis. The main contributions are summarized as follows:

- We develop a reproducible preprocessing and segmentation pipeline for EEG microstate extraction, consolidating best practices in filtering, referencing, artifact handling, and map normalization.
- We conduct a systematic, data-driven evaluation of model-order selection, comparing multiple criteria, including cluster-validity indices, cross-validation metrics, and information-theoretic measures to estimate the optimal number of microstates.
- We analyze how different microstate model orders propagate through unsupervised and supervised machine learning algorithms, assessing robustness, sensitivity, and overall classification performance.
- We provide a comparative study of multiple clustering methods (k-means, modified variants, AAHC, k-medoids, DBSCAN) in the context of EEG microstate segmentation, highlighting strengths, limitations, and convergence patterns.
- We establish practical recommendations and methodological guidelines to support reproducible research in microstate modeling and its application to neurological disorder assessment.

II. Material and Methods

A. Dataset

This study uses the Temple University Abnormal EEG Corpus (TUAB), a publicly available subset of the Temple University EEG Corpus (TUEG). TUAB contains clinically annotated scalp EEG recordings labeled as normal or abnormal, selected to provide a demographically balanced dataset while minimizing confounding factors. All recordings are distributed in EDF format and were originally acquired at the Temple University Hospital (TUH) Department of Neurology. The dataset follows HIPAA de-identification guidelines, with all personal identifiers removed prior to release.

TUAB comprises 2,993 EEG sessions from 2,329 unique subjects (52.1% female), with a mean age of 48.6 $\pm$ 17.9 years. The dataset is nearly balanced, containing 50.8% normal and 49.2% abnormal recordings. The official split includes 2,717 recordings for training and 276 for evaluation and is detailed by class in Table I, which reports non-pathological and pathological counts for each subset. Each session typically includes 21 EEG channels, most commonly sampled at 250 Hz. Recordings shorter than 15 minutes were excluded during dataset construction, and abnormal sessions were validated through concordance between automated detectors and clinical reports, achieving approximately 97–100% agreement between automated labels and clinical reports.

All recordings used in this work were obtained from the official TUH distribution portal and processed exclusively for research purposes. Although TUAB is already fully de-identified, all procedures adhere to the ethical guidelines established by the original data providers. Because the dataset is publicly released for research under a Temple University institutional review board (IRB) protocol, no additional ethical approval was required for secondary analysis.

TABLE I
Number of recordings and patients in the TUAB dataset used in previous machine learning studies

Set	Non-Pathological Recordings	Pathological Recordings	Total Recordings
Training	1371	1346	2717
Evaluation	150	126	276
Total	**1521**	**1472**	**2993**

Adapted from [14].

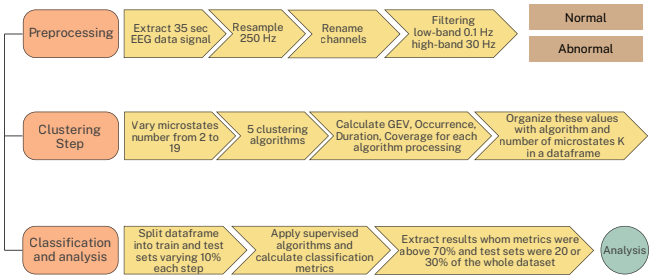

Fig. 3. Experimental workflow.

B. Workflow Overview

The experimental pipeline consists of four sequential stages (Fig. 3). First, EEG recordings from the TUAB dataset were preprocessed to standardize montage, sampling rate, and signal quality.

Second, microstate segmentation was performed using multiple clustering algorithms over a range of model orders, producing a structured set of microstate descriptors.

Third, clustering solutions were compared using standard validity indices.

Finally, the resulting microstate-feature tables were used to train several supervised learning models under 5-fold cross-validation.

Together, these stages form a unified pipeline designed to evaluate how different preprocessing, clustering strategies, and microstate model orders influence classification performance.

C. Preprocessing

All EEG recordings were preprocessed through a reproducible pipeline designed to standardize signal quality across subjects and sessions. For each TUAB recording, a fixed 35-second segment was extracted (from 175 s to 210 s), ensuring uniform temporal length while avoiding periods commonly

affected by recording artifacts or clinical interventions. Signals originally sampled at heterogeneous rates (250, 256, 400, or 512 Hz) were resampled to 250 Hz to ensure consistency across all analyses.

Channel names were then mapped to a unified 10–20 nomenclature using the correspondence defined in Table II, and recordings missing required channels were discarded. A 0.1–30 Hz band-pass filter was applied to retain the conventional EEG frequency bands associated with microstate dynamics while suppressing slow drifts and high-frequency muscular noise. After filtering, all signals were referenced to the average reference montage, a standard choice in microstate research due to its stability and topographic interpretability.

TABLE II

Source: the authors.

All preprocessing steps were executed in Python 3.11 using the MNE library, which provides robust and validated implementations of EEG transformation routines. To ensure the reproducibility of every data manipulation procedure, all stochastic operations were controlled using a fixed random seed (42). The resulting preprocessed signals served as the standardized input for the microstate clustering stage.

The preprocessing parameters were selected to remain consistent with common practices reported in the EEG microstate literature. The use of a 0.1–30 Hz band-pass filter preserves the frequency components most frequently associated with resting-state microstate dynamics while reducing slow drifts and high-frequency artifacts. Similarly, average referencing was adopted because it provides stable topographic representations and facilitates comparisons across subjects and recording sessions. The 35-second segment length was chosen to ensure a standardized analysis window for all recordings while maintaining a sufficient number of microstate transitions for reliable descriptor estimation.

D. Clustering

Microstate extraction was performed by applying multiple clustering algorithms to the preprocessed EEG topographies. For each recording, the Global Field Power (GFP) peaks were first identified and used as candidate topographic maps, following standard practice in microstate analysis. These maps were then submitted to five clustering algorithms: K-means, Modified K-means, K-medoids, Adaptive AAHC, and DBSCAN. This combination includes both centroid-based and density-based approaches, enabling a broad evaluation of methodological variability in microstate segmentation.

To systematically assess model-order effects, the number of microstates was varied from $K = 2$ to $K = 19$ for all algorithms except DBSCAN, whose number of clusters is data-driven. For each clustering solution, a set of microstate descriptors was computed, including global explained variance (GEV), occurrence, duration, coverage. These descriptors quantify spatial alignment, temporal stability, and dynamical structure, forming the feature space used in the subsequent classification stage.

Cluster quality was further assessed using the validity indices Silhouette Score, Calinski–Harabasz Index, Davies–Bouldin Index, and Dunn Index allowing comparison across clustering algorithms and microstate model orders.

E. Classification

Following the clustering stage, an intermediate feature dataset was constructed for supervised learning. For each recording, and for every combination of clustering algorithm and microstate model order, four microstate descriptors were extracted: global explained variance (GEV), mean occurrence, mean duration, and coverage. Each row of the resulting table corresponds to a single recording, and each column corresponds to one of these descriptors, yielding a structured representation of the temporal and dynamical properties of the microstate solution.

This feature table served as the input to the classification stage, in which several machine learning models were trained to distinguish normal from abnormal EEG recordings. The evaluated classifiers included Logistic Regression, Support Vector Machines (SVM), Random Forests, Decision Trees, k-Nearest Neighbors (KNN), Naive Bayes, Gradient Boosting, XGBoost, and the Optimum-Path Forest (OPF) classifier; for OPF, multiple distance functions available in OPF programming package were tested to account for different geometries in feature space.

All models were trained and assessed using 5-fold cross-validation. Performance was quantified using accuracy, precision, recall, and F1-score, with confusion matrices computed to inspect error distribution. Hyperparameters were kept at default settings unless required for numerical stability, ensuring fair comparison across methods.

By training classifiers on microstate descriptors derived under different clustering strategies and model orders, this stage provides a systematic evaluation of how upstream preprocessing and segmentation choices propagate into diagnostic performance.

Although classifier performance was assessed using multiple evaluation metrics under cross-validation, the primary objective of this work was not to identify a single best-performing model. Instead, the classification stage was used as a controlled framework to investigate how methodological choices made during microstate extraction influence downstream predictive performance. Therefore, differences among classifiers should be interpreted mainly as indicators of the quality and stability of the resulting microstate representations.

III. Discussion

The results demonstrate that methodological choices in microstate extraction substantially influence both the structure of the derived microstate representations and the classification of normal versus abnormal EEG recordings. Varying the number of microstates produced consistent changes in temporal descriptors, with lower model orders yielding more stable and interpretable dynamics, whereas higher values of K introduced fragmentation and reduced global explained variance (GEV). This behavior was observed across all clustering algorithms but was more pronounced in centroid-based methods such as K-means and Modified K-means.

The observed differences among clustering algorithms can be partially explained by their underlying assumptions. Hierarchical approaches such as AAHC tend to preserve topographic organization throughout the clustering process, whereas centroid-based methods favor compact cluster representations. In contrast, density-based methods are more sensitive to the distribution of GFP peak topographies, which may lead to greater variability in the resulting microstate structures. These characteristics help explain the differences observed in cluster validity measures and classification performance.

To illustrate these effects quantitatively, Table III summarizes representative cluster validity metrics obtained with the Modified K-Means algorithm across a range of model orders. The selected values show the trade-off between compactness, separation, and stability as K increases, supporting the observed pattern in which low to moderate model orders yield more coherent microstate structure, while larger K values introduce fragmentation and reduced descriptor reliability.

TABLE III
Cluster validity metrics for the Modified K-Means algorithm comparing different K values between 2 and 19

Microstates	Silhouette	Calinski–Harabasz	Davies–Bouldin	Dunn

Source: the authors.

Comparisons among clustering strategies revealed systematic differences in topographic stability and descriptor reliability. AAHC generally produced compact and well-separated clusters, reflected in higher Silhouette and Calinski–Harabasz scores, while DBSCAN showed strong dependence on density parameters and resulted in variable cluster counts. K-medoids offered robust performance in terms of temporal descriptors but exhibited lower GEV for larger values of K. These findings indicate that algorithmic assumptions directly shape the microstate solutions and should be considered when interpreting large-scale neural dynamics.

TABLE IV
Average cluster validity metrics across clustering algorithms comparing different K values between 2 and 19

Algorithm	Silhouette	Calinski–Harabasz	Davies–Bouldin	GEV

The intermediate feature dataset constructed from microstate descriptors enabled a structured evaluation of how these methodological variations propagate into supervised learning. Classification performance showed clear sensitivity to both the clustering method and the selected model order. Moderate values of K produced more discriminative feature spaces, supporting the idea that excessively coarse or overly fragmented microstate partitions reduce the separability of normal and abnormal EEG recordings. Among the classifiers, ensemble-based and kernel-based models generally achieved higher accuracy and F1-scores, whereas distance-based methods were more sensitive to descriptor scaling and class boundaries. Among all OPF configurations tested, the highest performance was obtained using the Euclidean distance, which consistently outperformed Manhattan, Chebyshev, and Minkowski variants in terms of accuracy, recall, and F1-score.

TABLE V
Classification performance across machine learning models (5-fold cross-validation)

Classifier	Accuracy	Precision	Recall	F1
Logistic Regression	0.71	0.70	0.69	0.69
SVM (RBF)	**0.78**	0.77	0.76	**0.76**

OPF (euclidean distance)	0.74	0.73	0.73	0.73

Source: the authors.

Taken together, these results reinforce the importance of methodological rigor in EEG microstate research. Small vari-

ations in preprocessing, clustering strategy, and model-order selection propagate into measurable differences in classification performance, underscoring the risks of relying on fixed heuristics or canonical parameter choices. The findings support the need for systematic, data-driven evaluation when designing microstate pipelines, particularly in diagnostic settings in which reproducibility and interpretability are essential.

Some limitations should be considered when interpreting the results. The analysis was conducted using a single public dataset and focused on resting-state EEG recordings acquired under specific recording conditions. Although TUAB provides a large and clinically relevant cohort, performance estimates may vary when different populations, acquisition protocols, or clinical settings are considered. In addition, the present study emphasizes methodological comparisons rather than neurophysiological interpretation of individual microstate classes. Future investigations may explore these aspects in greater detail.

IV. Conclusion

This study examined how methodological choices in EEG microstate extraction, including preprocessing decisions, clustering algorithms, and model-order selection, shape both the structure of microstate representations and the performance of classifiers. The results show that variations in number of microstates K, as well as differences among clustering strategies, produce measurable effects on temporal descriptors, cluster validity, and ultimately on the ability of machine learning models to discriminate normal from abnormal EEG recordings. Moderate values of K yielded the most stable and discriminative feature spaces, while excessively low or high model orders reduced descriptor reliability and degraded classification performance, suggesting that moderate model orders, particularly those close to the traditional four-microstate solution, provide a good balance between stability, interpretability, and classification performance in the evaluated dataset..

Among the evaluated clustering methods, AAHC and Modified K-Means produced the most coherent microstate structures, which translated into superior performance when combined with contemporary ensemble and kernel-based classifiers such as Gradient Boosting, XGBoost, and SVM. These findings highlight the importance of systematic, data-driven parameter exploration in microstate research, since small methodological variations can propagate into substantial differences in diagnostic accuracy.

The study also reinforces the need for reproducible and transparent microstate pipelines. By providing a controlled experimental design and a comprehensive comparison across clustering and classification techniques, this work contributes practical insights for researchers developing microstate-based analytical tools, particularly in clinical contexts where interpretability and robustness are essential.

Beyond classification performance, the findings may also be relevant for the design of EEG-based decision-support systems. More stable microstate representations can contribute to the development of reliable computational tools for screening, prioritization, and complementary assessment of neurological abnormalities, particularly in large-scale clinical environments where reproducibility is essential.

Future work may extend this analysis by exploring larger EEG datasets, testing additional clustering formulations, integrating deep learning models for microstate representation learning, and evaluating adaptive or subject-specific model-order selection procedures. Such directions may further advance the reliability and applicability of microstate-based approaches in computational neurodiagnostics.

***Abstract*—The application of deep learning models in brain-computer interfaces (BCIs) has increased in the last years, with many convolutional neural networks (CNNs) being developed to exploit both the temporal and spatial information contained in the electroencephalograms (EEGs). In this scenario, it is important to find models that not only have good classification performance, but also offer a certain level of interpretability for their results. The EEGNet model and its variants present such a feature, conciliating strong performance with an architectural design that allows the inspection of electrode importance and the analysis of the learned kernels in terms of frequency filters. Interestingly, another family of models emerged after the proposal of SincNet, which adopts sinc-based convolution kernels to learn a filterbank of bandpass filters with a reduced number of parameters. Thus, this work brings together seven models from these families with interpretable elements and establishes a comparison in the context of BCI systems based on SSVEP and motor imagery. Two databases were explored, and the average accuracy across subjects was evaluated. In addition, given the interpretable profile of the models, we also analyzed the learned filters (both temporal and spatial).**

***Index Terms*—Brain-computer interface, electroencephalography, deep learning, spatio-temporal processing, frequency filtering**

I. Introduction

The advancement of artificial intelligence technologies has driven the development of methods for analyzing complex biological signals, such as electroencephalograms (EEGs), which are widely used in medical and experimental applications, e.g. epilepsy diagnosis, sleep studies, and brain-computer interfaces (BCIs). In this context, deep learning techniques [1] have been widely explored [2]–[4] and present notable results in different scenarios: detection of seizures [5], motor rehabilitation [6], and mental workload monitoring [7]. Convolutional neural networks (CNNs) are predominant in this field, and proved to be suitable techniques for processing brain signals [8].

BCIs based on EEGs aim at establishing an alternative path to communicate human and machine, which can have a key role in the development of new assistive technologies, especially for people with disabilities. Deep learning methods have been explored in BCI systems based on different paradigms, such as motor imagery (MI) [9]–[12] and steady-state visually evoked potentials (SSVEP) [3], [13], [14], showing promising results. Interestingly, there has been an increasing interest not only in performance, but also in discussing how, and possibly why, the models carry out their decision-making process.

In this context, the implementation of interpretable models for decoding EEGs within BCI systems is fundamental to building trustworthy and helpful technology. In light of this, there are works in the BCI literature that incorporate interpretable components into deep models. In particular, EEGNet [15] can be considered a well-established reference, whose architecture explores different convolutional operations, e.g., depthwise and separable convolutions, to create temporal and spatial filtering layers.

Besides the performance, the authors highlight how the learned filters were connected to known neurophysiological phenomena, based on the analysis of the output spatial filters and the weights of the convolutional kernels.

Since then, a family of CNN models has emerged, taking inspiration from EEGNet, among which we mention EEG-TCNet [16], EEGITNet [17] and EEGNex [18]. All of these variations contain similar layers that allow some degree of interpretation, both in terms of frequency filtering and electrode (spatial) relevance.

Another model that was conceived with a strong appeal to interpretable layers was SincNet [19]. Originally applied to audio processing, this model employs a special first convolution layer whose kernels are designed according to a $sinc(\cdot)$ function, in order to create a set of band-pass filters parameterized by the cutoff frequencies, which are the only learnable elements of the layer.

As a consequence, the number of learnable parameters is reduced, and the role played by the learned kernels can be easily evaluated in the frequency domain. In fact, the prior knowledge imposed by the filters shape implies a constructive bias that gives enough flexibility to the filterbank to adapt to the data. Thus, the generated filter maps tend to be more intelligible and reflect the importance given to specific frequency bands.

This study was financed, in part, by the São Paulo Research Foundation (FAPESP, Process Number 2024/07783-5), as part of the BI0S - Brazilian Institute of Data Science (2020/09838-0).

This study was financed in part by the Coordination for the Improvement of Higher Education Personnel – Brazil (CAPES) – Finance Code 001.

In [10], the sinc-convolutions proposed in SincNet were explored in the context of EEGs and BCI systems, leading to the SincShallowNet model, which also rely upon depthwise convolutions to extract temporal and spatial features of the data.

The interpretability brought by SincNet motivated the development of more advanced designs for the band-pass filters, which form a second family of models, including SincSquareNet [20], PF-Net [21] and IIRI-Net [22]. All these variants adopt a specially-tailored first convolution layer that creates multiple frequency-band filters with simplified parameterizations, but present an architectural limitation: they can process univariate (single channel) temporal signals.

Having this scenario in view, in this work we propose to systematically study and compare several models from EEGNet [15] and SincNet [19] families in the context of BCI systems, evaluating not only the classification performance, but also the attained filters (temporal and/or spatial), highlighting the brain regions that were most activated based on the learned weights. Here, the concept of interpretability is understood in the restricted sense of inspectability: both the EEGNet and the SincNet families have initial layers that can act as frequency filters, which can be inspected in the frequency domain and may be connected with the nature of the data and of the task, as well as spatial filtering layers, which may reveal the electrode relevance that was learned by these models.

In order to explore more recent variations of SincNet [19] for EEG processing, we extend the PF-Net [21] and IIRI-Net [22] models to the multivariate scenario, making an adaptation similar to that employed in SincShallowNet [10]. To the best of our knowledge, these variations have not been applied to BCI-EEG systems yet.

In the end, a total of seven models were tested, considering both SSVEP and MI paradigms of BCIs, allowing a more comprehensive perception of the potential advantages of each design.

The sequence of the paper is organized as follows: Section II reviews the relevant literature related to EEGNet [15] and SincNet [19] families. Section III details the methodology, the datasets, and the experimental setup used in this study. Section IV presents the findings, followed by a discussion of their implications. Finally, Section V concludes the paper and outlines directions for future research.

II. Theoretical Background

The model named SincNet [19] was originally built for audio signal processing and the $sinc(\cdot)$ based convolutions extract features from raw data. The main idea consists in modeling each convolution kernel as a band-pass filter in the frequency domain, by means of a difference between two lowpass filters, as in:

$$G[f, f_1, f_2] = rect\left(\frac{f}{2f_2}\right) - rect\left(\frac{f}{2f_1}\right), \qquad (1)$$

where $rect(a) = 1,\ \text{for}\ |a| < 1/2$ and 0 otherwise.

Applying the inverse Fourier transform, the corresponding impulse response of each filter is as follows:

$$g[n, f_1, f_2] = 2f_2 sinc(2\pi f_2 n) - 2f_1 sinc(2\pi f_1 n) \qquad (2)$$

In practice, a truncated version of $g[n]$ is employed by means of windowing:

$$g_w[n, f_1, f_2] = g[n, f_1, f_2] \cdot w[n], \qquad (3)$$

where a Hamming window was chosen by [19] to mitigate the ripples in the passband and improve the attenuation in the stopband.

After the customized sinc-based convolutional layer, the SincNet architecture contains standard layers, with pooling, layer normalization, Leaky ReLU nonlinearity, dropout, a few convolutional layers and, finally, softmax [19].

Aiming to benefit from the interpretable characteristic present in SincNet, some works have adapted the model in multiple contexts, including scenarios with learnable and fixed parameters [23], as a feature extractor combined with modules that learn a sparse representation of the filtered data [12], and applications to high-dimensional EEG signals [24], and complex raw radar data [25]. In this way, a family of models based on SincNet has been introduced in the literature over the years and some of them are highlighted in this work.

The first extension is the SincShallowNet [10], a more lightweight version of the SincNet [19] applied to EEG signal processing. This approach is based on a three-block method: in the first block it applies temporal filtering via sinc-based convolutions, and spatial filtering with depthwise convolutional layers, aiming to reduce the number of parameters of the network and increase its interpretability; the second block performs a temporal pooling stage of the first block feature maps; the third block includes fully-connected layers to perform classification. Fig. 1 illustrates the first block of this architecture, highlighting how it adapts the approach for multivariate inputs. Specifically, the network input is structured as a 2D array of size $C \times T$, representing a single trial where C denotes the number of EEG channels and T represents the number of time samples.

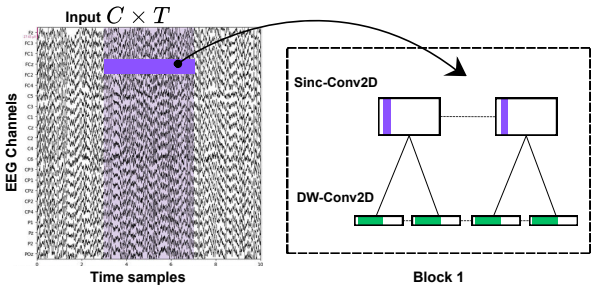

Fig. 1. Representation of the first block of SincShallowNet and its input format. Adapted from [10].

By doing that, SincShallowNet allows direct interpretation of the learned spectral–spatial features through kernel inspection, preserving an important characteristic of the SincNet

model, the interpretability, while training faster. SincShallowNet has also been applied in multiple contexts recently, e.g. mental healthcare [27] and drowsiness detection [28].

The second model is PF-Net [21], which adds higher flexibility for the input filters by parameterizing the cutoff limits of the band-pass filters based on the $sinc(\cdot)$ function. The approach models the frequency response by dividing it into small, learnable line segments defined by adjustable deformation points across low and high frequencies, which can be achieved through the reconstruction of the function g so that g contains more learnable variables. The frequency domain characteristics of each segment are defined below:

$$G[f, f_k, f_{k+1}] = \frac{h_{k+1} - h_k}{f_{k+1} - f_k}(f - f_k) + h_k, \tag{4}$$

where f_k and f_{k+1} are the low and high frequencies of each segment, with f within $[f_k, f_{k+1}]$, and h_k and h_{k+1} are their frequency amplitude intensity. All f and h are learnable.

In the time domain, the expression for the filtering frequency band from PF-Net can be defined as:

$$g[f, f_{beg}, f_{end}] = \sum_{k=beg}^{end-1} g[n, f_k, f_{k+1}]. \tag{5}$$

As a result, PF-Net accelerates convergence compared to standard CNNs and outperforms SincNet [19] due to its ability to extract more detailed features from the signal spectrum.

Also part of the SincNet family, we highlight IIRI-Net [22], a CNN network that was defined for audio processing as well and implements infinite impulse response (IIR) inspired filterbanks that are meaningful and controllable. In the first convolutional layer, it uses second order filters with IIR instead of truncated $sinc(\cdot)$ filters. The filters of this model have the shape of stable resonators and allow the adjustment of the bandwidth (2σ) and the center frequency (w_0), as in:

$$h[n] = \frac{\sin[(n+1)\omega_0]}{\sin(\omega_0)} e^{-n\sigma} u[n] \tag{6}$$

In this scenario, the only parameters required for learning are ω_0 and σ, which represent the location of the poles of the reference IIR filter. The learned filter is a band-pass filter that amplifies the frequencies around the center frequency, ω_0, and attenuates other frequencies. Additionally, as in SincNet [19], the gain of the filter is not a learning parameter because the subsequent layers are responsible for the importance of each filter's output.

To handle multivariate signals such as EEGs, both PF-Net [21] and IIRI-Net [22] required adaptation. These modifications are detailed in Section III (Methodology).

Alternatively, EEGNet [15] was conceived for BCI applications, and its first two layers operate with a direct signal processing meaning. A 2D convolution applies a fixed number of kernels along the time axis, each spanning a single channel and shared across all electrodes, so that every kernel acts as a temporal filter whose frequency response, obtained from the Fourier transform of its weights, reveals the bands emphasized during training. A depthwise convolution then operates along the channel axis, learning a fixed number of spatial filters per temporal filter, each assigning a coefficient to every electrode. A separable convolution and a fully-connected classifier complete the architecture, summarized in Fig. 2. Both temporal and spatial filtering stages are therefore inspectable by construction.

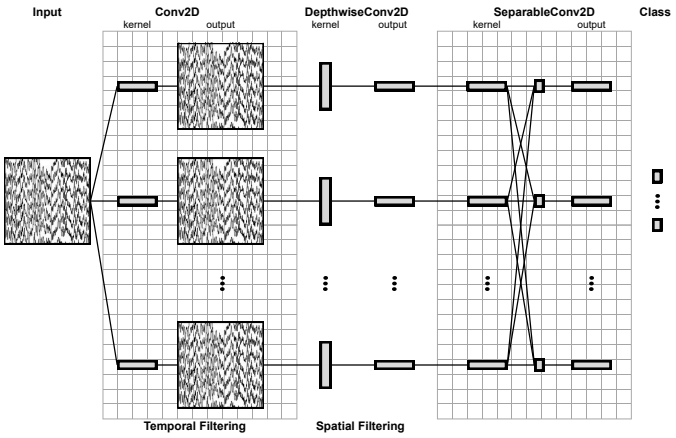

Fig. 2. EEGNet architecture. Adapted from [15].

EEGNet has become a significant baseline model to the BCI literature, being utilized as a benchmark in several subsequent works, and has also inspired the proposal of modifications of its core elements. These models were selected based on their potential to bring better classification performance while maintaining the interpretable characteristic of EEGNet.

The first EEGNet variant we can highlight is EEG-TCNet [16], which follows an usual structure for EEG data (convolutional layers for spatial-temporal feature extraction). This neural network differs by the implementation of TCN (Temporal Convolutional Network) module right after the depthwise and separable convolution modules and before entering a fully-connected network, aiming to identify temporal dependencies in motor imagery signals. Because of its limited computational complexity, it can be easily used in small devices. In the last years, this approach has been adapted with self-attention blocks to build a temporal convolutional transformer [29] and also adapted to learn more signal features through multiple convolutional kernels in parallel [26].

To work on the lack of interpretability of deep learning models in the context of motor imagery classification, EEG-ITNet [17] was proposed. This approach introduces an inception block in the beginning of the architecture, followed by a temporal convolutional (TC) block similar to the one in EEG-TCNet [16], a dimension reduction (DR) block and a classification block. Interestingly, this work explores an extra dimension in the inception block to achieve interpretability, i.e., the inception block consists of 2D convolutional layers applied over the time axis of multichannel EEG with different kernel sizes. These initial 2D layers act as frequency filters and, taking the Fourier transform of the convolutional kernels, they reveal the sub-bands selected during training. This model

has also been explored recently alongside data augmentation [30] and regularization [31] techniques.

The third variation selected in this work is EEGNex [18], which presents some structural changes in comparison with EEGNet, such as doubling the convolutional layer to capture more spatial patterns, and increasing the temporal learning by replacing the separable convolution with two standard convolutional blocks. As a result, EEGNex is an adaptable architecture that can be explored in different domains and applications, being considered recently as a state-of-the-art method for EEG classification and a widely explored model [32], [33].

All these variants were originally validated on motor imagery data, namely the BCI Competition [36] and High-Gamma [35] datasets, and none was assessed on SSVEP. It is possible to observe, therefore, a growing interest from the community in models that offer greater transparency regarding how brain data are processed, while also achieving high performance in classification tasks. Nevertheless, there is still room for studies that explore the application and analysis of interpretable deep architectures for BCI systems, including models not yet employed in the BCI context. We aim to reduce this gap by carrying out this comparative study with the seven aforementioned models, as well as by considering both MI and SSVEP BCI paradigms.

III. Methodology

We have selected EEG datasets based on SSVEP and MI paradigms, respectively: the Benchmark [34] and BCI Competition IV-2a [36] datasets.

The Benchmark dataset comprises recordings from 35 subjects. Each individual participated in six distinct sessions, with 40 stimuli each. On the monitor, a digital keyboard displayed each key flickering at a different frequency. For each stimulus, corresponding to the keys on the keyboard, a red square signaled the target to the individual. Thus, a cue appeared for half a second, followed by five consecutive seconds of stimulation, with a half-second pause before the next target. For each session, there were a few minutes of rest.

To capture the signal, 64 electrodes were positioned over the scalp following the 10-20 standard, with six samples collected for each key (corresponding to the sessions performed).

The BCI Competition IV-2a dataset comprises recordings from 9 subjects, with two sessions per participant, each consisting of six runs with 48 trials (12 per class), totaling 288 trials per session. The classes correspond to motor imagery tasks of the left hand, right hand, feet, and tongue.

At the beginning of each session, a 5-minute recording was performed to estimate EOG influence: two minutes with eyes open and fixed, one minute with eyes closed, and one minute with eye movements. Each trial began with a fixed cross on a black screen and an acoustic warning. After two seconds, an arrow indicated the task (up, down, left, or right) for 1.25 seconds, followed by an execution period with the central cross for an additional four seconds.

The first stage of data treatment involved splitting the available data in such a way that there was no leakage between training and test sets.

In the Benchmark dataset, as in the original paper, we have considered 9 electrodes from the occipital and parietal regions of the brain: Pz, PO5, PO3, POz, PO4, PO6, O1, Oz and O2. Also, from the 40 stimuli frequencies available, we have selected all integer frequencies from 8 Hz to 15 Hz, thus establishing a scenario with 8 classes in the BCI-SSVEP system. The proportion of trials was 3:1:2, i.e. 3 trials for training, 1 for validation and 2 for testing. The training data is segmented in 2s windows, with an overlap of 1s, while the test data remains raw. During the training process, we have used samples from all subjects.

In the BCI dataset, as we have 2 different sessions, one is fully used for testing and the other is split in half to create training and validation sets. All 22 electrodes were explored, and windowing process was not performed.

The data was pre-processed following the procedure adopted in [9], [17], i.e. (*i*) resampling to 128 Hz; (*ii*) z-Score normalization for training and validation sets; (*iii*) a band-pass filtering with a 3rd-order Butterworth filter to preserve the frequency band from 4 Hz to 38 Hz. We have only considered data from the same subject in the training/test stage.

All EEGNet models were accessed through BrainDecode [35], as well as SincShallowNet [10]. The other models from SincNet family, originally defined for audio processing, have the limitation of one channel for input data, which is not suited for EEG data. Based on that, we adapted these models by mimicking the structure of SincShallowNet, i.e., creating multiple filters for each channel. Thus, the models from SincNet family used in the experiments were SincShallowNet and, also, the adapted and renamed PFShallowNet and IIRIShallowNet.

This adaptation yields a controlled comparison within the SincNet family: the three networks share the same spatial filtering, pooling and classification blocks, differing solely in the first-layer kernels, i.e., truncated $sinc(\cdot)$ filters (SincShallowNet), piecewise-linear segments (PFShallowNet) and second-order IIR resonators (IIRIShallowNet). Hence, performance differences between them derive from the filterbank profile rather than from architectural capacity, which can be perceived through inspection of the learned frequency responses.

The performance of each model was evaluated by accuracy per subject, and the average of five independent runs was considered. Additionally, the temporal and/or spatial features learned by the interpretable layers were examined.

IV. Results

In this section, we present the experimental results obtained by the EEGNet- and SincNet-based models.

A. SSVEP

Fig. 3 exhibits the boxplots of the accuracy performance obtained by EEGNet and SincNet variants in the SSVEP dataset, whereas Table I presents the performance by individuals. In

bold are the best individual performances among the models of the EEGNet family, while highlighted in blue are the best performances obtained by a model of the SincNet family. The maximum accuracy per individual is further marked with an asterisk.

It is possible to notice that among all trained models, EEGNet presents the best performance, followed by EEGNex and EEG-ITNet by a maximum margin of 1.28 percentage points. We can also observe a notable performance gap occurred between subjects 16 and 32: while the latter was easily classified by most models, none exceeded 55% accuracy for the former. This is likely due to unique inter-subject variability and differing individual brain profiles, which can be recognized in Fig. 4 by comparing the frequency spectra for electrode Oz EEGs for stimuli frequencies of 10 Hz, 12 Hz and 15 Hz.

With respect to the SincNet family, there is a significant performance gap between the models, being the SincShallowNet the option that reaches the best average accuracy, approximately 3 percentage points worse than EEGNet. The more sophisticated bandpass filter designs from PF-Net and IIRI-Net were not beneficial in terms of final classification in this dataset.

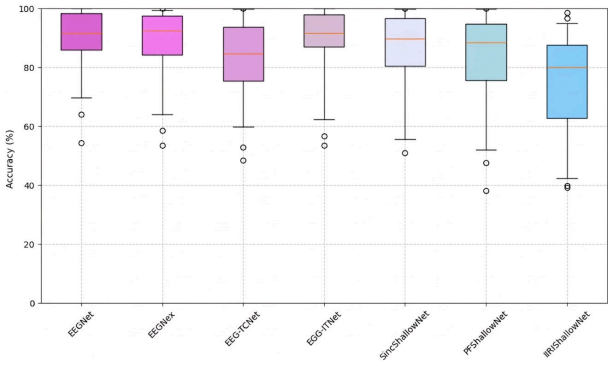

Fig. 3. Accuracy comparison by technique in the SSVEP paradigm.

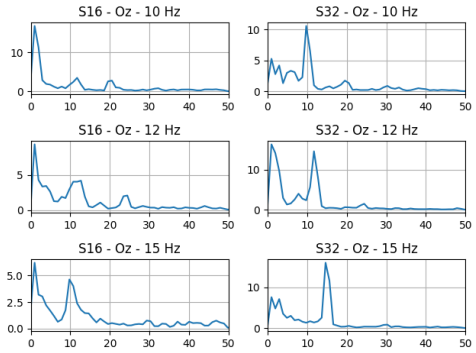

Fig. 4. Comparison between subjects 16 and 32 for different stimulus frequencies from electrode Oz.

Focusing on the temporal and spatial filters learned by EEGNet, Figs. 5 and 6 present four frequency spectrum corresponding to learned filters, in which we can observe the most relevant frequency band after model training and, based on the topoplots, the relative contribution from each electrode for the classification.

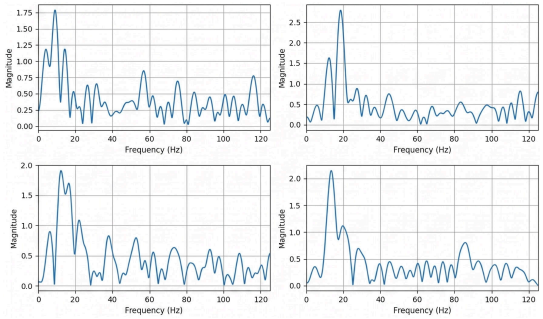

Fig. 5. Temporal filters learned by EEGNet for SSVEP.

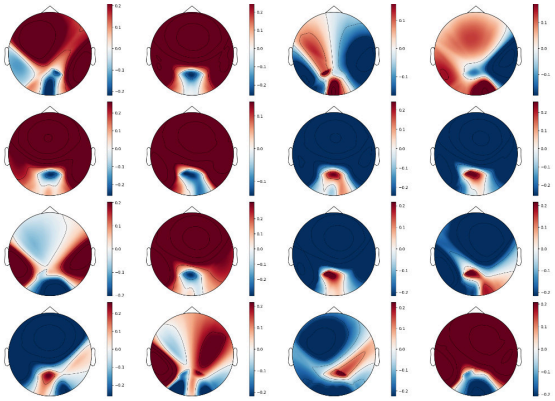

Fig. 6. Spatial filters learned by EEGNet for SSVEP.

It is important to observe that, in general, the spatial filters attribute larger coefficients to the occipital region than to the other regions of the brain, which is consistent with the visual nature of the SSVEP task. Besides that, we can notice that the frequency response of the temporal filters tend to prioritize regions related to stimulation frequencies (or their harmonics).

Another relevant remark is that the temporal filters can be quite different across the techniques, while the resulting spatial filters do not present clear changes. For example, Fig. 7 illustrates the temporal filters learned by the model with the worst average classification accuracy in the SSVEP paradigm. Clearly, the IIRIShallowNet model have not focused on the stimulation frequencies nor in their harmonics, as occurred with EEGNet.

B. MI

Fig. 8 exhibits the boxplots of the accuracies obtained by EEGNet and SincNet variants in the BCI Competition IV-2a dataset, while Table II separates the performance through the nine subjects.

Some remarks can be drawn from Table II. First, the performances we obtained with EEGNet and its variants are lower than those reported in [18]. However, it is worth mentioning that in the original works of EEGNex [18] and EEG-ITNet

TABLE I

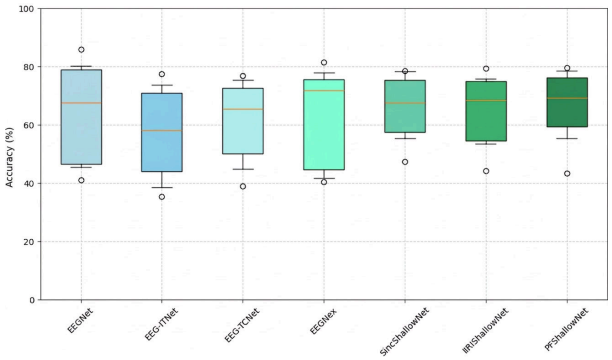

Fig. 8. Accuracy comparison by technique in the MI paradigm.

[17], a specialized initialization scheme was employed, in which the test samples participate in the parameter initial setting. Hence, there is some leakage between training and testing, so that the generalization performance may be overestimated. Second, the best average accuracy was attained by PFShallowNet, which obtained the top accuracy for five out of nine subjects. Regarding the number of trainable parameters, within the EEGNet family, the best average accuracy was reached by EEGNet, with 3 704 parameters in SSVEP and 2 484 in MI, whereas within the SincNet family the best models were SincShallowNet and PFShallowNet, with 20 296 and 11 812 parameters, respectively. All seven architectures remain lightweight, with fewer than 56 000 parameters. The learned temporal filters in Fig. 9 present a bandpass shape

with an emphasis on subregions within the alpha (8–13 Hz) and beta (13–30 Hz) bands. Motor imagery is associated with a reduction in power within the alpha (8–13 Hz) and beta (13–30 Hz) bands, a phenomenon known as event-related desynchronization (ERD), which typically occurs in the sensorimotor cortex contralateral to the imagined limb [17]. Several trained temporal filters, particularly from the EEGNet family, exhibit this effect through a decrease in magnitude within these specific frequency bands.

The spatial filters shown in Fig. 10 highlight sensor and motor areas of the brain, around the center of the scalp. The activations correspond to contralateral motor regions, which is consistent with the imagery of right- or left-hand movements. The filters of this section are from the training data of subject 3, in which we have the best performance.

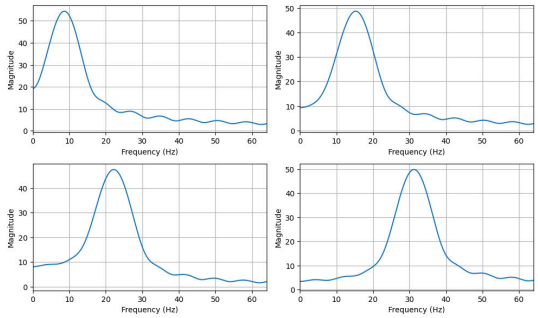

Fig. 9. Temporal filters learned by PFShallowNet for MI.

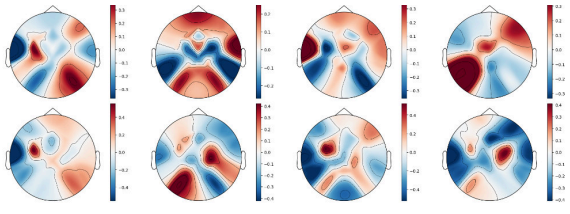

Fig. 10. Spatial filters learned by PFShallowNet for MI.

Similarly to the SSVEP context, in the MI paradigm the temporal filters also exhibit an important contrast across techniques compared to the spatial filters. Fig. 11 displays a subset of filters from the model with the lowest average classification accuracy in MI, illustrating a clear failure to exhibit the distinct bandpass characteristic observed in Fig. 9. As the SincNet variants differ only in the first-layer kernels, inspecting them indicates that the filters should match the spectral signature of the paradigm.

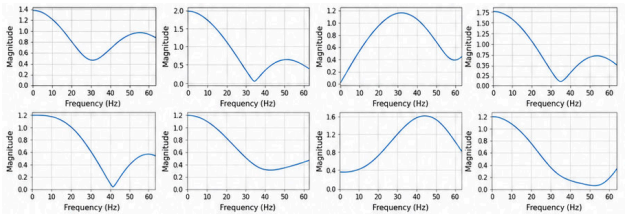

Fig. 11. Subset of temporal filters learned by EEG-ITNet for MI.

V. CONCLUSION

This study evaluated the performance and interpretability of different neural network models in different EEG paradigms. We have identified in the literature approaches that incorporate interpretable elements in two families of models: EEGNet, and its variants EEG-TCNet, EEG-ITNet and EEGNex; and SincNet, with the variants SincShallowNet, PF-Net and IIRI-Net. In the latter case, we have implemented extensions of the original models of PF-Net and IIRI-Net in order to allow the processing of multivariate signals, which we defined as PFShallowNet and IIRIShallowNet.

It was considered the scenarios of MI, already explored in EEG-ITNet [17] and EEGNex [18], and SSVEP, which is less considered in this context. Besides the observation of the performance of the models in terms of accuracy, we also have given special attention to how they learn and represent relevant neural information, a delicate matter when dealing with human data and using AI for decision-making processes.

On the one hand, for SSVEP classification, EEGNet and its variants performed well, though the original architecture achieved the highest average accuracy. Within the SincNet family, SincShallowNet yielded the best results. On the other hand, SincNet-based models surpassed EEGNet and its variants in the MI paradigm, where PFShallowNet yielded the top average accuracy.

The learned filters were directly inspectable in both paradigms. In the SSVEP context, temporal filters emphasized target frequencies, while spatial filters assigned larger coefficients over the occipital cortex, consistent with visual tasks. For MI, the temporal filters formed distinct bandpass shapes, while spatial activations concentrated over contralateral motor regions, reflecting the patterns expected during hand motor imagery.

For future works, we plan to extend the experiments to the cross-subject scenario and validate the generalizability of the PFShallowNet and IIRIShallowNet architectures by extending them to MI datasets that feature a larger number of subjects and greater inter-subject variability. We also intend to complement the present analysis with statistical comparisons between models and quantitative measures of the stability of the inspected filters.

***Abstract*— Stroke is one of the leading causes of motor disability, and recovery depends on mechanisms of cortical plasticity. Transcranial direct current stimulation (tDCS) has been used as a complementary approach to promote functional reorganization, and electroencephalography (EEG) has been applied to investigate this reorganization. However, most works using EEG analyze the data in the sensors' space. The aim of this study was to investigate the effect of a tDCS-based rehabilitation program in functional reorganization in the EEG sources' space, using LORETA software. More specifically, EEG band power in the sources' space was evaluated during motor imagery tasks. For this, 17 post-stroke subjects were analyzed, divided into two groups: 8 in the active group and 9 in the sham group. The active group received anodal tDCS on the lesioned hemisphere and the sham group received sham tDCS stimulation for 10 daily sessions during two weeks. Statistical analysis identified nine Brodmann areas (BAs) with significant variations, among which BA3 and BA6 stood out. Overall, the active group showed more consistent clinical improvement accompanied by balanced increases in the slow bands (delta, theta, and alpha), suggesting a more stable pattern of cortical reorganization. The sham group also exhibited elevated values in these bands, but inflated by extreme responses, reflecting greater heterogeneity. Fast bands (beta2 and gamma1) remained close to stability in both groups, indicating that the main differences between them occurred in the slow bands. These findings reinforce that the clinical gains observed in the active group are associated with more balanced functional reorganization, whereas the sham group presented accentuated variability and less predictable patterns.**

I. INTRODUCTION

Stroke is one of the leading causes of motor disability, and recovery depends on mechanisms of cortical reorganization [1]. Motor imagery is recognized as a strategy capable of activating cortical networks involved in movement, generating consistent neural patterns [2]. In addition to its use in brain–computer interface (BCI) systems, where it demonstrates applicability in different contexts [3], recent studies have also employed it as an assessment task in post-stroke patients. For example, [4] analyzed brain connectivity during motor imagery and movement execution, showing that it can reveal functional reorganization patterns crucial for monitoring clinical evolution. Similarly, [5] highlighted that EEG paradigms based on motor imagery are valuable tools for assessing motor deficits and tracking recovery, reinforcing its relevance as an experimental evaluation approach.

Transcranial direct current stimulation (tDCS) has been established as a non-invasive technique capable of modulating cortical excitability, influencing synaptic plasticity, and enhancing functional recovery [6], [7]. Studies such as those by [7], [8] demonstrated that tDCS, already established as a non-invasive technique capable of modulating cortical excitability and influencing synaptic plasticity, can have its effects assessed with motor imagery, contributing to the understanding of functional reorganization mechanisms and enhancing recovery. Clinical studies indicate that anodal stimulation over motor regions can promote the reorganization of circuits involved in movement planning and execution, showing promising results in post-stroke rehabilitation. Several studies have sought to understand the effects of these interventions through different analytical approaches, such as the analysis of sensorimotor band power and electroencephalogaphy (EEG) classification [6], systematic mapping of functional outcomes in post-stroke patients [7], and the evaluation of functional connectivity and brain symmetry in protocols combining tDCS with XR [9]. Among them, sLORETA (Standardized Low Resolution Electromagnetic Tomography), proposed by [10], [11], is a method for estimating the localization of cortical sources from EEG, capable of identifying functional reorganization patterns and providing a spatial view of spectral modulation. This type of approach has already been applied to investigate neural changes associated with electrical stimulation in frontoparietal networks [12], highlighting the potential of source localization methods to contribute to the understanding of plasticity mechanisms. Given this scenario, the present study conducted a preliminary analysis of the effects of tDCS using LORETA software to investigate

cortical reorganization patterns during motor imagery and provide additional evidence on the neurophysiological mechanisms underlying neurorehabilitation patterns.

II. Methodology

Fig. 1. presents the methodological pipeline adopted in this study, from the initial EEG signal processing to the clinical correlation. The diagram summarizes the main stages: (A) Dataset, (B) Signal Processing, (C) LORETA software (Spectral Source Transformation, statistical analysis, and selection of regions of interest), (D) Percentage Change Analysis, and (E) Clinical Correlation.

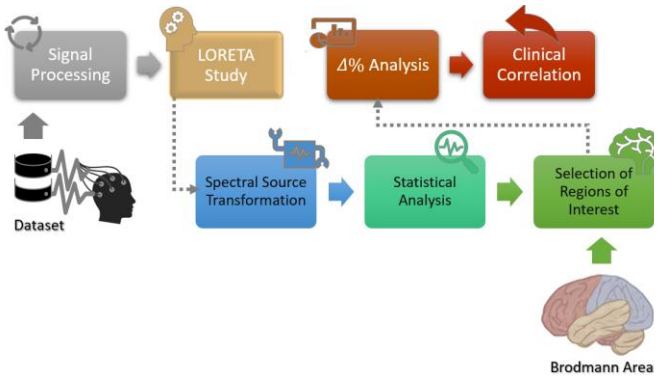

Fig. 1 - Methodological workflow of the study, from signal processing to clinical correlation.

We implemented the sLORETA technique using the LORETA software. Hereafter, 'LORETA' refers to the software, whereas 'sLORETA' denotes the localization method.

A. Dataset

The experimental protocol adopted in this study, combining transcranial direct current stimulation (tDCS) applied to the lesioned hemisphere (C3 or C4) with extended reality tasks. The dataset is composed of 17 patients with chronic stroke (mean 30 ± 23.3 months post-stroke; 9 women and 8 men; mean age 58.9 ± 12.7 years, range 33–86). All had a single stroke more than six months prior, were older than 18 years, and had no history of seizures, pacemaker, or metallic implants. The study adopted a single-blind design, with IDs 1–10 in the active tDCS group and IDs 11–20 in the sham group. In the active group (n=8), mean age was 60.2 ± 12.0 years, mean time post-stroke 35.7 ± 25.1 months, with 6 cases of right hemisphere lesions and 2 cases of left hemisphere lesions. In the sham group (n=9), mean age was 57.6 ± 14.0 years, mean time post-stroke 24.2 ± 21.0 months, with 5 cases of right hemisphere lesions and 4 cases of left hemisphere lesions.

The rehabilitation protocol consisted of 10 consecutive sessions, with upper and lower limb exercises in extended reality (GestureCollection, BRAINN_XR[13]. Tasks included puzzle-solving with reaching movements, stationary walking with virtual obstacles and environment based on Google Maps. Neuromodulation was applied using anodal tDCS (MicroEstim, NKL, Brazil) with 2 mA, 30-s ramp-up/down, for 30 minutes per session, during the extended reality exercises. Electrodes (35 cm², saline-soaked sponges) were positioned over the ipsilesional primary motor cortex (C3 or C4) and contralateral supraorbital region (Fp1 or Fp2). In the sham group, current was turned off after 1 min. EEG was recorded in the first and last session during motor imagery (MI) tasks, before rehabilitation, with 16 dry electrodes (g.USBamp, g.tec, Austria), positioned according to the 10–20 system and referenced to the left mastoid. Channels included F1, F2, Cz, AFz, F5, F6, C1, C2, C3, C4, C5, C6, P1, P2, P5, P6; sampling frequency 256 Hz. Each MI recording was composed of 8 trials (total duration of 128 s) consisting of: a cross appeared for 2 s, followed by an instruction (hand/foot, left/right) for 6 s and 8 s of rest before the next trial. Clinical assessment was performed before the first and after the last session, using the upper extremities Fugl-Meyer assessment (UE-FMA) (0–66), lower extremities FMA (LE-FMA) (0–34), Berg Balance Scale (0–56), and the 10-meter walk test.

B. Signal Processing

EEG signals were preprocessed using EEGLAB and MATLAB. Filtering was performed in two steps: a 4th-order Butterworth high-pass filter with a cutoff at 1 Hz to remove slow drifts and movement artifacts, and a 4th-order Butterworth low-pass filter with a cutoff at 40 Hz to reject high-frequency components and residual noise around 50–60 Hz. After filtering, signals were re-referenced to the average of all channels (average reference). Experimental events were adjusted to mark the onset of motor imagery instructions, considering a 2-second delay after the fixation marker. Independent Component Analysis (ICA) was applied using the runica algorithm (extended mode), a method already consolidated in the literature EEG [14]. Subsequently, automatic classification of independent components was performed with ICLabel (v1.7), which assigns probabilities to categories such as Brain, Eye, Muscle, and Line Noise. Automatic removal was restricted to components classified as Eye (probability > 0.90) and Line Noise (> 0.95), while Muscle components (> 0.85) were flagged for manual inspection. This procedure proved effective: ocular artifacts were identified and removed without compromising motor signals, and most subjects required little or no correction, indicating good data quality during acquisition [15].

C. LORETA

LORETA (Low Resolution Electromagnetic Tomography) is a functional neuroimaging technique developed to address the EEG inverse problem by estimating cortical current density distributions from scalp-recorded potentials. The method restricts the solution space to cortical gray matter and applies spatial smoothing to ensure continuity across neighboring voxels [11]. The forward problem can be expressed as:

$$b = Ax + n \tag{1}$$

where b represents the EEG signals measured at the electrodes, A is the lead field (gain) matrix linking cortical sources to sensors, x denotes the source activations over time, and n is the noise term. The inverse problem consists of estimating x from b. Since the number of dipoles far exceeds the number of electrodes, the solution is underdetermined. LORETA addresses this by applying Tikhonov regularization, formulated as:

$$\min_x \| Ax - b \|^2 + \lambda \| Wx \|^2 \tag{2}$$

where λ is a smoothing parameter and W is the regularization operator encoding prior information about the solution. The analytical solution is given by:

$$x^* = A^T (AA^T + \lambda W)^{-1} b \quad (3)$$

This transformation provides an estimate of cortical current densities, imposing spatial smoothness and favoring superficial dipoles. In LORETA, the regularization operator is based on a weighted Laplacian of the sources, ensuring spatial continuity and reducing the complexity of the inverse problem [11]. Thus, scalp potentials are converted into three-dimensional maps of neuronal activity, grouped into regions of interest (ROIs).

Previously cleaned and epoched signals were organized into two sessions (S1 and S10 tDCS), considering only subjects within each group (active or sham). Trials were classified according to the experimental condition (Left or Right MI), and each segment was extracted individually. So as to have the lesions corresponding always to the same side (right), for left hemisphere lesion subjects channel flipping of symmetric pairs (F1/F2, F5/F6, C1/C2, C3/C4, C5/C6, P1/P2, P5/P6) was applied, while midline channels (Cz and AFz) remained unchanged. Signals were then segmented into 2-second windows with 50% overlap, ensuring greater stability for spectral analysis. Each window was saved in text format (.txt), structured by subject, group, and experimental condition, forming the dataset prepared for LORETA analysis. From this organization, the next step consisted of spectral analysis, aimed at characterizing the frequency distribution of the signals across cortical regions.

Spectral Source Transformation

In LORETA, the brain is discretized into thousands of voxels, each representing a potential source of electrical current in three-dimensional coordinates (x, y, z). The lead field matrix A connects each voxel to the electrode measurements, and the inverse solution estimates the current density at each voxel. This discretization allows scalp-recorded signals to be transformed into three-dimensional maps of neuronal activity [16], [17].

1) EEG to Cross-Spectrum: EEG segments were transformed into cross-spectral matrices between channels. Formally, for two signals $xi(t)$ and $xj(t)$, the cross-spectrum is obtained by the Fourier transform of their cross-correlation function:

$$C_{ij}(f) = F\{R_{ij}(\tau)\} \quad (4)$$

where $R_{ij}(\tau)$ is the cross-correlation between channels i and j. This formulation is widely used in EEG spectral analysis [18].

2) Cross spectra to sLORETA: The cross-spectral matrices were then projected into the cortical source space using the sLORETA[10] inverse solution. In this phase, the inverse transformation matrix G^+ is applied to the spectral data:

$$S(f) = G^+ . C(f) \quad (5)$$

where $S(f)$ represents the spectral distribution of current densities across cortical voxels [19].

3) sLORETA to ROIs: In this process, voxel-level estimates are aggregated, and the spectral activity in each ROI is calculated as the mean of voxel estimates within the region:

$$ROI_k(f) = 1/N_k \sum_{v \in ROIk} S_v(f) \quad (6)$$

where v denotes each voxel belonging to ROI_k, $S_v(f)$ is the spectral current density estimated for voxel v at frequency f, and N_k is the total number of voxels in ROI_k. This procedure reduces data complexity and facilitates statistical comparisons across cortical regions [11], [17], [19]. All source localization procedures were performed using the standard sLORETA implementation, which relies on the default MNI head model, predefined lead field matrix, standard source grid, and default regularization parameters[10].

Statistical Analysis

We used the statistical module of the LORETA, which implements the Statistical non-Parametric Mapping (SnPM) methodology based on non-parametric randomization tests and correction for multiple comparisons [20], [21]. Analyses included between-session comparisons (session 1 × session 10), and between-group comparisons (active × sham), enabling evaluation of longitudinal and differential effects of the intervention. LORETA estimates the cortical origin of signals recorded by scalp electrodes and associates activation patterns with specific anatomical regions [11], [19]. For each frequency band (delta: 1–4 Hz; theta: 4–8 Hz; alpha: 8–12 Hz; low beta: 13–20 Hz; high beta: 21–30 Hz; gamma: 31–45 Hz [22], the software computes t-values derived from voxel-wise t-Student tests [23]. These values are linked to MNI coordinates, from which the software identifies possible Brodmann areas at different neighborhood distances (0 mm, 5 mm, 7 mm, 20 mm), allowing interpretation of the cortical regions involved in each comparison. The statistical process consisted of extracting t-values for each voxel and frequency band, defining the threshold of significance according to the number of subjects and the adopted significance level, and then comparing each value with this threshold. Values above the threshold were considered significant, those close to the threshold were classified as trends, and those far below were deemed non-significant. Results were organized into tables containing the t-value, statistical status, corresponding Brodmann area, and MNI coordinates. Finally, only regions with significant values were selected as regions of interest (ROIs) for subsequent analysis. Thus, the LORETA statistical analysis allowed the identification of the most relevant cortical activation peaks, ensuring that the interpretation of results was based on robust evidence corrected for multiple comparisons.

Selection of Regions of Interest

Based on the Brodmann areas (BA) identified in the statistical analysis, regions of interest were defined and linked to the corresponding frequency bands and EEG channels, establishing a direct relationship between the cortical estimates obtained by LORETA and the electrode recordings. The

regions identified included the postcentral gyrus (BA 2 and BA 3), the frontal/precentral region (BA 6), the middle frontal gyrus (BA 8 and BA 9), the insula (BA 13), the occipital cortex (BA 18), and multimodal parietal regions such as the angular gyrus (BA 39) and the supramarginal gyrus (BA 40). In total, 9 regions of interest were selected to guide the subsequent stages of investigation.

D. Percentage Change Analysis

Percentage variations were calculated by comparing mean values obtained at session 1 (S1) and session 10 (S10) in both the active and sham groups, according to the following formula:

$$Variation\ (\Delta\%) = \frac{S_{10}-S_1}{S_1}\ X\ 100 \qquad (7)$$

This comparison was chosen to evaluate longitudinal evolution throughout the protocol, thus reflecting the accumulated effects of the intervention. The analysis highlighted two regions of interest, BA3 and BA6, both showing relevant percentage changes across sessions. Each region of interest presented specific values for each subject and frequency band, reinforcing the independence of the findings. However, the analyses focused on BA6 due to its functional relevance for motor and premotor functions, which are central to the objectives of the study. BA6 encompasses premotor and supplementary motor regions, recognized as fundamental for movement preparation, execution, and motor imagery — processes directly modulated by tDCS [24], [25].

E. Clinical Correlation

In the final stage of the protocol, correlations were performed between the neurophysiological indicators obtained through LORETA and the clinical measures collected across sessions. The objective was to determine whether the percentage variations observed in the regions of interest, particularly BA6, were associated with changes in patients' functional outcomes. Pearson's correlation coefficient was applied as the standard method for assessing linear associations between continuous variables [26]. Despite the small sample size, this choice is justified by the widespread use of Pearson's coefficient in exploratory studies of neurophysiology and rehabilitation, where it provides interpretable estimates of the strength of association between continuous variables even in limited samples [27], [28]. This approach is consistent with previous studies investigating the relationship between cortical modulation induced by tDCS and clinical outcomes in post-stroke patients [9], reinforcing its applicability in rehabilitation contexts.

III. Results

Fig. 2 illustrates the mean percentage variations (Δ%) between session 1 and session 10 in the active and sham groups, evidencing cortical reorganization [24], [29] and particularly highlighting BA3 and BA6, which showed the most consistent changes. The analyses focused on BA6 detailed in Fig. 3, which presents percentage variations across spectral bands (δ, θ, α, β_1, β_2, γ_1). In the active group, the largest variations occurred in slow bands (δ, θ, α), confirming the predominance of effects in slower rhythms [22], [30]. In the sham group, more consistent variations were observed in δ, θ, α, and β_1, suggesting that, while less homogeneous, these bands also contributed to cortical reorganization. In both groups, the fast bands (β_2, γ_1) showed reduced variations.

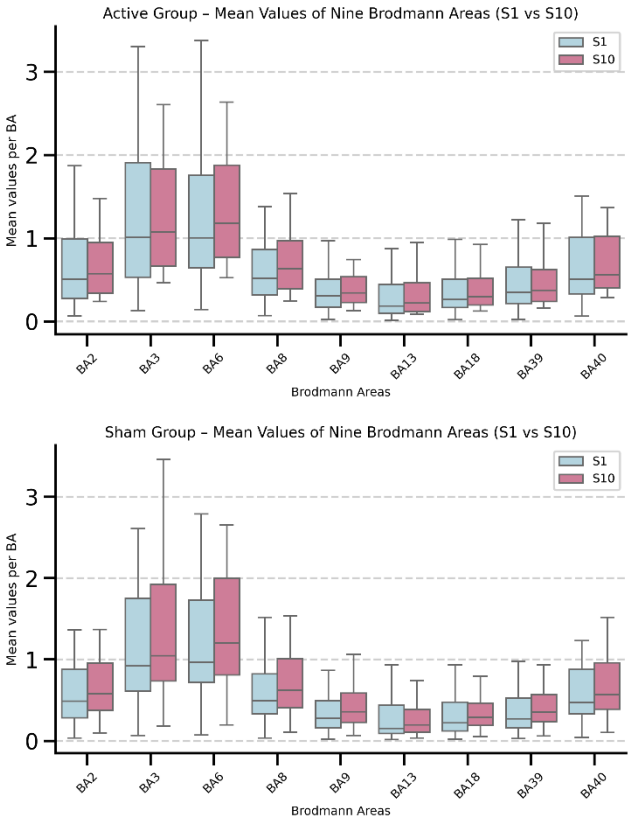

Fig. 2 - Mean values of EEG broadband (all frequency bands) spectral changes at S1 and S10 for Active and Sham groups across all investigated Brodmann areas.

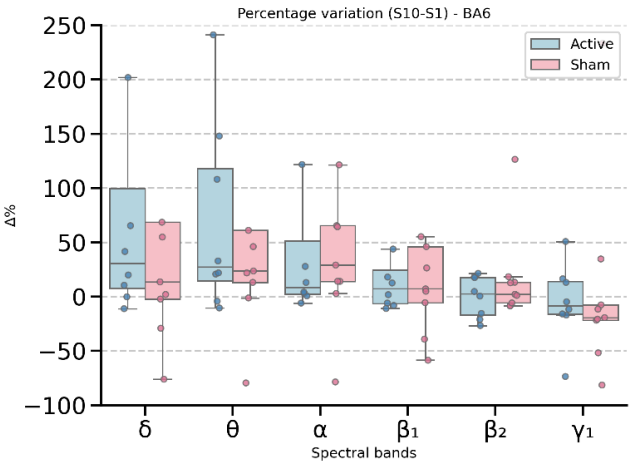

Fig. 3 - Percentage variation (Δ%) in BA6 across spectral bands for Active and Sham groups.

A total of 14 clinical metrics were initially evaluated, including FM upper limb (fm_sup_tot, fm_sup_66), FM lower limb (fm_inf_tot, fm_inf_34), FM total (fm_tot_100), Mini-Mental, MIF, Berg Balance Scale, TUG, TUG_cog, and gait parameters (time in seconds, number of steps, velocity, and cadence). Among these 14 metrics, eight showed significant

correlations with EEG spectral bands, as represented in the heatmap (Fig. 5): (1) Berg Balance Scale, (2) FM lower limb – 34 items (FM_inf_34), (3) FM lower limb – total (FM_inf_tot), (4) FM upper limb – 66 items (FM_sup_66), (5) FM total – 100 items (FM_tot_100), (6) MIF, (7) TUG, and (8) TUG_cog.

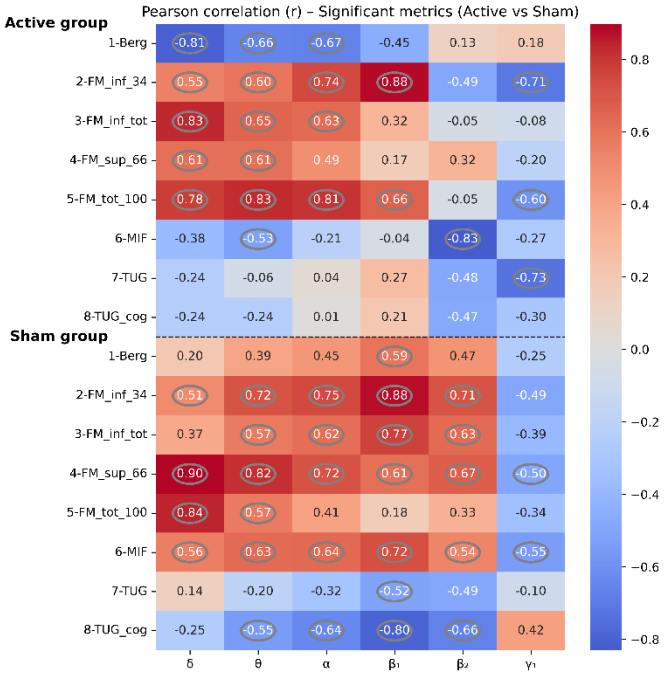

Fig. 4 - Pearson correlations (r) between significant metrics and the spectral bands in the Active and Sham groups. Dashed horizontal line separates the band pairs and gray circles highlight correlations that met the criteria for significance: sufficient strength ($|r| \geqslant 0.5$) and statistical evidence ($p < 0.05$).

Correlations between EEG and clinical metrics were calculated using the Pearson method [31], and only statistically significant results ($|r| \geqslant 0.5$, $p<0.05$) are highlighted. In the active group, significant correlations are more intense in δ, θ, and α, whereas in the sham group they are more homogeneously distributed, with greater concentration in β_1 and γ_1. The patterns reinforce that the clinical improvements observed in the active group are associated with cortical reorganization compatible with synchronization in slow rhythms [22], [32], [33]. Table 1 presents the individual and mean percentage variation values of the eight significant metrics in the active and sham groups, allowing visualization of the magnitude of clinical and functional changes. In the active group, consistent gains were observed, especially in motor metrics, with averages above 8%, and while some subjects showed neutral results in certain metrics (s1, s6, s10), these cases were less frequent, suggesting a more uniform progression.

Table 1 - Individual and mean percentage variation values of clinical assessments (Active vs Sham groups). (1) Berg Balance Scale, (2) FM lower limb – 34 items (FM_inf_34), (3) FM lower limb – total (FM_inf_tot), (4) FM upper limb – 66 items (FM_sup_66), (5) FM total – 100 items (FM_tot_100), (6) MIF, (7) TUG, and (8) TUG_cog. M: mean, SD: standard deviation.

In the sham group, the results were more heterogeneous. Expressive variations were observed in FM total (+22.30%) and relevant reductions in TUG (–17.23%), along with a significant correlation in TUG_cog (Fig. 5). However, a greater number of subjects presented more than one null value (s12, s13, s18, s19, s20), in contrast to the active group. Thus, the comparison between groups shows that, in addition to more homogeneous gains, the active group presented fewer neutral results compared to the sham group, highlighting the greater impact of the intervention on clinical progression [34], [35].

Table 2 presents the percentage variations of spectral energy (Δ%) across six frequency bands (δ, θ, α, β_1, β_2, γ_1) for the subjects in the active and sham groups and the mean ± standard deviation (SD) across subjects. Some subjects presented extreme percentage variations (>600–1000%), driven by very low baseline values. In the Active group, subject s10 showed unusually high increases across several bands, while in the Sham group subjects s15 and s18 presented extreme variations. These outliers inflated group averages and standard deviations, and results should therefore be interpreted with caution.

On average, there was a large increase in band power for the lower frequency bands, namely, δ, θ, α and β_1, after the intervention. This increase was larger for the sham group. On the other hand, the large SDs found for both groups corroborate the high inter-subject variability observed in EEG measurements. Looking at results individually, in the active group subjects s1, s4, s6, and s7 showed partial clinical improvement accompanied by increases in δ, θ, and α, suggesting cortical reorganization compatible with functional evolution [22], [32]. Subject s9 stood out by presenting broad clinical improvement and consistent increases across all bands, representing a profile of global evolution aligned between clinical and EEG findings [33]. Subject s8 presented clinical improvement accompanied by reductions in all bands, characterizing a dissociation between clinical evolution and cortical activity [22]. Subject s10 was an outlier, with relevant clinical gains and extreme increases in δ, θ, α, and β_1, accompanied by reductions in γ_1, suggesting cortical reorganization that was intense and unstable [24]. In the sham group, subjects s14 and s15 showed robust clinical improvement accompanied by increases in several EEG bands. Subject s14 presented a mixed profile, with gains in δ, θ, α, and β_1, along with a marked reduction in γ_1 [22]. Subject s15 stood out as an extreme outlier, with extreme increases in δ, θ, α, β_1, and β_2, accompanied by a reduction in γ_1, suggesting intense cortical reorganization [9]. Subject s18 showed marked clinical improvement in motor metrics and marked increases in δ, θ, and α, while also showing reductions in β_1 and γ_1, configuring a mixed profile with strong enhancement of slow bands [29]. Subject s20 maintained clinical stability with improvement in TUG and TUG_cog, and in the EEG increases were observed in δ, θ, α, and β_1, accompanied by reductions in β_2 and γ_1, suggesting a mixed profile in which functional gains coexist with partial cortical reorganization [2]. To illustrate the relationship between EEG spectral variations and clinical outcomes at the individual level, Fig. 6 presents representative subjects from the active and sham groups, showing side-by-side changes in spectral bands and the eight clinical metrics that reached significance. This visualization highlights the heterogeneity of responses and complements the correlation patterns described in Fig. 5.

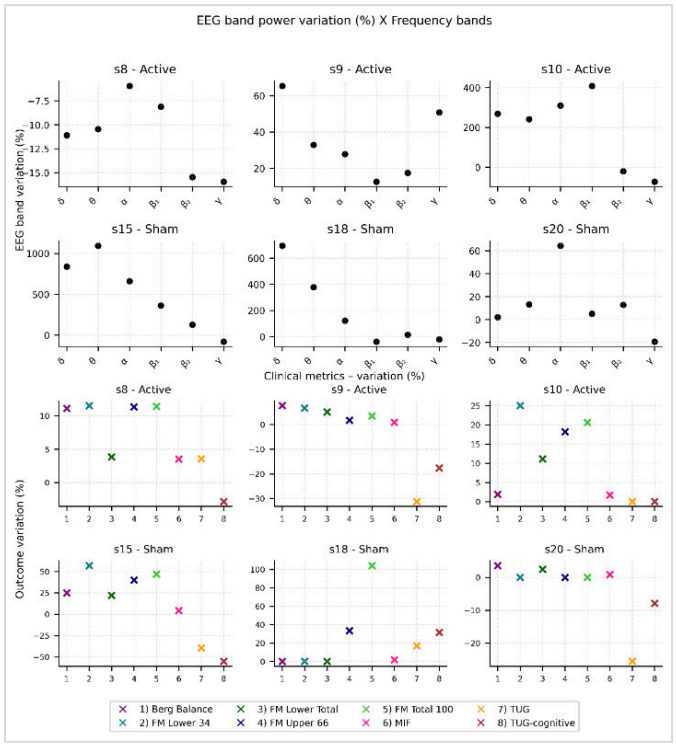

Fig. 5 - Representative subjects from the active and sham groups, illustrating EEG spectral band percentage variations alongside significant clinical metrics percentage variation (Equation 7).

In the active group, s8 showed clinical improvement with reductions across all bands, s9 presented global improvement with consistent increases, and s10 appeared as an outlier with extreme slow band increases. In the sham group, s15 exhibited extreme responses across several bands, s18 showed partial improvement with slow band increases and fast band reductions, and s20 maintained clinical stability with partial reorganization in slow bands.

IV. Discussion

The use of LORETA allowed us to identify patterns of cortical reorganization across sessions, providing a spatial view of the spectral modulation induced by the intervention. In previous work [36], LORETA was shown to reveal cortical generators in specific neural contexts. In the present study, it evidenced increases in slow rhythms (delta, theta, and alpha) as well as increases in fast bands (high beta and low gamma), directly linking the method to the reorganization patterns observed. [12] applied LORETA in electrical stimulation protocols and also observed consistent changes in the beta and gamma bands, reinforcing that this technique is sensitive to detecting cortical reorganization induced by neuromodulation. Another study using LORETA [2] also highlighted the BA6 region, reinforcing its relevance in cortical reorganization processes.

Beyond findings with LORETA, several studies have specifically investigated the association between tDCS and motor imagery. [6] demonstrated that anodal stimulation applied to the motor cortex and cerebellum improves motor imagery classification in EEG, modulating specifically the alpha and beta bands. This result suggests that tDCS enhances the capacity of cortical networks to sustain motor patterns during mental practice, in line with the effects observed in our subjects. [34] conducted a comprehensive mapping of evidence on tDCS in post-stroke motor function, including more than 170 studies, concluding that the technique is safe and potentially effective for

motor recovery, while emphasizing the need for higher-quality clinical trials with larger samples.

The convergence between our findings and previous studies strengthens the interpretation that anodal stimulation not only modulates cortical activity in key regions such as BA6, but also enhances mechanisms already described in motor imagery protocols, expanding the capacity for functional reorganization in post-stroke subjects [2], [6], [7], [12], [36]. The results obtained highlight the potential of tDCS combined with extended reality as a complementary strategy in post-stroke rehabilitation. The identification of early and sustained reorganization suggests that electrical stimulation protocols may promote functional plasticity [1], increasing the capacity for motor recovery in subjects with sequelae.

However, increases in slow bands and in alpha may be considered relevant markers of recovery. In the active group, these patterns were more evenly distributed among subjects, whereas in the sham group they relied mainly on extreme responses from a few individuals.

Compared to the active group, the sham group presented higher means in almost all metrics, except for metric (4) FM upper limb – 66 and metric (8) TUG_cog, and equivalent performance in metric (6) MIF (Table 1). This result, however, should be interpreted with caution, as it may be associated with the higher number of null values observed rather than reflecting clinical superiority. In addition, the greater variability found in the sham group contrasts with the more homogeneous progression verified in the active group, later related to the correlation patterns evidenced in the heatmap (Fig. 4). This difference reinforces the interpretation that tDCS combined with extended reality favors a more consistent and homogeneous reorganization. Nevertheless, some limitations must be acknowledged: the small sample size, the constraints of source localization with a reduced EEG montage (16 electrodes), the absence of direct behavioral measures of motor performance, and the restriction to electrophysiological analyses limit the generalization of the findings. In addition, clinical heterogeneity among subjects may have influenced response patterns. The correlational analyses should also be interpreted with caution, given the small sample sizes and the large number of tested combinations. It should be noted, however, that the statistical routines implemented in LORETA include corrections for multiple voxel-wise comparisons through nonparametric randomization tests, which control for the risk of false positives when testing thousands of voxels simultaneously [10]. The findings showed that the clinical superiority of the active group was not clearly demonstrated, as the sham group presented equal or higher averages in several outcomes. However, these results must be interpreted in light of the very small sample sizes (8 subjects in the active group and 9 in the sham group), which increase the impact of extreme values. In fact, the sham outcomes were accompanied by markedly greater variability, suggesting heterogeneous responses, whereas the active group showed more consistent neurophysiological changes in BA6 spectral activity. This difference reinforces the interpretation that the intervention favors a more stable reorganization pattern, even if clinical superiority was not evident in this sample. Future studies with larger samples, integration of functional measures, and multimodal protocols and the application of robust statistical approaches, including formal outlier inspection and repeated-measures models, may confirm and expand the clinical applicability of the results presented here.

***Abstract*—Auditory selective attention enables listeners to focus on a target sound embedded in a complex acoustic mixture. When competing sound sources are spatially separated, auditory spatial attention modulates neural activity, particularly alpha-band oscillations. Alpha power typically increases in the hemisphere ipsilateral to the attended stimulus and decreases in the contralateral hemisphere. This study investigated whether alpha-power lateralization could be elicited by monotonic sinusoidal and musical stimuli and whether this lateralization differed between participant groups stratified according to their theta/alpha ratio (TAR). Twenty-two participants were stratified into lower-TAR (Group I) and higher-TAR (Group II) groups. A significant three-way interaction among Group, Stimulus, and Hemisphere was observed, indicating that the pattern of alpha power across hemispheres differed between groups and stimulus types. Group I exhibited significant alpha-power lateralization during auditory stimulation period, but only under musical stimulation. In contrast, no significant alpha-power lateralization was observed in Group II under either stimulus condition. These findings indicate that alpha-power lateralization during auditory spatial attention depends on the combination of participant TAR profile and stimulus type, with musical stimulation eliciting a more pronounced lateralized response than sinusoidal stimulation. Thus, the alpha-power lateralization induced by musical stimulation may provide a promising control signal for auditory brain-computer interfaces.**

***Index Terms*—auditory spatial attention, alpha-power lateralization, electroencephalography (EEG), theta/alpha ratio, musical stimulation.**

I. Introduction

The ability to selectively attend to a target sound while ignoring competing auditory stimuli, known as the cocktail party effect, has been widely used to investigate the neural mechanisms underlying top-down auditory attention [1], [2]. Experimental paradigms investigating auditory attention are often conducted in sound-attenuated rooms with participants' eyes closed, a setting particularly suitable for auditory brain-computer interfaces (BCIs) [3]. However, maintaining wakefulness under these conditions is challenging, making it essential to monitor participants' level of alertness. Although behavioral measures, such as reaction time or target detection, are commonly used for this purpose [4], [5], requiring a behavioral response may influence the neural activity of interest by engaging additional cognitive processes, including motor preparation and response planning [6]. Furthermore, behavioral-response-free paradigms are essential for the development of auditory BCIs for individuals with complete locked-in syndrome (CLIS), whose communication relies exclusively on neural activity generated during attentional processing [7].

Wakefulness refers to the physiological state in which an individual is conscious and able to appropriately perceive and respond to external stimuli while performing cognitive and motor tasks [8]. Reduced wakefulness can impair sustained attention and consequently degrade the performance of BCI systems [9]. Evidence indicates that signs of drowsiness can emerge rapidly during resting-state EEG recordings. For example, [10] reported that approximately one-third of participants exhibited reduced alertness after only three minutes of eyes-closed recording. Despite extensive evidence showing that attentional processes are strongly influenced by the level of alertness [8], [11], [12], fluctuations in vigilance are still frequently overlooked in cognitive neuroscience studies. Consequently, EEG trials acquired during periods of reduced alertness are often included in analyses of attention and other cognitive functions [13]. Therefore, identifying episodes of

This study was financed by Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Fundação de Amparo à Pesquisa do Estado de Minas Gerais (FAPEMIG), and Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) – Brazil (Finance Code 001).

reduced wakefulness before subsequent analyses is essential to exclude unsuitable trials and improve the reliability of the findings.

In this context, the theta/alpha ratio (TAR) has been proposed as a neurophysiological indicator associated with drowsiness [4], [5], [14], [15], particularly when assessed over the occipital cortex [16]. Theta (4–8 Hz) and alpha (8–13 Hz) oscillations can be readily measured at the scalp using electroencephalography (EEG), and EEG recordings acquired under eyes-closed conditions in awake individuals generally exhibit prominent alpha activity over the occipital cortex [17]. Previous studies have shown that during the transition from wakefulness to sleep, or sleep onset period (SOP), theta activity generally becomes more prominent, whereas alpha activity decreases, resulting in higher TAR values [5]. Thus, higher TAR values may reflect changes in the EEG spectral profile associated with the SOP.

At the same time, alpha activity is closely involved in the allocation of auditory spatial attention, making its lateralization particularly relevant to selective listening. Previous studies have consistently reported alpha-power lateralization during listening tasks, with alpha power increasing in the cortical hemisphere ipsilateral to the attended auditory hemifield and decreasing in the contralateral hemisphere [18]–[20]. During selective auditory spatial attention, two distinct mechanisms contribute to attentional selection: target selection and distractor suppression. Reference [21] demonstrated that both mechanisms are associated with alpha-power lateralization and that their neural signatures are dissociable and uncorrelated, suggesting that distractor suppression can occur independently of target selection. In addition, previous studies have shown that alpha-power lateralization can emerge even before the onset of auditory stimulation, during the interval between the presentation of the spatial cue and stimulus onset [18], [20]–[24]. Together, these findings support alpha-band lateralization as a reliable neural signature of both the anticipatory deployment and sustained maintenance of auditory spatial attention.

The magnitude of alpha lateralization, however, depends on the characteristics of the auditory stimuli. When sounds are presented through headphones without natural spatial cues, such as interaural time differences (ITDs) and interaural level differences (ILDs), alpha lateralization tends to be substantially weaker [23], [24]. Moreover, most previous studies investigating alpha lateralization have employed speech-based stimuli, such as spoken syllables or numbers [18], [20], [22], [23], whereas alternative classes of auditory stimuli remain comparatively underexplored.

Among the available alternatives, musical stimulation has the potential to provide a more comfortable and engaging experimental experience. Compared with the conventional sinusoidal amplitude-modulated (AM) stimuli commonly used to evoke 40-Hz auditory steady-state responses (ASSRs) in auditory BCI research [19], [25], musical stimuli may reduce the physical and psychological burden on participants while preserving the inherently pleasant experience of listening to music [26], [27]. Besides improving participant acceptance, musical stimulation may also help maintain alertness throughout the recording session, as its melodic structure allows participants to follow the auditory stream and remain engaged with the task.

Given the association between drowsiness and changes in theta and alpha oscillations, this study uses the theta/alpha ratio to stratify participants into higher- and lower-TAR groups. It then investigates whether dichotic stimulation with both musical and monotonic (single-carrier sinusoidal) stimuli induces alpha-power lateralization in each group. By assessing alpha-power lateralization across these conditions, this study provides further insight into the robustness of alpha-power lateralization as a neural marker and its potential application in auditory BCIs [19].

II. Materials and Methods

A. Participants

A total of 22 volunteers participated in this study (9 females, mean age = 29.3 years, SD = 6.4 years). All participants self-reported normal hearing. EEG data were acquired in a soundproof cabin while participants were seated comfortably and instructed to keep their eyes closed throughout the recordings. The study protocol received approval from the Research Ethics Committee of the Universidade Federal de Viçosa (CEP/UFV: 3.773.292). All participants gave informed consent before participation.

B. Experimental Paradigm

The experiment started with the completion of a questionnaire containing binary questions, such as “At this moment, are you wearing a watch?”, “Do you consider yourself tall?”, and “Did you drink coffee today?”. Although each question required a binary decision, participants could choose among three response options: “Yes”, “No”, or “?”, where the question mark indicated either uncertainty or a preference not to answer. Questions marked with “?” were not considered in the subsequent experimental procedures. After completing the questionnaire, participants proceeded with the experimental protocol, as shown in Fig. 1. For each participant, the questions were randomly selected from the questionnaire and consisted of five questions that had been answered with “Yes” and five that had been answered with “No”. Before the presentation of the questions used in the attention task, a 34-s calibration trial was recorded to obtain baseline EEG activity. During this phase, the two auditory stimuli were simultaneously presented through earphones, and participants were instructed not to attend to either stimulus. To maintain a neutral attentional state, participants were asked to mentally sing the Brazilian National Anthem throughout the calibration period.

EEG acquisition was performed on a trial-by-trial basis rather than continuously across the entire experiment. For each trial, recording started at least 1 s before the onset of the auditory stimulation. Each participant completed a total of eleven EEG recordings: one 34 s calibration trial without selective auditory attention and ten attention trials, each lasting

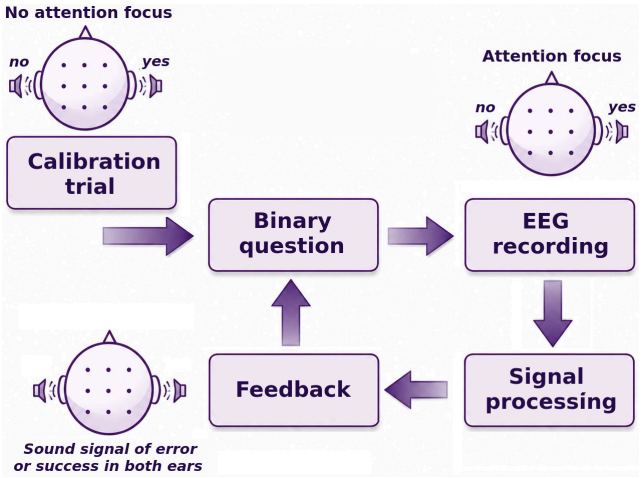

Fig. 1. Experimental paradigm. The experiment began with a 34 s calibration recording, during which the auditory stimuli were delivered through insert earphones. During this period, participants were instructed not to attend to either stimulus. After the calibration trial, a binary question requiring a "Yes" or "No" response was presented, immediately followed by the simultaneous dichotic delivery of two auditory stimuli. Depending on the experimental condition, the stimuli consisted of either sinusoidal tones or musical instrument sounds, both of which were amplitude-modulated. The stimulus associated with the "No" response was always presented to the left ear, whereas the "Yes" stimulus was presented to the right ear. EEG activity was recorded throughout the 5.1 s stimulation interval while participants selectively directed their attention toward the stimulus corresponding to their intended answer. At the end of each trial, the recorded EEG was processed to identify the attended stimulus, and auditory feedback was provided to inform participants whether the decoded response matched their intended answer. A 5 s resting interval was then introduced before the onset of the next question.

5.1 s, in which participants selectively attended to the stimulus corresponding to their intended response.

The experimental protocol was originally developed to investigate the modulation of ASSRs by auditory spatial attention for the implementation of an online binary communication system. However, because the proposed system achieved limited classification performance, the recorded data were subsequently reanalyzed offline to investigate whether participants' reduced wakefulness could have contributed to the lower decoding accuracy. Based on this analysis, the scope of the study was expanded to evaluate the effects of auditory spatial attention on alpha-band activity, with particular emphasis on alpha-power lateralization induced by spatially separated auditory stimuli. Consequently, the feedback provided to participants during the experiment was based on the comparison between their questionnaire responses and the EEG classifications generated by the ASSR-based modular classifier proposed by [25]. Accordingly, all analyses reported in the present study were conducted as a post hoc analysis of the previously acquired EEG dataset. To ensure transparency and reproducibility, the raw EEG recordings are publicly available on GitHub at https://github.com/Luciana-Nicacio/eeg_dataset.

C. Auditory Stimulation

Binary response options were encoded using amplitude-modulated (AM) auditory stimuli. The experiment consisted of two blocks of 10 questions, each employing a different type of carrier signal. In the first block, pure sinusoidal tones served as carriers, with frequencies of 500 Hz and 4 kHz corresponding to the "No" and "Yes" responses, respectively. In the second block, musical instrument sounds were used as carriers, consisting of a piano melody for "No" and a harmonica melody for "Yes". These audio files were obtained from the Internet Archive (https://archive.org/) and, like the sinusoidal stimuli, were sampled at 44.1 kHz. To avoid possible order effects, the presentation sequence of the two stimulus blocks was counterbalanced across participants.

The carrier signals were amplitude-modulated at 31.13 Hz for the "No" stimulus and 39.36 Hz for the "Yes" stimulus. These modulation frequencies were adopted according to the protocol proposed by [25]. The sound intensity of all stimuli was calibrated to 70 dB SPL (sound pressure level), ensuring comfortable listening while remaining well above the ambient noise level. Audio files containing the amplitude-modulated stimuli are available on GitHub at https://github.com/Luciana-Nicacio/Stimulation-audio-files.

D. EEG Recording and Processing

Signal acquisition was performed using a BrainNet BNT-36 amplifier (EMSA Equipamentos Médicos, Brazil) and 22 Ag/AgCl scalp electrodes positioned according to the international 10–20 system. The ground electrode was placed at Fpz, and Cz served as the reference electrode. Data were acquired with analog band-pass filtering between 1 and 100 Hz and digitized at a nominal sampling rate of 600 Hz (601.5 Hz according to the manufacturer's specifications). The amplifier's hardware notch filter was intentionally disabled, and power-line interference at 60 Hz and its harmonics was removed during offline processing using a digital infinite impulse response (IIR) notch filter.

Subsequent offline analyses were performed in Python (version 3.10.12) using the MNE-Python toolbox (version 1.9.0) [28].

1) TAR-Based Grouping: Participants were stratified into two groups according to the occurrence of higher TAR values across the attention trials, based on the hypothesis that higher TAR values may be associated with lower levels of wakefulness. To extract spectral features from the EEG signals, the theta (4–8 Hz) and alpha (8–13 Hz) rhythms were first isolated using digital band-pass filtering with the *mne.filter.filter_data* function from the MNE-Python package and its default settings. Subsequently, the amplitude envelope of each frequency band was derived from the magnitude of the analytic signal obtained using the Hilbert transform. Instantaneous power in the three occipital channels (O_1, O_2, and O_z) was estimated as the squared amplitude envelope, $P(t) = A(t)^2$, and mean power was calculated over time for each channel. The TAR was then computed for each channel as the ratio of theta to alpha mean power, and the final TAR was obtained by averaging the ratios across the three occipital channels. This procedure was applied to the 20 attention trials of all 22 participants, comprising 10 trials under

musical stimulation and 10 under sinusoidal stimulation. Four TAR thresholds were considered separately (1.00, 0.75, 0.60, and 0.50), resulting in four distinct participant groupings. For each threshold, participants who exhibited a TAR greater than the respective threshold in more than 5 of the 20 attention trials ($> 25\%$) were assigned to Group II, hereafter referred to as the higher-TAR group. The remaining participants were assigned to Group I, referred to as the lower-TAR group. For each TAR threshold, subsequent analyses examined the main effects and interactions of Group, Stimulation, and Hemisphere using the alpha-power attentional modulation index (AMI_α), as described below.

2) Alpha-Power Lateralization: At this stage, the EEG recordings were re-referenced to the average of the two mastoid channels. The alpha-band-filtered EEG signals were then normalized on a trial-by-trial basis using z-scores computed from the mean and standard deviation calculated across all EEG channels. Subsequently, the envelope of the normalized EEG signal was extracted for two time windows: the pre-stimulus interval (-0.5 to 0 s) and the auditory stimulation interval (0 to 5.1 s). Alpha power in each interval was estimated as the mean squared amplitude envelope within the corresponding time window. The alpha power values were then averaged across the five "No" trials and the five "Yes" trials for each participant. Finally, the AMI_α was computed for each participant and channel following the approach proposed by [18]. This metric quantified the hemispheric lateralization of alpha power induced by auditory spatial attention for each analysis period and was calculated as follows:

$$AMI_\alpha = \frac{X_{att_{No}} - X_{att_{Yes}}}{X_{att_{No}} + X_{att_{Yes}}} \tag{1}$$

where X represents the mean alpha power measured while selectively attending to either the "No" or the "Yes" stimulus. Accordingly, positive AMI_α values indicate higher alpha power during attention to the "No" stimulus, whereas negative values indicate higher alpha power during attention to the "Yes" stimulus.

To quantify the degree of alpha-power lateralization, the mean AMI_α was calculated across all electrodes within the left hemisphere (LH) and right hemisphere (RH).

3) Statistical Analysis: To evaluate the effects of Group, Stimulus, and Hemisphere on the AMI_α, separate linear mixed-effects models (MixedLM) were fitted for the two time windows. Statistical analyses were performed using the *statsmodels* package in Python. In both models, Group (between-subjects factor), Stimulus (within-subjects factor: musical vs. sinusoidal), and Hemisphere (within-subjects factor: left vs. right), together with all corresponding two-way and three-way interactions, were included as fixed effects. Participant ID was included as a random intercept to account for the repeated-measures design. Residual normality (Shapiro–Wilk test) and homoscedasticity (Levene's test) were assessed. When these assumptions were satisfied, the AMI_α values were analyzed on their original continuous scale. Sphericity was considered automatically satisfied because all within-subjects factors had only two levels ($\varepsilon = 1.0$). When the normality or homoscedasticity assumptions were violated, a robust non-parametric rank-transformation procedure was applied to the AMI_α values before model fitting. The fixed effects were assessed using Wald χ^2 tests at a 5% significance level. When a significant three-way interaction among Group, Stimulus, and Hemisphere was identified, post-hoc analyses were performed to further characterize the interaction by comparing mean AMI_α between the left and right hemispheres within each group and stimulation type. The normality of the differences in mean AMI_α between hemispheres was first assessed using the Shapiro–Wilk test. If the distribution of these differences did not deviate significantly from normality, paired *t*-tests were used to compare mean AMI_α between hemispheres. Otherwise, the Wilcoxon signed-rank test was applied to the paired observations.

III. Results

A. Participant Grouping

Descriptive statistics for TAR across the musical and sinusoidal stimulation conditions, along with the percentage of trials exceeding four distinct TAR thresholds (1.00, 0.75, 0.60, and 0.50), are summarized in Table I. The number of participants assigned to each group across the four TAR-based groupings is presented in Table II.

B. Alpha-Power Lateralization: Main Effects and Interactions

The effects of the main factors and their interactions were evaluated separately for each EEG time window: the pre-stimulus interval (-0.5 to 0 s) and the auditory stimulation interval (0 to 5.1 s), as described in the following subsections.

1) Before Stimulation Onset: For this period, the assumptions of normality and homoscedasticity were satisfied for all groupings. The linear mixed-effects model (MixedLM, Wald test) revealed a significant main effect of Stimulus in groupings 1 ($\chi^2 = 7.20$, $p = 0.0073$), 2 ($\chi^2 = 10.06$, $p = 0.0015$), and 3 ($\chi^2 = 6.96$, $p = 0.0083$), but not in grouping 4 ($\chi^2 = 3.28$, $p = 0.070$). No significant main effects of Group or Hemisphere were found at any threshold ($p > 0.05$). Likewise, none of the two-way or three-way interactions reached statistical significance.

2) During Auditory Stimulation: The Shapiro-Wilk test indicated a violation of the normality assumption ($p < 0.0001$), requiring a robust rank-transformed linear mixed-effects model for all four grouping configurations. A significant main effect of Hemisphere was observed in groupings 2 ($\chi^2 = 4.28$, $p = 0.039$) and 3 ($\chi^2 = 4.62$, $p = 0.032$), whereas grouping 1 showed a marginal effect ($\chi^2 = 3.63$, $p = 0.057$). A significant two-way Group $\times$ Hemisphere interaction was consistently observed in groupings 1 ($\chi^2 = 3.98$, $p = 0.046$), 2 ($\chi^2 = 4.02$, $p = 0.045$), and 3 ($\chi^2 = 3.91$, $p = 0.048$). In addition, significant Stimulus $\times$ Hemisphere interactions were observed in groupings 2 ($\chi^2 = 3.86$, $p = 0.049$) and 3 ($\chi^2 = 3.93$, $p = 0.047$), together with significant three-way Group $\times$ Stimulus $\times$ Hemisphere interactions ($\chi^2 = 4.55$, $p = 0.033$ and $\chi^2 = 3.89$, $p = 0.048$, respectively). No

TABLE II
NUMBER OF PARTICIPANTS IN EACH GROUP ACCORDING TO THE ADOPTED TAR THRESHOLD

Grouping	Group I	Group II
1: TAR > 1.00	16	6
2: TAR > 0.75	13	9
3: TAR > 0.60	10	12
4: TAR > 0.50	8	14

main effects or interactions reached statistical significance in grouping 4.

The three-way interaction patterns for the grouping 3 (TAR > 0.60) are illustrated in Fig. 2. The interaction plots revealed distinct patterns of hemispheric alpha-power modulation between groups. In Group I, musical stimulation was associated with higher AMI_α ranks over the left hemisphere, whereas sinusoidal stimulation showed higher ranks over the right hemisphere. In Group II, this pattern was reversed, with higher AMI_α ranks for musical stimulation over the right hemisphere and for sinusoidal stimulation over the left hemisphere. Thus, the relationship between stimulus type and hemispheric alpha-power lateralization differed between the two groups.

Post hoc pairwise comparisons using paired t-tests (with normality confirmed by Shapiro–Wilk tests, $p > 0.12$ across conditions) further clarified the factors underlying the three-way interaction during stimulus presentation. For grouping 3, Group I showed a statistically significant interhemispheric difference in alpha-power lateralization during musical stimulation, with higher values over the left hemisphere than over the right hemisphere (Fig. 3A; $p = 0.035$). In contrast, no significant interhemispheric difference was observed in Group I under sinusoidal stimulation (Fig. 3B; $p = 0.43$). Group II showed no significant interhemispheric differences under either musical (Fig. 3C; $p = 0.42$) or sinusoidal (Fig. 3D; $p = 0.85$) stimulation. Notably, the same pattern was also observed for grouping 2, with a significant interhemispheric difference in Group I during musical stimulation ($p = 0.049$).

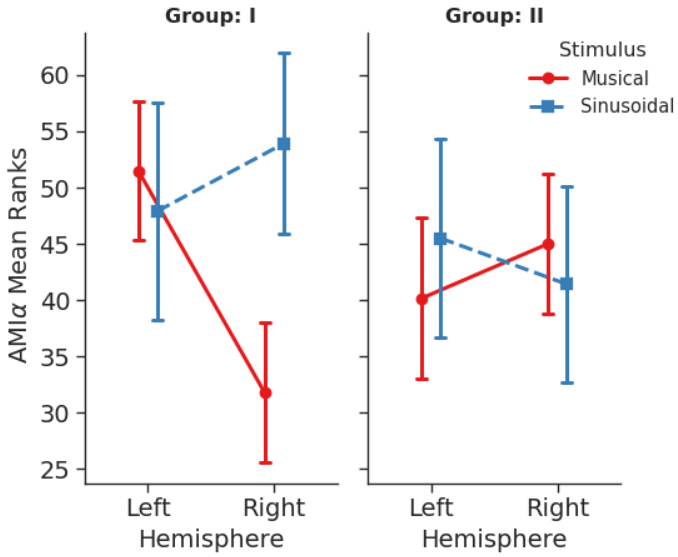

Fig. 2. Interaction profile of alpha power asymmetry (AMI_α mean ranks) during the stimulus presentation interval (0–5.1 s) for grouping 3. Point plots depict mean ranks across hemispheres (Left vs. Right) for musical (red solid line, circles) and sinusoidal (blue dashed line, squares) stimuli, faceted by group profile (Group I, $n = 10$; Group II, $n = 12$). Error bars represent standard errors of the mean (±SE).

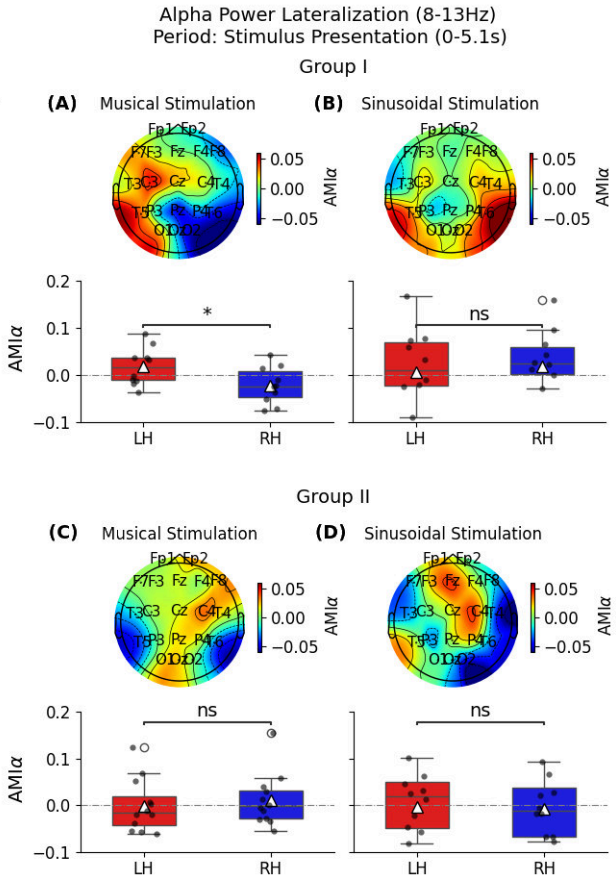

Fig. 3. Topographic maps and boxplots of alpha-power lateralization AMI_α during the stimulus presentation interval (0–5.1 s) for the grouping 3 under musical and sinusoidal stimulation. Panels (A) and (B) correspond to Group I, whereas panels (C) and (D) correspond to Group II. The topographic maps display the mean AMI_α across participants. The boxplots summarize the mean AMI_α for the left (LH) and right (RH) hemispheres. White triangles indicate the mean value, gray circles represent individual participants, and the horizontal dashed line denotes $AMI_\alpha = 0$. Statistical significance between hemispheres is indicated above each boxplot ($^*p < 0.05$, $^{**}p < 0.01$, $^{n.s.}p > 0.05$).

IV. Discussion

The present study investigated alpha-power lateralization associated with auditory spatial attention across individuals stratified according to distinct TAR thresholds during musical and sinusoidal auditory stimulation. Participants were stratified according to their TAR levels into Group I (lower-TAR) and Group II (higher-TAR) using four different grouping criteria. Although the literature does not establish a universal TAR threshold for reliably distinguishing an individual's level of alertness, two of the four thresholds used for participant stratification yielded a significant three-way interaction among Group, Stimulus, and Hemisphere during the stimulation period.

Post hoc analyses further showed that a significant alpha-power lateralization effect was observed only in Group I during musical stimulation. Alpha-power lateralization associated with auditory spatial attention exhibited the expected opposite pattern of modulation, with positive AMI_α values over the left hemisphere and negative values over the right hemisphere. Consistent with previous studies, alpha-power lateralization was primarily evident over the posterior cortex [18]–[20]. In contrast, no significant interhemispheric differences were observed in Group II under either stimulation condition, suggesting that alpha-power lateralization was less evident among participants with higher TAR values. This finding is in line with previous studies reporting a strong association between higher TAR values and reduced wakefulness or increased sleep propensity [4], [5], [15], which may have affected the participants' ability to sustain attention during the experiment.

These findings highlight the importance of assessing wakefulness in EEG experiments involving prolonged eye closure and the absence of behavioral measures of alertness. Failure to account for differences in wakefulness may affect the interpretation of neural activity by obscuring attention-related neural signatures. Therefore, assessing wakefulness before including EEG recordings in subsequent analyses may help reduce variability associated with vigilance and improve the reliability of attention-related EEG measures.

The absence of significant alpha-power lateralization during sinusoidal stimulation may reflect the limited acoustic information available to sustain auditory spatial attention. Unlike the musical stimuli, the sinusoidal stimuli consisted of amplitude-modulated pure tones in which the sinusoidal carrier had a constant amplitude, thus providing little acoustic information to sustain auditory spatial attention. Furthermore, because both stimulus types were delivered through headphones in a dichotic listening paradigm, they did not provide the natural spatial cues generated by acoustic sources surrounding the listener, including interaural time differences (ITDs), interaural level differences (ILDs), and pinna-related spectral cues. These cues are normally available in everyday listening environments, where a single sound source reaches both ears, and contribute to the cocktail party effect. As discussed by [23], these spatial cues are important for generating realistic spatial auditory percepts and engaging cortical networks involved in auditory spatial attention. Their findings showed that attentional modulation of parietal alpha activity was strongest when natural spatial cues derived from individualized head-related transfer functions (HRTFs) were available. In contrast, diotic stimulation based on isolated spatial cues, such as ITDs and ILDs, produced weaker and less consistent alpha-power lateralization, suggesting that these cues alone may provide less effective engagement of the neural mechanisms underlying auditory spatial attention.

In this context, the findings reported by [19] corroborate those of [23]. Although their study also employed sinusoidally amplitude-modulated stimuli, they observed alpha-power lateralization over parieto-occipital regions. However, unlike the present study, their stimuli were presented through loudspeakers positioned at azimuths of $\pm 45°$. Thus, their experimental setup provided spatial information associated with the physical location of the sound sources, as well as acoustic cues generated by the head and pinnae. The

observation of alpha lateralization under these conditions suggests that sinusoidal AM stimuli can elicit attentional lateralization when presented with richer spatial information. Together with the findings of [23], these results suggest that the absence of significant alpha-power lateralization during sinusoidal stimulation in the present study may be related not only to the limited spectrotemporal structure of the stimuli but also to the restricted spatial information available during dichotic headphone presentation.

Based on the hypothesis that the dynamic acoustic features of musical stimuli may facilitate the sustained allocation of auditory attention during dichotic stimulation, our findings can be interpreted in the context of previous evidence showing that temporally structured auditory signals enhance attentional modulation. This interpretation is supported by the studies of [18], [22], which successfully demonstrated alpha-power lateralization during dichotic stimulation without individualized spatial cues. In these studies, the target stimuli consisted of spoken numbers, whose naturally varying temporal envelopes provided low-frequency temporal structures synchronized with speech dynamics. Together, these findings indicate that, beyond spatial information, temporally structured auditory features contribute to the engagement of top-down attentional control mechanisms.

Reference [24] investigated the influence of nonspatial acoustic features on auditory spatial attention using diotic stimulation with simulated spatial cues generated through interaural time differences. Three temporally regular auditory stimuli were designed to be perceived as originating from different spatial locations (left, center, and right) by applying ITDs of -100, 0, and +100 μs, respectively. Their findings showed that parietal alpha lateralization reflected the spatial cue associated with the target stimulus before stimulus onset, indicating an initial allocation of attention toward the expected auditory location. However, after stimulus presentation began, alpha lateralization was no longer observed when the target and distractor stimuli had large pitch separation, whereas it remained present when pitch differences were smaller. The authors suggested that large pitch differences between target and distractor stimuli may reduce the reliance on sustained spatial attention during auditory selection. In contrast, [23] demonstrated that parieto-occipital alpha lateralization varied monotonically as the direction of attention shifted from far left (-600 μs) to far right (+600 μs). Therefore, the lower spatial salience of the cues employed by [24] may have limited the recruitment of spatial attention mechanisms and contributed to the attenuation of sustained alpha lateralization during stimulation. These findings suggest that, in paradigms based on diotic stimulation where pitch differences between the target and distractor stimuli are larger, greater ITDs may be required to robustly engage the neural mechanisms underlying sustained auditory spatial attention and induce alpha-power lateralization.

Finally, an interesting finding of this study was the significant main effect of Stimulus observed during the pre-stimulus period for groupings 1, 2, and 3. Because no auditory stimulation was presented during this interval, this effect cannot be attributed to the immediate processing of the auditory stimuli themselves. Instead, it may reflect anticipatory or preparatory neural activity associated with knowledge of the upcoming stimulus type. Before the attention trials, participants had already completed the calibration trial and were therefore familiar with the stimulus type that would be presented in each subsequent trial. This prior knowledge may have allowed participants to anticipate the upcoming auditory stimulation and engage stimulus-specific preparatory processes before stimulus onset.

A. Limitations and Future Work

This study has some limitations that should be addressed in future investigations. Participant grouping relied on the same TAR thresholds across all participants, whereas future studies should consider individualized thresholds established from a baseline recording obtained under confirmed wakefulness conditions to reduce the potential for misclassification. Because eye closure was not objectively monitored, higher TAR values observed in the present study may have been influenced by periods of eye opening, which are known to reduce occipital alpha-power amplitude. Therefore, elevated TAR values cannot be attributed exclusively to possible reductions in wakefulness or drowsiness. Moreover, approximately 10% of healthy individuals do not exhibit prominent alpha rhythms even under eyes-closed conditions [17]. Therefore, future studies should assess alpha activity under both eyes-open and eyes-closed conditions before the experiment to identify individuals who do not exhibit the typical increase in occipital alpha-power amplitude associated with eye closure. Additionally, experiments without ASSR-based feedback should be conducted to determine whether alpha lateralization remains stable in the absence of potential influences from classifier outcomes. The use of more realistic spatial stimulation based on head-related transfer functions (HRTFs) may also enhance auditory spatial attention and elicit stronger alpha-power lateralization. Furthermore, although the present study evaluated the conventional alpha band (8–13 Hz), future analyses should investigate individualized alpha sub-bands, as [20] demonstrated that attentional modulation was more accurately captured by analyzing a narrow frequency band centered on each participant's individual parietal alpha peak rather than the entire alpha range. In addition, previous studies investigating the transition from wakefulness to sleep using the TAR have employed narrower frequency bands within the theta and alpha ranges, suggesting that more narrowly defined frequency bands may provide greater sensitivity to changes in wakefulness [4], [14]. Considering the dynamic temporal structure of musical stimuli, future studies should also examine whether alpha lateralization synchronizes with the envelope of the attended stimulus, as previously observed for speech-based attention [18], [22]. Finally, analyses using shorter temporal windows and restricting the analysis to centro-parieto-occipital regions may help identify the temporal periods and cortical areas associated with stronger attentional alpha-power modulation.

V. Conclusion

This study demonstrated that TAR-based participant stratification and stimulus type were associated with differences in alpha-power lateralization during auditory spatial attention. Significant lateralization was observed only in Group I (lower-TAR) during musical stimulation, suggesting that this type of stimulation may have contributed to sustained attentional engagement throughout the experiment. Future studies combining temporally dynamic auditory stimuli, including musical stimuli, with richer spatial cues provided by individualized HRTFs may further enhance alpha-power lateralization and strengthen its potential as a neural marker of auditory spatial attention. Building on this approach, a classifier for decoding the direction of attention based on alpha-power lateralization could be implemented and integrated with ASSR-based classification to improve the performance and reliability of auditory BCIs. Together, these complementary approaches could support the development of hybrid auditory BCIs for binary communication in patients with CLIS.

***Abstract*—This exploratory study examined parietal EEG activity before and after a visual cancellation task in six participants with autism spectrum disorder (ASD) and six controls. EEG was acquired at 256 Hz for 180 s per resting condition, and P3 and P4 channels were analyzed. Holo-Hilbert spectral analysis (HHSA) maps were used to describe carrier-frequency and amplitude-modulation patterns; visual map differences were not treated as evidence of neural adaptation. A complementary analysis estimated relative theta power, defined as 4–8 Hz power divided by 1–45 Hz power, from nonoverlapping 4-s epochs (45 epochs per recording). A linear mixed-effects model included group, period, channel, their interactions, and a participant-specific random intercept. Channel-specific pre-to-post change contrasts were tested with Holm correction. The ASD-minus-control difference in change was +0.0050 at P3 (adjusted $p = 0.8906$) and -0.0710 at P4 (unadjusted 95% CI, -0.1329 to -0.0091; adjusted $p = 0.0491$). However, the three-way group-by-period-by-channel interaction was not significant ($p = 0.1018$). Due to small sample size and incomplete clinical characterization, the findings are preliminary and do not establish a robust group-specific task response or a validated functional marker.**

***Index Terms*—EEG, autism spectrum disorder, theta band, Holo-Hilbert spectral analysis, visual attention, mixed-effects model.**

I. Introduction

Autism spectrum disorder (ASD) is a neurodevelopmental condition involving differences in social communication and restricted or repetitive patterns of behavior [1]–[3]. EEG allows noninvasive assessment of brain electrical activity and has been used to investigate atypical brain dynamics in ASD [4], [5]. Theta activity has been associated with cognitive control, sustained attention, and performance monitoring, especially in midfrontal EEG studies [6]–[9]. However, this literature does not establish that parietal theta changes at a single electrode reflect a specific cognitive mechanism.

This study analyzed EEG recorded at P3 and P4 during resting periods before and after a visual cancellation task, a paradigm used to assess visual search and attentional performance [10]–[14]. These electrodes sample left and right parietal scalp regions according to the international 10–20 system [15]. Although parietal regions are involved in attention networks [16], [17], scalp location alone does not identify neural generators or demonstrate lateralized attentional function. Prior studies have reported atypical theta-band responses and attentional-network differences in ASD [18]–[21].

Holo-Hilbert spectral analysis (HHSA) represents carrier and amplitude-modulation frequencies through adaptive decompositions, making it suitable for nonlinear and nonstationary signals [22], [23]. In this work, HHSA maps were retained for descriptive inspection, while a complementary Welch-based relative theta analysis provided a reproducible quantitative outcome [24]. The objective was to estimate whether pre-to-post changes in relative theta power differed between ASD and control groups and whether this difference varied between P3 and P4. Given the limited sample and unresolved data-quality issues, the analysis was treated as exploratory.

II. Theoretical Background

A. Theta Activity and Parietal Scalp Signals

Theta activity motivates cognitive investigation, but evidence from midfrontal cognitive-control studies does not establish a specific function for parietal theta changes [6]–[9]. EEG studies in ASD have reported atypical oscillatory activity, altered connectivity, and differences in attentional processing [4], [5], [18]–[21]. P3 and P4 therefore denote scalp recording sites rather than isolated neural generators [15]. Consequently, this study does not directly measure neural flexibility, adaptive reorganization, or physiological recovery.

B. Holo-Hilbert Spectral Analysis

HHSA extends adaptive signal decomposition to represent carrier and amplitude-modulation frequencies [22], [23]. In empirical mode decomposition, the signal is expressed as

$$x(t) = \sum_{i=1}^{n} c_i(t) + r_n(t), \tag{1}$$

where $c_i(t)$ are intrinsic mode functions and $r_n(t)$ is the residual [22]. An IMF can be represented as

$$c_i(t) = a_i(t)\cos\phi_i(t), \qquad f_i(t) = \frac{1}{2\pi}\frac{\mathrm{d}\phi_i(t)}{\mathrm{d}t}. \tag{2}$$

Here, f_i is expressed in hertz. A further decomposition of the envelopes characterizes modulation frequencies, yielding a representation denoted here by $H(f_c, f_m)$, where f_c and f_m are carrier and modulation frequencies. The original HHSA region of interest comprised $4 \le f_c \le 8$ Hz and $0.5 \le f_m \le 4$ Hz. This differs from the complementary relative-power outcome, which integrates a conventional power spectral density over frequency [24] and is not interchangeable with HHSA energy.

III. Materials and Methods

A. Participants and Experimental Protocol

The sample comprised 12 participants: six with ASD and six controls. The source manuscript reports that ASD diagnoses were established by specialized professionals using DSM-5 criteria [2]. Controls reportedly had no history of neurological or psychiatric disorders or psychoactive medication use. Reported exclusion criteria included epilepsy, brain injury, and medical conditions that could compromise EEG interpretation. The study reports written informed consent and approval by the Research Ethics Committee of the Federal University of Pará, under CAAE 56365722.9.0000.0018.

Participants completed a computerized visual cancellation task on a 21.5-inch monitor in a quiet room. Visual cancellation tasks are used to assess visual search and attentional performance [10]–[14]. Each display contained 64 stimuli in an 8×8 grid, with 16 targets and 48 distractors, following the automated cancellation-task design described by Cascaes et al. [11]. Task duration was fixed at 7 min 30 s. The planned sequence included approximately 3 min of initial rest, task execution, and approximately 3 min of final rest, totaling approximately 13 min 30 s. Only the pre-task and post-task resting periods were analyzed, as summarized in Fig. 1. The original protocol diagram labels both resting periods as eyes open; this condition requires confirmation against acquisition records.

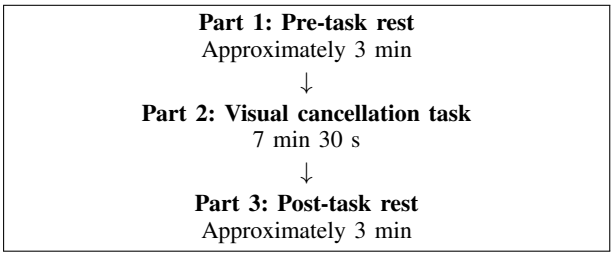

Fig. 1. Planned experimental sequence. Only Parts 1 and 3 were analyzed. The diagram does not depict measured physiological recovery.

B. Acquisition and Relative Theta Power

EEG was acquired with the NeuroMap system (Neurotec, Brazil), using 21 channels in the international 10–20 arrangement [15], 16-bit resolution, bilateral mastoid referencing, and a sampling frequency of 256 Hz. The available analysis used separately exported P3 and P4 MATLAB files for each resting period. All recordings corresponded to 180 s of effective acquisition, yielding 45 nonoverlapping 4-s epochs for every participant, period, and channel.

The quantitative reanalysis read the numeric signal stored in the variable `data`. The source manuscript describes visual inspection, 0.5–40 Hz band-pass filtering, and independent component analysis before channel extraction; however, these steps were not implemented by the supplied Python reanalysis and could not be verified from the available processing records.

For each 4-s epoch, the mean was removed and a power spectral density was computed using `scipy.signal.welch` [24], with a Hann window, full-epoch segment length, and no additional detrending. The Fourier spacing was 0.25 Hz. The epoch-level outcome was

$$R_{\theta,e} = \frac{\int_4^8 S_e(f)\,\mathrm{d}f}{\int_1^{45} S_e(f)\,\mathrm{d}f}, \tag{3}$$

where $S_e(f)$ is the epoch power spectral density. Integrals were approximated by the trapezoidal rule. The participant-period-channel outcome was the arithmetic mean of valid epoch-level ratios. This dimensionless fraction was not normalized by group maximum, baseline, image color scale, signal amplitude, or z-score, and should not be described as HHSA energy normalization.

The code excluded epochs with nonfinite samples and omitted ratios when total power was nonpositive. It also allowed amplitude-based rejection, but no amplitude threshold was supplied because the signal unit and an appropriate threshold were not documented. The saved analysis records contained zero rejected epochs. These checks establish numerical eligibility, not freedom from ocular, muscular, or movement artifacts.

C. HHSA Maps and Parameter Definitions

The original manuscript reports customized MATLAB processing based on HHSA, including IMF decomposition, Hilbert analysis, envelope decomposition, and Gaussian smoothing for visualization [22], [23]. The supplied figures show carrier frequency on the horizontal axis and modulation frequency on the vertical axis, but the executable MATLAB pipeline and numerical HHSA arrays were not included. Therefore, HHSA maps are retained for descriptive inspection only.

The available description does not specify the exact EMD implementation, sifting threshold, maximum number of iterations or modes, boundary extension, IMF-selection rule, or reproducible HHSA normalization formula. Embedded peak annotations are not treated as participant-level measurements, and color intensities are not compared quantitatively because units, logarithmic transformation, normalization, and aggregation order remain unverified.

For future verification, let H_{jk} be a nonnegative, time-aggregated spectral density evaluated at carrier/modulation bin centers $(f_{c,j}, f_{m,k})$. For the region R defined by carrier frequencies 4–8 Hz and modulation frequencies 0.5–4 Hz, a grid-based peak can be defined as

$$(\hat{j}, \hat{k}) = \arg \max_{(j,k)\in R} H_{jk}, \qquad (\hat{f}_c, \hat{f}_m) = (f_{c,\hat{j}}, f_{m,\hat{k}}). \quad (4)$$

If H_{jk} is a density per unit carrier and modulation frequency, regional energy can be specified as

$$E_R = \sum_{(j,k)\in R} H_{jk} \Delta f_{c,j} \Delta f_{m,k}. \quad (5)$$

These definitions require numerical arrays with documented grids, units, weighting, boundary conventions, and normalization. Logarithmic displays, smoothing, interpolation, and raster rendering may alter apparent peaks; therefore, visual displacements remain descriptive.

Image resolution and analytical resolution are distinct. Coarse binning, interpolation, Gaussian smoothing, and raster rendering can each affect the apparent location and intensity of spectral peaks. The 0.25-Hz Fourier spacing of the complementary Welch-based calculation does not specify HHSA resolution or guarantee 0.25-Hz resolving power for the HHSA maps. Therefore, decimal precision in the original visual annotations should not be interpreted as demonstrated frequency accuracy.

D. Complementary Statistical Analysis

The analysis included 48 participant-level observations: 12 participants × two periods × two channels. Epochs estimated each observation and were not treated as independent participants. A linear mixed-effects model was fitted by restricted maximum likelihood to account for repeated measurements, with a random intercept for participant and fixed effects for group, period, channel, all two-way interactions, and the three-way interaction [25]. Reference categories were control, pre-task, and P3. Optimization used the Powell method, and the reported model converged.

Table I
RELATIVE THETA POWER BY GROUP, PERIOD, AND CHANNEL.

Ch.	Group	Pre-task	Post-task	Change
P3	Control	0.1471 ± 0.0347	0.1568 ± 0.0527	+0.0097
P3	ASD	0.1123 ± 0.0594	0.1269 ± 0.0850	+0.0147
P4	Control	0.1361 ± 0.0277	0.2170 ± 0.0633	+0.0808
P4	ASD	0.1376 ± 0.0694	0.1399 ± 0.0581	+0.0023

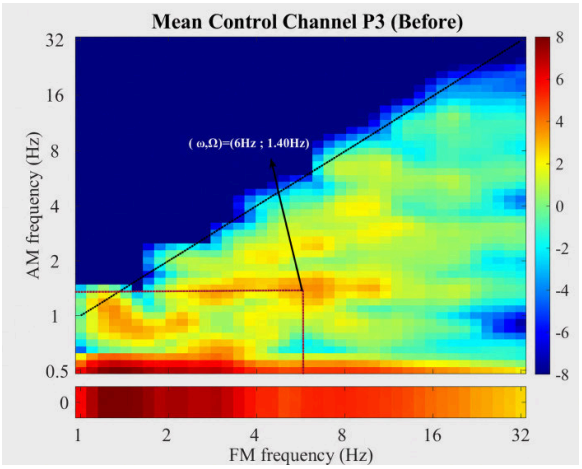
For each channel c, the contrast of interest was

$$\delta_c = (\mathrm{ASD}_{\mathrm{post},c} - \mathrm{ASD}_{\mathrm{pre},c}) - (\mathrm{Control}_{\mathrm{post},c} - \mathrm{Control}_{\mathrm{pre},c}). \quad (6)$$

Contrasts were derived from the fixed effects and covariance matrix. Two-sided asymptotic Wald z tests and unadjusted 95% confidence intervals were calculated. Holm correction was applied across the two channel-specific contrasts [26]. These confidence intervals are pointwise, not simultaneous intervals adjusted for the two comparisons. Effect sizes are reported as differences in relative power on the original scale. The three-way interaction evaluated whether the between-group difference in change differed between channels. No finite-sample or small-sample correction was applied.

IV. RESULTS

A. Descriptive HHSA Maps



The HHSA maps display spectral-intensity distributions and annotated carrier/modulation coordinates. These annotations describe selected positions on group-labeled images and do not establish a reproducible peak-selection rule or a statistically supported group difference. Shifts in annotated coordinates are not termed desynchronization or adaptive reorganization. The maps also include frequencies beyond the theta region, so not every visible feature represents theta activity. The original within-group HHSA significance claims and Cohen's $d = 0.50$ are not retained because participant-level inputs, channel-specific tests, and uncertainty estimates could not be verified. Significance in one group and nonsignificance in another would not, by itself, demonstrate a difference in task response.

B. Relative Theta Power and Change Contrasts

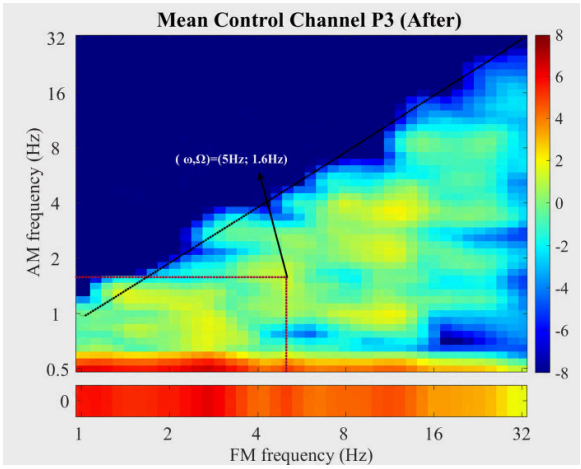


Table I reports participant-level means and standard deviations. Relative theta power increased descriptively in each group-by-channel cell, with the largest mean increase in control P4. These summaries refer to relative power, not absolute theta power or HHSA map energy.

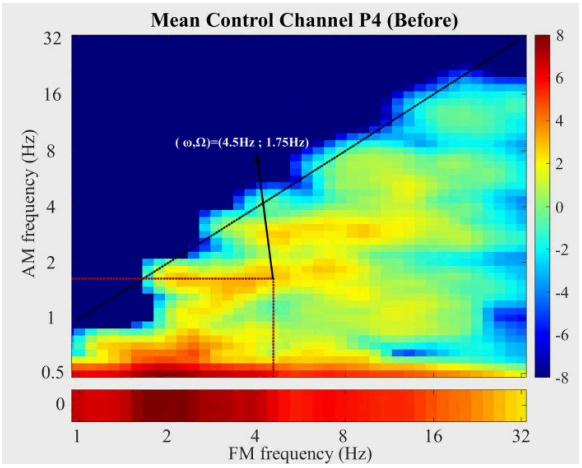
The channel-specific difference in change was not significant at P3 but reached the Holm-adjusted threshold at P4 (Table II). At P4, the negative contrast indicates a smaller mean pre-to-post increase in relative theta power in ASD than in controls. The unadjusted test yielded $p = 0.0246$, with a pointwise 95% CI from -0.1329 to -0.0091. After correction, the P4 contrast remained significant ($p_{\mathrm{Holm}} = 0.0491$), whereas the P3 contrast was not significant ($p_{\mathrm{Holm}} = 0.8906$).



The group-by-period-by-channel interaction was not significant (Wald $\chi^2(1) = 2.6769$, $p = 0.1018$). Thus, although the

V. Discussion

The quantitative analysis showed increased post-task relative theta power in control P4 and little average change in ASD P4. This observation is discussed in light of literature relating theta activity to attentional and cognitive-control processes [6]–[9]. The P4 contrast reached the Holm-adjusted threshold, whereas the P3 contrast did not. However, the nonsignificant group-by-period-by-channel interaction indicates no evidence that the between-group difference in change varied significantly between P3 and P4. Therefore, the P4 result should be interpreted cautiously and confirmed in a larger independent sample.

The HHSA maps and the relative-power analysis address different quantities. A change in HHSA peak location or intensity need not correspond to a change in band-integrated relative power. Relative theta power may also change through variation in the denominator, so an increase in this ratio does not establish an increase in absolute theta activity. The available analysis does not resolve which spectral components account for the observed ratios.

Interpretations involving neural flexibility, recovery efficiency, or hemisphere-specific attentional mechanisms exceed the available measurements, although attention-network models and ASD studies provide useful context [16], [17], [19]–[21]. Two scalp electrodes do not establish source localization, and this analysis did not quantify connectivity, cross-frequency coupling, or association with behavioral performance. Without a no-task condition, changes between resting periods cannot be uniquely attributed to the visual attention task.

A. Comparison with Conventional Spectral Analysis

HHSA represents carrier and envelope-modulation frequencies jointly [22], [23]; Welch's method estimates power spectral density over frequency [24]. The present Welch-based relative-theta analysis provides a reproducible quantitative reference but not a direct validation of HHSA, because relative band power and HHSA modulation-region energy are different outcomes. A direct benchmark was not possible because the numerical HHSA arrays and executable pipeline were unavailable.

Future comparisons should apply HHSA and conventional methods to the same verified, duration-matched, artifact-controlled segments. Shared outcomes would require compatible normalization before agreement and repeatability are assessed. Synthetic AM–FM signals could estimate bias and robustness, while EEG comparisons should evaluate reproducibility and uncertainty rather than rank methods by their smallest p value. No classification or independent validation was conducted; therefore, the present findings do not establish a biomarker.

B. Limitations and Next Steps

The sample included only six participants per group, and individual values may influence group summaries and contrasts. Missing age, sex, cognitive-level, ASD-severity, and medication information prevents assessment of group comparability and confounding. The bounded relative-power outcome also requires evaluation of model fit, and the random-intercept model imposes a common participant-level covariance contribution across periods and channels. Residual diagnostics and sensitivity to alternative covariance assumptions have not yet been documented.

Artifact handling and upstream preprocessing remain incompletely documented. A verified pipeline should report retained duration, exclusions, signal units, filtering, spectral normalization, residual diagnostics, and sensitivity to alternative model or normalization assumptions. Future work should use larger characterized samples, documented behavioral outcomes, consistent resting-state conditions, reproducible HHSA outputs, and independent validation where relevant.

VI. Conclusion

HHSA provided descriptive representations of carrier and modulation frequencies in parietal EEG before and after a visual attention task. Visual peak differences alone do not demonstrate adaptive reorganization, neural flexibility, or physiological recovery. In the complementary relative-theta analysis, the between-group difference in pre-to-post change at P4 reached the Holm-adjusted threshold, whereas the P3 contrast was not significant. However, the group-by-period-by-channel interaction was not significant, and the small sample and methodological limitations warrant cautious interpretation. These findings remain preliminary and exploratory. Larger independent studies with reproducible HHSA outcomes and fuller participant characterization are required before theta modulation can be proposed as a functional marker.

Abstract*—Deep learning-based speech enhancement has emerged as an alternative to classical noise reduction techniques, particularly in non-stationary acoustic scenarios. This study proposes a supervised approach based on a one-dimensional U-Net architecture, applied directly to the raw waveform, aimed at attenuating impulsive noise in speech signals. To prevent information leakage across experimental subsets, the LibriSpeech corpus was partitioned by speaker prior to segmentation, yielding 176 speakers for training, 38 for validation, and 37 for testing, with no overlap between groups. From this partitioning, 16,000 four-second segments were generated at a 16 kHz sampling rate—12,000 for training, 2,000 for validation, and 2,000 for final evaluation.Eighteen independent recordings of impulsive noise from door knocks and impacts, released under a Creative Commons Zero license, were distributed independently across the training, validation, and test subsets. Noisy signals were synthesized under four controlled input signal-to-noise ratio conditions (-5, 0, 5, and 10 dB), and model performance was assessed using four metrics: SNR, Scale-Invariant Signal-to-Distortion Ratio (SI-SDR), Short-Time Objective Intelligibility (STOI), and Perceptual Evaluation of Speech Quality (PESQ).On the independent test set of 2,000 samples, the average SNR improvement reached 3.21 dB, with a positive gain observed in 99.9% of the evaluated samples. SI-SDR increased by an average of 3.00 dB. STOI and PESQ, in turn, showed average variations of 0.0076 and 0.0394, respectively—values indicating comparatively modest effects on intelligibility and perceptual quality relative to the energy-based gains. These findings suggest that, although the U-Net effectively reduced impulsive noise energy under the tested conditions, the corresponding perceptual gains were considerably more limited. This work constitutes a preliminary step toward a broader research effort, which is expected to include perceptual evaluation and testing with individuals diagnosed with Central Auditory Processing Disorder.

Keywords: speech enhancement; U-Net; deep learning; impulsive noise; SNR; SI-SDR; STOI; PESQ.

I. Introduction

Speech enhancement (SE) aims to recover signals degraded by environmental noise and acoustic distortions, with the goal of improving their quality and intelligibility. These techniques are applied in telecommunications systems, automatic speech recognition, hearing aids, and human-machine interfaces [1]–[3].

Traditionally, noise reduction relied on methods such as Wiener filtering, spectral subtraction, and least-squares estimation. However, these approaches have limitations when dealing with non-stationary noise and variable acoustic conditions. With advances in deep learning, neural networks have begun to deliver superior results in speech enhancement tasks, operating in the time domain, the frequency domain, or in time-frequency representationsa [1], [4].

Among the architectures employed are Convolutional Neural Networks, Recurrent Neural Networks, and encoder-decoder models. Subsequently, attention mechanisms, multistage structures, Transformers, and diffusion models were incorporated to improve the representation of the temporal and spectral dependencies of the signals [1], [4]. Adversarial approaches, such as Generative Adversarial Networks (GANs), have also been used to generate signals with greater naturalness and perceptual quality [5].

In GANs, a generator produces enhanced signals, while a discriminator seeks to distinguish real samples from the

generated ones. Recent variants incorporate attention mechanisms and discriminative latent representations to improve speech reconstruction, especially under low signal-to-noise ratio conditions [3], [6]. However, these architectures require the simultaneous training of competing networks, thereby increasing computational complexity.

Encoder-decoder models with shortcut connections, such as U-Net and Wave-U-Net, offer a simpler alternative, as they preserve relevant temporal information and require fewer components to be optimized simultaneously [7], [8]. In light of this, this study proposes a one-dimensional U-Net architecture, trained in a supervised manner directly in the time domain, to evaluate its ability to reduce impulsive noise in speech signals.

The motivation for this study stems from the difficulties faced by people with Central Auditory Processing Disorder (CAPD), a condition that can impair speech comprehension, especially in the presence of competing or degraded acoustic stimuli. Everyday noises, such as computer keyboards, barking, the movement of objects, and background speech, can compete with the target voice and impair the identification and comprehension of the spoken message. This effect is particularly relevant in educational and professional settings, where background noise can impair speech perception, auditory attention, and the ability to follow instructions [9]–[11].

In this context, this study constitutes a preliminary stage of an investigation focused on individuals with CP. In this first stage, we develop and objectively evaluate a system for reducing impulsive noise in speech signals. Subsequently, we intend to evaluate the impact of this processing on speech intelligibility and comprehension by people with CP, as well as to investigate the incorporation of a discriminator for comparison with an equivalent adversarial architecture

II. Materials and Methods

This study proposes the development of a deep learning-based speech enhancement system using a one-dimensional U-Net architecture applied directly to audio signals in the time domain. The choice of this approach was motivated by recent studies demonstrating the feasibility of encoder-decoder models with skip connections for noise reduction and speech enhancement tasks, especially when applied directly to the signal's waveform [7], [12].

A. Base de Dados

The database for this study was constructed from clean speech signals extracted from the LibriSpeech corpus, a widely used reference in speech processing and automatic speech recognition research. Derived from public-domain audiobooks, the corpus organizes its signals by speaker, chapter, and reading segment—a structure that allows for controlling the identity of the individuals present in each experimental subset. All files are available in a single channel, with a sampling rate of 16 kHz [13].

The *train-clean-100* subset was selected, containing approximately 100 hours of speech, in which 251 distinct speakers were identified. The recordings of these speakers formed the basis for the training, validation, and test datasets used in this study.

Data partitioning was performed at the speaker level, prior to any signal segmentation, ensuring independence among the subsets. A fixed pseudorandom seed (42) was adopted to ensure the reproducibility of the procedure. The 251 speakers were distributed into three mutually exclusive groups: 176 for training, 38 for validation, and 37 for testing, corresponding to approximately 70.1%, 15.1%, and 14.7% of the total, respectively.

Once this division was complete, the speaker identifiers were automatically verified, confirming the absence of overlap among the three sets. The purpose of this step was to ensure that the model was evaluated exclusively with voices not used during training.

In terms of files, the training set comprised 20.001 recordings, corresponding to approximately 70.37 hours of speech. The validation set totaled 4.400 files, amounting to about 15.52 hours, while the test set comprised 4,138 files, equivalent to approximately 14.70 hours. In all cases, the original sampling rate of 16 kHz was maintained.

The recordings were then segmented into fixed 4-second windows, each containing 64.000 samples. This standardization ensured a uniform time scale for the network inputs and enabled batch processing during training. This procedure yielded 16.000 clean speech segments, of which 12.000 were allocated for training, 2,000 for validation, and 2.000 for testing

Segments were selected based on a criterion of balance across speakers, ensuring that individuals with a larger number of recordings did not contribute disproportionately to the composition of the dataset. Thus, each speaker contributed approximately 68 to 69 segments to the training set, 52 to 53 to the validation set, and 54 to 55 to the test set.

Throughout all stages of processing—including segmentation, mixture generation, and neural network processing—the signals remained in a single channel at their original frequency of 16 kHz. Thus, each input provided to the model was represented by 64.000 time points.

Noisy signals were generated independently for each subset. Each set received only the noise sources previously reserved for its respective experimental stage, preserving the separation both between speakers and between noise recordings.

Ultimately, the dataset used in the study consisted of 16.000 clean–noisy signal pairs, distributed among training, validation, and testing without any overlap between speakers or noise sources. This organization allows for a more reliable assessment of the model's generalization ability when faced with voices and impulsive events not observed during training.

B. Impulsive Noise Dataset

o construct the degraded signals, 18 independent recordings of impulsive noise were used, including knocks, impacts, and events associated with doors, obtained from the Freesound repository under a Creative Commons Zero (CC0) license. The use of multiple recordings was intended to introduce variability

in aspects such as intensity, duration, spectral content, and temporal distribution of the events. Impulsive noises generally exhibit non-stationary behavior, characterized by abrupt variations in energy over short intervals, which poses particular challenges for speech enhancement systems [14].

These recordings were previously divided into three mutually exclusive groups, corresponding to the training, validation, and test sets. Six noise sources were reserved for each stage, with no file sharing between the subsets. Thus, the final evaluation was performed using impulse events derived from recordings that were completely unobserved during model training. Before generating the mixtures, all noise material was standardized to a single channel and a sampling rate of 16 kHz, ensuring compatibility with the speech signals used in this study. The original recordings were kept separately, while only their standardized versions were used in the experimental stages.

When constructing the noise windows, care was taken to ensure that each segment contained at least one impulsive event. For recordings lasting four seconds or less, the signal was inserted in its entirety into a four-second window, with variable temporal positioning. For recordings longer than this interval, regions of interest were identified based on the signal's energy envelope, and four-second windows centered on the detected events were then extracted

During the construction of the noise windows, care was taken to ensure that each segment contained at least one impulsive event. For recordings with a duration equal to or shorter than four seconds, the signal was inserted in its entirety into a four-second window, with variable temporal positioning. For recordings longer than this interval, regions of interest were identified based on the signal energy envelope, and four-second windows centered on the detected events were then extracted.

After removing duplicate excerpts and confirming the presence of at least one impulsive event in each segment, 58 distinct noise windows were obtained. Of these, 30 were assigned to the training set, 7 to the validation set, and 21 to the test set.

The use of independent noise sources across the three subsets, combined with the requirement that all segments contain impulsive events, was adopted to reduce the possibility of memorizing specific characteristics of the recordings. This strategy also enables a more rigorous assessment of the model's ability to generalize to previously unseen impulsive events belonging to the same acoustic class.

To ensure the traceability and reproducibility of the experimental dataset, the 18 impulsive-noise recordings used in this study were made available in the public repository associated with this work. The files were preserved with identifiers that allow them to be linked to their respective source recordings on Freesound. The repository also presents the distribution of the noise sources among the training, validation, and test subsets, preserving a record of the recordings effectively used in the experiments. The files can be accessed at GitHub.

C. Generation of Noisy Signals

Each noisy signal was obtained by combining a clean speech segment with an impulsive-noise window belonging to the same experimental subset. Thus, signals assigned to the training set were combined exclusively with noise recordings reserved for training, and the same procedure was adopted for the validation and test sets, with no crossover between the sources used at different stages. This organization preserved the independence among the subsets during the mixture-generation process as well.

The signals were combined directly in the time domain. For each clean speech segment $x(n)$, an impulsive-noise window $r(n)$ was selected, both with a duration of four seconds and a sampling rate of 16 kHz. Before summing the signals, the noise amplitude was adjusted to produce a predefined input signal-to-noise ratio. This control was performed based on the RMS (*Root Mean Square*) values of the speech and noise signals, according to the conventional SNR formulation commonly employed in speech processing and enhancement [15].

Four input SNR conditions were considered: -5, 0, 5, and 10 dB.

These levels represent different degrees of acoustic degradation. At -5 dB, the energy contribution of the noise is greater than that of the speech signal, representing the highest-interference condition among those evaluated. As the SNR increases to 0, 5, and 10 dB, the relative contribution of the noise to the mixture is progressively reduced.

The four conditions were evenly distributed across all experimental subsets. In the training set, composed of 12,000 segments, 3,000 mixtures were generated for each SNR level. In the validation and test sets, each containing 2,000 segments, 500 mixtures were generated per condition. Thus, all degradation levels remained equally represented both during model training and in the final evaluation.

The relationship between speech and noise was controlled based on the RMS value of each signal. For a discrete signal $x(n)$, composed of N samples, the RMS is defined as

$$\mathrm{RMS}(x) = \sqrt{\frac{1}{N}\sum_{n=1}^{N} x^2(n)}.$$

Considering the clean speech signal $x(n)$ and the already scaled noise $r_s(n)$, the signal-to-noise ratio in decibels is expressed as

$$\mathrm{SNR}_{\mathrm{dB}} = 20\log_{10}\left(\frac{\mathrm{RMS}(x)}{\mathrm{RMS}(r_s)}\right).$$

Based on the previously established target SNR, the desired RMS value of the noise is determined by

$$\mathrm{RMS}_{r,\mathrm{desejado}} = \frac{\mathrm{RMS}(x)}{10^{\mathrm{SNR}_{\mathrm{alvo}}/20}}.$$

Next, the scaling factor α required to adjust the amplitude of the original noise window is calculated as

$$\alpha = \frac{\mathrm{RMS}_{r,\mathrm{desejado}}}{\mathrm{RMS}(r)}.$$

The scaled noise is then obtained as $r_s(n) = \alpha r(n)$, while the final noisy signal is produced by the sum $y(n) = x(n) + r_s(n)$.

This procedure allows direct control of the relationship between the RMS amplitudes of the speech and noise signals in each segment, reproducing the four SNR conditions established for the experiment.

After generating each mixture, the maximum absolute amplitude value of the signal was checked. Whenever this value exceeded 0.99, the same gain factor was applied to the clean signal, the scaled noise, and the corresponding mixture. Since all three signals were multiplied by the same factor, digital clipping was avoided without modifying the relative relationship between speech and noise and, consequently, without altering the previously defined SNR.

Once the mixtures had been generated, an automatic audit of the dataset was performed. The number of pairs produced in each subset, the distribution of the four SNR levels, the correspondence between clean and noisy signals, the presence of non-numeric or infinite values, possible clipping occurrences, and the difference between the target SNR and the SNR effectively obtained in each mixture were verified.

The audit confirmed the generation of the expected 16,000 pairs, with 12,000 assigned to the training set, 2,000 to the validation set, and 2,000 to the test set, all with a balanced distribution across the four SNR levels. The mean absolute error between the target SNR and the obtained SNR was practically zero, while the maximum error remained on the order of 3×10^{-6} dB. No *NaN* (*Not a Number*) values, infinite values, or remaining clipping cases were identified in the final signals.

In 4,757 of the 16,000 generated pairs, the application of the common gain factor was required for amplitude control. Because this adjustment was applied equally to the clean signal, the scaled noise, and the corresponding mixture, the SNR established for each segment was preserved.

Finally, a detailed record of each mixture was maintained, including the segment identifier, experimental subset, noise source and noise window used, target SNR, effectively obtained SNR, scaling factor applied to the noise, and any gain factor used for amplitude control. This record ensures sample traceability and the reproducibility of the dataset generation process.

D. Signal Preprocessing

Each pair of clean and noisy speech signals maintained temporal alignment, a single channel, a sampling rate of 16 kHz, and a fixed duration of 4 seconds, corresponding to 64,000 samples per segment.

The U-Net received the noisy signal $y(n)$ as input, while the clean signal $x(n)$ was used as the supervised reference. Before being provided to the network, the segments were arranged with dimensions of $64{,}000 \times 1$, corresponding to the temporal axis and the single audio channel.

Both training and inference were performed directly in the time domain, without prior conversion to spectral representations. This approach is consistent with Wave-U-Net-type architectures, which apply one-dimensional convolutions directly to the signal waveform [7], [8].

Throughout the entire processing pipeline, the three subsets remained strictly separated. The 12,000 training pairs were used to update the network parameters, while the 2,000 validation pairs were used to monitor performance during training and guide model selection. The 2,000 test pairs, in turn, were reserved exclusively for the final evaluation.

E. Neural Network Architecture

The adopted architecture was based on a one-dimensional U-Net, composed of four encoding levels, an intermediate region (*bottleneck*), and four symmetric decoding levels. Architectures of this type have been employed in speech enhancement tasks because they enable the combination of representations obtained at different temporal resolutions through skip connections (*skip connections*) [7], [8].

In the encoding path, the four levels used 16, 32, 64, and 128 convolutional filters, respectively, while the *bottleneck* consisted of 256 filters. Each convolutional block contained two one-dimensional convolutional layers with a kernel size of 15 and *same* padding, followed by batch normalization (*batch normalization*) and a *Leaky ReLU* activation function.

Throughout the encoder, the temporal resolution was progressively reduced using *max pooling* layers with a factor of 2. In the decoding path, this dimension was gradually restored through upsampling (*upsampling*) operations, also with a factor of 2. The skip connections concatenated the representations produced at each encoder level with the corresponding decoder layers, favoring the preservation of temporal information during signal reconstruction.

The output layer consisted of a one-dimensional convolution with a kernel size of 1, a single filter, and a hyperbolic tangent (*tanh*) activation function, responsible for generating the enhanced speech signal from the noisy input. In total, the architecture contained 3,275,457 parameters, of which 3,272,513 were trainable and 2,944 were non-trainable.

F. Model Training

The model was trained in a supervised manner, using the noisy signal as the network input and the corresponding clean signal as the reference. The Adam optimizer was employed for parameter optimization, with an initial learning rate of 10^{-4}.

As the loss function, a combination of Mean Absolute Error (MAE) and Mean Squared Error (MSE) was adopted, defined as

$$\mathcal{L} = \mathrm{MAE} + 0.5\,\mathrm{MSE}.$$

This combination was used to simultaneously account for the absolute deviations between the estimated signal and the clean reference signal while assigning a greater penalty to errors of larger magnitude.

Training was conducted with a batch size of 4 and a maximum limit of 50 epochs. During this process, three control mechanisms were employed. *ReduceLROnPlateau* was used to reduce the learning rate when the validation loss stopped

improving; *Early Stopping* allowed training to be interrupted in the absence of further progress on the validation set; and *Model Checkpoint* was used to preserve the weights associated with the best validation performance.

The 12,000 pairs belonging to the training set were used to update the network parameters, whereas the 2,000 validation pairs were used to monitor performance during training and guide model selection. The 2,000 pairs belonging to the test set remained isolated throughout this entire process and were used only during the final evaluation stage.

Training was stopped at epoch 20 according to the early-stopping criterion. At the end of the process, the weights corresponding to epoch 8, at which the best performance on the validation set was obtained, were restored.

The entire experiment was implemented in Python using TensorFlow 2.21 in a WSL 2 environment, with acceleration provided by an NVIDIA GeForce RTX 3050 Laptop GPU with 6 GB of memory.

G. Performance Evaluation

The final evaluation was performed on the 2,000 samples belonging to the test set, which were kept separate throughout all training and validation stages. To analyze the model performance, four complementary metrics were used: *Signal-to-Noise Ratio* (SNR), *Scale-Invariant Signal-to-Distortion Ratio* (SI-SDR), *Short-Time Objective Intelligibility* (STOI), and *Perceptual Evaluation of Speech Quality* (PESQ).

SNR was employed to quantify the relationship between the energy of the clean reference signal and the energy of the residual error. Considering a reference signal $x(n)$ and an evaluated signal $y(n)$, the metric was calculated as

$$\mathrm{SNR} = 10 \log_{10} \left(\frac{\sum_{n=1}^{N} x^2(n)}{\sum_{n=1}^{N} [x(n) - y(n)]^2} \right).$$

The metric was calculated before and after processing by the U-Net, with the improvement defined as $\Delta\mathrm{SNR} = \mathrm{SNR}_{\mathrm{after}} - \mathrm{SNR}_{\mathrm{before}}$. Positive values of ΔSNR indicate a reduction in the residual error relative to the clean reference signal [15].

SI-SDR was used as a complementary measure of distortion between the estimated signal and the reference signal. Unlike metrics that are directly sensitive to absolute amplitude, SI-SDR compensates for global scale differences between the signals, allowing a more specific assessment of the distortion introduced during processing. This characteristic makes the metric particularly suitable for signal separation and enhancement tasks [16].

To estimate objective speech intelligibility, STOI was employed, which compares short-time temporal characteristics between the processed signal and its corresponding clean reference. The metric typically produces values ranging from 0 to 1, with values closer to 1 associated with higher estimated intelligibility [17].

Finally, PESQ was used as an objective measure of perceptual quality. This metric compares the processed signal with the clean reference signal using a perceptual model developed to represent aspects related to human perception of speech quality, with higher values associated with better perceived quality [18].

All four metrics were calculated before and after U-Net processing. In addition to the overall analysis of the 2,000 samples in the test set, the results were also evaluated separately for each input SNR condition, corresponding to -5, 0, 5, and 10 dB. This analysis made it possible to observe the model behavior under different levels of acoustic degradation.

III. Results

Training was stopped at epoch 20 according to the *Early Stopping* criterion. The best performance on the validation set was achieved at epoch 8, whose weights were restored for the final evaluation. As shown in Fig. 1, the training loss decreased continuously, whereas the validation loss remained relatively stable after the first epochs, indicating stabilization of the model performance on the validation set.

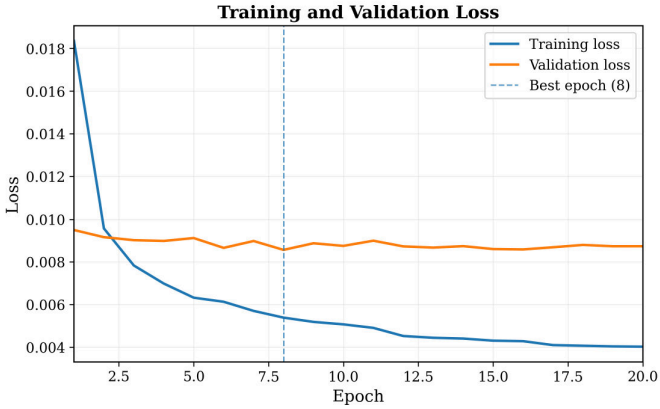

Fig. 1. Evolution of the loss function on the training and validation sets during U-Net optimization. The dashed line indicates the epoch with the best performance on the validation set.

A. Overall Performance on the Test Set

The final evaluation was performed on all 2,000 samples in the test set, with no observations excluded. Overall, the U-Net showed improvements across all four evaluated metrics. The mean gain was 3.21 dB in SNR and 3.00 dB in SI-SDR, whereas STOI and PESQ showed more modest mean variations of 0.0076 and 0.0394, respectively. In addition, 99.9% of the samples exhibited $\Delta\mathrm{SNR} > 0$. The mean values before and after processing are presented in TableI.

Tabela I
Overall performance on the test set.

Metric	Noisy	Enhanced	Change
SNR (dB)	2.500	5.713	+3.213
SI-SDR (dB)	2.092	5.094	+3.003
STOI	0.8580	0.8655	+0.0076
PESQ	1.6581	1.6975	+0.0394

The largest gains were observed for the SNR and SI-SDR metrics, whereas STOI and PESQ showed improvements of smaller magnitude.

B. Performance as a Function of Input SNR

When the 2.000 test samples were stratified according to the input SNR condition, with 500 samples at each level, the highest mean SNR gains were observed at 0 dB and -5 dB, with improvements of 3.53 dB and 3.49 dB, respectively. This was followed by a mean gain of 3.17 dB for the 5 dB condition and, finally, 2.66 dB at 10 dB, corresponding to the smallest improvement among the four evaluated conditions.

SI-SDR showed a similar trend, with mean gains ranging from 2.58 to 3.30 dB. STOI and PESQ also exhibited positive mean variations across all four conditions, although with smaller magnitudes. Regarding the proportion of samples with $\Delta\text{SNR} > 0$, the model achieved 100% in the -5, 0, and 5 dB conditions, with a slight reduction to 99.6% at 10 dB. Table II details these results according to the input condition.

Tabela II
U-NET PERFORMANCE AS A FUNCTION OF INPUT SNR.

SNR	n	ΔSNR	95% CI	ΔSI-SDR	ΔSTOI	ΔPESQ
-5 dB	500	3.490	[3.283; 3.697]	3.091	0.0075	0.0330
0 dB	500	3.530	[3.334; 3.727]	3.295	0.0091	0.0526
5 dB	500	3.173	[3.002; 3.344]	3.043	0.0093	0.0571
10 dB	500	2.661	[2.505; 2.816]	2.583	0.0044	0.0147

A progressive reduction in the mean SNR gain can be observed under less degraded input conditions, with the smallest relative benefit occurring at 10 dB.

C. Distribution of SNR Improvement

Fig. 2 illustrates the distribution of ΔSNR across the four evaluated input conditions. In all cases, most samples showed a positive gain after processing by the U-Net. In the -5, 0, and 5 dB conditions, the distributions remained entirely above zero, whereas at 10 dB only a small fraction of negative results was observed. In addition, a trend toward lower central values of ΔSNR can be noted as the input SNR increases, suggesting that the relative gain provided by the model is smaller under conditions in which the signal already presents a lower level of degradation.

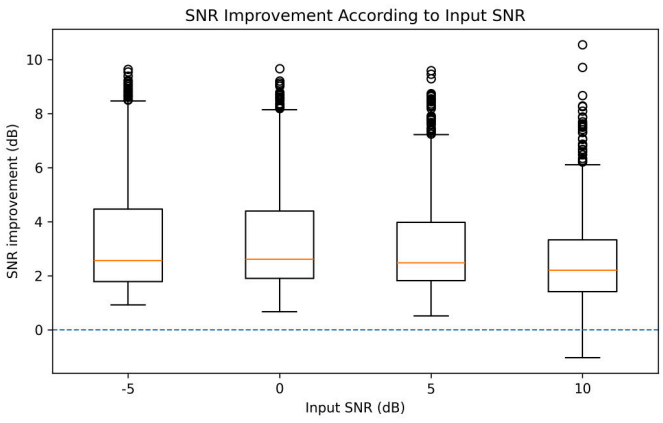

Fig. 2. Distribution of SNR improvement (ΔSNR) under the input conditions of -5, 0, 5, and 10 dB. Each group contains 500 samples from the test set. The dashed horizontal line indicates $\Delta\text{SNR} = 0$, corresponding to the absence of variation after processing.

D. Magnitude of the Observed Effects

The paired analysis between the signals before and after processing indicated large effects for SNR and SI-SDR, with Cohen's d_z values of 1.51 and 1.38, respectively. For STOI, a moderate effect was observed ($d_z = 0.58$), whereas PESQ showed a small effect ($d_z = 0.18$).

For the inferential analysis, paired tests were applied to the values obtained before and after processing, using the paired t-test and, complementarily, the Wilcoxon signed-rank test. The overall differences were statistically significant for all four metrics ($p < 0.001$). However, under the 10 dB input condition, the variation in PESQ did not show statistically significant evidence according to the Wilcoxon test ($p = 0.779$).

These results indicate that the most pronounced changes occurred in SNR and SI-SDR, whereas the effects on STOI and, particularly, PESQ were of smaller magnitude.

E. Qualitative Analysis of the Signals

Additionally, a qualitative analysis was carried out by contrasting the clean reference signal, the noisy input signal, and the corresponding U-Net output. Fig. 3 presents the spectrograms of the three signals for sample `test_001863`, all represented using the same magnitude scale to facilitate visual comparison. It can be observed that the network output preserves a large part of the spectrotemporal structure of the speech signal while attenuating the components associated with impulsive interference.

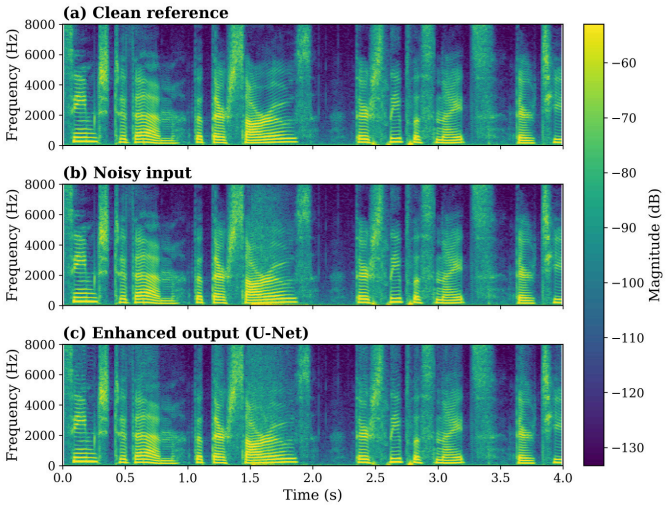

Fig. 3. Spectrogram comparison for sample `test_001863`: (a) clean reference signal, (b) noisy input signal, and (c) signal enhanced by the U-Net. All three spectrograms use the same magnitude scale to allow direct comparison.

Fig. 4 presents the corresponding comparison in the time domain. Panel (a) shows the complete signals over the four-second interval, whereas panel (b) presents a magnified region to facilitate visualization of local differences among the three waveforms. In the enlarged interval, the noisy signal exhibits local deviations from the clean reference, while the U-Net output follows the reference waveform more closely in several regions.

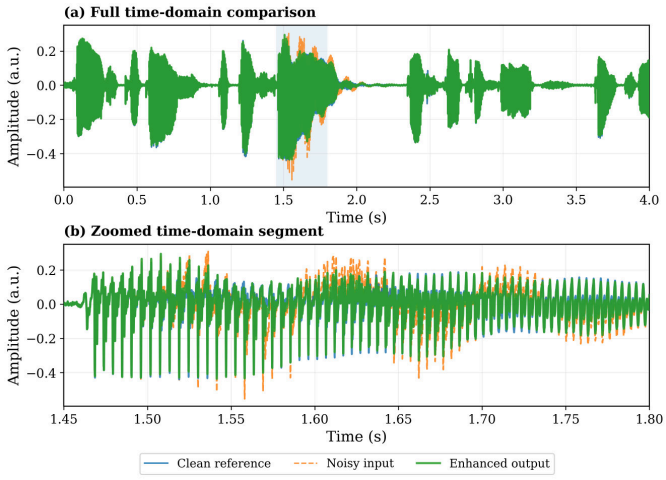

Fig. 4. Time-domain comparison for sample `test_001863`. (a) Complete signals over the 4-s segment, with the selected region highlighted. (b) Enlarged view of the highlighted interval, showing the clean signal, the noisy signal, and the output enhanced by the U-Net.

These figures are illustrative and qualitative in nature, whereas the conclusions regarding model performance are based on the aggregate analysis of the 2.000 samples in the test set.

F. Audio Example

To complement the quantitative evaluation and visual analysis, audio examples containing the clean reference signal, the noisy input signal, and the output produced by the U-Net were made available. To facilitate the auditory perception of the impulsive interference and its attenuation after processing, a sample from the test set with an input SNR of -5 dB and positive performance across the evaluated metrics was selected. The audio files are available in the public repository associated with this work, as presented in Table III.

Tabela III
AUDIO EXAMPLE AVAILABLE IN THE PUBLIC REPOSITORY ASSOCIATED WITH THIS WORK.

Signal	**Link**
Clean reference	Listen to audio
Noisy	Listen to audio
Enhanced by the U-Net	Listen to audio

IV. Discussion and Limitations

Taken together, the results indicate a consistent reduction in the error present in signals degraded by impulsive noise through the use of the one-dimensional U-Net. The mean improvements of 3.21 dB in SNR and 3.00 dB in SI-SDR, together with a positive SNR gain in 99.9% of the 2,000 test samples, demonstrate stable model performance under the evaluated conditions. Notably, the largest gains occurred under the most adverse conditions, -5 and 0 dB, whereas at 10 dB the mean benefit was more modest, suggesting a smaller margin for improvement when the input signal already presents a lower relative noise level.

Although STOI and PESQ also showed mean improvements, their variations were of smaller magnitude. Consistently, the effect size was large for SNR and SI-SDR, moderate for STOI, and small for PESQ, indicating that a reduction in error energy does not necessarily imply a proportional gain in intelligibility or objective perceptual quality. The 10 dB condition illustrates this behavior, since the variation in PESQ was not statistically significant in this case, reinforcing the importance of interpreting the metrics jointly.

From a methodological perspective, the organization of the experimental dataset, with speakers and noise sources kept independent across the training, validation, and test sets, together with the use of four controlled SNR conditions and the requirement that each contaminated signal contain at least one impulsive event, contributed to a more rigorous assessment of the network's generalization capability within the proposed scenario.

Despite the results obtained, some limitations should be considered. The scope of the study was restricted to impulsive noises associated with knocks, impacts, and door-related events, which prevents direct extrapolation of the observed performance to continuous noise or other acoustic scenarios. In addition, the LibriSpeech corpus consists of recordings derived from audiobooks, a condition that does not represent the full variability found in real-world communication situations. It is also important to consider that STOI and PESQ are objective metrics and therefore do not replace perceptual evaluations conducted with human listeners.

Finally, the system has not yet been directly evaluated in individuals with Central Auditory Processing Disorder (CAPD). Therefore, the results presented here exclusively reflect the objective performance of the method under the analyzed experimental conditions, and no clinical benefit or effective improvement in speech comprehension for individuals with CAPD can be inferred at this stage.

V. Conclusion

This study evaluated a one-dimensional U-Net applied to the enhancement of speech signals degraded by impulsive noise, while maintaining independent speakers and noise sources across the training, validation, and test sets. Across the 2,000 test samples, the model achieved mean gains of 3.21 dB in SNR and 3.00 dB in SI-SDR, with a positive SNR improvement in 99.9% of the cases. STOI and PESQ, on the other hand, although also presenting positive mean variations, showed considerably smaller gains, indicating that the error reduction observed through SNR and SI-SDR does not necessarily translate into a proportional perceptual improvement. Therefore, the results demonstrate the network's ability to attenuate impulsive noise under the evaluated experimental conditions, without, however, supporting claims of superiority over other architectures or allowing any anticipated clinical benefit to be inferred.

VI. Acknowledgments

The authors would like to express their gratitude for the guidance, availability, and fundamental contributions to the development of this work. They also thank their parents, who have always been present and supportive, especially Mr. Edvaldo Gomes and Mrs. Vera Lúcia, as well as their sisters, who have consistently provided affection and encouragement throughout this journey, especially Nayara Kellen. The authors also extend their thanks to their partners for their understanding, encouragement, and support during the different stages of this work.

The authors also acknowledge the Graduate Program in Biomedical Engineering at the University of Brasília (PPGEB/UnB) for its academic support and encouragement of research, as well as the Coordination for the Improvement of Higher Education Personnel (CAPES) for supporting academic training and scientific development.

Finally, the authors thank both longtime and new friends who were present throughout this journey, offering support, motivation, and words of encouragement during the most challenging moments.

In summary, the preparation of this article included the use of generative artificial intelligence tools for formatting-related tasks, including the organization of equations in LaTeX, the structuring of bibliographic entries in the `bibitem` format, and the positioning of figures within the text. The technical content, results, analyses, and conclusions are entirely the responsibility of the authors.

Abstract*—Panoramic dental radiography is the most common supplementary imaging exam in dental practice, yet automated detection systems for it require annotated training data that is scarce and expensive to obtain. Zero-shot vision-language models offer an annotation-free path, but how accurately they localize pathologies on domain-specific images is not well characterized. This work compares Grounding DINO, a widely used open-vocabulary object detector, against a YOLOv11m model fine-tuned on 474 of the 678 annotated disease images from the DentexChallenge 2023 public dataset (950 after augmentation), targeting three pathologies: Caries, Periapical lesion, and Impacted tooth. On the DentexChallenge test split ($n = 103$), Grounding DINO achieved mAP@50 = 0.00 for all three classes across a range of prompt formulations, model sizes, and IoU thresholds down to 0.10, while the fine-tuned YOLOv11m reached mAP@50 = 0.557 (mAP@50:95 = 0.361), with Impacted tooth at 0.931 and Caries at 0.551. A three-stage pipeline was then applied to 50 externally sourced OPGs: YOLOv11 detection (466 total detections, mean 9.3 per image), spontaneous recall evaluation against dentist-written clinical descriptions (mean SR = 89.7% across 34 evaluable images), and LLM-based structured pre-clinical report generation via Gemini 2.5 Flash (BERTScore F1 = 0.779 raw, -0.309 rescaled, on 50 reports). An input ablation isolating the contribution of the image versus the detection summary to report text found that neither input alone was clearly superior on text-similarity metrics, a result we attribute to the brevity of the reference descriptions rather than to the image being uninformative. The results show that the evaluated zero-shot detector (Grounding DINO Tiny) is insufficient for clinical OPG analysis at standard IoU thresholds, and that supervised fine-tuning on a small public dental dataset produces a usable detection baseline.

***Index Terms*—panoramic radiography, dental pathology detection, YOLOv11, Grounding DINO, zero-shot detection, transfer learning, DentexChallenge, automated report generation**

I. Introduction

Panoramic dental radiography (orthopantomography, OPG) produces a single wide-field exposure covering the entire dentition, mandible, maxilla, and surrounding structures. It is the standard first-line imaging request in dental clinical practice, used for screening caries, periapical lesions, bone loss, impacted teeth, retained roots, and orthodontic findings [1]. Systematic interpretation takes time and requires experience, and access to dental radiologists varies considerably across healthcare settings.

Automated detection systems based on convolutional neural networks and, more recently, transformer architectures have shown promising results on specific dental imaging tasks: Tuzoff et al. [2] applied Faster R-CNN to tooth detection and numbering in OPGs, Ekert et al. [3] used a U-Net for periapical lesion detection, and Alqhtani et al. [4] benchmarked multiple YOLO variants against 17 fine-grained dental anomalies, reporting mAP@50 between 0.54 and 0.78 depending on pathology. All these approaches depend on large, fully annotated bounding box datasets, which take considerable clinical expertise to produce.

A possible path around that bottleneck comes from vision-language models (VLMs) trained at internet scale. These models learn open-vocabulary visual representations that can be queried at inference time using text prompts, without any task-specific fine-tuning [5]. Grounding DINO [6], presented at ECCV 2024, extends the DINO transformer architecture with grounded pre-training and reported 52.5 AP on COCO zero-shot at publication. Deploying such a model directly on OPGs, prompted with disease names and without annotation effort, is an appealing idea.

This work tests whether that idea holds in practice. Specifically: at a standard IoU threshold of 0.5, does Grounding DINO detect Caries, Periapical lesion, and Impacted tooth at a useful level of precision? If not, what does supervised fine-tuning on the largest available public dental dataset achieve on the same task, and with what training resources?

Grounding DINO achieved mAP@50 = 0.00 on all three classes. YOLOv11m fine-tuned on 474 DentexChallenge training images (950 after augmentation) reached mAP@50 = 0.557 overall, with per-class results that reflect training data imbalance directly. A complete end-to-end pipeline then applied those detections to the 50 external OPGs and fed the output to a multimodal LLM to generate structured pre-clinical reports, evaluated against dentist-written reference descriptions using standard NLP metrics. Code and data splits are publicly available at https://github.com/ErnaneJ/orthopantomography.

II. Related Work

A. Supervised Dental Pathology Detection

Convolutional detectors applied to OPGs generally report mAP in the 0.50–0.80 range for well-represented classes. Alqhtani et al. [4] found that performance varies sharply by pathology, with visually distinctive findings such as impactions and large restorations outperforming subtle ones such as early caries and periodontal bone loss by 20–30 mAP points within the same model, a per-class pattern that also appears in our results. The DentexChallenge 2023 [7], [8], a MICCAI workshop challenge, provided a public benchmark with disease-level bounding box annotations across three pathology classes, used here as both training source and evaluation benchmark.

B. Zero-Shot and Open-Vocabulary Detection

Grounding DINO [6] uses a Swin Transformer image encoder paired with a BERT-based text encoder, fused through a feature enhancer, to produce open-vocabulary bounding box predictions from text prompts. Prior work applying CLIP [5] to zero-shot classification in medical imaging found that general-purpose vision-language representations transfer to clinical domains for coarse classification, but noted performance gaps relative to supervised models [9]; localization at IoU ≥ 0.5 is substantially harder than classification, and our experiments confirm a larger gap here.

C. Automated Radiology Report Generation

Large multimodal language models have been applied to chest radiograph reporting [10], with evaluation using BLEU [11], ROUGE-L [12], and BERTScore [13]. BERTScore F1, computed from contextual token embeddings, correlates more reliably with human quality ratings than n-gram metrics when reference and hypothesis texts differ substantially in length and style [13]. That is the case in our Stage 3 evaluation. Dasanayaka et al. [14] applied a multimodal LLM to OPG report generation and question answering; the 50 externally sourced OPGs evaluated in our Stage 3 (Section III-A) are drawn from the public Apache License 2.0 subset of their DPT Image and Caption Dataset [15]. Our task decomposition and evaluation protocol still differ from theirs (three separate stages of detection, recall, and report generation, evaluated against independently produced dentist descriptions, versus their single end-to-end captioning model evaluated against the dataset's original captions), so results are not directly comparable, even though the source imagery overlaps. Balel et al. [16] trained a detector on 30,954 panoramic radiographs, converted the output to structured JSON, and generated reports with several locally hosted and commercial LLMs evaluated by specialists; the commercial models tested, including a Gemini variant, hallucinated findings in every report reviewed. That result, at almost two orders of magnitude more training images than used here, cautions against treating LLM-generated dental reports as reliable without the specialist review step we identify as a limitation and future work below.

III. Materials and Methods

Fig. 1 summarizes the three-stage pipeline described in this section: YOLOv11 detection (Stage 1, Section III-B), spontaneous recall evaluation against dentist descriptions (Stage 2, Section III-C), and LLM-based report generation (Stage 3, Section III-D).

A. Datasets

DentexChallenge 2023 (training and evaluation). The DentexChallenge 2023 quadrant-enumeration-disease subset [7], [8] is the largest publicly available OPG dataset with instance-level disease annotations (CC0 license). The full release contains 1,154 images; of these, 678 contain at least one bounding box annotation for the four disease categories used here: Caries, Deep Caries (merged with Caries in preprocessing), Periapical Lesion, and Impacted tooth. The remaining images have only quadrant or tooth-enumeration labels and were excluded from training and evaluation. The class distribution is skewed: across the 678 annotated images there are 2,767 Caries instances, 604 Impacted tooth instances, and 158 Periapical lesion instances (3,529 total). Images were split 70/15/15 into train ($n = 474$), validation ($n = 101$), and test ($n = 103$) sets using stratified random sampling (seed = 42). Per-split instance counts (Caries / Periapical lesion / Impacted tooth) are 1,934 / 111 / 458 in train, 408 / 25 / 77 in validation, and 425 / 22 / 69 in test. Images containing Periapical lesion or Impacted tooth annotations in the training split received two additional augmented copies each (Section III-B), yielding 950 effective training images and per-class training totals of 3,942 / 333 / 1,374 after augmentation.

External OPG dataset (pipeline evaluation). Fifty panoramic radiograph images (JPEG format, mean resolution approximately 2976×1488 pixels) were drawn from the publicly released subset of the DPT Image and Caption Dataset accompanying Dasanayaka et al. [14], [15], made available under the Apache License 2.0. The original authors report obtaining ethical clearance and informed consent for this data from Teaching Hospital Peradeniya and the Postgraduate Institute of Science, University of Peradeniya (Sri Lanka), with personally identifiable information removed prior to release (see Ethical Statement). Independent written clinical descriptions for these 50 images were subsequently produced by a trained dentist, co-author Y. González Sánchez, at the Fundación Odontológica Social Luis Seiquer (Seville, Spain); thirteen of these additionally have an audio recording of the verbal report. These independently produced

descriptions, not the original dataset captions, serve as the reference text for the Stage 2 and Stage 3 evaluations below. Bounding box annotations are not available for this dataset; it was used exclusively for the Stage 2 recall and Stage 3 report generation evaluations.

B. Stage 1: Detection Model

Preprocessing and augmentation. Images were resized to 640×640 pixels using letterbox padding. Training augmentation included CLAHE (clip limit 3.0) for X-ray contrast normalization, horizontal flip ($p = 0.5$), random brightness and contrast perturbation (± 0.2, $p = 0.5$), Gaussian noise ($p = 0.3$), and affine transformations (scale 0.9–1.1, translate $\pm 5\%$, rotate ± 5, $p = 0.4$), implemented with Albumentations. Color augmentations (HSV hue and saturation) were disabled because OPGs are grayscale. Images containing Periapical lesion or Impacted tooth annotations received two additional augmented copies each, tripling their effective training frequency.

YOLOv11m fine-tuning. YOLOv11m (medium variant, approximately 20M parameters) was initialized from COCO-pretrained weights and fine-tuned on the DentexChallenge training split using the Ultralytics framework [17]. Hyperparameters: AdamW optimizer, initial learning rate 10^{-3}, linear decay to 1% over training, batch size 8, image size 640×640, up to 100 epochs with early stopping (patience = 20). Training ran on an Apple M5 MacBook Air (16 GB unified memory) using the Metal Performance Shaders backend. The model reached best validation mAP@50 = 0.547 at epoch 27 and stopped at epoch 41. Table I results (Section IV-A) follow the standard Ultralytics mAP evaluation protocol, which sweeps a low confidence threshold (≥ 0.001) to construct the full precision-recall curve; the operational threshold used for the qualitative Stage 1 output on the external OPGs (Section IV-B) and for the fixed-decision comparison against Grounding DINO in Fig. 2 is ≥ 0.25, which trades recall for precision at deployment time. These are two different, individually standard use cases for the same trained model and should not be read as inconsistent thresholds for the same number.

YOLOv11n comparison. A smaller YOLOv11n variant (nano, 2.62M parameters, 181 layers, 6.6 GFLOPs) was trained under the same protocol for 50 epochs, reaching best validation mAP@50 = 0.484 at epoch 32. The gap to YOLOv11m's 0.547 reflects the capacity difference between the two variants; YOLOv11m was used for all downstream pipeline stages, and YOLOv11n is reported here only as a lightweight-deployment reference point.

Grounding DINO zero-shot baseline. Grounding DINO Tiny (`IDEA-Research/grounding-dino-tiny`, Hugging Face Transformers) was evaluated on the same test split without fine-tuning. The three class names were used as text prompts. Detection thresholds: box confidence ≥ 0.25, text score ≥ 0.20. Predictions were matched to ground-truth boxes at IoU ≥ 0.5, consistent with COCO evaluation. Section V-A reports a broader ablation over prompt formulations, model size (Tiny vs. Base), and IoU threshold to test whether this single configuration understates the model's true performance.

C. Stage 2: Spontaneous Recall Evaluation

The 50 external OPGs were processed with the fine-tuned YOLOv11m. For each image, the corresponding dentist description was parsed to identify mentions of the three YOLO-trained classes through substring matching. The Spontaneous Recall (SR) score for image i is:

$$SR(i) = \frac{|\hat{C}(i) \cap C^*(i)|}{|C^*(i)|} \tag{1}$$

where $\hat{C}(i)$ is the set of classes detected by YOLOv11 and $C^*(i)$ is the set of classes mentioned in the dentist description, both restricted to the three trained classes. The detector processes each image with a fixed confidence threshold of 0.25 and receives no information from the reference text. Images for which no YOLO-trained class appeared in the description were excluded from SR statistics (16 images), leaving 34 evaluable images.

Mentions of $C^*(i)$ are extracted from the free-text description by substring matching against a keyword-to-class alias dictionary, written in English to match the dentist descriptions. The dictionary has 31 distinct alias keys mapping to 24 clinical classes; 8 keys affect the SR metric reported here: *caries* and *carious* $\rightarrow$ Caries; *periapical* $\rightarrow$ Periapical lesion; *impacted* and *impaction* $\rightarrow$ Impacted tooth. A manual audit of the 20 images initially excluded found three misspellings the original dictionary missed, *carie*, *careis*, and *imapcted*, all present verbatim in the dentist's free-text notes; these were added as additional aliases to Caries and Impacted tooth respectively, which is why the excluded count above is 16 rather than 20. The remaining 23 keys match disease and treatment terms outside the three-class detection scope and do not influence SR.

D. Stage 3: Automated Report Generation

Structured pre-clinical reports were generated for all 50 external OPGs using Gemini 2.5 Flash via the OpenRouter API. Each request contained: (1) the OPG image in base64 encoding, and (2) a summary of detections from Stage 1 (class, confidence, and spatial location for the top 15 detections). The reference clinical description was not included in the prompt. The model was instructed to produce a five-section structured report using FDI tooth notation and to report only findings visible in the image. All requests used the OpenRouter-routed `google/gemini-2.5-flash` alias, queried in June and August 2026; OpenRouter does not expose a fixed dated snapshot for this alias, so results reflect whichever backend revision Google had live at request time, a reproducibility constraint of API-hosted models that we did not control.

Generated reports were compared to dentist-written reference descriptions using BLEU-4 [11], ROUGE-L [12], and BERTScore F1 [13] with RoBERTa-large embeddings.

To isolate the contribution of each input modality, the same 50 cases were regenerated under two additional conditions

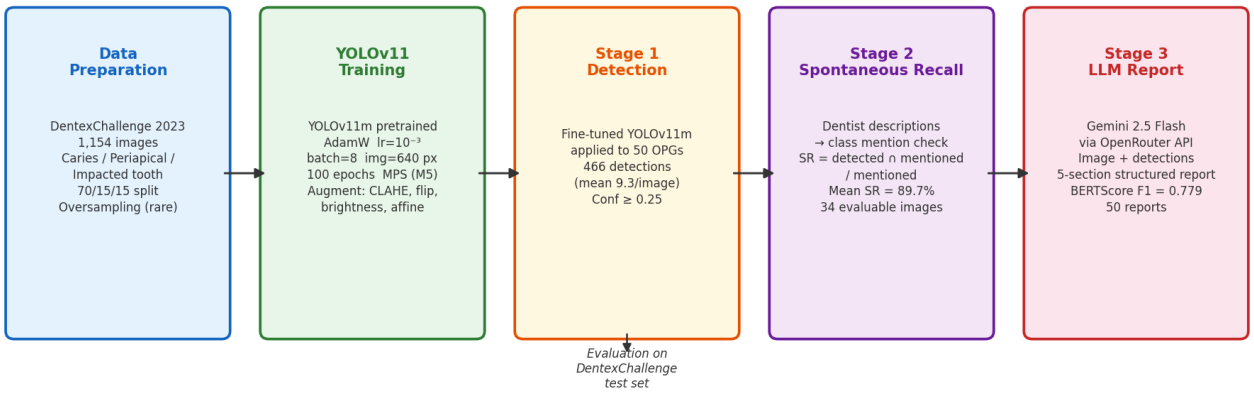

Fig. 1. Three-stage pipeline: YOLOv11 detection (Stage 1), spontaneous recall evaluation against dentist descriptions (Stage 2), and LLM-based report generation via Gemini 2.5 Flash (Stage 3).

with the LLM, prompt structure, and evaluation held fixed: *image-only* (the OPG image with no detection summary) and *detections-only* (the Stage 1 detection summary as text with no image). Results are reported below (Section IV-D) alongside the default *both* configuration described above.

IV. Results

A. Zero-Shot vs. Fine-Tuned Detection

Table I shows detection results on the DentexChallenge 2023 test split ($n = 103$ images), the only evaluation set with ground-truth bounding boxes.

TABLE I
DETECTION PERFORMANCE ON DENTEXCHALLENGE 2023 TEST SET (IOU = 0.5)

Model	Car.	Peri.	Imp.	mAP@50
GDINO-Tiny (zero-shot)	0.000	0.000	0.000	0.000
YOLOv11m (fine-tuned)	0.551	0.189	0.931	0.557

Car. = Caries; Peri. = Periapical; Imp. = Impacted. YOLOv11m evaluated at conf $\geq$ 0.001 (standard Ultralytics protocol, full PR curve); GDINO-Tiny at conf $\geq$ 0.25, text $\geq$ 0.20 (Section III-B). Per-class mAP@50:95, P/R, and bootstrap CI reported in text below.

Grounding DINO produced bounding box outputs when queried with the three class names, but none reached IoU $\geq$ 0.5 with any ground-truth box across the test split. The model generates text-anchored candidate regions that do not align closely enough with annotated pathology boundaries for clinical localization; Section V-A shows this holds across prompt formulations, model size, and looser IoU thresholds.

The fine-tuned YOLOv11m reached mAP@50 = 0.557 (bootstrap 95% CI [0.501, 0.645], Section IV; mAP@50:95 = 0.361), with Precision = 0.583 and Recall = 0.550 at the confidence ($\approx$0.30) that maximizes mean F1 across classes on the confidence sweep, not at the fixed conf $\geq$ 0.25 deployment threshold used elsewhere in this paper. Fig. 2 shows the per-class comparison. Per-class results track the training data distribution: Impacted tooth (AP@50 = 0.931) has a distinctive radiographic appearance and strong training coverage relative to its class size; Caries (AP@50 = 0.551) is the most prevalent pathology but also the most morphologically variable; Periapical lesion (AP@50 = 0.189) had only 158 annotated training instances.

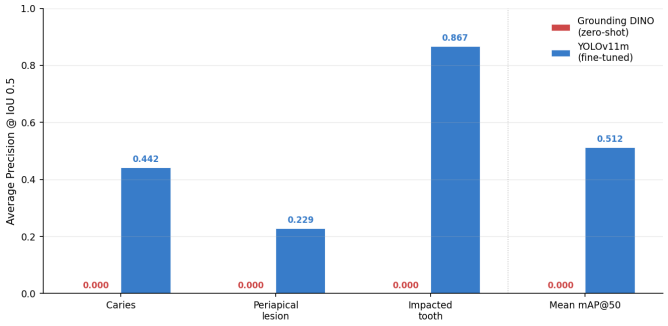

Fig. 2. Per-class AP@50 for Grounding DINO (zero-shot) and YOLOv11m (fine-tuned) on the DentexChallenge test set, both evaluated at the fixed conf $\geq$ 0.25 operational decision threshold with a custom 11-point AP implementation (Section III-B); distinct from the confidence-sweep values in Table I.

B. Detection on the External OPGs (Stage 1)

Applied to the 50 external OPGs, the fine-tuned YOLOv11m produced 466 total detections (mean 9.3 ± 3.2 per image, range 3–20). By class: Caries 387 (83.0%), Impacted tooth 59 (12.7%), Periapical lesion 20 (4.3%). This distribution is close to the class balance of the training data itself (78.4% Caries, 17.1% Impacted tooth, 4.5% Periapical lesion of 3,529 annotated instances, Section III-A), which is the more direct explanation than a general claim about prevalence in unrelated clinical populations; the low Periapical count also follows from the model's weaker AP for that class.

Fig. 3 shows a representative Stage 1 output on one of the external OPGs. Multiple Caries detections appear bilaterally in the posterior sectors, a single Impacted tooth is flagged

in the upper left third molar region, and a single Periapical lesion is flagged at low confidence (0.31) in an adjacent lower posterior region, consistent with that class's overall lower AP@50. The color scheme follows the application convention: red for disease-category findings (Caries, Periapical lesion) and green for tooth-status findings (Impacted tooth).

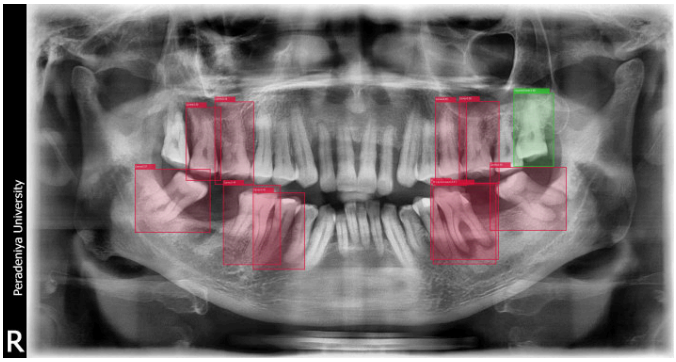

Fig. 3. Representative Stage 1 detection output on one of the external OPGs. Red bounding boxes indicate Caries and Periapical lesion detections (disease-category findings, bilateral posterior sectors); the green bounding box marks an Impacted tooth in the upper left third molar region. Confidence scores are displayed on each label; the Periapical lesion box has the lowest confidence (0.31), consistent with that class's overall lower AP@50.

C. Spontaneous Recall (Stage 2)

Of the 50 external OPGs, 34 had dentist descriptions mentioning at least one YOLO-trained class. Mean SR across those 34 images was 89.7% (SD = 29.2%; median = 1.000). Table II shows the distribution.

TABLE II
STAGE 2 SPONTANEOUS RECALL DISTRIBUTION ($n = 34$ EVALUABLE IMAGES)

SR band	n	%
SR = 0.0	3	8.8
$0 < \text{SR} < 0.5$	0	0.0
$0.5 \leq \text{SR} < 0.8$	1	2.9
$\text{SR} \geq 0.8$	30	88.2

Wilson 95% CI for SR $\geq$ 0.8: [73.4%, 95.3%].

Two of the three images with SR = 0.0 (Image_23, Image_25) mention only Impacted tooth as the testable class, and YOLOv11m returned no Impacted tooth detection for either despite that class's high aggregate AP@50 = 0.931 on DentexChallenge; the third (Image_48) mentions only Periapical lesion, consistent with that class's low AP@50 = 0.189. The first two cases show that a class's strong aggregate benchmark performance does not guarantee detection on every individual image. Given the small evaluable sample ($n = 34$), the Wilson 95% CI for the high-recall proportion is wide ([73.4%, 95.3%]); the point estimate of 88.2% should be read with that uncertainty in mind.

One case illustrates SR = 1.0 concretely: the dentist's description mentioned a vertically impacted lower right third molar (tooth 48, FDI notation), and the model detected an Impacted tooth in the same image. YOLOv11m also detected Caries in this image, but Caries was not among the classes the dentist mentioned and is therefore not evaluated by the SR metric for this image.

D. Report Generation Quality (Stage 3)

Gemini 2.5 Flash generated structured five-section preclinical reports for all 50 images without error (136,257 input tokens, 26,057 output tokens). Table III shows NLP metrics against dentist-written reference descriptions.

TABLE III
NLP EVALUATION OF GENERATED REPORTS VS. DENTIST REFERENCE DESCRIPTIONS ($n = 50$)

Metric	Mean	SD	Embeddings
BLEU-4	0.0010	0.0008	n-gram
ROUGE-L	0.0315	0.0177	n-gram
BERTScore F1 (raw)	0.7792	0.0129	RoBERTa-large
BERTScore F1 (rescaled)	-0.3085	0.0767	RoBERTa-large

Rescaled BERTScore [13] is normalized against a general-domain baseline distribution; negative values reflect that structured, domain-specific report pairs sit outside that baseline's typical range and are not by themselves evidence of poor semantic match (see text). Model: `roberta-large`, 17 layers, no IDF weighting (hash: `roberta-large_L17_no-idf_version=0.3.12(hug_trans=5.10.2)`).

Low BLEU-4 and ROUGE-L values are expected: generated reports average approximately 300 words across five structured sections while dentist references average approximately 45 words of free text, so exact n-gram overlap is low regardless of semantic accuracy. Raw BERTScore F1 = 0.779 alone would suggest substantial shared semantic content, but this needs a control: to test whether BERTScore discriminates a correct report from an incorrect one here, rather than saturating near a floor for any English text pair in this domain, we recomputed it with each report paired against a mismatched reference description (a fixed derangement of the 50 cases, seed = 42, so no case is paired with its own reference). The mismatched-pair mean was 0.7777 raw (-0.317 rescaled) against 0.7792 raw (-0.309 rescaled) for correctly matched pairs; the two distributions overlap almost completely (SD $\approx$ 0.013–0.014 raw for both), so neither raw nor rescaled BERTScore separates correct from randomly wrong pairings on this sample. This confirms, rather than merely anticipates, the concern raised about this metric: neither variant is evidence of clinical accuracy, or even of same-versus-different-image correctness, for these short technical texts. The concrete example below carries more evidentiary weight than the aggregate BERTScore number.

A concrete example illustrates this gap: for Image_00, the generated report identified impacted teeth 18 and 38 with correct angulation descriptions, listed multiple carious lesions in FDI notation with severity estimates, and recommended appropriate follow-up actions. The dentist's reference note for the same image read: "Grossly carious 48 and deep caries in 36 with pulp exposure. Septic root of 25." BLEU and ROUGE scores for this pair are near zero because the texts differ in structure and length; BERTScore F1 for this pair was 0.783

raw (-0.286 rescaled), reflecting that both texts describe the same pathological findings.

Table IV compares the default *both* configuration against the *image-only* and *detections-only* conditions described in Section III-D. Detections-only scored marginally higher than both other conditions on ROUGE-L and BERTScore F1 (raw and rescaled), while image-only scored lowest on every metric. BLEU-4 stayed near zero across all three and is not informative here for the reason given above. This pattern is discussed in Section V.

TABLE IV
INPUT ABLATION FOR STAGE 3 REPORT GENERATION ($n = 50$ PER CONDITION)

Condition	BLEU-4	ROUGE-L	BERT (raw)	BERT (resc.)
Image-only	0.0010	0.0304	0.7761	-0.3269
Detections-only	0.0015	0.0335	0.7956	-0.2113
Both (default)	0.0010	0.0315	0.7792	-0.3085

V. DISCUSSION

A. Localization Failure in Zero-Shot Detection

Grounding DINO is not blind to dental anatomy: when prompted with class names, it generates candidate boxes in plausible image regions. The failure is at localization precision, not semantic recognition. Standard mAP evaluation counts a detection as correct only if $\text{IoU}(\hat{b}, b^*) \geq 0.5$. For small lesions like periapical radiolucencies (typically a few millimeters in diameter at clinical scale), a box that roughly surrounds the affected region but is 30% too large fails this threshold entirely. Grounding DINO was trained to ground language to visual regions from natural image datasets, where objects are much larger and more salient than millimeter-scale dental pathologies. That spatial precision is simply not in what the model learned.

To test whether this failure is an artifact of prompt or model size, we ran the Tiny model under three prompt formulations (bare class names, descriptive phrases, full noun phrases) and added the Base model under the class-name prompt as a model-size check, each of these 4 prompt/model configurations evaluated at three IoU thresholds (0.50, 0.25, 0.10), for 12 conditions in total. mAP stayed at or near zero across all of them: the highest value observed at any condition, including IoU $\geq$ 0.10, was 0.015 (Tiny, class-name prompt, Periapical lesion); most conditions scored exactly 0.000 even at IoU $\geq$ 0.10, and Base scored no higher than 0.005 at any threshold, performing no better than Tiny. This rules out prompt engineering and model size as explanations: candidate regions do not consistently land inside the correct anatomical area at all, not merely outside the IoU $\geq$ 0.5 boundary.

We also tested whether the fixed box confidence threshold (0.25) was filtering out correctly located but low-confidence boxes, re-running the Tiny model with the class-name prompt at confidence thresholds 0.05, 0.10, 0.15, and 0.25, crossed with the same three IoU thresholds. At the loosest IoU ($\geq$ 0.10), lowering confidence from 0.25 to 0.05 nearly tripled mAP (0.015 $\rightarrow$ 0.041); at the clinically relevant IoU $\geq$ 0.5, mAP never exceeded 0.007 at any confidence tested. Confidence threshold matters only when the acceptance criterion already rewards approximately correct boxes; it does not rescue performance at the standard localization threshold, confirming the failure is in where boxes are placed, not how many are filtered before scoring.

In practice, this means that Grounding DINO, as evaluated here across both size variants and multiple prompt formulations, is not usable as a detection component in any pipeline that requires IoU-based localization on panoramic dental radiographs, even at thresholds well below the clinical standard. Whether other zero-shot or foundation detection architectures, or in-context/few-shot prompting strategies not tested here, would behave differently remains an open question. The result should be read as evidence against this specific family of models on this task, not as a general claim about zero-shot detection.

B. Transfer Learning from a Small Public Dataset

The mAP@50 = 0.557 from 474 training images (950 after augmentation) supports two conclusions. First, transfer from ImageNet/COCO pre-training generalizes to the X-ray domain at this dataset size when augmentation matches the modality (CLAHE, disabled color perturbation, oversampling of rare classes), consistent with recent evidence that YOLO-family transfer learning remains competitive with newer architectures on dental panoramic radiographs at small dataset scale [18]. Second, Impacted tooth at AP@50 = 0.931, a class among the most commonly missed findings in routine OPG review, is a promising starting point for computer-aided screening, pending clinical validation on larger and more diverse populations.

C. Spontaneous Recall as a Proxy Metric

The SR metric defined in (1) measures only whether the detector identifies at least one instance of each class the dentist mentioned: it does not measure spatial precision, does not penalize detections of classes not mentioned in the description (which may be genuine incidental findings or false positives), and does not validate bounding box accuracy. An image where the dentist wrote "caries present" and the detector produced ten spatially incorrect Caries boxes still scores SR = 1.0 for that class. SR is thus a class-level recall proxy, useful for characterizing pipeline behavior on the external OPGs where no bounding-box ground truth exists, but a necessary rather than sufficient condition for clinical utility; the high mean SR (89.7%) is consistent with the model's detection rates on DentexChallenge and should not be read as a clinical accuracy figure.

D. Periapical Lesion: A Data Problem

Periapical lesion AP@50 = 0.189, well below Caries (0.551) and Impacted tooth (0.931), follows partly from having only 111 annotated training instances (333 after augmentation), a third of the next-smallest class; periapical radiolucencies

are also small (2–10 mm), subtle in early stages, and easily confused with anatomical structures or noise, so some of the gap may reflect a harder visual task rather than data volume alone. This experiment cannot separate the two factors, since scaling annotated data while holding architecture fixed was not tested.

Asif and Khan [18] trained YOLO26l-seg on a Roboflow-processed DENTEX subset and reported mAP@50 = 0.591 across four disease classes, close to our 0.557 across three, but argue visual distinctiveness, not annotated volume, is the stronger per-class driver on this dataset. Our results do not settle this: Impacted tooth here has both the second-highest instance count and the most distinctive appearance, so volume and architecture are confounded in the same direction as in their setup. Separating them would require training on volume-matched subsets, which we did not do; we frame the data-volume account as a plausible partial explanation, not a demonstrated one.

Improving this class would require more training data, targeted augmentation, or semi-supervised learning from unlabeled OPGs, ideally evaluated against an architecture ablation to isolate how much of the gap is data-driven versus intrinsic to the detector.

E. Image and Detection Contributions to Report Text

Table IV shows that detections-only text matched the dentist's reference description at least as well as, and on ROUGE-L and BERTScore slightly better than, the full image-plus-detections configuration used elsewhere in this paper; image-only scored lowest on every metric. Taken at face value this could be misread as evidence that the image contributes nothing once a detection summary is available, but we attribute it to a property of the reference texts rather than the image: dentist reference descriptions average approximately 45 words and list only the findings judged clinically salient, so a report instructed to describe only the detection list stays closer in content and length to that short reference. The full *both* condition gives the model room to describe additional visually plausible findings (e.g., restorations or edentulous spaces) outside the three trained classes and outside what the reference mentions, which lowers overlap with a short reference without indicating a worse report.

This does not show that the image is unnecessary. It shows that BLEU-4, ROUGE-L, and BERTScore, which all score similarity to a short reference text, cannot by themselves settle whether visual grounding improves report quality, since a terser, more constrained output tends to score better against a terse reference regardless of clinical completeness. A more informative test would compare the three conditions against dentist judgment of completeness and correctness directly, i.e., the clinical review step identified as a limitation above. Practically, a text-only deployment tier, using the detection summary without re-transmitting the image to the LLM, is worth considering for cost and latency, provided a clinical reviewer confirms it does not omit visually apparent findings outside the detector's three classes.

F. Web Prototype

To assess compatibility with clinical workflows, a proof-of-concept web application was built on the three-stage pipeline: a FastAPI backend runs Stage 1 detection via YOLOv11m, calls Stage 3 Gemini 2.5 Flash, and stores the annotated image and report; a React frontend overlays detection boxes with a raw/annotated toggle, lists findings by class, displays the five-section report in tabbed form, and accepts voice input for clinician corrections.

End-to-end latency from image upload to a fully rendered annotated radiograph and structured pre-clinical report was approximately 15 seconds on an Apple M5 MacBook Air with a standard broadband connection to the OpenRouter API. The dominant cost is the Gemini API call, not the local YOLO inference, which completes in under one second.

The prototype confirms that the computational requirements of the pipeline are compatible with commodity hardware: no discrete or datacenter GPU is required at inference time, and YOLO inference runs locally via Apple's Metal Performance Shaders backend if the pipeline runs offline. This is a proof of concept for interactive deployment, not a clinically validated tool; a production system would require prospective clinical evaluation, regulatory compliance, and server-side inference at scale, outside the scope of this work.

G. Limitations

Four constraints limit these conclusions. First, quantitative detection evaluation relies on a single public benchmark (DentexChallenge 2023); performance on other equipment, populations, or annotation protocols may differ. Second, Stage 2 SR and Stage 3 NLP metrics are proxy evaluations on the external OPGs without bounding box ground truth: SR measures class-level agreement, not spatial precision or false-positive rate; BERTScore measures text similarity, not clinical correctness, and our random-pairing control (Section IV-D) shows it barely distinguishes a correct reference from a mismatched one here, so it carries little independent weight. The same limitation applies to the image-vs-detections ablation (Section IV-D): it measures similarity to a short reference, not clinical completeness, so it cannot alone determine whether the image is dispensable. Third, the generated reports were not reviewed by clinicians; a blinded expert evaluation is planned as immediate future work before any clinical utility claim can be made. Fourth, training and inference ran on an Apple M5 MPS backend, consumer hardware; throughput figures are a proof-of-concept reference, not a production benchmark.

VI. Conclusion

Grounding DINO, tested without fine-tuning across three prompt formulations and two model sizes, achieved mAP@50 = 0.00 (and near-zero even at IoU $\geq$ 0.10) on the Dentex-Challenge 2023 test set for all three target classes because its localization precision is insufficient for millimeter-scale dental pathologies. YOLOv11m fine-tuned on 474 annotated training images (950 after augmentation) from the same public dataset reached mAP@50 = 0.557 overall (95% CI [0.501, 0.645]),

with Impacted tooth at 0.931, Caries at 0.551, and Periapical lesion at 0.189. Applied to 50 externally sourced OPGs without bounding box ground truth, the pipeline produced a mean spontaneous recall of 89.7% (class-level agreement with dentist descriptions, Wilson 95% CI [73.4%, 95.3%] for the high-recall proportion) and structured pre-clinical reports with BERTScore F1 = 0.779 raw (-0.309 rescaled; semantic text similarity against reference notes, though a random-pairing control found this metric barely separates correct from mismatched report-reference pairs on this sample); all figures are exploratory proxies pending clinical validation.

Grounding DINO, evaluated zero-shot across both size variants and multiple prompts, was not suitable for clinical dental detection here, even at IoU thresholds well below the clinical standard; this should not be generalized to all zero-shot or foundation models without further evaluation. Supervised fine-tuning on a small public dataset, with augmentation tailored to the modality, produces a viable detection baseline. A React/FastAPI web prototype of the complete pipeline delivers a structured pre-clinical report from image upload in approximately 15 seconds on commodity hardware, with no discrete or datacenter GPU required at inference time.

Future work will focus on scaling the annotated training set, exploring semi-supervised approaches for Periapical lesion, extending detection to the full 31-class clinical vocabulary, and obtaining clinical validation of the generated reports by specialist dentists.

Ethical Statement

The DentexChallenge 2023 benchmark used for Stage 1 training and evaluation is released under a CC0 license and contains no identifiable patient information. The 50 external OPGs used for the Stage 2 and Stage 3 evaluations are drawn from the publicly available subset of the DPT Image and Caption Dataset [15] accompanying Dasanayaka et al. [14]. The original authors report that ethical clearance for this data was obtained from the relevant hospital ethics committees under international ethical standards, that informed consent was obtained from all subjects, and that the released images were de-identified prior to publication; the dataset is distributed under the Apache License 2.0. No additional patient contact, data collection, or identifiable information handling was performed by the present authors; our use is limited to secondary analysis of this already-published, de-identified, licensed dataset, together with independently authored clinical descriptions (see Section III-A). The authors declare no conflicts of interest.

Acknowledgment

The authors thank the DentexChallenge 2023 organizers for making the dataset publicly available under a CC0 license, and Dasanayaka et al. [14], [15] for releasing the DPT Image and Caption Dataset under the Apache License 2.0. Independent clinical descriptions and audio recordings for the 50 external evaluation images were produced by co-author Y. González Sánchez at the Fundación Odontológica Social Luis Seiquer (Seville, Spain). Code and evaluation artifacts are publicly available at https://github.com/ErnaneJ/orthopantomography.

***Abstract*—Steady-state visual evoked potential (SSVEP)-based brain-computer interfaces (BCIs) rely on spatial filtering algorithms to suppress background noise and interference. Traditionally, the literature evaluates the standard formulation of canonical correlation analysis (CCA) as a calibration-free, unsupervised method, contrasting it with the supervised task-related component analysis (TRCA). To establish a methodologically equitable comparison, this study formulates a supervised version of CCA and investigates the collinearity between its spatial weight vectors and those extracted by TRCA. Additionally, we analyze the structural impact of deploying empirical biological templates versus synthetic sinusoids within a unified filter-bank, multidimensional ensemble projection pipeline. Utilizing two public benchmark datasets, our spatial convergence analysis reveals that the electrode weight vectors optimized by supervised CCA and TRCA reach a highly collinear alignment for window size exceeding 0.7 s. In the decoding stage, a cross-substitution ablation study considering both single-band and multi-band filter-bank architectures demonstrates that configuring the ensemble supervised CCA with biological reference templates yields decoding accuracies and information transfer rates equivalent to those of standard ensemble TRCA, while outperforming traditional synthetic sinusoid configurations. These findings indicate that the performance superiority typically attributed to TRCA in the literature stems primarily from the structural integration of empirical biological templates, filter-bank and ensemble techniques, rather than an intrinsic mathematical advantage of its underlying spatial optimization objective function.**

***Index Terms*—Brain-computer interface, SSVEP, Spatial filter, Canonical Correlation Analysis (CCA), Task Related Component Analysis (TRCA).**

I. Introduction

Brain Computer Interfaces based on Steady State Visual Evoked Potentials (SSVEP) stand out in neuroengineering for providing high Information Transfer Rates (ITR) [1], [2]. However, the low Signal-to-Noise Ratio (SNR) inherent to the Electroencephalogram (EEG) requires spatial filtering algorithms. [3].

Historically, Canonical Correlation Analysis (CCA) is a recognized method that stands out because it does not require user calibration and relies on finding linear correlations between EEG channels and synthetic sine-cosine templates [4]. In contrast, Task Related Component Analysis (TRCA) has been consolidated as an approach that extracts filters maximizing signal reproducibility based on the covariance calibration data. When researchers evaluate these two methods in standard configuration, the literature shows TRCA outperforming CCA in classification accuracy [5].

TRCA implementations are typically evaluated as part of a comprehensive signal processing pipeline, incorporating sub-band decomposition (Filter Bank) [7] and multiple spatiotemporal projections (Ensemble) [3], [5]. These architectural enhancements, however, are mathematically independent of the underlying spatial filter. They can be integrated into a filter built upon linear correlation with synthetic references (CCA) as well as to a filter optimizing empirical signal reproducibility (TRCA).

In this context, the present study has a twofold objective. First, we conduct a similarity analysis to evaluate the equivalence between the spatial filters optimized by TRCA and supervised CCA. Second, we perform an ablation study, evaluating the various combinations of these spatial filters when integrated with complementary structural techniques, specifically Filter Bank and Ensemble methods. Through this approach, we aim to elucidate whether the overall classification performance depends predominantly on the specific mathematical formulation of the spatial filters, or if it is driven by the complementary structural signal processing techniques.

II. SSVEP Classification Pipeline

A general classification framework for SSVEP based BCIs is depicted in Figure 1. Classification methods based on CCA and TRCA can be described within this general framework. We consider a system designed to recognize N_c distinct visual stimuli, where each stimulus represents a unique target class $c \in \{1, 2, \ldots, N_c\}$. The classification task consists of inferring which of these N_c targets the user was focusing on during a given EEG time window.

The processing flow begins by separating both the input test signal $\mathbf{X} \in \mathbb{R}^{C \times N_s}$ (where C is the number of channels and

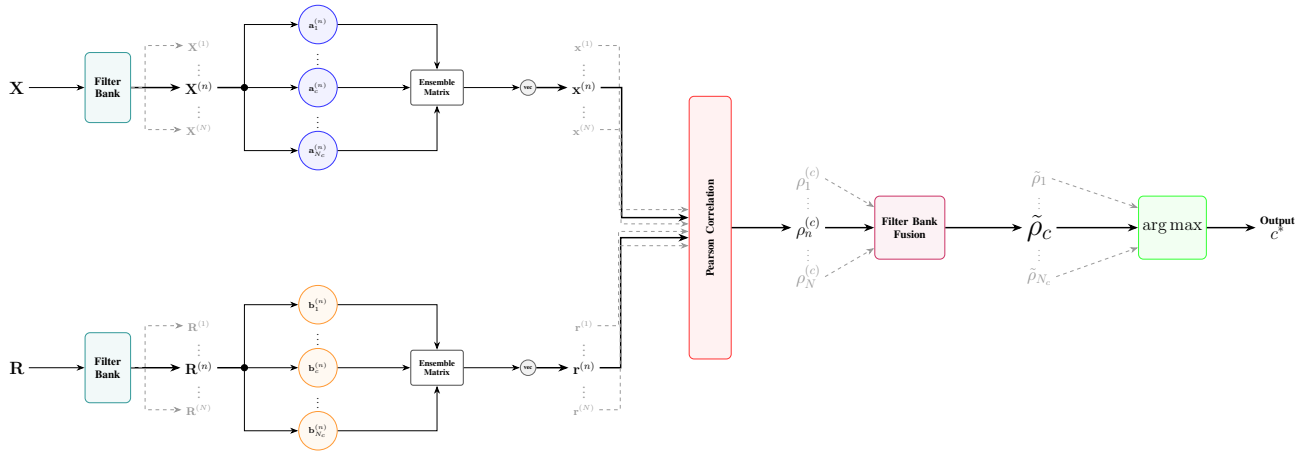

Fig. 1. Spatiotemporal processing pipeline diagram. The top path processes the test EEG signal $\mathbf{X}$, while the bottom path processes the reference template $\mathbf{R}$. Nodes $\mathbf{a}_c^{(n)}$ and $\mathbf{b}_c^{(n)}$ represent the class-specific spatial filters for the c-th stimulus.

N_s is the number of samples) and a class reference template $\mathbf{R}$ into N distinct sub-bands via Filter Bank. Depending on the adopted decoding paradigm, this reference $\mathbf{R}$ can represent either a synthetic sinusoidal matrix or an empirical biological mean. For each sub-band $n \in \{1, \ldots, N\}$, the multichannel data are projected through the class-specific spatial filters $\mathbf{a}_c^{(n)}$ and $\mathbf{b}_c^{(n)}$ and organized into their respective Ensemble matrices.

These multidimensional projections are then flattened by the vectorization (vec) operators to generate the structured vectors $\mathbf{x}^{(n)}$ and $\mathbf{r}^{(c,n)}$ for a evaluated candidate class c. The similarity between these vectorized test and template responses is quantified through Pearson correlation, yielding an individual coefficient $\rho_c^{(n)}$ for each sub-band and class combination.

The Filter Bank Fusion block then aggregates these sub-band metrics for each class independently, producing a single fused similarity score $\tilde{\rho}_c$. In the final stage of the pipeline, the system evaluates the entire set of accumulated class scores $[\tilde{\rho}_1, \tilde{\rho}_2, \ldots, \tilde{\rho}_{N_c}]$ through an $\arg\max$ operation. The target class that maximizes this final fused correlation coefficient is selected as the system decision C^*:

$$C^* = \arg\max_c \tilde{\rho}_c \tag{1}$$

A. Filter Bank

To effectively capture the harmonic components of SSVEP signals, we implement a Filter Bank (FB) architecture. Originally proposed for the FB-CCA method [7] and later adapted for FB-TRCA [5], this approach overcomes a fundamental limitation in standard feature extraction.

When a subject gazes at a flickering target, the visual cortex responds not only at the fundamental stimulation frequency (f), but also at its harmonic integer multiples. While incorporating these upper harmonics into the analysis is essential, their signal-to-noise ratio decays sharply at higher frequencies. Consequently, extracting harmonic features through a single, broad frequency band is inefficient, as these upper components are easily masked by background noise [7].

Within the decoding pipeline depicted in Figure 1, the Filter Bank serves as the primary preprocessing layer. Given an input multichannel signal $\mathbf{Z} \in \mathbb{R}^{C \times N_s}$, representing either the test trial $\mathbf{X}$ or the reference template $\mathbf{R}$, the architecture decomposes it into N sub-band components. For the n-th sub-band ($n \in \{1, 2, \ldots, N\}$), the filter outputs a band-limited signal $\mathbf{Z}^{(n)} \in \mathbb{R}^{C \times N_s}$, retaining the same spatial and temporal dimensions.

Following the design established in [7], the first sub-band covers the fundamental frequency and all subsequent harmonics, the second skips the fundamental to start at the first harmonic and captures everything above it, and so on. This separation forces the target detection algorithms to operate strictly within the spectral regions where the harmonic energy is concentrated.

For each of these N sub-bands, the system independently calculates a similarity coefficient, $\rho_c^{(n)}$, representing the correlation strength for that specific frequency band and candidate class c. To reach a consolidated similarity measure, these individual sub-band coefficients are merged using the linear fusion rule [5]

$$\tilde{\rho}_c = \sum_{n=1}^{N} w_n \cdot \text{sign}(\rho_c^{(n)}) \cdot \left(\rho_c^{(n)}\right)^2, \tag{2}$$

where w_n acts as a scaling factor for each sub-band coefficient, while the sign$(\cdot)$ operator preserves the algebraic sign of the correlation. Squaring $\rho_c^{(n)}$ highlights the peaks associated with the true target class [5].

Because higher-order harmonic components carry less spectral energy, treating every sub-band equally is suboptimal. Therefore, the weights w_n decay mathematically as the sub-band index increases, adopting the empirical formulation proposed in [7]

$$w_n = n^{-a} + b. \tag{3}$$

Following established BCI literature, our experiments evaluate $N = 5$ sub-bands, with the weighting parameters locked at $a = 1.25$ and $b = 0.25$ [7].

B. Ensemble

To boost classification performance, the ensemble technique projects the signals into a multidimensional subspace generated by the optimized spatial filters of all available classes [3], [5]. As illustrated by the parallel spatial filter groups in Figure 1, this method accommodates generalized filter pairs: vectors $\mathbf{a}_c^{(n)}$ applied to the incoming test signal, and vectors $\mathbf{b}_c^{(n)}$ applied to the reference template. We build the respective ensemble matrices, $\mathbf{W}_A^{(n)}$ and $\mathbf{W}_B^{(n)}$, by stacking these individual filter vectors obtained across all N_c classes (stimuli)

$$\begin{aligned}\mathbf{W}_A^{(n)} &= [\mathbf{a}_1^{(n)}, \mathbf{a}_2^{(n)}, \ldots, \mathbf{a}_{N_c}^{(n)}],\\ \mathbf{W}_B^{(n)} &= [\mathbf{b}_1^{(n)}, \mathbf{b}_2^{(n)}, \ldots, \mathbf{b}_{N_c}^{(n)}].\end{aligned} \tag{4}$$

The diagram inf Figure 1 highlights a symmetric processing route for this projection stage. Along the top pathway, the raw test signal $\mathbf{X}^{(n)}$ is mapped directly into its subspace, yielding the feature matrix

$$\tilde{\mathbf{X}}^{(n)} = (\mathbf{W}_A^{(n)})^T \mathbf{X}^{(n)} \in \mathbb{R}^{Nc \times N_s}. \tag{5}$$

The system processes a reference signal in the same way for each target class c along the bottom pathway. This architecture is independent of the nature of the template. The reference $\mathbf{R}^{(c)}$ can be an empirical biological mean derived from calibration data (as in TRCA), a synthetic sinusoidal matrix (as CCA) or any other template signal. The template is projected as

$$\tilde{\mathbf{R}}^{(c,n)} = (\mathbf{W}_B^{(n)})^T \mathbf{R}^{(c,n)} \in \mathbb{R}^{Nc \times N_s}. \tag{6}$$

At this point, the projections $\tilde{\mathbf{X}}^{(n)}$ and $\tilde{\mathbf{R}}^{(c,n)}$ remain two-dimensional spatiotemporal responses. To calculate the Pearson correlation, the system must evaluate both dimensions simultaneously by applying a vectorization operator [3], visually denoted by the vec$(\cdot)$ nodes in Figure 1. This operator flattens the projected matrices by sequentially stacking their columns, converting the two-dimensional response into a single column vector $\mathbf{v} \in \mathbb{R}^{(Nc \cdot N_s) \times 1}$,

$$\mathbf{x}^{(n)} = \text{vec}(\tilde{\mathbf{X}}^{(n)}), \quad \mathbf{r}^{(c,n)} = \text{vec}(\tilde{\mathbf{R}}^{(c,n)}). \tag{7}$$

Finally, we quantify the similarity between the test signal and class c within sub-band n using the Pearson correlation coefficient ($\rho_c^{(n)}$). Mathematically, this metric corresponds to the ratio between the sample covariance of the flattened vectors and the product of their standard deviations [5]

$$\begin{aligned}\rho_c^{(n)} &= \frac{\text{cov}\left(\mathbf{x}^{(n)}, \mathbf{r}^{(c,n)}\right)}{\sigma_{\mathbf{x}^{(n)}}\, \sigma_{\mathbf{r}^{(c,n)}}}\\ &= \frac{\sum_{i=1}^{N_c \cdot N_s} \left(x_i^{(n)} - \bar{x}^{(n)}\right)\left(r_i^{(c,n)} - \bar{r}^{(c,n)}\right)}{\sqrt{\sum_{i=1}^{N_c \cdot N_s} \left(x_i^{(n)} - \bar{x}^{(n)}\right)^2} \sqrt{\sum_{i=1}^{N_c \cdot N_s} \left(r_i^{(c,n)} - \bar{r}^{(c,n)}\right)^2}},\end{aligned} \tag{8}$$

where $x_i^{(n)}$ and $r_i^{(c,n)}$ represent the i-th elements of the flattened vectors $\mathbf{x}^{(n)}$ and $\mathbf{r}^{(c,n)}$, while $\bar{\mathbf{x}}^{(n)}$ and $\bar{\mathbf{r}}^{(c,n)}$ represent their respective sample means.

Once these coefficients are extracted across all N sub-bands for a specific class c, the Filter Bank Fusion module consolidates them into a single aggregated score $\tilde{\rho}_c$. Finally, the target class C^* that yields the maximum aggregated correlation is selected according to (1).

III. Design of the Spatial Filters

The CCA and the TRCA are two methodologies that can be used to design spatial filters for extracting the evoked potential information from the EEG signals. The following sections describe these two techniques.

A. Canonical Correlation Analysis (CCA)

CCA is a multivariate statistical method that evaluates the linear relationship between two sets of random variables, making it effective for SSVEP decoding [4]. In its original formulation, the algorithm aims to find an optimal pair of linear combinations that maximize the correlation between the recorded EEG signal $\mathbf{X}$ and a set of synthetic reference signals. For any given stimulus class c, the artificial reference matrix $\mathbf{Y}_c \in \mathbb{R}^{2N_h \times N_s}$ is defined as

$$\mathbf{Y}_c = \begin{bmatrix} \sin(2\pi f_c t) \\ \cos(2\pi f_c t) \\ \vdots \\ \sin(2\pi N_h f_c t) \\ \cos(2\pi N_h f_c t) \end{bmatrix}, \tag{9}$$

where f_c denotes the fundamental stimulation frequency of class c, $(N_h - 1)$ represents the number of considered harmonics, and $t = \left[\frac{1}{f_s}, \frac{2}{f_s}, \ldots, \frac{N_s}{f_s}\right]$ is the time vector dependent on the sampling frequency f_s.

The objective is to determine the spatial weight vectors $\mathbf{w}_X$ and $\mathbf{w}_Y$ that maximize the Pearson correlation between the canonical variables $\mathbf{w}_X^T\mathbf{X}$ and $\mathbf{w}_Y^T\mathbf{Y}$ [4],

$$(\mathbf{w}_X, \mathbf{w}_Y) = \arg\max_{\mathbf{u}_X, \mathbf{u}_Y} \frac{\mathbf{u}_X^T \mathbf{X}\mathbf{Y}^T \mathbf{u}_Y}{\sqrt{\mathbf{u}_X^T \mathbf{X}\mathbf{X}^T \mathbf{u}_X \cdot \mathbf{u}_Y^T \mathbf{Y}\mathbf{Y}^T \mathbf{u}_Y}}. \tag{10}$$

In [4], this optimization problem must be solved for each class in every incoming window of EEG, without relying on labeled calibration data. The system computes a unique set of filters for each target frequency, and the class that achieves the highest maximum canonical correlation is selected as the intended target.

However, the CCA can be used to optimize the spatial filters in a different way, exploring labeled calibration data. In this setup, which will be called supervised CCA hereinafter, instead of solving the optimization problem during online testing, the spatial filters are computed during a dedicated training stage using labeled calibration trials, i.e., trials in which the target stimulus is known.

This supervised framework maps directly onto the modular architecture illustrated in Figure 1. During calibration, the

training trials corresponding to class c are used to solve (10). This optimization determines $\mathbf{w}_X$, which corresponds directly to the spatial filter $\mathbf{a}_c^{(n)}$ operating along the test pathway, and $\mathbf{w}_Y$, which corresponds directly to the filter $\mathbf{b}_c^{(n)}$ operating along the template path in Figure 1.

During the online phase, the spatial filters are not modified and are used to process all the EEG test windows. As shown in Figure 1, the incoming test signal $\mathbf{X}$ is routed through the top pathway and projected through the pre-optimized spatial filters $\mathbf{a}_c^{(n)}$. Along the bottom pathway, the synthetic sine-cosine references take the place of the template matrix ($\mathbf{R} = \mathbf{Y}_c$) and are projected through their respective harmonic weights $\mathbf{b}_c^{(n)}$. These precomputed filters extract the canonical variables for each sub-band n prior to the vectorization (vec) and Pearson correlation stages, providing a subspace that isolates the target SSVEP responses.

B. Task-Related Component Analysis (TRCA)

TRCA is a spatial filtering method designed to extract robust signal components by maximizing reproducibility across multiple trials of the same task [5]. Rather than looking for correlations with synthetic templates, TRCA focuses entirely on the underlying biological consistency of the brain responses [5]. The algorithm seeks an optimal spatial filter vector $\mathbf{w}$ that maximizes the similarity of the filtered EEG signals across trials of a given stimulus class.

This optimization objective is mathematically formulated as the maximization of the ratio between the inter-trial covariance and the total intra-trial variance. The optimal weight vector $\mathbf{w}$ is computed through the following formulation

$$\mathbf{w} = \arg\max_{\mathbf{u}} \frac{\mathbf{u}^T \mathbf{S} \mathbf{u}}{\mathbf{u}^T \mathbf{Q} \mathbf{u}}, \tag{11}$$

where the matrix $\mathbf{S}$ isolates the task-related neural activity by accumulating the cross-covariance between all possible combinations of distinct calibration trials for a specific class. In contrast, the matrix $\mathbf{Q}$ captures the total intra-trial covariance across the concatenated EEG dataset, serving as a spatial regularizer that accounts for both the targeted evoked potentials and the background noise. This optimization problem is solved by transforming it into a generalized eigenvalue problem

$$\mathbf{S}\mathbf{u} = \lambda \mathbf{Q}\mathbf{u}, \tag{12}$$

where the optimal spatial filter corresponds to the eigenvector associated with the largest eigenvalue λ.

The optimization process in TRCA extracts a single spatial filter vector $\mathbf{w}$ for each class. This single filter is applied identically to both the online test signal and the reference template.

This symmetric deployment is visualized within the modular architecture of Figure 1. When evaluating a target class c at a specific sub-band n, the precomputed TRCA spatial filter is mapped directly onto both paths of the pipeline, meaning that $\mathbf{a}_c^{(n)} = \mathbf{b}_c^{(n)} = \mathbf{w}$. Along the top pathway, the incoming test signal $\mathbf{X}$ is projected through the spatial weights $\mathbf{a}_c^{(n)}$, and the template signal $\mathbf{R}$ takes the form of the mean of the training trials ($\bar{\mathbf{X}}_c$) and is projected through the identical filter weights $\mathbf{b}_c^{(n)}$ [5].

IV. Methodology

A. Databases

This study utilized two well-known public SSVEP-BCI datasets, which differ in their level of experimental control and the volume of data available for calibration. The first is the Benchmark Dataset [6], recorded in a controlled laboratory environment. The dataset contains EEG signals from 35 subjects operating a speller with 40 visual stimuli ($N_c = 40$) structured under the Joint Frequency-Phase Modulation (JFPM) technique. The stimulation frequencies ranged from 8.0 Hz to 15.8 Hz (increments of 0.2 Hz), with phases ranging from 0 to 1.5π radians (increments of 0.5π). The protocol consisted of 6 independent recording blocks, resulting in 240 trials per individual (6 trials for each stimulus), with each trial comprising 0.5 s of pre-stimulus and 5.0 s of active visual stimulation. The second is the BETA Database (BEnchmark database Towards BCI Application) [8]. Designed to simulate a practical real-world scenario, this dataset was recorded outside rigorously isolated environments, introducing higher levels of background noise. Although it shares the exact same 40-target JFPM visual configuration as the previous dataset, BETA expands the sample to 70 subjects and imposes a greater challenge on the classifiers, since the subjects performed only 4 independent recording blocks (totaling 160 trials). Furthermore, the visual stimulation time is reduced and variable, being 2.0 s for subjects S1 to S15, and 3.0 s for subjects S16 to S70 (both preceded by 0.5 s of pre-stimulus).

To evaluate the generalization performance of the algorithms, a leave-one-block-out cross-validation scheme was adopted across all subjects, ensuring that no participants were excluded from the analysis. For each trial designated as evaluation data, all spatial filter optimization stages, template generation, and parameter estimations were performed exclusively using the remaining independent calibration blocks. Under this separation, no test trial information was incorporated into the training phase.

B. Preprocessing

The analysis focused on 9 electrodes distributed over the parietal and occipital regions of the scalp (Pz, PO5, PO3, POz, PO4, PO6, O1, Oz, O2), as they capture the largest portion of the visual evoked response energy [5]. The EEG signal, originally sampled at 1000 Hz, was down-sampled to 250 Hz and subjected to digital band-pass filtering between 7 Hz and 90 Hz to attenuate baseline drift and high-frequency noise inherent to the acquisition [5]. Additionally, a 50 Hz notch filter was applied to eliminate power-line interference.

According to the literature [5], [6], we considered a physiological visual latency of approximately 140 ms. Therefore, by adding this biological delay to the 0.5 s static pre-stimulus period of each trial, the effective start of the feature extraction and analysis window for all algorithms was set at 0.64 s.

V. Experimental Evaluation

The experimental evaluation was conducted across windows size ranging from 0.1 s to 2.5 s, comprising two complementary experiments. The first experiment, the spatial equivalence analysis, assesses whether the spatial filters optimized by supervised CCA and TRCA achieve directional collinearity as the window size increases. The second experiment consists of a cross-substitution ablation study designed to decouple the influence of the spatial filter formulation from the complementary structural techniques (Filter Bank and Ensemble), comparing accuracy and Information Transfer Rate (ITR).

A. Spatial Equivalence Analysis

The first experiment evaluates the spatial equivalence between the filters across distinct stimulation window lengths. For each considered window size and stimulus class $c \in \{1, \ldots, 40\}$, the spatial filters $\mathbf{w}_{cca}$ (specifically the EEG spatial weight vector $\mathbf{w}_X$, obtained via supervised CCA (10)) and $\mathbf{w}_{trca}$ (obtained via TRCA (11), $\mathbf{w}$) were independently computed using calibration data. The implementation utilized a broadband configuration, omitting Filter Bank decomposition ($N = 1$ sub-band), with $N_h = 5$ harmonics for the CCA reference signals. To verify how the spatial filters generated by both methods compare as the window length increases, we employ the normalized inner product, or directional cosine, as a metric of collinearity. To ensure the measure reflects the directional alignment regardless of the filter's magnitude, both weight vectors $\mathbf{w}_{cca}$ and $\mathbf{w}_{trca}$ are normalized to unit norm within the calculation. For any given stimulus class c, the similarity metric S_c is defined as:

$$S_c = \frac{|\mathbf{w}_{cca}^T \mathbf{w}_{trca}|}{\|\mathbf{w}_{cca}\| \|\mathbf{w}_{trca}\|}. \tag{13}$$

The absolute value in this formulation is mathematically justified by a global polarity ambiguity inherent in the classification stage. As illustrated in the general processing flow of Figure 1, the target identification relies on the Pearson correlation coefficient. Because Pearson correlation is immune to sign inversions ($\mathbf{w} \to -\mathbf{w}$), two weight vectors pointing in diametrically opposed directions may produce functionally identical projections. This property holds as long as the consistency of the polarity is preserved between the test and template pathways of the pipeline. By omitting the algebraic sign, the index $S_c \in [0, 1]$ strictly measures the collinearity of the electrode weights across the spatial filter vectors, evaluating their directional alignment without being influenced by arbitrary signal inversions. Consequently, as S_c approaches 1, it serves as a direct indicator of equivalence between the two methodologies. The final spatial similarity metric, denoted as $\bar{S}_c$, was computed by averaging the individual coefficients across all N_c stimulus classes and M evaluated subjects:

$$\bar{S}_c = \frac{1}{M} \sum_{m=1}^{M} \left(\frac{1}{N_c} \sum_{i=1}^{N_c} S_{i,m} \right) \tag{14}$$

where $S_{i,m}$ represents the spatial similarity index obtained for the m-th participant and the i-th stimulus class.

B. Ablation Study

Supported by our unified classification architecture, we conducted an ablation study focusing on the cross-substitution of spatial filters. The objective was to investigate the classification performance when substituting the native spatial filter of one technique with the projection weights derived from another, thereby examining whether the spatial filters optimized by CCA and TRCA exhibit operational equivalence.

This systematic evaluation was first applied to the unsupervised CCA, supervised CCA, and TRCA algorithms, all implemented in a broadband configuration without Filter Bank decomposition or Ensemble architectures, and subsequently extended to incorporate these stages to isolate the individual contribution of each processing component.

The ablation study evaluates the following configurations, defined by their spatial projection matrices $\mathbf{W}_A$ and $\mathbf{W}_B$ and reference template $\mathbf{R}$ within the framework of Figure 1:

- *CCA (Unsupervised)* [4]: The filter bank and the ensemble mapping are bypassed, i.e., $N = 1$, $\mathbf{W}_A = \mathbf{a}_c^{(1)}$, $\mathbf{W}_B = \mathbf{b}_c^{(1)}$ and $\tilde{\rho}_c = \rho_c$. The system computes the spatial filter $\mathbf{a}_c^{(1)} = \mathbf{w}_X$ and the reference weight vector $\mathbf{b}_c^{(1)} = \mathbf{w}_Y$ dynamically for each EEG window solving (10), considering the template matrix $\mathbf{R} = \mathbf{Y}_c$.
- *Supervised CCA*: Uses the same configuration as the unsupervised version: $N = 1$, $\mathbf{W}_A = \mathbf{a}_c^{(1)} = \mathbf{w}_X$, $\mathbf{W}_B = \mathbf{b}_c^{(1)} = \mathbf{w}_Y$ and $\tilde{\rho}_c = \rho_c$. However, $\mathbf{a}_c^{(1)} = \mathbf{w}_X$ and $\mathbf{b}_c^{(1)} = \mathbf{w}_Y$ are computed using labeled calibration data and remain fixed during testing.
- *TRCA* [5]: The filter bank and the ensemble mapping are bypassed ($N = 1$, $\tilde{\rho}_c = \rho_c$). It uses the empirical biological mean through the template pathway ($\mathbf{R} = \bar{\mathbf{X}}_c$), which is computed by averaging the N_t available calibration trials for class c:

$$\bar{\mathbf{X}}_c = \frac{1}{N_t} \sum_{i=1}^{N_t} \mathbf{X}_{c,i} \tag{15}$$

  where $\mathbf{X}_{c,i}$ represents the i-th training trial. It applies symmetric spatial filtering, setting $\mathbf{W}_A = \mathbf{a}_c^{(1)} = \mathbf{w}$ and $\mathbf{W}_B = \mathbf{b}_c^{(1)} = \mathbf{w}$, where $\mathbf{w}$ is obtained solving (11).
- *TRCA with CCA Filter*: Uses the same configuration as standard TRCA ($N = 1$, $\tilde{\rho}_c = \rho_c$, template $\mathbf{R} = \bar{\mathbf{X}}_c$). However, it adopts the precomputed supervised CCA spatial filter, setting $\mathbf{W}_A = \mathbf{a}_c^{(1)} = \mathbf{w}_X$ and $\mathbf{W}_B = \mathbf{b}_c^{(1)} = \mathbf{w}_X$ instead of the native TRCA spatial filter.
- *Ensemble TRCA (eTRCA)* [5]: Operates in a broadband configuration ($N = 1$, $\tilde{\rho}_c = \rho_c$) with biological templates ($\mathbf{R} = \bar{\mathbf{X}}_c$). The ensemble mapping is activated across all N_c classes by stacking the optimized TRCA spatial filters to form projection matrices: $\mathbf{W}_A = \mathbf{W}_B = [\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_{N_c}]$.
- *eTRCA with CCA Filter*: Uses the same configuration as eTRCA ($N = 1$, $\tilde{\rho}_c = \rho_c$, template $\mathbf{R} = \bar{\mathbf{X}}_c$). However, the projection matrices are constructed using the precomputed supervised CCA spatial filters: $\mathbf{W}_A = \mathbf{W}_B = [\mathbf{w}_X^{(1)}, \mathbf{w}_X^{(2)}, \ldots, \mathbf{w}_X^{(N_c)}]$.

- *eFB-TRCA* [5]: Enables filter-bank decomposition ($N = 5$) and the sub-band fusion block. For each sub-band $n \in \{1, \ldots, 5\}$, the test signal $\mathbf{X}^{(n)}$ and biological template $\mathbf{R}^{(n)} = \bar{\mathbf{X}}_c^{(n)}$ are projected through sub-band specific ensemble matrices $\mathbf{W}_A^{(n)} = \mathbf{W}_B^{(n)} = [\mathbf{w}_1^{(n)}, \ldots, \mathbf{w}_{N_c}^{(n)}]$. The final score $\tilde{\rho}_c$ aggregates the sub-band Pearson correlations $\rho_c^{(n)}$.
- *eFB-TRCA with CCA Filter*: Uses the same configuration as eFB-TRCA ($N = 5$, template $\mathbf{R}^{(n)} = \bar{\mathbf{X}}_c^{(n)}$). However, the sub-band projection matrices are constructed using supervised CCA spatial filters calibrated independently for each frequency band: $\mathbf{W}_A^{(n)} = \mathbf{W}_B^{(n)} = [\mathbf{w}_X^{(1,n)}, \ldots, \mathbf{w}_X^{(N_c,n)}]$.

With the exception of the unsupervised CCA, to evaluate these configurations, we adopted a Leave-One-Block-Out cross-validation strategy. For each subject, one block of trials was held out as the test dataset, while the remaining blocks served as the training data. During the training phase, the offline pipeline is activated to calibrate the spatial filter vectors ($\mathbf{a}_c^{(n)}$ and $\mathbf{b}_c^{(n)}$) and to calculate the biological template matrices ($\bar{\mathbf{X}}_c$). During the online testing phase, the system classifies the held-out trials using the pre-optimized weights, and the average decoding accuracy and Information Transfer Rate across all subjects is reported as the final performance metric.

VI. Results and Discussion

A. Similarity of the Spatial Filters

As illustrated in Figure 2 for the Benchmark dataset, the evolution of the similarity ($\bar{S}_c$) between the spatial filters optimized by TRCA and supervised CCA revealed a convergent behavior.

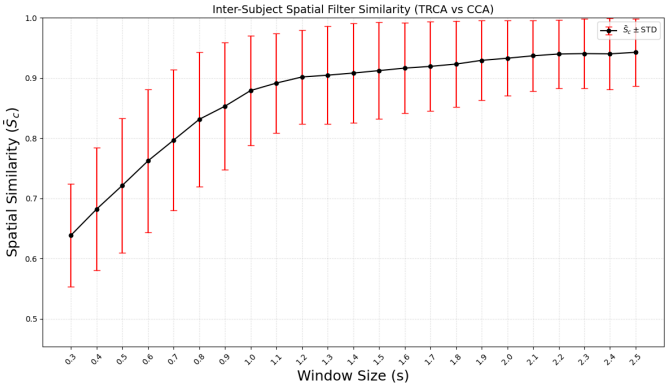

Fig. 2. Effect of window size on the spatial similarity ($\bar{S}_c$) between the filters generated by TRCA and supervised CCA.

For short stimulation windows, a low spatial correlation was observed between the weight vectors. A possible hypothesis for this divergence lies in the dynamics of the visual onset response. In shorter windows, the initial transient accounts for a significant proportion of the visual evoked potential. Because TRCA relies on empirical biological templates ($\bar{\mathbf{X}}_c$), its optimization naturally captures the dynamic of this early transient. In contrast, supervised CCA projects the data against synthetic sinusoids with constant amplitude ($\mathbf{Y}_c$), which fail to model the transient response, forcing the filter to align with the sustained steady-state oscillation. Consequently, for short window size, the algorithms obtain filters with low spatial collinearity.

However, as the window size increases, the spatial similarity increases monotonically with the S_c index stabilizing at high concordance values for a window size exceeding 0.7 s. Aligning with our dynamics hypothesis, a plausible explanation is that the sustained steady-state oscillation progressively accounts for a larger fraction of the total signal energy over a longer period of time. Once the initial transient settles, the empirical covariance captured by TRCA becomes governed by the stationary periodic rhythm. Under this interpretation, because such rhythmic activity aligns with the synthetic sinusoids of supervised CCA, both methods appear to converge toward extracting functionally equivalent spatial filters of the underlying neural response.

B. Classification Performance and Information Transfer Rate

To evaluate how the observed collinearity of the weight vectors translates into classification performance, we now analyze the classification accuracy and ITR provided by the ablation configurations.

The classification outcomes of these cross-substitution pipelines are detailed in Figures 3 and 4, which plot the classification accuracy curves for both the Benchmark and BETA datasets.

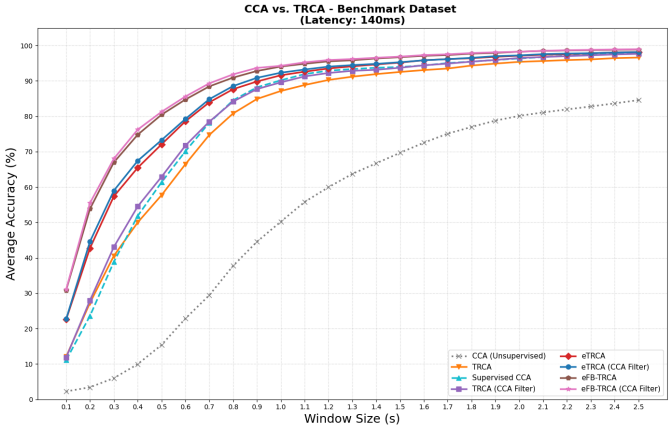

Fig. 3. Classification accuracy for the Benchmark dataset.

In the Benchmark dataset, characterized by a high SNR and the availability of 5 blocks for calibration (one block is used for test), the overall classification accuracy is high across all window lengths compared to the BETA dataset. For configurations without Filter Bank and Ensemble, *Supervised CCA* outperformed *TRCA*, indicating that synthetic reference sinusoids yielded higher decoding accuracy than the empirical mean, while *Unsupervised CCA* resulted in the lowest accuracy. Overall, configurations without Filter Bank and Ensemble presented lower decoding accuracy across

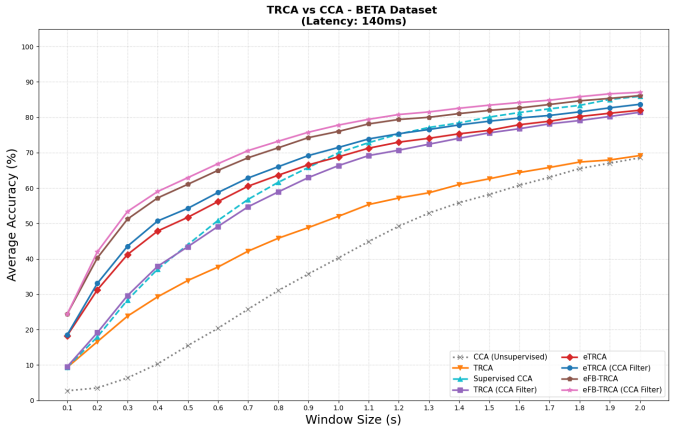

Fig. 4. Classification accuracy for the BETA dataset.

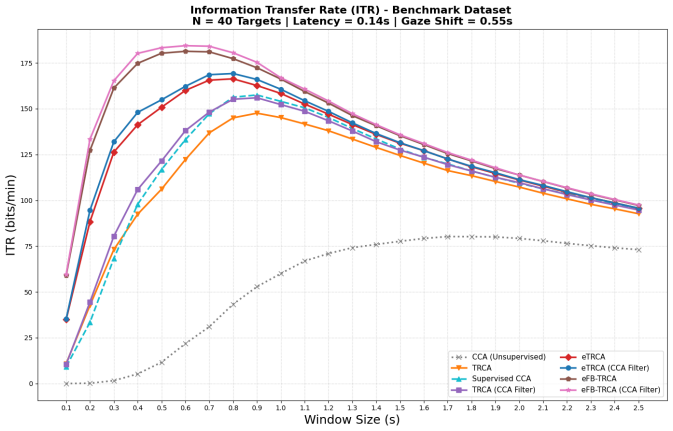

Fig. 5. Information Transfer Rate for the Benchmark dataset.

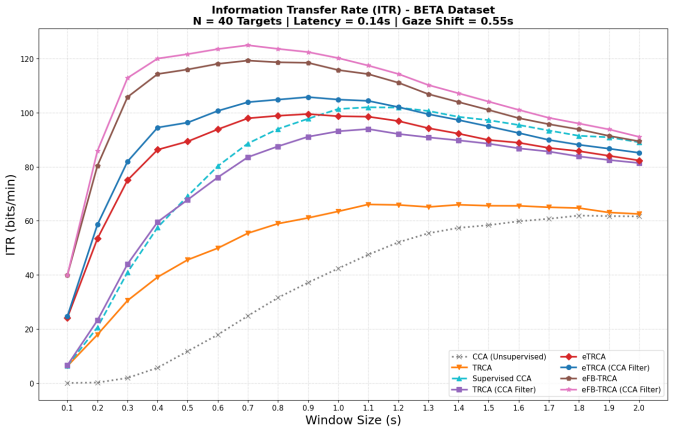

Fig. 6. Information Transfer Rate for the BETA dataset.

all window sizes than those incorporating these modules. Regarding the cross-substitution analysis, the native methods and their counterparts operating with the CCA filter exhibit a consistent behavior. The performance curves of the TRCA variations and those adapted with the CCA filter are almost superimposed. This behavior extends to the Filter Bank and Ensemble architectures, where eFB-TRCA and the eFB-TRCA with the substituted filter exhibit nearly identical performance, supporting the spatial convergence hypothesis ($S_c \rightarrow 1$).

In the BETA dataset, characterized by a less controlled environment with lower SNR and the availability of 3 blocks for calibration, the overall classification accuracy is reduced across all window lengths compared to the Benchmark dataset. For configurations without Filter Bank and Ensemble, *Supervised CCA* outperformed *TRCA*, while *Unsupervised CCA* resulted in the lowest accuracy. Overall, configurations without Filter Bank and Ensemble presented lower decoding accuracy across all window lengths than those incorporating these modules, with this performance gap widening under low-SNR conditions. Regarding the cross-substitution analysis, the native methods and their counterparts operating with the CCA filter exhibit a consistent behavior. The performance curves of the TRCA variations and those adapted with the CCA filter remain closely aligned along. This parity extends to the Filter Bank and Ensemble architectures, where eFB-TRCA and the eFB-TRCA with the substituted filter exhibit nearly identical performance.

To further evaluate the practical communication efficiency of the BCI system, the ITR was calculated following the standard evaluation protocol described in [6], assuming a gaze shifting time of 0.5 s. Figure 5 and Figure 6 illustrates the ITR curves for both datasets.

As shown in Figures 5 and 6, the maximum ITR is achieved at intermediate window lengths, typically before the accuracy curve reaches its saturation point. Consistent with the accuracy results, the Filter Bank and Ensemble architectures, particularly eFB-TRCA, achieve higher peak ITRs compared to the baseline methods in both controlled and noisy environments. Moreover, the substitution of the native TRCA spatial filter with the supervised CCA filters maintains the communication rates. The similar ITR profiles between the native and cross-substituted methods reinforce the spatial convergence and seems to not compromise the overall throughput of the system.

VII. Conclusion

The spatial convergence analysis showed collinearity ($S_c \rightarrow 1$) between supervised CCA and TRCA weight vectors for windows exceeding 0.7 s. However, the ablation study revealed equivalent decoding performance across all window lengths, suggesting the hypothesis that filter bank decomposition, ensemble, and template matching compensate for the spatial weight divergence observed at shorter windows. Further investigation is required to fully explain this mechanism.

Consequently, these findings suggest that the performance gap reported in literature between CCA and TRCA arises primarily from the classification structure rather than the criteria used to design the spatial filters. When deployed within identical frameworks with equivalent reference signals, TRCA and CCA appear to yield comparable decoding outcomes.

***Resumo*—Este estudo avaliou um pipeline multitarefa de triagem conjunta para retinopatia diabética referenciável e glaucoma em imagens de fundo de olho que combina EfficientNet-B0 com análises de discriminação, calibração, incerteza preditiva, limiares operacionais e explicabilidade post-hoc. O objetivo foi caracterizar, em validação interna e avaliação externa, o comportamento dessas propriedades preditivas sob deslocamento de domínio, delimitando o sistema como uma estrutura experimental de avaliação, e não como ferramenta clinicamente pronta para uso. As principais constatações foram: desempenho discriminatório elevado para retinopatia diabética referenciável na validação interna histórica do APTOS, com AUC de 0,9791 (IC95%: 0,9704–0,9865), cuja interpretação requer cautela devido à identificação retrospectiva de duplicatas exatas entre treinamento e validação, e redução no EyePACS, com AUC de 0,7181 (IC95%: 0,7051–0,7310); maior instabilidade para glaucoma, com AUC de 0,8060 (IC95%: 0,7237–0,8801) no REFUGE-CLAHE, 0,5525 (IC95%: 0,4382–0,6625) no ACRIMA-CLAHE e 0,5949 (IC95%: 0,5834–0,6058) no EyePACS-AIROGS-light-V2-CLAHE; efeitos do CLAHE dependentes do domínio, sem eliminação da baixa especificidade observada na avaliação externa; comportamento tarefa-dependente de MC Dropout e Temperature Scaling; e explicações Grad-CAM/SLIC mais concentradas em predições corretas e mais difusas em erros ou casos incertos.**

***Palavras-chave*—retinopatia diabética, glaucoma, fundo de olho, aprendizado multitarefa, validação externa, calibração, incerteza, explicabilidade.**

I. Introdução

Retinopatia diabética e glaucoma estão entre as causas relevantes de perda visual evitável, e ambas podem ser rastreadas por fotografias de fundo de olho [7], [9], [13]. Em oftalmologia, porém, modelos de deep learning frequentemente perdem acurácia quando avaliados em bases externas [14], [26], devido a variações de aquisição, população, prevalência, resolução e critérios de rotulagem [22]. Esse cenário justifica investigar abordagens multitarefa, pois a triagem clínica pode exigir a avaliação de mais de uma patologia na mesma imagem [4].

Este manuscrito avalia um pipeline multitarefa baseado em EfficientNet-B0 [12], com cabeças separadas para retinopatia diabética e glaucoma acopladas ao mesmo extrator de características [11]. Foram analisados MC Dropout [20], Temperature Scaling [8], CLAHE apenas para glaucoma [17], limiares operacionais empíricos e interpretabilidade post-hoc com Grad-CAM [23] e superpixels SLIC [24], em validação interna e avaliação externa, sem assumir prontidão clínica.

As contribuições são: i) avaliar um pipeline multitarefa auditável; ii) comparar o desempenho em validação interna e avaliação externa em bases públicas; iii) examinar calibração, incerteza, limiares e deslocamento de domínio; e iv) analisar erros com Grad-CAM e SLIC. O foco é caracterizar a confiabilidade além da AUC [15].

II. Materiais e Métodos

A. Delineamento do Estudo

Este estudo retrospectivo avaliou um sistema multitarefa aplicado a imagens coloridas de fundo de olho. O sistema gera duas saídas: glaucoma, tratado como classificação binária, e retinopatia diabética, inicialmente mapeada em cinco classes e posteriormente binarizada em referível ou não referível.

$$\left(p_i^{DR}, p_i^{G}\right) = h_\theta\left(x_i\right) = \left(h_{DR}\left(f_\theta\left(x_i\right)\right), h_G\left(f_\theta\left(x_i\right)\right)\right). \quad (1)$$

As funções h_{DR} e h_G correspondem, respectivamente, às cabeças de classificação para retinopatia diabética e glaucoma. Os métodos foram avaliados em conjuntos internos, para experimentos controlados, e em conjuntos externos, para examinar generalização de domínio. Para auditoria e reprodutibilidade, registraram-se as predições do modelo, os limiares adotados, as medidas de calibração, as estimativas de incerteza e as métricas de cada configuração experimental.

B. Modelo Multitarefa

A configuração experimental multitask_real_v2 foi adotada como base. A EfficientNet-B0 foi escolhida por sua reprodutibilidade e baixo custo computacional [12]. O classificador original foi substituído por duas cabeças: uma de cinco classes para retinopatia diabética e outra binária para glaucoma. Uma camada Dropout com probabilidade de 0,3 foi posicionada antes dessas cabeças, permitindo regularização e posterior inferência com MC Dropout.

Para retinopatia diabética, a cabeça de classificação em cinco classes produziu logits $z_{i,k}^{DR}$, com $k \in \{0, 1, 2, 3, 4\}$. Antes da etapa de calibração, as probabilidades de classe correspondentes são dadas pela função softmax:

$$p_{i,k}^{DR} = \frac{\exp\left(z_{i,k}^{DR}\right)}{\sum_{c=0}^{4} \exp\left(z_{i,c}^{DR}\right)},\ k \in \{0,1,2,3,4\}. \quad (2)$$

Para a tarefa de glaucoma, a cabeça binária do modelo produziu um logit z_i^G:

$$p_i^G = \sigma\left(z_i^G\right) = \frac{1}{1+\exp\left(-z_i^G\right)}. \quad (3)$$

A probabilidade de retinopatia diabética referenciável foi obtida pela soma das probabilidades associadas aos graus 2 a 4. No pipeline final, tais probabilidades correspondem às saídas resultantes do escalonamento de temperatura (Temperature Scaling), descrito na sequência:

$$p_i^{RDR}(T_{DR}) = \sum_{k=2}^{4} p_{i,k}^{DR}(T_{DR}). \quad (4)$$

As decisões binárias de rastreamento foram obtidas mediante a aplicação de limiares específicos para cada tarefa, definidos como:

$$\widehat{y}_i^{RDR} = I\left(p_i^{RDR}(T_{DR}) \geq \tau_{DR}\right),\ \widehat{y}_i^{G} = I\left(p_i^{G} \geq \tau_{G}\right), \quad (5)$$

em que $I(\cdot)$ denota a função indicadora, τ_{DR} corresponde ao limiar adotado para a retinopatia diabética referenciável e τ_G, ao limiar adotado para o glaucoma. A decisão conjunta de encaminhamento foi definida pela união lógica das saídas específicas de cada tarefa, expressa por:

$$\widehat{y}_i^{Joint} = \widehat{y}_i^{RDR} \vee \widehat{y}_i^{G}. \quad (6)$$

Assim, a imagem foi encaminhada quando pelo menos uma das saídas específicas foi positiva.

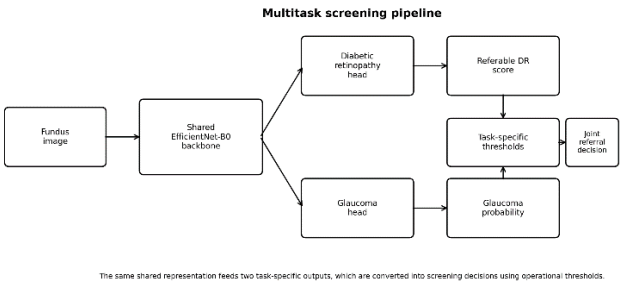

Fig. 1. Uma visão geral da arquitetura do modelo multitarefa proposto. Uma rede de backbone EfficientNet-B0 é empregada e seus mapas de características finais são enviados para duas cabeças específicas para cada tarefa (retinopatia diabética e glaucoma), seguidas pelos limiares operacionais e pela decisão conjunta de encaminhamento.

A proveniência documental da configuração `multitask_real_v2` foi reconstruída a partir dos artefatos experimentais preservados. Ela manteve as 3.662 imagens do APTOS de `multitask_real_v1`, redistribuídas por particionamento estratificado 80/20 (semente 42) em 2.929 imagens de treinamento e 733 de validação interna. Como os registros não documentam uma busca formal de hiperparâmetros, `multitask_real_v2` é tratada como configuração experimental consolidada, e não como modelo vencedor. As análises estatísticas utilizaram predições individuais congeladas preservadas, que reproduzem as estimativas pontuais originalmente reportadas. Não foi possível verificar documentalmente uma correspondência unívoca entre essas predições e um arquivo de checkpoint atualmente preservado; assim, a reprodutibilidade dos resultados aqui reportada refere-se à recomputação das métricas a partir das predições congeladas, e não à regeneração dessas predições a partir dos pesos do modelo.

C. Conjuntos de Dados e Coortes de Avaliação

Este estudo utilizou bases de dados públicas tanto para a validação interna, compreendendo APTOS [1] e REFUGE [10], quanto para a avaliação externa, compreendendo EyePACS [5], ACRIMA [3] e EyePACS-AIROGS-light-V2 [2]. Para a retinopatia diabética, os graus 0–1 foram agrupados na categoria não referível e os graus 2–4 na categoria referível, ao passo que o glaucoma foi tratado como tarefa de classificação binária. A Tabela I resume a composição das coortes resultantes.

Tabela I
COMPOSIÇÃO DOS CONJUNTOS DE DADOS UTILIZADOS NA AVALIAÇÃO CONSOLIDADA

Tarefa	Dataset	Função	Formato do rótulo	n
Glaucoma	REFUGE	Treinamento	Binário	400
	REFUGE	Validação interna/desenvolvimento	Binário	400
	ACRIMA	Teste externo	Binário	106
	EyePACS-AIROGS-light-V2	Teste externo	Binário	9,540
Retinopatia diabética	APTOS	Treinamento	Grau de RD em cinco classes	2,929
	APTOS	Validação interna/desenvolvimento	Grau de RD em cinco classes	733
	EyePACS	Teste externo	Grau de RD em cinco classes	10,906
Total				25,014

EyePACS, ACRIMA e EyePACS-AIROGS-light-V2 foram tratados como conjuntos de teste externo para a avaliação de generalização sob deslocamento de domínio. Os limiares operacionais aplicados nessas coortes foram definidos a partir dos dados de validação interna e posteriormente mantidos fixos na avaliação externa. Dessa forma, os resultados externos são apresentados como estimativas de transferência do pipeline para domínios distintos, e não como desempenho ajustado especificamente a essas coortes.

Uma auditoria retrospectiva das partições identificou comportamentos distintos entre as tarefas. Para glaucoma, não foram observadas duplicatas exatas entre as partições internas REFUGE nem entre REFUGE e as coortes externas avaliadas. Para retinopatia diabética, APTOS e EyePACS permaneceram separados no nível de duplicatas exatas; entretanto, foram identificados 41 hashes SHA-256 compartilhados entre as partições de treinamento e validação interna do APTOS, envolvendo 83 registros. Assim, não se pode assumir independência completa em nível de imagem entre essas duas partições, e as métricas internas de desenvolvimento para retinopatia diabética devem ser interpretadas com essa limitação. A independência em nível de paciente não pôde ser verificada uniformemente, devido à ausência de identificadores de paciente nas bases utilizadas.

Não houve conjunto interno de teste independente utilizado para a avaliação final de nenhuma das duas tarefas. Para a retinopatia diabética, o conjunto APTOS foi particionado em 2.929 imagens destinadas ao treinamento e 733 imagens destinadas à validação interna/desenvolvimento, sem a

definição de uma partição adicional de teste interno. Para glaucoma, as mesmas 400 imagens do REFUGE-CLAHE classificadas como validação interna/desenvolvimento foram utilizadas tanto para examinar os pontos de operação de τ_G quanto para estimar o desempenho interno dependente de limiar apresentado neste manuscrito. Consequentemente, essas métricas devem ser interpretadas como resultados de desenvolvimento, e não como estimativas obtidas em um teste interno independente, podendo refletir otimismo associado ao uso do mesmo conjunto na definição do ponto de operação. A avaliação das coortes externas mantidas separadas das decisões de desenvolvimento constitui a principal evidência de generalização do pipeline.

D. Pré-processamento

Todas as imagens de fundo de olho foram redimensionadas para 224×224 pixels, convertidas em tensores e normalizadas segundo os valores de média e desvio-padrão do ImageNet, em conformidade com a distribuição de entrada requerida pelo EfficientNet-B0 [12], sendo cada canal normalizado, após o redimensionamento, conforme a expressão a seguir:

$$\tilde{x}_{i,c} = \frac{x_{i,c} - \mu_c}{\sigma_c}, \quad c \in \{R, G, B\}, \tag{7}$$

em que $x_{i,c}$ denota a intensidade da imagem no canal c, μ_c corresponde à média do ImageNet e σ_c, ao desvio-padrão correspondente.

Para o ramo de glaucoma, o CLAHE [17] foi avaliado apenas em inferência, sem retreinamento ou alteração dos parâmetros do modelo. As cópias processadas por CLAHE foram geradas no canal de luminância do espaço LAB, com limite de corte de 2.0 e grade de blocos 8×8:

$$\begin{aligned} L_i^{'} &= \text{CLAHE}\left(L_i; \alpha = 2.0, g = 8 \times 8\right), \\ I_i^{'} &= \text{RGB}\left(L_i^{'}, a_i, b_i\right). \end{aligned} \tag{8}$$

Aqui, L_i, a_i e b_i denotam os canais LAB da imagem i; α é o limite de corte; g define a grade de blocos; e I_i' é a imagem RGB resultante. O CLAHE foi usado apenas na avaliação de glaucoma. Para retinopatia diabética, manteve-se o fluxo padrão de pré-processamento.

E. Avaliação de Duplicatas e Vazamento de Dados

Foi realizada uma auditoria retrospectiva de possível vazamento de dados com base em identificadores de amostra e hashes SHA-256 dos arquivos [16]. No APTOS, essa auditoria identificou 41 hashes compartilhados entre treinamento e validação interna, envolvendo 83 registros, enquanto não foram observadas colisões SHA-256 entre APTOS e EyePACS. Para glaucoma, não foram observadas duplicatas exatas entre as partições internas do REFUGE nem entre REFUGE e as coortes externas avaliadas. Essa verificação detecta identidade binária dos arquivos, mas não exclui versões visualmente equivalentes obtidas por recorte, redimensionamento ou recompressão; adicionalmente, a independência em nível de paciente não pôde ser verificada de forma uniforme por ausência de identificadores apropriados.

F. Métricas de Avaliação

A capacidade discriminatória foi avaliada pela AUC [6], e a calibração pelo Brier score e pelo Expected Calibration Error (ECE) [8], [18], este último calculado com $M = 10$ intervalos igualmente espaçados. O desempenho nos pontos operacionais foi caracterizado por sensibilidade, especificidade, acurácia, PPV, NPV, F1-score, acurácia balanceada, falsos positivos e falsos negativos, sendo a acurácia balanceada definida como a média entre sensibilidade e especificidade. Para retinopatia diabética, os graus 0–1 foram considerados não referíveis e os graus 2–4 referíveis; o glaucoma foi tratado como classificação binária.

G. Calibração com Temperature Scaling

O Temperature Scaling [8] foi aplicado como pós-processamento específico por tarefa, sem retreinamento dos pesos do modelo. Para retinopatia diabética, a temperatura escalar previamente determinada na validação interna do APTOS ($n = 733$), $T_{DR} = 0.9358$, foi aplicada aos logits da cabeça multiclasse antes da função softmax:

$$p_{i,k}^{DR}(T_{DR}) = \frac{\exp\left(z_{i,k}^{DR}/T_{DR}\right)}{\sum_{j=0}^{4}\exp\left(z_{i,j}^{DR}/T_{DR}\right)}. \tag{9}$$

A temperatura foi mantida no pipeline final de retinopatia diabética por reduzir o ECE na validação interna e foi aplicada sem novo ajuste à coorte externa EyePACS. O escore de retinopatia diabética referível utilizado nas análises binárias foi calculado a partir dessas probabilidades calibradas como $p_i^{RDR}(T_{DR}) = p_{i,2}^{DR}(T_{DR}) + p_{i,3}^{DR}(T_{DR}) + p_{i,4}^{DR}(T_{DR})$.

Para glaucoma, o Temperature Scaling foi examinado separadamente em uma análise auxiliar de calibração utilizando o REFUGE sem CLAHE (raw). Como Brier score e ECE pioraram após a transformação, nenhuma temperatura de glaucoma foi incorporada ao pipeline final. Os registros preservados documentam os valores de temperatura e as comparações antes/depois, mas não preservam informação suficiente para reconstruir o procedimento numérico utilizado originalmente para determinar as temperaturas; por isso, nenhum algoritmo específico de otimização é atribuído neste manuscrito.

H. Inferência Estatística

Para as principais métricas de discriminação, calibração e desempenho operacional, foram calculados intervalos de confiança de 95% por bootstrap não paramétrico em nível de imagem, com 10.000 reamostragens e semente fixa 42. Em cada combinação de tarefa e conjunto de dados, as imagens foram reamostradas com reposição, e AUC, sensibilidade, especificidade, F1-score, Brier score e ECE foram recomputados. O ECE foi recalculado em cada réplica mantendo $M = 10$ intervalos igualmente espaçados. Réplicas contendo apenas uma classe foram excluídas do cálculo da AUC. PPV e NPV foram mantidos como estimativas pontuais. Cada réplica foi obtida recalculando a métrica θ:

$$\widehat{\theta}^{*(b)} = T\left(D^{*(b)}\right), \; b = 1, \ldots, B, \tag{10}$$

em que $D^{*(b)}$ representa o b-ésimo conjunto de dados bootstrap, $T(\cdot)$ corresponde à função da métrica considerada

e $B = 10\,000$. O intervalo de confiança bootstrap percentílico foi definido, por sua vez, como:

$$\mathrm{CI}_{95\%}(\theta) = \left[Q_{0.025}\left(\widehat{\theta}^{*}\right), Q_{0.975}\left(\widehat{\theta}^{*}\right)\right], \qquad (11)$$

em que $Q_q(\cdot)$ denota o q-quantil empírico da distribuição bootstrap [21]. O teste de McNemar foi mantido exclusivamente para comparações pareadas auxiliares selecionadas, ao passo que as análises de DeLong e de Holm-Bonferroni não foram preservadas como resultados primários.

I. Análise de Limiar

O limiar $\tau_G = 0.10$ foi preservado como ponto operacional congelado da avaliação principal de glaucoma, tendo sido conduzida, adicionalmente, uma análise exploratória de sensibilidade ao ponto de operação no conjunto REFUGE-CLAHE [10]. Dentre os pontos examinados nessa análise, $\tau_G = 0.249$ foi selecionado internamente como ponto balanceado, por apresentar a maior acurácia balanceada no REFUGE-CLAHE, enquanto $\tau_G = 0.300$ foi mantido como alternativa conservadora destinada a ilustrar a redução de falsos positivos. O ponto balanceado exploratório foi definido, assim, como:

$$\tau_G^{*} = \arg\max_{\tau \in \mathcal{T}} \frac{1}{2}\left[\text{Sensitivity}(\tau) + \text{Specificity}(\tau)\right], \qquad (12)$$

em que $\mathcal{T}$ denota os pontos de operação examinados no REFUGE-CLAHE. Para cada ponto, foram calculados sensibilidade, especificidade, acurácia balanceada, falsos positivos e falsos negativos. Os IC95% de sensibilidade, especificidade e acurácia balanceada na avaliação externa foram estimados pelo mesmo bootstrap não paramétrico em nível de imagem, com $B = 10\,000$ e semente 42. ACRIMA-CLAHE e EyePACS-AIROGS-light-V2-CLAHE foram usados apenas para avaliação externa, sem participação na escolha dos pontos exploratórios. Em particular, os resultados externos não foram utilizados para redefinir retrospectivamente nem o limiar principal de 0.10 nem o ponto balanceado selecionado internamente.

J. Experimentos de Glaucoma em Tarefa Única

Também foram avaliados modelos de tarefa única para glaucoma, a fim de verificar se as limitações observadas decorriam do desenho multitarefa [3], [9]. Cinco configurações foram testadas: CLAHE com entropia cruzada binária (224 × 224), CLAHE com focal loss (224 × 224), CLAHE com entropia cruzada binária (384 × 384), CLAHE com corte central de 80% e entropia cruzada binária (384 × 384), e CLAHE com corte central de 80% e entropia cruzada binária (512 × 512). Esses testes avaliaram o efeito da normalização de contraste, da focal loss, do aumento de resolução e da centralização do disco óptico na classificação de glaucoma. A entropia cruzada binária foi definida por:

$$L_{\text{BCE}} = -\frac{1}{N}\sum_{i=1}^{N}\left[y_i \log\left(p_i\right) + \left(1 - y_i\right)\log\left(1 - p_i\right)\right]. \qquad (13)$$

O modelo de focal loss foi escrito como [25]:

$$L_{\text{focal}} = -\frac{1}{N}\sum_{i=1}^{N}\alpha_t\left(1 - p_{t,i}\right)^{\gamma}\log\left(p_{t,i}\right), \qquad (14)$$

onde $p_{t,i} = p_i$ quando $y_i = 1$ e $p_{t,i} = 1 - p_i$ quando $y_i = 0$. Os parâmetros α_t e γ controlam, respectivamente, o balanceamento entre classes e a redução de peso de exemplos já bem classificados. Devido ao tamanho limitado e ao desequilíbrio do conjunto de dados, os modelos de tarefa única foram tratados como configurações comparativas, não como classificadores definitivos.

K. Análise de Erros

Falsos positivos e falsos negativos foram avaliados quanto a contraste, iluminação global, foco, grau de zoom, obstruções visuais, artefatos e visibilidade da anatomia relevante. Como informações clínicas adicionais não estavam disponíveis, os erros foram descritos como visuais ou relacionados à qualidade da imagem, e não como categorias clínicas de erro.

L. Estimativa de Incerteza com MC Dropout

A incerteza preditiva foi estimada por MC Dropout com $T = 10$ passagens estocásticas durante a inferência, sem retreinamento [20]. Foram calculados média de predição, desvio-padrão preditivo e entropia preditiva para predições corretas, incorretas, falsos positivos e falsos negativos. Para cada imagem, a média e o desvio-padrão preditivos foram definidos como:

$$\bar{p}_i = \frac{1}{T}\sum_{t=1}^{T} p_i^{(t)}, \qquad (15)$$

$$s_i = \sqrt{\frac{1}{T-1}\sum_{t=1}^{T}\left(p_i^{(t)} - \bar{p}_i\right)^2}, \qquad (16)$$

em que $p_i^{(t)}$ é a probabilidade prevista na t-ésima passagem estocástica. Para a predição binária de glaucoma, a entropia preditiva foi calculada como:

$$H_i^{G} = -\bar{p}_i^{G}\log\left(\bar{p}_i^{G}\right) - \left(1 - \bar{p}_i^{G}\right)\log\left(1 - \bar{p}_i^{G}\right). \qquad (17)$$

Para a retinopatia diabética, a entropia preditiva multiclasse foi calculada a partir das probabilidades médias de classe obtidas em múltiplas passagens estocásticas:

$$H_i^{DR} = -\sum_{k=0}^{4}\bar{p}_{i,k}^{DR}\log\left(\bar{p}_{i,k}^{DR}\right). \qquad (18)$$

A incerteza foi caracterizada, para o glaucoma, pela probabilidade média de glaucoma, pelo desvio-padrão entre as passagens estocásticas e pela entropia preditiva binária associada a essa predição; de modo análogo, para a retinopatia diabética, foi avaliada pelo escore médio de retinopatia diabética referenciável, pelo desvio-padrão entre as passagens estocásticas e pela entropia preditiva multiclasse. Tais medidas foram derivadas diretamente das predições estocásticas, sem qualquer alteração dos parâmetros ou dos limiares empregados na predição.

M. Avaliação de Eficiência Computacional

A eficiência computacional foi avaliada em duas frentes: a sobrecarga associada às 10 passagens estocásticas do MC Dropout e a comparação entre o backbone multitarefa compartilhado e dois modelos EfficientNet-B0 independentes. As medições foram conduzidas com 400 imagens do conjunto REFUGE-CLAHE, batch size de 16, entradas de 224 × 224 pixels e uma GPU NVIDIA A100 80GB PCIe. Esse benchmark teve finalidade exclusivamente computacional, não tendo sido utilizado para recalcular os resultados clínicos ou probabilísticos.

III. Resultados

A. Desempenho Geral do Sistema Multitarefa Final

O sistema multitarefa apresentou comportamento dependente da tarefa. Nas predições preservadas, a retinopatia diabética apresentou AUC de 0,9791 (IC95%: 0,9704–0,9865) na validação interna do APTOS, estimativa que deve ser interpretada à luz da sobreposição por duplicatas exatas descrita nos Métodos, e AUC de 0,7181 (IC95%: 0,7051–0,7310) no EyePACS externo; o glaucoma foi mais sensível ao deslocamento de domínio. No REFUGE-CLAHE, a AUC do glaucoma foi 0,8060 (IC95%: 0,7237–0,8801), enquanto no ACRIMA-CLAHE foi 0,5525 (IC95%: 0,4382–0,6625) e no EyePACS-AIROGS-light-V2-CLAHE, 0,5949 (IC95%: 0,5834–0,6058). O intervalo observado no ACRIMA-CLAHE evidencia maior incerteza nessa coorte externa de menor tamanho amostral e inclui 0,50, sendo portanto compatível com discriminação ao nível do acaso nessa coorte. Nos limiares originais, o glaucoma no EyePACS-AIROGS-light-V2-CLAHE apresentou alta sensibilidade e baixa especificidade, enquanto a retinopatia diabética apresentou alto desempenho no APTOS e, no teste externo, maior especificidade que sensibilidade.

Tabela II
Desempenho probabilístico do sistema multitarefa final nos conjuntos de avaliação internos e externos. Os valores entre parênteses representam IC95% bootstrap percentílicos.

Conjunto de dados	n	AUC (IC95%)	Brier (IC95%)	ECE (IC95%)
Glaucoma – REFUGE-CLAHE	400	0.8060 (0.7237–0.8801)	0.0841 (0.0680–0.1012)	0.0824 (0.0647–0.1127)
Glaucoma – ACRIMA-CLAHE	106	0.5525 (0.4382–0.6625)	0.4389 (0.3580–0.5198)	0.4410 (0.3564–0.5423)
Glaucoma – EyePACS-AIROGS-light-V2-CLAHE	9,540	0.5949 (0.5834–0.6058)	0.2868 (0.2819–0.2917)	0.1987 (0.1890–0.2088)
Diabetic ret. – APTOS	733	0.9791 (0.9704–0.9865)	0.0550 (0.0450–0.0657)	0.0254 (0.0223–0.0468)
Diabetic ret. – EyePACS	10,906	0.7181 (0.7051–0.7310)	0.1472 (0.1415–0.1529)	0.1048 (0.0984–0.1121)

Tabela III
Desempenho clínico-operacional do sistema multitarefa final nos limiares operacionais originais

Conjunto de dados	n	Sens. (IC95%)	Spec. (IC95%)	F1 (IC95%)
Glaucoma – REFUGE-CLAHE	400	0.8250 (0.6999–0.9388)	0.5722 (0.5205–0.6236)	0.2907 (0.2115–0.3684)
Glaucoma – ACRIMA-CLAHE	106	0.3833 (0.2586–0.5088)	0.6522 (0.5102–0.7857)	0.4646 (0.3333–0.5794)
Glaucoma – EyePACS-AIROGS-light-V2-CLAHE	9,540	0.9356 (0.9286–0.9424)	0.1050 (0.0964–0.1137)	0.6611 (0.6519–0.6702)
Diabetic ret. – APTOS	733	0.9597 (0.9355–0.9806)	0.8920 (0.8614–0.9195)	0.9065 (0.8813–0.9290)
Diabetic ret. – EyePACS	10,906	0.3439 (0.3234–0.3645)	0.9236 (0.9180–0.9292)	0.4112 (0.3903–0.4314)

Aplicado ao problema do glaucoma, o CLAHE trouxe resultados de discriminação e calibração que variaram conforme o domínio avaliado. No REFUGE, por exemplo, chegou-se a uma AUC de 0,8060 (IC95%: 0,7237–0,8801), com Brier score de 0,0841 e ECE de 0,0824, enquanto no ACRIMA a AUC caiu para 0,5525 (IC95%: 0,4382–0,6625), acompanhada de Brier de 0,4389 e ECE de 0,4410, e no EyePACS-AIROGS-light-V2 registrou-se AUC de 0,5949 (IC95%: 0,5834–0,6058), com Brier de 0,2868 e ECE de 0,1987; dessa forma, ficou claro que os efeitos do CLAHE dependeram do domínio em que o modelo foi testado, e que a perda de desempenho verificada na avaliação externa não foi resolvida por essa técnica.

B. Pontos Operacionais de Limiar para Glaucoma

Como análise exploratória da sensibilidade ao ponto de operação, este estudo avaliou retrospectivamente a aplicação de limiares alternativos ao EyePACS-AIROGS-light-V2-CLAHE sem reajuste a partir da coorte externa. O objetivo foi caracterizar o trade-off operacional sob $\tau_G = 0.249$, selecionado internamente no REFUGE-CLAHE como ponto balanceado, e $\tau_G = 0.300$, adotado como alternativa conservadora, mantendo-se $\tau_G = 0.10$ como limiar principal congelado. Como apresentado na Tabela IV, o aumento do limiar reduziu falsos positivos e elevou a especificidade, à custa de menor sensibilidade e maior número de falsos negativos. Esses achados evidenciam o trade-off operacional esperado em triagem, sem redefinição retrospectiva dos pontos de operação a partir da coorte externa.

Tabela IV
Pontos Operacionais para Glaucoma no EyePACS-AIROGS-light-V2 usando a configuração multitarefa com CLAHE. Os valores entre parênteses representam IC95% bootstrap percentílicos.

Ponto operacional	Sens. (IC95%)	Spec. (IC95%)	BAcc (IC95%)	FP	FN
$\tau = 0.100$ (principal)	0.9356 (0.9286–0.9424)	0.1050 (0.0964–0.1137)	0.5203 (0.5147–0.5258)	4,269	307
$\tau = 0.249$ (balanceado interno)	0.6721 (0.6588–0.6854)	0.4662 (0.4520–0.4803)	0.5692 (0.5596–0.5785)	2,546	1,564
$\tau = 0.300$ (conservador)	0.5551 (0.5411–0.5691)	0.5857 (0.5714–0.5995)	0.5704 (0.5602–0.5801)	1,976	2,122

C. Robustez Externa Além da AUC

Além da redução de AUC na avaliação externa, o ramo de glaucoma exibiu calibração inferior e acentuada dependência do limiar operacional. A elevação desse limiar diminuiu os falsos positivos, porém incrementou os falsos negativos. O ajuste, desse modo, redistribuiu a fragilidade sob deslocamento de domínio, sem removê-la.

D. Experimentos Multitarefa Versus Tarefa Única e Baselines

No experimento exploratório conduzido no REFUGE-CLAHE, a configuração multitarefa alcançou AUC de 0,8060, ao passo que as configurações de tarefa única examinadas registraram AUCs situadas entre 0,4619 (CLAHE com focal loss em 224 × 224) e 0,5610 (CLAHE com recorte central de 80% em 512 × 512). Essa comparação deve ser lida como evidência experimental restrita às configurações avaliadas, e não como demonstração geral de superioridade da abordagem multitarefa. O desbalanceamento e a escassez crítica de dados de glaucoma constituem os fatores que atribuem caráter estritamente preliminar a esses achados, cuja consolidação científica demandará a inclusão de um baseline para retinopatia diabética e o desenvolvimento de modelos independentes com backbones separados em ablações futuras.

E. Resultados de MC Dropout para Glaucoma

A utilidade do MC Dropout na triagem de glaucoma variou entre as coortes de forma consistente com sensibilidade ao deslocamento de domínio. No REFUGE-CLAHE, um desvio-padrão médio mais elevado (0,0539 versus 0,0218 nos acertos) e uma maior entropia (0,6017 contra 0,2456), com um pico nítido nos falsos positivos (DP de 0,0578 e

entropia de 0,6443), foram os comportamentos apresentados pelos erros. Uma clara distinção entre falsos positivos e falsos negativos (DP de 0,0429 vs 0,0176; entropia de 0,6581 vs 0,1936) também foi estabelecida pela incerteza no cenário do ACRIMA-CLAHE. Em contrapartida, uma dissolução quase completa dessa separação foi o que ocorreu no EyePACS-AIROGS-light-V2-CLAHE, ambiente em que uma entropia de 0,5559 nos acertos e de 0,5638 nos erros acabou sendo quantificada.

$$\Delta U = \mathrm{E}\left[U_i \mid \widehat{y}_i \neq y_i\right] - \mathrm{E}\left[U_i \mid \widehat{y}_i = y_i\right], \tag{19}$$

em que U_i representa a métrica de incerteza, como entropia ou desvio-padrão preditivo. Valores positivos e maiores de ΔU indicam maior separação entre predições incorretas e corretas.

F. Resultados de MC Dropout para Retinopatia Diabética

Uma separação de acertos e erros mais consistente do que a observada no glaucoma sugeriu maior capacidade informativa do MC Dropout para a retinopatia diabética nas coortes avaliadas, inclusive no cenário de avaliação externa. Maior entropia média (1,0161 vs 0,5263 nas corretas) e maior desvio-padrão preditivo (0,0442 vs 0,0122) caracterizaram as predições incorretas no APTOS, ao passo que aumentos acentuados na entropia (de 0,3996 para 0,7373) e no desvio-padrão (de 0,0147 para 0,0295) marcaram o comportamento do modelo no EyePACS. Por fim, os maiores níveis de incerteza do sistema acabaram se concentrando nos falsos positivos, registrando marcas de entropia de 1,0587 no APTOS e 1,2566 no EyePACS. Para que a predição seletiva fosse avaliada [19], foram mantidas apenas as amostras cujo nível de incerteza ficou abaixo de um ponto de corte q:

$$R(q) = \{i : U_i \leq q\}, \tag{20}$$

e a acurácia dos casos retidos foi calculada como:

$$\mathrm{Acc}_{\mathrm{retained}}(q) = \frac{1}{|R(q)|} \sum_{i \in R(q)} I\left(\widehat{y}_i = y_i\right). \tag{21}$$

Um salto expressivo na acurácia retida de 0,9195 para 1,0000 no APTOS e de 0,8191 para 0,8951–0,9013 no EyePACS foi provocado pela redução da cobertura de 100% para 50%. Em contrapartida, uma evolução bem mais contida caracterizou o quadro de glaucoma, no qual uma elevação na acurácia retida de 0,8925 para 0,9650 foi obtida no REFUGE-CLAHE, ao passo que ganhos meramente marginais ou instáveis foram apresentados por ACRIMA-CLAHE e EyePACS-AIROGS-light-V2-CLAHE. Assim, esses achados sugerem maior utilidade da predição seletiva para a retinopatia diabética do que para o glaucoma nas coortes avaliadas, sem estabelecer superioridade geral fora desses cenários experimentais.

G. Análise Explicável de Erro e Incerteza Baseada em Superpixels Sob Desvio de Domínio Externo

A análise XAI-SLIC combinou mapas Grad-CAM e superpixels SLIC em 381 imagens revisadas manualmente das bases APTOS, EyePACS, REFUGE-CLAHE, ACRIMA-CLAHE e EyePACS-AIROGS-light-V2-CLAHE. As amostras foram agrupadas, conforme disponibilidade de dados, em predições corretas de baixa incerteza, corretas de alta incerteza, falsos positivos e falsos negativos. Foram avaliadas entropia explicativa normalizada, área percentual de alta atribuição, razão de atribuição nos 10 principais superpixels e métricas complementares.

Atribuições mais concentradas foram mantidas pelas predições corretas com baixa incerteza, ao passo que explicações visivelmente mais difusas foram apresentadas por cenários de maior incerteza. No âmbito das bases APTOS e EyePACS, uma redução expressiva na razão Top-10 (passando de 0,602 para 0,230 e de 0,724 para 0,266, respectivamente) combinada a um salto na entropia (de 0,856 para 0,960 e de 0,769 para 0,951, respectivamente) foram as dinâmicas registradas. A reprodução desse mesmo comportamento caracterizou a análise do glaucoma (Tabela V), cenário no qual declínios acentuados na razão Top-10 foram observados no REFUGE-CLAHE (de 0,593 para 0,207), no ACRIMA-CLAHE (de 0,595 para 0,281) e no EyePACS-AIROGS-light-V2-CLAHE (de 0,467 para 0,238), de forma simultânea à estabilização da entropia em patamares próximos a 0,94–0,95.

A análise XAI-SLIC deve ser interpretada como avaliação post-hoc da consistência espacial das atribuições, não como validação clínica. Máscaras de lesão, mapeamento do disco óptico e validação por especialistas não foram realizados.

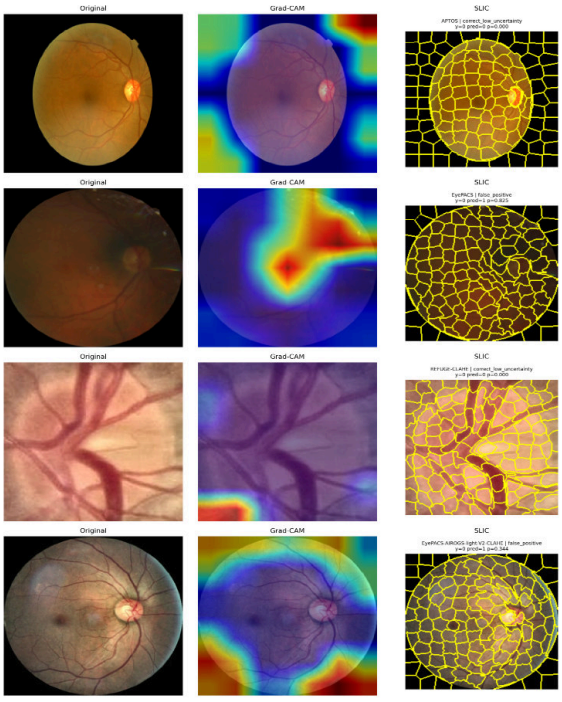

Fig. 2. Explicações representativas por Grad-CAM e SLIC. Imagens originais, sobreposições Grad-CAM e mapas de superpixels SLIC ilustram os padrões de atribuição espacial em casos de triagem por imagens de fundo de olho.

As atribuições mais densas ocorreram nas predições corretas de baixa incerteza; erros e casos incertos produziram explicações mais difusas. O efeito foi maior na retinopatia diabética (EyePACS, $\Delta = 0,458$) do que no glaucoma sob deslocamento externo (EyePACS-AIROGS-light-

Tabela V
MÉTRICAS DE EXPLICABILIDADE EM DIFERENTES DESFECHOS DE PREDIÇÃO

Conjunto de dados	Baixo	Alto	Δ	Padrão
DR–APTOS	0.602	0.230	0.372	Forte
DR–EyePACS	0.724	0.266	0.458	Forte
G–REFUGE-CLAHE	0.593	0.207	0.386	Bem definido
G–ACRIMA-CLAHE	0.595	0.281	0.314	Heterogêneo
G–EyePACS-V2-CLAHE	0.467	0.238	0.229	Mais fraco

V2, $\Delta = 0,229$), sugerindo menor estabilidade espacial das explicações em cenários de domain shift.

H. Temperature Scaling

O Temperature Scaling teve efeito dependente da tarefa. Para retinopatia diabética, $T_{DR} = 0,9358$ preservou a acurácia em 0,7804, praticamente não alterou a AUC OVR multiclasse (0,9240 para 0,9239) e reduziu o ECE de 0,0379 para 0,0276; por isso, foi mantido. Para glaucoma, na análise auxiliar REFUGE raw, $T = 1,2739$ preservou a AUC em 0,7581, mas piorou Brier (0,0881 para 0,0900) e ECE (0,0587 para 0,0741), sendo rejeitado. Esses valores de calibração são distintos das métricas operacionais do pipeline principal.

I. Resumo da Ablação em Nível de Componentes

A presente análise de ablação caracterizou efeitos dependentes da tarefa entre os componentes do modelo multitarefa. No ramo de glaucoma, a aplicação de CLAHE elevou a AUC, ao passo que o deslocamento de limiares voltado à mitigação de falsos positivos culminou em incremento correspondente de falsos negativos. O MC Dropout apresentou capacidade variável de separar acertos e erros e perdeu utilidade sob deslocamento externo acentuado; em contrapartida, o Temperature Scaling reduziu o ECE na validação interna da retinopatia diabética, mas piorou Brier score e ECE na análise auxiliar de glaucoma. Tais resultados evidenciam que as saídas do modelo multitarefa demandam a implementação de estratégias de pós-processamento específicas, condicionadas ao escopo individual de cada tarefa, em vez da adoção de uma configuração uniforme aplicada indistintamente.

J. Eficiência Computacional em Comparação com Modelos Independentes

No benchmark com 400 imagens REFUGE-CLAHE em GPU A100, o modelo multitarefa obteve 0,4661 ms/imagem e 30,99 MB, contra 0,9458 ms/imagem e 61,93 MB para dois EfficientNet-B0 sequenciais. Isso correspondeu a 2,03$\times$ menor latência e 49,96% menos armazenamento, ganhos de engenharia que não implicam superioridade clínica.

IV. DISCUSSÃO

Os resultados evidenciam heterogeneidade entre tarefas e domínios. A retinopatia diabética apresentou melhor discriminação relativa, enquanto o glaucoma foi mais vulnerável à transferência; no ACRIMA-CLAHE, por exemplo, o IC95% da AUC (0,4382–0,6625) inclui 0,50. Limiares, MC Dropout, Temperature Scaling e Grad-CAM/SLIC também responderam de modo dependente da tarefa e do domínio. A vantagem computacional do backbone compartilhado deve ser interpretada apenas como ganho de engenharia, não como evidência de superioridade clínica.

O pipeline deve, portanto, ser entendido como protótipo de pesquisa auditável, com métricas recomputáveis a partir das predições preservadas. Controle de qualidade, segmentação do disco óptico, adaptação de domínio, coortes mais representativas e validação prospectiva permanecem prioridades.

V. LIMITAÇÕES

O glaucoma permaneceu sensível ao deslocamento de domínio, e os modelos de tarefa única devem ser considerados exploratórios. MC Dropout utilizou apenas dez passagens, enquanto Grad-CAM/SLIC não contou com segmentação anatômica nem validação por especialistas.

Não houve teste interno independente. Para retinopatia diabética, a auditoria identificou 41 hashes SHA-256 compartilhados entre treinamento e validação do APTOS, envolvendo 83 registros; portanto, a estimativa interna pode ser otimista e deve ser interpretada como resultado de desenvolvimento. Para glaucoma, as mesmas 400 imagens REFUGE-CLAHE foram usadas no exame dos pontos de operação e na estimação das métricas internas dependentes de limiar.

A ACRIMA-CLAHE é pequena ($n = 106$), o que amplia a incerteza. Além disso, o bootstrap foi realizado em nível de imagem; no EyePACS, a possível presença de dois olhos do mesmo paciente pode violar independência e estreitar os IC95%, pois não havia identificadores suficientes para reamostragem agrupada por paciente.

VI. CONCLUSÃO

O pipeline multitarefa mostrou melhor robustez relativa para retinopatia diabética e maior vulnerabilidade externa para glaucoma. A elevada estimativa interna do APTOS deve ser interpretada com cautela devido à sobreposição retrospectivamente identificada entre treinamento e validação, enquanto o EyePACS fornece a principal evidência externa para essa tarefa. CLAHE, limiares, calibração e incerteza apresentaram efeitos dependentes do domínio. O sistema deve, portanto, ser considerado um protótipo experimental auditável, não uma ferramenta clínica validada. Trabalhos futuros devem priorizar glaucoma, adaptação de domínio e validação prospectiva em nível de paciente.

Resumo— **Este artigo descreve a implementação de uma arquitetura de redes neurais convolucionais 3D com o objetivo de classificar pacientes nas categorias controle, esquizofrenia e transtorno bipolar, com base em características extraídas de dados de MRI. A arquitetura utilizada consiste em uma rede neural híbrida multimodal do tipo multi-input com fusão tardia, combinando uma CNN 3D para extração de características espaciais ao longo da sequência dos vídeos com uma rede MLP para processamento de atributos tabulares. O modelo apresentou acurácia de 61,9% (IC95%: 42,9%–81,0%), acurácia balanceada de 61,9% (IC95%: 42,9%–81,0%), precisão macro de 61,3% (IC95%: 38,3%–83,3%), sensibilidade macro de 61,9% (IC95%: 42,9%–81,0%) e F1-score macro de 60,7% (IC95%: 39,5%–80,4%). A AUC macro, calculada pela estratégia One-vs-Rest, foi de 0,738 (IC95%: 0,588–0,878). Os resultados indicam capacidade discriminativa inicial entre as classes avaliadas.**

Palavras-chaves: **Redes Neurais Convolucionais 3D, Ressonância Magnética, Classificador, Esquizofrenia, Transtorno Bipolar**

I. INTRODUÇÃO

A esquizofrenia e o transtorno bipolar estão entre os transtornos psiquiátricos mais complexos, pois embora clinicamente parecidos possuem características sintomáticas distintas [1]. O transtorno bipolar caracteriza-se principalmente por acentuadas oscilações de humor e níveis de energia, as quais podem comprometer significativamente o desempenho nas atividades cotidianas. Em contraste, na esquizofrenia, há presença de distorções perceptivas que podem dificultar a distinção entre realidade e irrealidade [1]. Além disso, indivíduos com esquizofrenia podem apresentar prejuízos nos processos cognitivos e nas interações sociais [1].

Nas últimas décadas, a neuroimagem tem proporcionado uma perspectiva promissora e não invasiva para o estudo do cérebro humano. Técnicas baseadas em ressonância magnética, como a ressonância magnética estrutural (sMRI), a ressonância magnética funcional (fMRI) e a ressonância magnética por difusão (dMRI), possibilitam a obtenção de informações espacialmente detalhadas acerca da estrutura e do funcionamento cerebral, além de permitirem a análise da conectividade funcional e estrutural. O avanço dessas metodologias tem ampliado significativamente a compreensão sobre o cérebro humano e fortalecido as perspectivas de pesquisadores dedicados a investigar um dos sistemas mais complexos conhecidos, o funcionamento cerebral [2].

Os sistemas de compreensão de imagens baseados em técnicas de aprendizado de máquina (Machine Learning – ML) avançaram na área de neuroimagem para distúrbios cerebrais [3]. Entre as abordagens mais utilizadas, destacam-se algoritmos como árvores de decisão, métodos de agrupamento (clustering), máquinas de vetores de suporte (SVM), k-vizinhos mais próximos (k-NN), máquinas de Boltzmann restritas (RBMs) e florestas aleatórias (Random Forests). Um dos principais desafios na aplicação dessas técnicas reside na etapa de extração de características discriminantes, que em muitos casos, depende de conhecimento prévio da pessoa que está manuseando, especialmente em aplicações relacionadas à análise e compreensão de imagens [3].

Nesse contexto, modelos baseados em aprendizado profundo têm ganhado destaque atualmente, em particular as redes neurais convolucionais (Convolutional Neural Networks – CNN). Essas arquiteturas são capazes de aprender automaticamente representações relevantes a partir dos dados, eliminando, em grande medida, essa etapa de extração manual de características. As CNNs são compostas por camadas convolucionais formadas por filtros que atuam na detecção e extração de padrões essenciais, contribuindo para uma interpretação mais eficiente e precisa dessas imagens médicas [3].

Estudos anteriores utilizaram técnicas de aprendizado profundo a partir de imagens de ressonância magnética [4] [7] e utilizaram redes neurais para analisar padrões de ciclos temporais a partir de rsfMRI [5]. Apesar desses avanços, a distinção entre dois distúrbios permanece desafiadora [6].

Nesse estudo, foi desenvolvido um modelo de rede neural convolucional tridimensional (CNN 3D) com o objetivo de classificar pacientes em três categorias distintas: indivíduos com esquizofrenia, transtorno bipolar e controles saudáveis. A escolha por uma abordagem tridimensional justifica-se pela natureza volumétrica das imagens de ressonância magnética, permitindo a exploração mais completa das informações espaciais presentes nos dados cerebrais.

II. MATERIAIS E MÉTODOS

A. Base de dados e aquisição de imagens

Todos os dados foram disponibilizados pelo Hospital Nina Rodrigues. O recrutamento ocorreu entre julho de 2017 e abril de 2019, no serviço ambulatório de humor e psicose do Hospital Nina Rodrigues. A amostra foi composta especificamente por indivíduos de etnia afrodescendente (negros e pardos) e indígenas. Os diagnósticos foram estabelecidos de acordo com os critérios do Manual Diagnóstico e Estatístico de Transtornos Mentais, 5ª edição (DSM-5), da Associação Americana de Psiquiatria. [8]. A Entrevista Diagnóstica para Psicose e Transtornos Afetivos (Di-PAD), baseada nos algoritmos do DSM-IV, foi utilizada para estabelecer o diagnóstico de ESQ e TB, além de avaliar sintomas depressivos e maníacos [8].

A idade dos participantes variou entre 22 e 31 anos, com mediana de idade de 25 anos entre os 36 homens e 28 mulheres, contudo o sexo não foi incluído como covariável no modelo estatístico principal. Em relação à composição étnica, 49 participantes foram classificados como pardos, 14 como negros e um como indígena. Os critérios de exclusão incluíram casos de transtornos orgânicos como tumor cerebral, AIDS, trauma craniano ou infecções no sistema nervoso central, casos de deficiência intelectual ou dependência química foram retirados também [8] [9].

O conjunto de dados inclui imagens de ressonância magnética estrutural no formato NIfTI (Neuroimaging Informatics Technology Initiative) de 20 pacientes bipolares, 23 pacientes esquizofrênicos e 21 indivíduos saudáveis. Cada participante contribuiu, em média, com 160 imagens, abrangendo cortes coronais, sagitais e axiais do volume cerebral. O software de processamento utilizado foi o FreeSurfer 7.4.1 com o atlas Desikan-Killiany que segmenta o córtex em 68 regiões de interesse [9].

No total, foram selecionadas 10.240 imagens de 64 sujeitos. Todas as imagens foram analisadas por profissionais do hospital para eliminar aquelas com movimento excessivo ou ruídos que pudessem comprometer a eficácia do algoritmo de classificação.

B. Comitê de Ética

A utilização dos dados empregados neste estudo foi aprovada pelo Comitê de Ética em Pesquisa do Hospital Nina Rodrigues, sob o Certificado de Apresentação para Apreciação Ética (CAAE) nº 45.604.215.3.1001.5162 e seguiu os protocolos estabelecidos pela declaração de Helsinque, em conformidade com a Resolução nº 466, de 12 de dezembro de 2012, do Conselho Nacional de Saúde. Todos os participantes assinaram o termo de consentimento livre e Esclarecido (TCLE) após explicação completa, com autorização adicional por escrito de seus familiares. As imagens de ressonância magnética foram disponibilizadas pelo Hospital Nina Rodrigues exclusivamente para fins de pesquisa científica e previamente anonimizadas, garantindo a confidencialidade e a privacidade dos participantes

C. Aquisição e pré – processamento das imagens

Todas as imagens no formato NIfTI foram submetidas a uma etapa de pré-processamento e avaliadas manualmente pelos profissionais por meio do software FSL (FMRIB Software Library), desenvolvido pelo Oxford Centre for Functional MRI of the Brain (FMRIB). Esse conjunto de ferramentas é utilizado principalmente em pesquisas neurocientíficas para o processamento e análise de dados de ressonância magnética [15].

Inicialmente, para a correção de artefatos e distorções decorrentes do movimento dos pacientes durante a aquisição das imagens, empregou-se a ferramenta MCFLIRT do FSL. Esse método realiza o registro e o alinhamento das imagens em um espaço comum, garantindo maior consistência dos dados e aumentando a precisão das análises subsequentes. Em seguida, procedeu-se à remoção do crânio por meio do algoritmo BET (Brain Extraction Tool), responsável por segmentar e extrair o tecido cerebral, eliminando estruturas não cerebrais. Após essa etapa, foi realizada uma inspeção visual por especialistas do hospital, com o objetivo de assegurar a qualidade da extração e identificar possíveis falhas, tais como remoção inadequada de tecidos, erros operacionais ou saídas corrompidas.

Posteriormente, realizou-se o registro linear das imagens utilizando a ferramenta FLIRT (FMRIB's Linear Image Registration Tool). Esse processo envolveu a normalização das imagens de cada paciente para o espaço anatômico padrão MNI152, com resolução de 1 mm^3, por meio de transformações lineares, incluindo rotações, translações e escalonamentos [16]. Tal procedimento possibilitou a padronização dos dados, permitindo comparações consistentes entre diferentes indivíduos.

Em seguida, foi aplicada a ferramenta FNIRT para a realização do registro não linear, com o objetivo de ajustar variações anatômicas individuais e corrigir distorções mais complexas, especialmente na região da substância cinzenta, no espaço MNI152. Essa etapa contribuiu para o aumento da precisão nas análises interindividuais.

Assim, foram gerados dois conjuntos de neuroimagens para cada paciente. O primeiro conjunto, mostrado na Figura 1, consiste em imagens normalizadas para 1 mm3 no espaço anatômico MNI152. O segundo conjunto, representado na Figura 2, foi obtido a partir de imagens pré-processadas com a aplicação da máscara da substância cinzenta, também no padrão MNI152 utilizado o FNIRT, com o objetivo de realçar a região da substância cinzenta do cérebro.

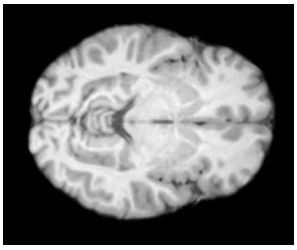

Figura 1- Exemplo de imagem de ressonância magnética normalizadas para 1 mm3 no espaço anatômico MNI152.

Figura 2- Exemplo de máscara de substancia cinzenta no espaço MNI152.

D. Extração de características

A etapa de extração de características foi realizado com o intuito de transformar os dados volumétricos de neuroimagem em representações numéricas compactas e discriminativas, adequadas para tarefas de classificação supervisionada.

Inicialmente, os volumes de imagens de ressonância magnética foram organizados como sequências tridimensionais $A \in \mathbb{R}^{T \times H \times W}$, onde T representa o número de cortes (frames), e $H \times W$ correspondem às dimensões espaciais de cada imagem. Paralelamente, foi considerada uma máscara cerebral $B \in \mathbb{R}^{T \times H \times W}$, responsável por delimitar regiões de interesse.

Como etapa fundamental de padronização, aplicou-se a normalização do tipo *z-score* sobre os valores de intensidade da imagem, considerando apenas os voxels pertencentes à região cerebral utilizando a máscara como guia. Essa transformação é definida pela equação 1:

$$z = \frac{x - \mu}{\sigma} \qquad (1)$$

Em que x representa a intensidade original do voxel, μ a média e σ o desvio padrão calculados exclusivamente sobre os voxels da máscara cerebral. Após a normalização, foram extraídas características estatísticas ao longo da sequência de cortes, considerando apenas os voxels pertencentes ao cérebro. Para cada frame T, foi definida uma região de interesse $\Omega = \{(i,j) | B\ (i,j) > \tau\}$, sendo τ um limiar. A média de intensidade em cada frame T é dada pela equação 2:

$$\mu_T = \frac{1}{|\Omega_T|} \sum_{(i,j \in \Omega_T)} A_T(i,j) \qquad (2)$$

Para cada frame, foram calculadas as seguintes medidas: média, desvio padrão, mediana, intervalo interquartil, desvio absoluto mediano, assimetria e curtose. Essas medidas permitem capturar propriedades centrais, dispersão e forma da distribuição das intensidades dos voxels cerebrais. Além das estatísticas por frame, foram calculadas características baseadas na variação temporal entre cortes consecutivos, definidas pela equação 3:

$$\Delta A_T = A_T + 1 - A_T \qquad (3)$$

A partir dessas diferenças, foram extraídas novamente as mesmas estatísticas, permitindo modelar mudanças estruturais ao longo do eixo volumétrico.

Após a extração inicial, os dados foram particionados em conjuntos de treinamento e teste de forma independente por participante, garantindo que um mesmo paciente não estivesse presente em ambos os conjuntos. A etapa de seleção de características foi então realizada exclusivamente sobre o conjunto de treinamento com o objetivo de reduzir redundâncias com objetivo de melhorar a capacidade de generalização do modelo. Primeiramente, todas as características foram padronizadas via z-score, garantindo comparabilidade entre diferentes escalas. Em seguida, aplicou-se o teste ANOVA (*F-test*) para avaliar a relevância estatística de cada característica em relação às classes, selecionando aquelas com valor de $p < 0.05$.

E. Particionamento dos Dados

Os dados foram divididos por paciente, cada participante foi representado uma sequência tridimensional contendo 160 cortes axiais, onde cada corte da seção transversal foi convertido em um frame, e esses frames foram combinados em um vídeo de 16 segundos de duração e com dimensões de 96x96 pixels.

A proporção adotada para a divisão dos dados foi de 70% dos pacientes para treinamento e 30% dos pacientes para teste, onde a separação foi realizada de forma aleatória, não sfoi utilizada a validação cruzada, pois essa estratégia foi adotada considerando o custo computacional da arquitetura 3D proposta e a possibilidade, por conta do tamanho reduzido da amostra, uma única partição pode produzir estimativas dependentes da composição do conjunto de teste.

Para evitar vazamento nenhuma imagem de um paciente presente no conjunto de treinamento foi incluída no conjunto de teste, essa separação foi feita utilizando o identificador do participante como variável de agrupamento no algoritmo GroupShuffleSplit. Assim, embora cada participante tenha contribuído com aproximadamente 160 fatias para a representação volumétrica, essas fatias não foram consideradas observações independentes durante a divisão dos dados.

Não houve aumento da base de dados por meio de técnicas como deslocamento ou ruído, uma vez que cada participante é representado por um volume completo de 160 cortes axiais.

F. Entradas na rede neural

Para entrada da rede neural, medições do número de cortes no eixo Z, correspondendo ao topo do crânio, e das coordenadas XY do mesencéfalo foram realizadas a partir da visualização axial de cada imagem como demonstrado na figura 3.

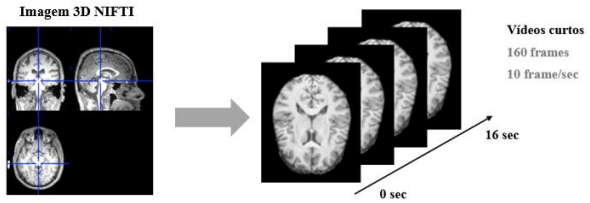

Figura 3-Processo de conversão de uma imagem cerebral 3D NIfTI em vídeos curtos de slices axiais.

A ressonância magnética estrutural utilizada não corresponde a um vídeo real, pois os cortes adquiridos representam diferentes posições anatômicas do cérebro. A utilização dos vídeos ocorreu como estratégia para preservar a sequência espacial dos cortes axiais do volume cerebral. A escolha dessa abordagem também ocorreu por se assemelhar a abordagem clínica de interpretação dessas imagens pelos médicos.

G. Fusão tardia

As caraterísticas tabulares são processadas por uma MLP que gera uma representação vetorial, paralelamente a CNN 3D processa todos os mapas de características e calcula a media dos valores daquele mapa e os transformar em um vetor de caraterísticas que representa as informações aprendidas pela rede de forma compacta.

Os dois vetores são concatenados para gerar um vetor de características multimodal sendo encaminhado para as camadas seguintes que irão produzir as probabilidades de pertencimento a uma das classes propostas como demonstrado pela figura 4.

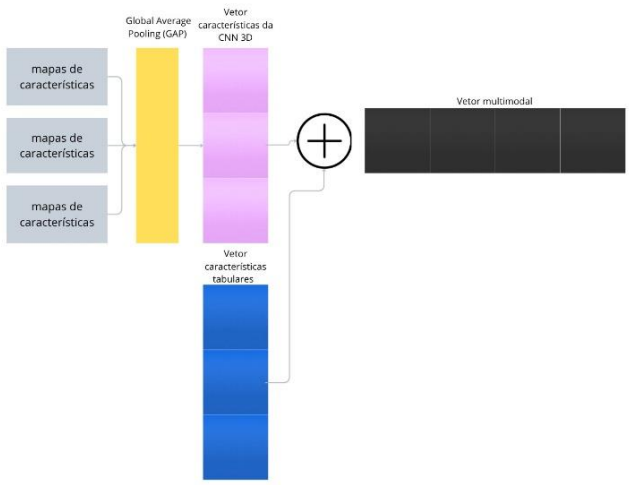

Figura 4- Esquema da fusão tardia da rede.

H. Rede neural 3D

A arquitetura da rede neural consiste em três blocos convolucionais 3D sequenciais. O primeiro bloco da rede é composto por camadas convolucionais tridimensionais com 24 filtros e kernels de dimensão 3×3×3 para extração de padrões locais iniciais; em seguida, são aplicadas operações de normalização e funções de ativação do tipo ReLU, introduzindo não-linearidade e estabilizando o processo de treinamento. É realizado um MaxPool3D para reduzir a resolução espacial (altura e largura) pela metade em cada uma das medidas, mas mantendo a dimensão temporal *T* inalterada.

O segundo bloco convolucional segue estrutura semelhante, porém com aumento do número de filtros para 48, permitindo detectar padrões mais complexos e combinações de características do bloco anterior.

No terceiro bloco, o número de filtros é expandido para 72, permitindo a extração de representações ainda mais abstratas e o pooling reduz a dimensão temporal, dimensão altura e dimensão largura para diminuir risco de overfitting.

Após os três blocos, a rede aplica uma Global Average Pooling 3D, que reduz toda a informação do espaço temporal em um vetor de 72 características. Por fim, uma camada densa com ativação ReLU processa essas características, preparando-as para a concatenação com as features tabulares e a classificação final.

Paralelamente ao processamento das imagens pela CNN 3D, as características tabulares selecionadas são inseridas em uma camada de normalização e posteriormente processadas por uma camada densa de 64 neurônios com ativação ReLU, seguida de Dropout de 0,15. As saídas dos dois ramos (convolucional e de características) são concatenadas e encaminhadas para ás camadas finais de classificação. O otimizador utilizado foi o AdamW com taxa de aprendizado de 3×10^{-4}, associado à função de perda Focal Loss que foi utilizado para lidar com possíveis desbalanceamentos entre as classes. A arquitetura da rede neural e representada pela figura 5 com as camadas de convolução e entrada das caraterísticas para a decisão.

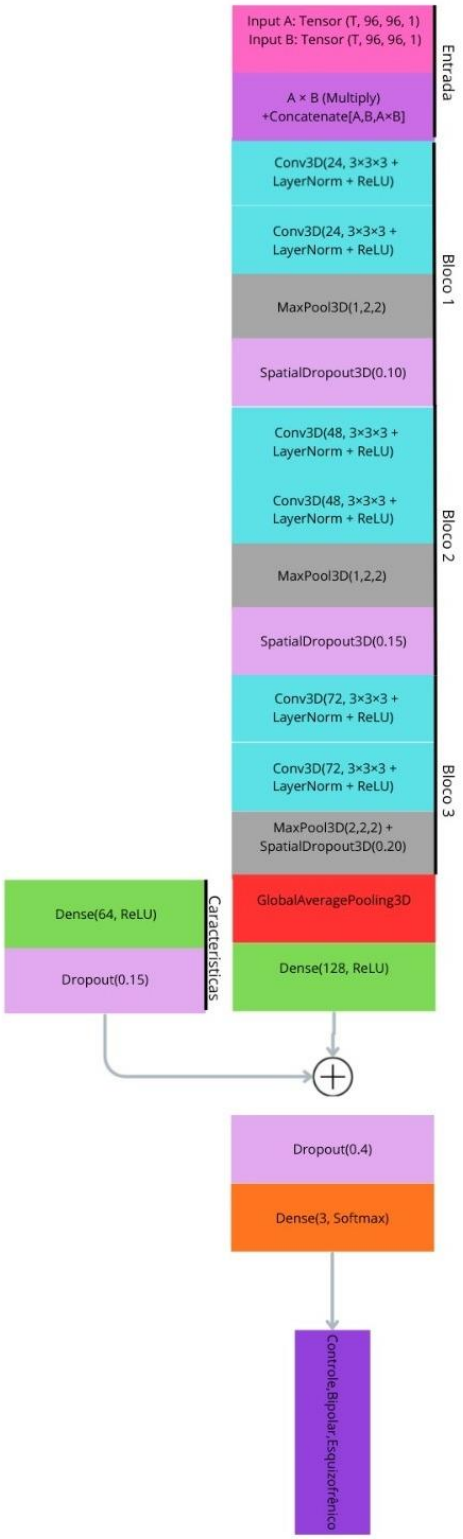

Figura 5-Arquitetura da rede neural 3D.

I. Treinamento e seleção de hiperparâmetros

Os hiperparâmetros foram primordialmente escolhidos com base na literatura utilizada em tarefas similares. Consecutivamente, a partir de experimentos exploratórios e

ajustes iterativos do modelo e considerando o desempenho observado no conjunto de teste se chegou nos parâmetros da rede observados na tabela 1. Os experimentos foram executados utilizando o ambiente Google Colab com aceleração por GPU, com implementação em Python utilizando o framework TensorFlow/Keras. Foi utilizado uma GPU NVIDIA Tesla T4 com 16 GB de memória dedicada.

Tabela 1: Parâmetros da rede

Parâmetro	Valor
Tensor de entrada de cada vídeo	160 × 96 × 96 × 1
Número de pacientes (Treino/Teste)	64 (43/21)
Filtros Conv3D	24,48,72
Otimizador	AdamW
Número máximo de épocas	100
Dropout espacial	0.10;0.15; 0.20
Taxa de aprendizado inicial	3×10^{-4}
Função de perda	Focal Loss ($\gamma = 2,0$)

III. Resultados e discursões

A. *Metricas de avaliação por nivel de participante*

A métricas foram avaliadas considerando cada participante como uma unidade. A acurácia calcula a taxa de acertos do modelo dividido pelo total de casos, a acurácia balanceada é calculada pela média do recall de cada classe. A Precisão macro corresponde à média aritmética das precisões obtidas individualmente para cada classe, atribuindo o mesmo peso a todas elas. A sensibilidade corresponde à média dos valores de recall das três classes. O F1 combina precisão e sensibilidade por meio da média harmônica dessas duas medidas, enquanto o F1-score macro corresponde à média dos F1-scores das classes [10]. Os resultados do modelo estão descritos na tabela 2.

Tabela 2: Resultados nas métricas.

Métricas do teste em nível de participante	
Acurácia	0,6190
Acurácia Balanceada	0,6190
Precisão macro	0,6127
Sensibilidade macro	0,6190
F1 score macro	0,6071

A acurácia está acima de um chute aleatório, contudo ainda não é o bastante para apresentar uma boa capacidade de generalização do modelo, o valor semelhante de sensibilidade macro e da acurácia balanceada se dá principalmente porque o conjunto teste possui numero de participantes em cada classe sendo sete pacientes para cada classe durante o teste.

A dificuldade em identificar os participantes em suas respectivas classes e demonstrando principalmente pelo baixo valor da sensibilidade, indicado que um parcela dos participantes não foi categorizada de forma correta. O F1 e a precisão demonstram uma dificuldade em atribuir os pacientes em suas categorias corretas e um desempenho limitado no equilíbrio e evitar classificações incorretas.

B. *Intervalo de confiança de 95% e desempenho por classe*

O intervalo de confiança é uma faixa de valores que demonstra a incerteza a estimativa de um parâmetro. O nível de 95% foi adotado por ser o mais utilizado em trabalhos semelhantes. A amplitude do intervalo de confiança mede o grau de incerteza do resultado final, para garantir os 95% os limites de 42.9% a 81% foram estipulados como intervalos de incertezas. Os resultados da tabela 3 foram obtidos pelo método de bootstrap estratificado por classe demonstrando o resultado do modelo nesses intervalos.

Tabela 3: Estimas das métricas de avaliação

Métricas	Estimativa	IC95% Inferior	IC95% Superior
Acurácia	0,619	0,429	0,810
Acurácia Balanceada	0,619	0,429	0,810
Precisão macro	0,613	0,383	0,833
Sensibilidade macro	0,619	0,429	0,810
F1 score macro	0,607	0,395	0,804
AUC macro	0,738	0,588	0,878

Os intervalos de confiança apresentam amplitude considerável, refletindo a incerteza associada ao tamanho reduzido da amostra. A acurácia e a sensibilidade macro apresentaram IC95% entre 0,429 e 0,810, enquanto a precisão macro variou entre 0,383 e 0,833. Esses resultados indicam que as estimativas apresentam elevada variabilidade e elevada oscilação entre os valores.

O melhor resultado do sistema se mostra no seu valor de AUC macro, que foi calculado utilizando por meio do One-vs-Rest, que não se intercepta pela limites do acaso mostrando que o algoritmo desenvolveu capacidade relevante de discriminação entre as classes exibindo uma consistência maior que as outras métricas.

C. *Curva ROC*

A curva ROC é usada para avaliar a capacidade discriminativa de um teste e comparar o desempenho de dois ou mais testes . Também é usado para selecionar um valor de corte ótimo para determinar a presença ou ausência de uma doença.[11].

Quanto mais a curva ROC se aproxima do canto superior esquerdo, melhor é a qualidade do teste quanto à sua capacidade para discriminar os grupos. No centro, a linha de referência diagonal da curva ROC representa uma região de completa aleatoriedade do teste, mostrando um modelo incapaz de classificar tanto doentes como saudáveis [12].

Uma das métricas de avaliação é o AUC (Área sobre a curva) que demonstra a capacidade do modelo de diferenciar as classes. Um valor AUC próximo de um 1 indica um bom poder discriminatório, enquanto um valor próximo de 0.5 indica uma escolha aleatória. A curva ROC do modelo obtido é representado pela figura 6, onde a classe controle é representada pela linha de cor azul, a bipolar pela linha de cor

laranja e esquizofrênico pela linha de cor verde e a reta de referência do chute aleatório é a de cor vermelha.

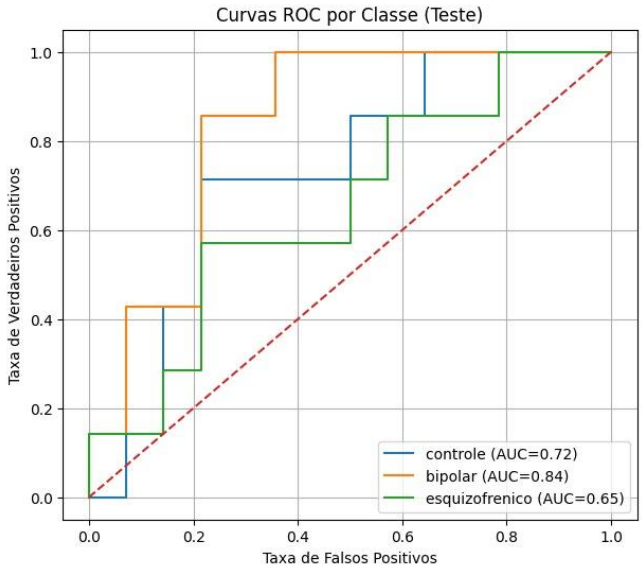

Figura 6- Curva ROC do sistema.

A classe controle apresentou o valor de AUC sendo 0.72 demonstrando uma capacidade de diferenciação do modelo entre pacientes saudáveis em relação aos portadores de transtornos psiquiátricos, com a curva demonstrando elevada sensibilidade mesmo para baixos níveis de falso positivo.

Por outro lado, a classe esquizofrenia obteve AUC de 0,65 sendo o pior de todas as classes avaliadas, enquanto a classe bipolar apresentou o maior desempenho, com AUC de 0,84. Uma das causas desse menor desempenho é a existência de semelhanças clínicas e neurobiológicas entre esses transtornos como, por exemplo, o compartilhamento de características sintomatológicas relacionados [14]. Além disso, pode ocorrer sobreposição nos circuitos cerebrais afetados, o que torna mais difícil a diferenciação, pois os modelos precisam detectar diferenças finas, o que reduz a acurácia.

A limitação do tamanho da base de pacientes também demonstra impacto no resultado, pois em aprendizado profundo, conjuntos de dados reduzidos podem dificultar a generalização do modelo e limitar sua capacidade de aprender características discriminativas mais robustas para cada classe. Além disso modelos treinados com diferentes quantidades de paciente podem favorecer classes mais representadas.

O modelo alcançou um AUC médio de 0.7381, todos os valores de AUC ficaram acima da linha de referência (AUC = 0.50), confirmando que o modelo possui poder preditivo capaz de produzir classificações corretas com destaque a classe bipolar que se saiu superior as outras nos testes.

D. Matriz de confusão

A Matriz de confusão apresenta a distribuição entre as classes reais e as classes previstas pelo modelo [13]. As linhas representam as classes reais, enquanto as colunas representam as classes previstas pelo modelo. A diagonal principal, apresenta os acertos do modelo em prever corretamente a classificação do indivíduo. A matriz do conjunto de teste do modelo gerado é representado pela figura 7.

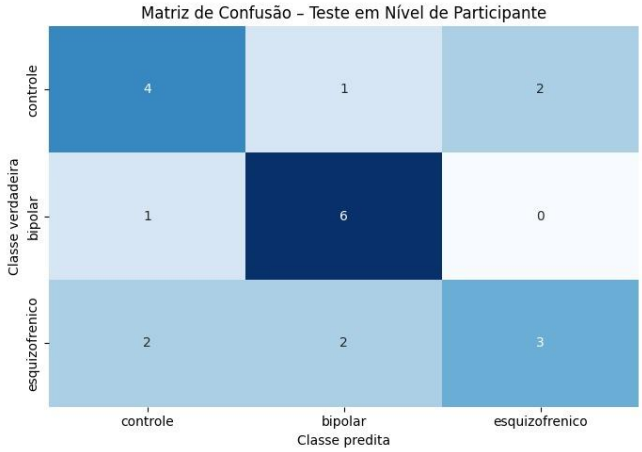

Figura 7- Matriz de confusão do teste.

O modelo previu a classe controle categorizando errado uma de seus participantes para bipolar e dois para esquizofrênico de forma incorreta formando uma sensibilidade para a classe de 57.14%.

Em contrapartida, para a classe esquizofrênico, das sete amostras reais, o modelo acertou apenas três com sensibilidade de 42,86% indicando uma dificuldade em capturar padrões discriminativos adequados para essa categoria e alinhando-se com os resultados obtidos na análise das curvas ROC, onde a classe esquizofrênico, apresentou o menor AUC.

Para a classe de pacientes com bipolar, nenhum deles foi classificado como esquizofrênico e um de seus participantes foram classificados incorretamente como da categoria controle, com uma sensibilidade de 85,71% demonstrando um desempenho superior a toda as outras classes. Demonstrando que o modelo teve facilidade para diferenciar a classe bipolar das outras duas, onde a classe esquizofrênica apresentou erros entre controle e bipolar demonstrando que engano não se concentra em uma classe especifica

IV. Conclusão

Como conclusão do estudo, foi possível observar que há capacidade discriminativa limitada utilizando a rede neural híbrida multimodal e os resultados de experimento exploratório com um conjunto de dados locais. Com esse estudo, se espera contribuir para os estudos sobre a capacidade de modelos de aprendizado profundo em identificar padrões cerebrais associados a transtornos psiquiátricos complexos.

Espera-se que este trabalho utilizado para novas pesquisas que utilizam técnicas de aprendizado profundo, pois os resultados apontam para um potencial das redes neurais convolucionais 3D como ferramenta auxiliar para identificação de transtornos mentais, incentivando o desenvolvimento de modelos mais robustos, interpretáveis e com potencial para ferramenta experimental para estudos futuros.

Portanto, diante dos resultados modelo de rede neural proposto para a base de dados particular, pretende-se aplicar e avaliar o modelo em outras bases de dados que contenham

as mesmas classes e aplicação de técnicas mais avançadas para obter resultados mais expressivos.

***Abstract*—Raw digital breast tomosynthesis (DBT) projections exhibit noise whose variance depends on both signal intensity and detector position. Analytical stabilization using the Generalized Anscombe Transform (GAT) requires a spatial quantum-gain map and an electronic-noise parameter, which may be unavailable without access to equipment calibration data. This preliminary study investigates whether a residual convolutional neural network can approximate the analytical transformation directly from noisy projections, without receiving these parameters at inference. The network was trained on 700 OpenVCT-simulated patches from 70 phantoms and tested on 150 patches from 15 independent phantoms. A single spatially varying gain map and a fixed electronic-noise level were used throughout; therefore, evaluation addressed new anatomies under the same calibration configuration. Wavelet-based estimation yielded an output noise standard deviation of 0.897 ± 0.044, compared with the target value of 1.0. Monte Carlo evaluation using 20 noise realizations for each of 75 test patches yielded a mean stabilization error of 50.45%, with a standard deviation of 14.32% across the 15 phantom means and a 95% confidence interval of $[43.20\%, 57.70\%]$. Patch-level error was strongly correlated with local quantum gain ($r = 0.782$). The analytical GAT yielded an error of 0.095% under the same evaluation procedure, supporting the interpretation that the network's larger error reflects limitations of the learned transformation. The network partially approximated the GAT but did not achieve uniform variance stabilization under the evaluated conditions. Future work will train and evaluate the network across different gain maps and electronic-noise levels to assess generalization beyond the calibration configuration used here.**

***Index Terms*—digital breast tomosynthesis, variance stabilization, generalized Anscombe transform, residual neural network, heteroscedastic noise, virtual clinical trials.**

I. Introduction

Digital breast tomosynthesis (DBT) complements conventional digital mammography by reducing tissue-overlap effects, reconstructing a 3D volume from multiple projections acquired over a limited angular arc [1], [4].

In raw ("for processing") DBT projections, noise is heteroscedastic: it arises predominantly from the quantum nature of X-ray radiation and follows an affine variance model, where each pixel's variance depends linearly on the underlying signal and on the detector's spatially varying quantum gain, plus a constant electronic-noise component [1], [2].

Variance-stabilizing transforms (VSTs), such as the Generalized Anscombe Transform (GAT), convert this signal-dependent noise into approximately signal-independent noise, facilitating denoising. However, accurate GAT application requires the detector's quantum-gain map and electronic-noise parameter, estimable when calibration images are available [1], [2] but often unknown for images from unfamiliar equipment. This motivates the present work: investigating whether a network can stabilize a raw DBT projection from the image alone, without the gain map or electronic-noise parameter at inference time.

Brandão et al. [3] addressed this with an iterative method that implicitly estimates these parameters from a single projection (errors of 1.16–7.69% across three systems), but requires per-image optimization at inference. Convolutional networks have also been used to learn stabilizing transforms directly: Zhang et al. [5] proposed VST-Net for Poisson denoising; Eckert et al. [6] used the Anscombe transform for physics-driven augmentation in mammography; and in DBT specifically, Vimieiro et al. [4] applied CycleGAN in a variance-stabilized domain (an unpaired approach with no pixel-wise fidelity guar-

antee), while Araújo et al. [7] and Gao et al. [8] denoised DBT projections and reconstructed slices, respectively, without an explicit variance-stabilization step and with strong dependence on dose/sample size. More recently, Herbreteau and Unser [11] proposed Noise2VST, a self-supervised, model-free VST, though untested on medical X-ray images and still requiring per-image optimization. Mota et al. [12] instead used a 2D total variation filter on reconstructed DBT slices, without a learned, data-driven transformation.

This work reports a *first stage* of a broader investigation into calibration-free variance stabilization for DBT: a residual neural network (ResNet) is trained and evaluated using a single, fixed quantum-gain map and electronic-noise level, simulated via OpenVCT [9] to keep calibration exactly known. Under this fixed configuration, we evaluate only whether the network generalizes to new, unseen anatomies; generalization across different gain maps, noise levels, or acquisition systems is not claimed and is left for future work (Section V).

II. MATERIALS AND METHODS

Fig. 1 summarizes the main steps of the methodology described in this section, from the generation of synthetic noisy projections to the evaluation metrics used to assess variance stabilization performance.

A. Noise Model and Synthetic Data Generation

Images were obtained from the 100-Phantom DBT Hologic dataset, generated by the OpenVCT platform for mammography and DBT simulation [9]. For each phantom, the central projection of the acquisition arc, corresponding to index 7, was used, as it presents the least beam obliquity and most adequately represents the average signal-to-noise ratio of the dataset.

The adopted noise model follows the affine variance model described by Borges et al. [1], [2], in which the observed pixel value $z(i,j)$, conditioned on the underlying noise-free signal $y(i,j)$, presents variance:

$$\mathrm{Var}\{z(i,j) \mid y(i,j)\} = \alpha(i,j)\, y(i,j) + \sigma_e^2 \tag{1}$$

where $\alpha(i,j)$ represents the spatially varying quantum gain of the detector, and σ_e corresponds to the electronic noise standard deviation, assumed constant across the detector. In this work, a single spatially-varying gain map was used throughout training and evaluation, with values ranging between 0.130 and 0.365 over the full detector and between 0.131 and 0.182 within the breast region (Section III-D); the electronic-noise level used was $\sigma_e = 1.3743$ ADU. The noise parameters were estimated following the calibration protocol described by Borges et al. [10].

Both $z(i,j)$ and $y(i,j)$ are expressed in raw detector counts (ADU, analog-to-digital units), following the vendor's linearized pixel values prior to any offset correction. Consequently, since $\mathrm{Var}\{z(i,j) \mid y(i,j)\}$ has units of ADU^2 and $y(i,j)$ is expressed in ADU, the quantum gain $\alpha(i,j)$ is expressed in ADU, and the electronic noise standard deviation σ_e is expressed in ADU as well.

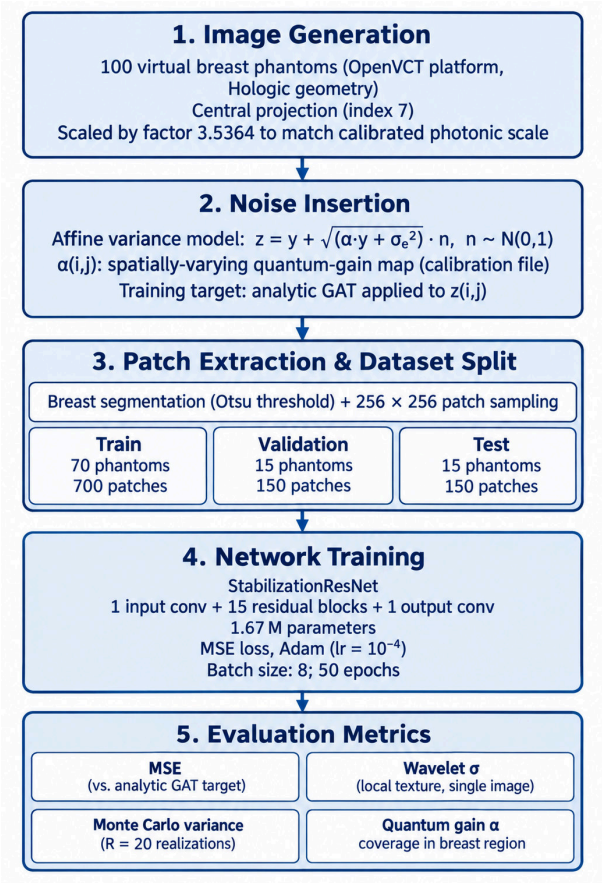

Fig. 1. Overview of the methodology: synthetic image generation, heteroscedastic noise insertion, patch extraction with phantom-level dataset split, network training, and evaluation metrics.

Since the signal level of the synthetic image derived from VCT does not correspond to the signal level of a clinical image, a scaling factor procedure was performed to match the signal levels. Thus, a multiplicative scale factor of 3.5364 was computed from a sample of 20 phantoms and applied to all noise-free projections (y) before noise simulation. Heteroscedastic noise was then generated as:

$$\begin{aligned} z(i,j) &= y(i,j) + \sigma(i,j)\,\eta(i,j), \\ \sigma^2(i,j) &= \alpha(i,j) y(i,j) + \sigma_e^2, \\ \eta(i,j) &\sim \mathcal{N}(0,1). \end{aligned} \tag{2}$$

where $\sigma(i,j)$ denotes the signal- and spatial-dependent noise standard deviation, and $\eta(i,j)$ represents a zero-mean, unit-variance Gaussian noise field.

It is important to clarify the scope of this simulation: the gain map $\alpha(i,j)$ used here already varies *spatially* across the detector (Eq. 1); what was *not* varied was the calibration configuration itself between simulations — the same gain map and the same electronic-noise level σ_e were used for every phantom, in training, validation, and test. Consequently, evaluating the network on the 15 test phantoms (Section III) assesses its behavior on new anatomies *within this fixed*

calibration configuration; it does not assess its ability to operate with a gain map or noise level unseen during training. Extending the training data to span multiple gain maps and noise levels is discussed in Section V.

B. Breast Segmentation and Patch Extraction

The breast region was segmented using Otsu thresholding with threshold inversion to separate the breast from the background. From the binary mask, 10 patches of 256×256 pixels were randomly extracted per phantom, fully contained within the segmented region, allowing up to 1000 attempts per patch. The 100 phantoms were randomly divided — with a fixed seed — into 70 for training, 15 for validation, and 15 for testing at the phantom level, avoiding anatomy sharing between sets. All 100 phantoms successfully contributed patches, yielding 700 training, 150 validation, and 150 test patches, for a total of 1000 patches. Fig. 2 illustrates breast segmentation and patch extraction for a representative phantom.

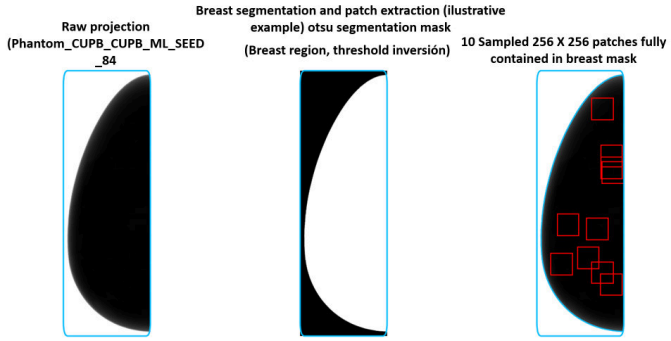

Fig. 2. Illustration of the breast segmentation and patch extraction process for a representative phantom. From left to right: raw DBT projection, Otsu segmentation mask (breast region, threshold inversion), and the 10 sampled 256×256 patches fully contained within the segmented breast mask.

C. Training Target: Generalized Anscombe Transform

The training target was defined as the GAT applied directly to the simulated noisy projection $z(i,j)$:

$$\hat{z}(i,j) = \frac{2}{\alpha(i,j)} \sqrt{\max\left(0,\ \alpha(i,j)\, z(i,j) + \frac{3}{8}\alpha^2(i,j) + \sigma_e^2\right)} \tag{3}$$

This expression is algebraically equivalent to the classical GAT formulation described by Borges et al. [1], assuming $\lambda(i,j) \equiv \alpha(i,j)$ and $\tau = 0$, which is valid for the virtual phantoms used. Thus, the training target corresponds to the analytical VST applied directly to the noisy projection, rather than to a noise-free image.

1) Two-step interpretation of the analytical GAT: The analytical stabilization procedure summarized in Eq. (3) can be understood as two successive operations, and it is useful to make this explicit, since the network is trained to approximate their joint effect. First, the noisy projection is normalized by the spatial gain map. With a null offset ($\tau = 0$, Eq. (1)), define

$$u(i,j) = \frac{z(i,j)}{\alpha(i,j)}. \tag{4}$$

After this normalization, the conditional variance becomes

$$\mathrm{Var}\{u(i,j) \mid y(i,j)\} = \frac{y(i,j)}{\alpha(i,j)} + \frac{\sigma_e^2}{\alpha^2(i,j)}. \tag{5}$$

Dividing by $\alpha(i,j)$ makes the quantum-gain term unitary with respect to the normalized signal, but it does *not* eliminate the spatial dependence of the noise: the electronic-noise term is rescaled as well, with its standard deviation becoming $\sigma_e/\alpha(i,j)$ and its variance $\sigma_e^2/\alpha^2(i,j)$. Second, the GAT is applied to $u(i,j)$ with unit gain, using the rescaled electronic-noise variance from Eq. (5):

$$\hat{z}(i,j) = 2\sqrt{\max\left(0,\ u(i,j) + \frac{3}{8} + \frac{\sigma_e^2}{\alpha^2(i,j)}\right)}. \tag{6}$$

Substituting $u(i,j) = z(i,j)/\alpha(i,j)$ from Eq. (4) into Eq. (6) and factoring $1/\alpha^2(i,j)$ out of the square root recovers exactly Eq. (3). This confirms that the two-step procedure (spatial-gain normalization followed by a unit-gain GAT with rescaled electronic noise) is algebraically identical to the single-step formula already used as the training target; the network's task is therefore to learn this joint transformation — reducing the dependence of the variance on both signal and detector position — directly from the noisy image, without being given $\alpha(i,j)$ or σ_e explicitly at inference time. We verified that the noise-simulation code (Eq. (2)) and the target-generation code (Eq. (3)) apply this electronic-noise rescaling consistently.

D. Network Architecture

The proposed architecture, named *StabilizationResNet*, is a fully convolutional residual network composed of three main stages: an input layer consisting of a 3×3 convolution mapping one input channel to 64 feature channels, followed by a ReLU activation; 15 residual blocks, each composed of three 3×3 convolutional layers with 64 channels, interleaved with Batch Normalization and ReLU activations, and connected through residual skip connections; and an output layer consisting of a 1×1 convolution mapping 64 feature channels to one output channel, with linear activation. The network contains a total of 1,668,225 trainable parameters. Table I summarizes the main hyperparameters used during training.

E. Normalization and Training

Input images (z) and targets ($\hat{z}$) were normalized independently by z-score standardization using training-set statistics, with clipping at ±5 standard deviations, to account for their different dynamic ranges. Averaged over the 150 test patches, this clipping affected 0.68% of input pixels and 0.73% of target pixels, confirming that, on average, the normalization range preserves the vast majority of the signal distribution. However, this average conceals substantial variability across individual patches: as discussed in Section III-B, the patches with the highest MSE show clipping fractions between 7% and 19%, an order of magnitude above this average. Training used MSE loss, Adam optimizer (lr $= 1 \times 10^{-4}$), batch size 8, and 50 epochs on Google Colab GPU. The model with lowest validation loss was selected.

TABLE I
NETWORK ARCHITECTURE AND TRAINING HYPERPARAMETERS.

Parameter	Value
Input	$256 \times 256 \times 1$ normalized raw patch
Initial layer	3×3 convolution, $1 \rightarrow 64$ channels, ReLU
Residual blocks	15 blocks, 64 channels each
Final layer	1×1 convolution, $64 \rightarrow 1$ channel, linear activation
Trainable parameters	1,668,225
Loss function	MSE
Optimizer	Adam, $lr = 1 \times 10^{-4}$
Batch size	8
Epochs	50
Input normalization, z	$\mu = 586.14$, $\sigma = 84.05$
Target normalization, $\hat{z}$	$\mu = 128.61$, $\sigma = 8.19$
Data split	700 / 150 / 150 patches from 70 / 15 / 15 phantoms

F. Evaluation Metrics

Performance was evaluated through: (i) MSE between the denormalized network output and the analytic GAT target; (ii) local residual noise standard deviation, $\hat{\sigma}$, estimated using a wavelet-based estimator (median absolute deviation of the finest-scale wavelet detail coefficients, following Donoho and Johnstone [13]), with a target value of 1.0; and (iii) Monte Carlo validation with $R = 20$ independent noise realizations per patch, computing the empirical pointwise variance (sample variance, unbiased estimator, ddof $= 1$) across realizations — the physically correct criterion for variance stabilization. For each patch, the stabilization error is defined as

$$E_{\%} = 100 \times \left| \overline{\widehat{\mathrm{Var}}_R[\cdot]} - 1 \right|, \tag{7}$$

where $\widehat{\mathrm{Var}}_R[\cdot]$ is the unbiased sample variance computed pixelwise across the $R = 20$ realizations, and $\overline{(\cdot)}$ denotes the spatial average of this pointwise variance over all pixels of the patch.

Note that the wavelet-based $\hat{\sigma}$ measures the local texture of a single output image, while the Monte Carlo variance measures reproducibility across independent noise instances, which are fundamentally different assessments [2]. As a control, the same Monte Carlo procedure (identical patches and identical noise realizations) was also applied to the analytic GAT itself, providing a reference for the error attributable to the evaluation procedure as opposed to the network. Additionally, quantum gain, α, coverage within breast patches was analyzed.

III. RESULTS

A. Training

The network was trained for 50 epochs using the training and validation sets. The final model was selected based on the lowest validation loss, achieved at epoch 47, with a validation loss of 0.079018, as shown in Fig. 3. The training curve shows a consistent decrease in both training and validation losses, with validation oscillations between epochs 25 and 40, which may be attributed to the small batch size and limited dataset size.

B. Quantitative Evaluation on Test Set

Table II summarizes the metrics obtained from the 150 test patches. The MSE distribution was strongly asymmetric, with a mean of 9.92, a median of 5.49, and a standard deviation of 21.00: a small number of patches with markedly elevated error increased the mean substantially above the median.

TABLE II
METRICS COMPUTED OVER THE 150 TEST PATCHES.

Metric	Mean	Median	Std. dev.	Min.	Max.
MSE relative to analytic target	9.92	5.49	21.00	0.55	194.43
Estimated σ in network output	0.897	–	0.044	0.670	0.973
Estimated σ in analytic target	0.999	–	0.008	0.973	1.020

Regarding the estimated σ, the network output presented a mean value of 0.897 ± 0.044, while the analytic GAT target presented $\sigma \approx 0.999 \pm 0.008$, confirming that the analytic GAT correctly stabilizes the variance close to unit value under this pointwise, single-image metric. The network systematically underestimates this parameter, although only 1 out of 150 patches, corresponding to 0.7%, presented a deviation $|\sigma - 1| > 0.3$. As discussed below, this pointwise metric substantially understates the network's stabilization error relative to the reproducibility-based Monte Carlo assessment (Section III-C).

Visual inspection of representative test patches, shown in Fig. 4, reveals over-smoothing in the network output relative to the analytic target, suggesting partial loss of fine noise texture in some patches. Table III presents the five test patches with the highest MSE values, consolidating patch identification, error, local gain, spatial location, and normalization-clipping fraction in a single table.

To assess whether patches with elevated MSE are concentrated near the detector edges, where the quantum gain α is higher, as could be expected from the acquisition geometry, a spatial audit was performed on the full test set (150 patches), recording, for every patch, the coordinates, local mean α, distance to the detector edge, and internal signal statistics. Across all 150 test patches, MSE showed essentially no linear association with local α ($r = -0.019$) or with distance to the detector edge ($r = 0.119$).

Contrary to an edge/high-α hypothesis, none of the five highest-MSE patches are close to the detector edge, and their local gain (mean $\alpha \approx 0.136$ ADU) is close to the mean α of the 20 lowest-MSE patches ($\alpha \approx 0.137$ ADU) — local gain and edge proximity do not distinguish the worst patches from the rest. Instead, the strongest distinguishing factor is the internal signal variability of the patch, computed in the analytic-GAT (dimensionless) domain: the five highest-MSE patches had a mean internal standard deviation of 21.03 and a mean dynamic range of 119.98, versus 3.26 and 20.28, respectively, for the 20 lowest-MSE patches — roughly a sixfold difference.

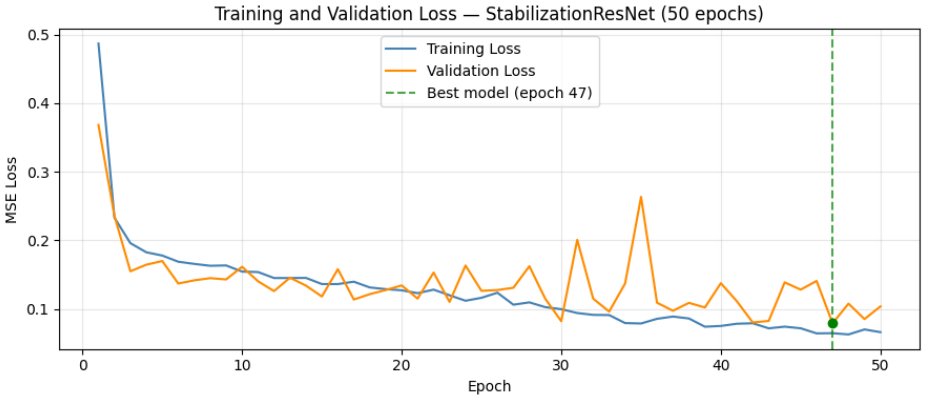

Fig. 3. Training and validation loss curves for the proposed StabilizationResNet model. The lowest validation loss was achieved at epoch 47.

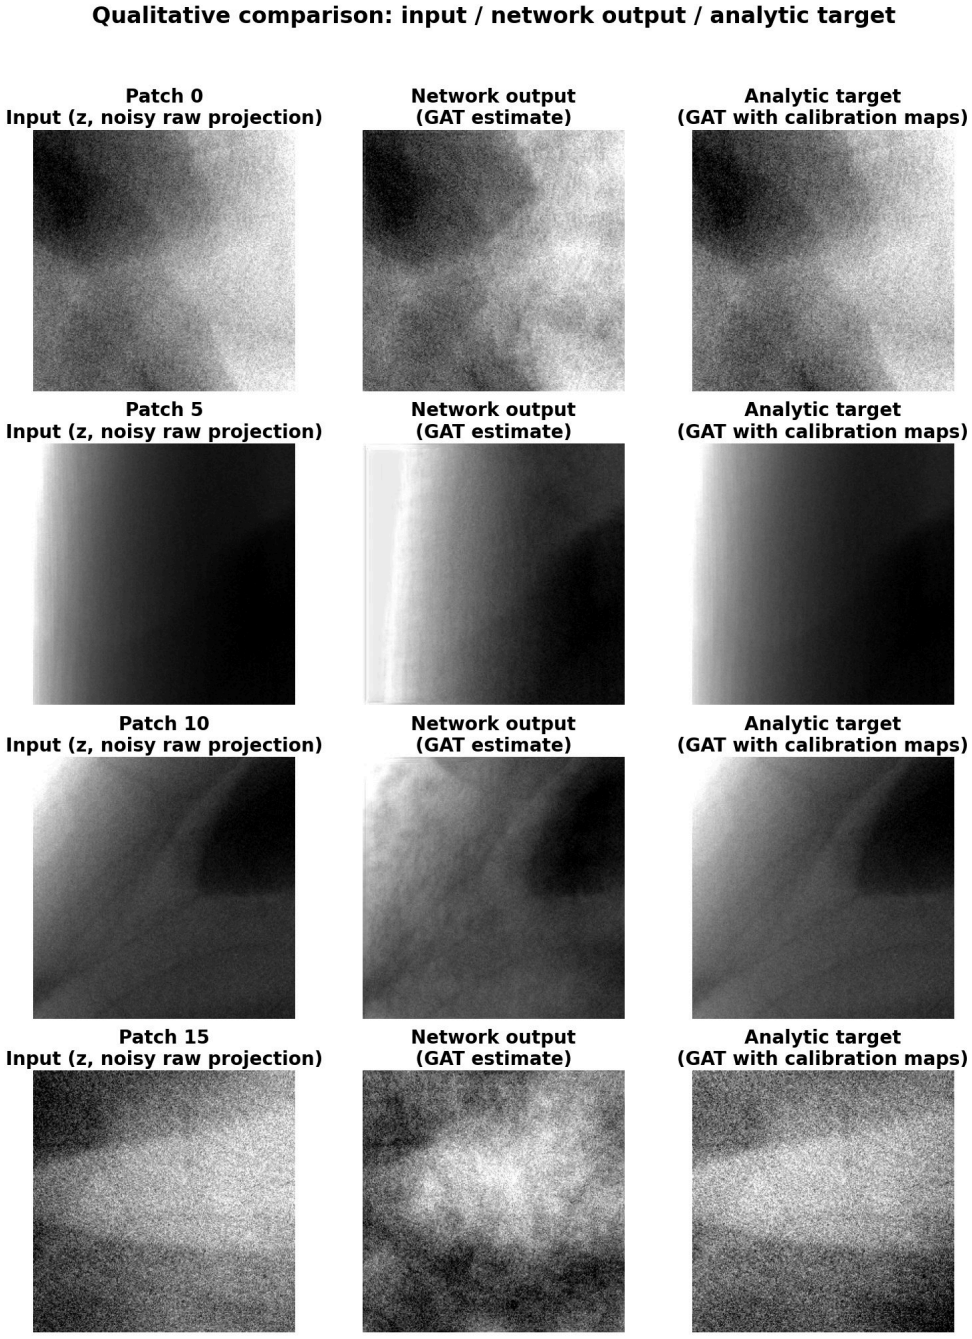

Fig. 4. Qualitative comparison: noisy input (left), network output — GAT estimate (center), analytic target — GAT with calibration maps (right), for patches 0, 5, 10, and 15. Patch 0 (top) represents a typical case; Patch 5 illustrates a case of pronounced over-smoothing.

TABLE III
FIVE HIGHEST-MSE TEST PATCHES: IDENTIFICATION, ERROR, LOCAL GAIN, POSITION, DISTANCE TO DETECTOR EDGE, AND NORMALIZATION-CLIPPING FRACTION (INPUT / TARGET).

Patch	Phantom	MSE	Mean α (ADU)	Position (i, j)	Dist. to edge	Clip. %
18	CUPB_ML_seed_28	194.43	0.135	(1490, 2522)	550 px	15.96 / 19.47
137	CUPB_ML_seed_92	120.95	0.133	(1678, 2470)	602 px	10.09 / 13.81
5	CUPB_ML_seed_56	106.54	0.132	(2176, 2377)	695 px	11.02 / 14.45
122	CUPB_ML_seed_21	53.55	0.146	(1057, 2731)	341 px	8.38 / 7.79
133	CUPB_ML_seed_92	43.63	0.135	(2520, 2386)	686 px	7.28 / 9.82

The worst patches also show elevated clipping fractions (Table III, 7–19%, against a $0.68\%/0.73\%$ average over all 150 test patches, Section II-E); however, wide dynamic range alone does not directly explain this effect, since the fraction of clipped pixels also depends on the mean signal level of the patch relative to the $\pm 5\sigma$ normalization threshold, in both the input and the target. Reported MSE values were computed against the original (unclipped) analytic GAT target (Y_{test}), not against a clipped version of it; the clipping described here therefore affects only the normalized network *input* and *training target*, not the reference against which test-time MSE is evaluated.

Visual inspection of the highest-MSE patches revealed that they correspond to regions with sharp anatomical transitions (near the skin line), where the network output shows a locally saturated boundary artifact not present in the analytic GAT target. One plausible explanation is that the network's Batch Normalization layers, whose batch-level statistics may become poorly calibrated for patches whose local dynamic range substantially exceeds the typical training-batch range, contribute to this artifact; however, this explanation has not been directly tested in this work and should be regarded as a hypothesis, not a demonstrated cause. The measured association between clipping fraction and MSE (Table III), by contrast, is a direct empirical finding. This observation motivates future work on normalization strategies less sensitive to per-sample dynamic range (e.g., instance or group normalization) to mitigate this specific failure mode.

Inference time was benchmarked on a Tesla T4 GPU and, for reference, on CPU. A single 256×256 patch required 65.75 ± 0.44 ms on GPU (mean $\pm$ std over 100 repetitions, after warm-up) and 2719 ± 365 ms on CPU (20 repetitions). Stabilizing a full DBT projection (4096×3328 pixels, tiled into 208 non-overlapping patches) required approximately 13.7 s in total on GPU. The proposed network requires a single forward pass per patch, with no per-image optimization at inference time, unlike the iterative method of Brandão et al. [3], which repeats a per-block noise-variance estimation step until convergence for each new acquisition; a direct, head-to-head runtime comparison against that method was not performed in this work, so no quantitative speed advantage is claimed.

C. Monte Carlo Variance Stabilization Evaluation

Table IV presents the Monte Carlo evaluation results for the network and, as a control, for the analytic GAT evaluated under the identical procedure (same 75 patches, same $R = 20$ noise realizations per patch). For both the network and the analytic-GAT control, the reported mean, standard deviation, and 95% CI are computed from the 15 per-phantom mean errors (one mean per test phantom, averaging its 5 patches), not from the 75 individual patches, since five patches originate from each phantom and therefore share anatomy and are not statistically independent; the patch-level standard deviation was 28.93% for the network. To account for the grouping of patches within phantoms, the statistics reported in Table IV were calculated from the 15 per-phantom mean errors. Note also that Eq. (7) evaluates the spatial *average* of the pointwise variance over each patch; it does not verify whether that variance is spatially uniform within the patch.

TABLE IV
MONTE CARLO EVALUATION RESULTS ($R = 20$, 75 PATCHES, 15 TEST PHANTOMS). CONFIDENCE INTERVALS ARE CLUSTER-ROBUST ACROSS PHANTOMS ($n = 15$).

Metric	Network	Analytic GAT (control)
Mean stabilization error	$50.45\% \pm 14.32\%$	$0.095\% \pm 0.023\%$
95% CI (cluster-robust)	$[43.20\%, 57.70\%]$	$[0.083\%, 0.107\%]$
Mean pointwise variance	1.503 (target: 1.000)	1.000 (target: 1.000)
Correlation α vs. error (%), r	0.782	0.028
Correlation y vs. error (%), r	0.325	–

The analytic GAT control confirms that the Monte Carlo procedure itself is sound: applied to the known analytic transformation, it recovers a pointwise variance of 1.000 with negligible error (0.095%) and no dependence on α ($r = 0.028$). The network's error is therefore not an artifact of the evaluation methodology, but reflects a genuine limitation of the learned transformation: a mean stabilization error of $50.45\% \pm 14.32\%$ (95% CI $[43.20\%, 57.70\%]$) and a mean pointwise variance of 1.503, substantially above the ideal value of 1.000. This is a markedly larger error than suggested by the pointwise wavelet-based $\hat{\sigma}$ metric of Section III-B, underscoring the importance of the Monte Carlo criterion. Figure 5 provides a visual summary: the stabilization error distribution shows substantial variability among patches, and the strong association between error and α ($r = 0.782$) indicates that patches with higher local detector gain tend to present larger stabilization errors.

D. Quantum Gain Coverage in the Breast Region

Table V and Fig. 6 present the α coverage analysis. The full detector operating range spans $[0.130, 0.365]$. However, within the segmented breast region, α varies only between 0.131 and 0.182, covering approximately 21.5% of the total system range. Training patches of 256×256 pixels, restricted to the breast region, present an even narrower range of 0.132–0.168, with a mean value of 0.145.

It is important to note that this narrow coverage arises from the breast's position relative to a single, fixed gain map used throughout this study (Section II-A), not from a variation in the gain map itself.

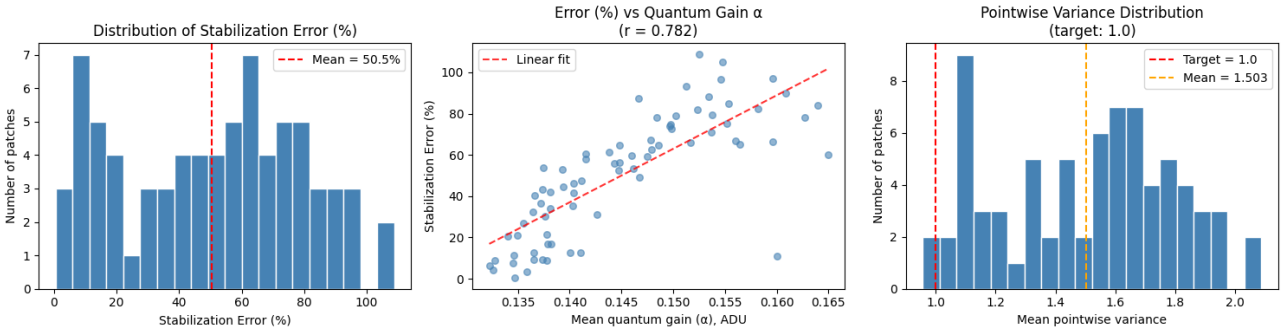

Fig. 5. Monte Carlo results for the network (75 patches, $R = 20$ realizations): left, distribution of stabilization error (%); center, stabilization error versus mean quantum gain α ($r = 0.782$, linear fit in red); right, pointwise variance distribution, with mean equal to 1.503 and target equal to 1.0.

Whether this restricted coverage is a primary cause of the network's stabilization error (Section III-C), and whether training with multiple gain maps spanning a wider α range would improve generalization, remain hypotheses to be tested in future work (Section V); the present results do not establish a causal relationship, only the co-occurrence of narrow gain coverage and a strong error–α correlation within this single-configuration dataset.

TABLE V
QUANTUM GAIN (α) COVERAGE BY REGION.

Region	α **range (ADU)**	**Mean** α **(ADU)**
Training patches (256 × 256)	0.1318–0.1683	0.1445
Full breast region	0.1309–0.1816	0.1469
Full detector	0.1300–0.3653	–

IV. DISCUSSION

Training a compact residual network (1.67 million parameters) to *partially* approximate the GAT without explicit calibration at inference is feasible, but this preliminary, single-gain-map study sits between two established strategies: the precise, calibration-dependent framework of Borges et al. [1], [2], and the calibration-free, per-image iterative method of Brandão et al. [3], who reported errors of 1.16–7.69% in their own published experiments (not evaluated here). Against those published figures, the proposed network showed a much larger Monte Carlo error (50.45%, Table IV); this is not a head-to-head comparison, but it shows that, at this stage, the approach trades accuracy for single-pass inference rather than matching [3]'s accuracy. It also differs from VST-Net [5] (globally parameterized noise, no spatial gain dependence) and Noise2VST [11] (self-supervised but still per-image optimization). Inference took 65.75 ms per patch (∼13.7 s per full projection) on a Tesla T4 GPU, avoiding per-block iterative convergence; no direct runtime comparison against [3] was performed, so this is a qualitative architectural difference, not a measured speed advantage.

A key finding is the gap between pointwise and Monte Carlo metrics: the wavelet-based $\hat{\sigma} \approx 0.897$ (Table II) reflects local texture and can be confused with true variance reduction [2], whereas the Monte Carlo pointwise variance (1.503) measures reproducibility across realizations — the physically correct criterion — revealing a much larger gap from ideal. The analytic-GAT control (error 0.095%, variance 1.000, Section III-C) confirms this gap is a genuine network limitation, not an evaluation artifact; both metrics are complementary.

The strong error–α correlation ($r = 0.782$), together with the narrow α coverage of the breast region under this single gain map (21.5% of the detector range), is consistent with a sampling-limitation hypothesis, but only as a co-occurrence within one configuration, not a controlled result; isolating this from other causes (architecture, normalization, training-set size) requires training across multiple gain maps and noise levels (Section V). Geometric augmentation (rotations/flips) was also tried but did not improve performance and was not used; the cause was not confirmed.

This study has several limitations. First, all experiments used a single central angular projection per phantom; other angles were not evaluated. Second, and most importantly, a single quantum-gain map and electronic-noise level ($\sigma_e = 1.3743$ ADU) were used throughout, so results characterize generalization to new anatomies *under this fixed calibration*, not across gain maps, noise levels, or systems. Third, the error–α correlation (Sections III-C and IV) is an association within this single-configuration dataset, not experimentally isolated from other factors. Fourth, no real clinical or physical-phantom validation was performed; all results are OpenVCT-simulated.

V. CONCLUSION

This work presented a preliminary, first-stage evaluation of a ResNet-based approach to estimate the Generalized Anscombe Transform directly from simulated noisy raw DBT projections, without requiring the quantum-gain map or the electronic-noise parameter as input during inference. Under a single, fixed calibration configuration (one gain map, one noise level), the network partially approximated the analytical transformation for new, unseen anatomies. Pointwise evaluation showed a mean wavelet-based $\sigma = 0.897$, with only 0.7% of patches presenting a large pointwise deviation.

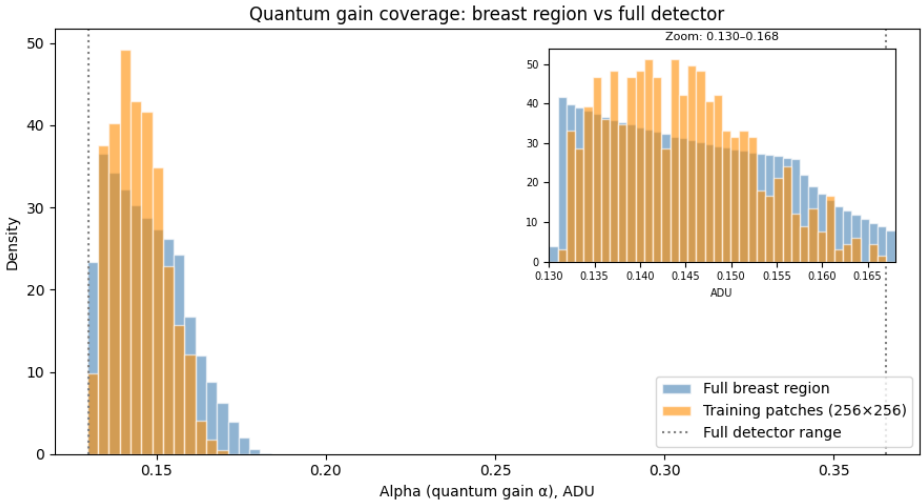

Fig. 6. Quantum gain (α, in ADU) density distribution for the full breast region and training patches of 256×256 pixels. Dotted lines indicate the full detector operating range $[0.130, 0.365]$ ADU. The breast region covers only 21.5% of the total detector range, for the single gain map used in this study.

However, Monte Carlo validation, using an analytic-GAT control to confirm the soundness of the procedure, revealed a substantially larger and non-uniform stabilization error (mean 50.45%, 95% CI $[43.20\%, 57.70\%]$ across 15 independent test phantoms), strongly associated with local quantum gain ($r = 0.782$). The network has therefore not yet achieved uniform variance stabilization under the evaluated conditions, and generalization to gain maps, noise levels, or acquisition systems other than the one used here was not demonstrated.

These findings reinforce the importance of combining pointwise metrics with Monte Carlo validation, and of using an analytic control to distinguish genuine model limitations from artifacts of the evaluation procedure, when assessing learned variance-stabilizing transformations. Future work will use the OpenVCT platform to generate training data spanning multiple spatially-varying quantum-gain maps and electronic-noise levels, and will evaluate the network on combinations of these parameters not seen during training, while preserving the phantom-level separation between training and test anatomies already used in this study. This will allow the sampling hypothesis raised in Section IV to be tested directly. Subsequently, transferability to real clinical or physical-phantom acquisitions will need to be assessed. Additional future directions include investigating alternative network architectures or normalization strategies (e.g., instance or group normalization, motivated by the clipping-related artifact discussed in Section III-B) to improve variance stabilization while preserving the calibration-free nature of the proposed approach.

***Abstract*—The early detection of venous thrombosis is important for preventing complications and improving patient outcomes. This study implements a Convolutional Neural Network (CNN) for binary classification of venous thrombosis in ultrasound images using a dataset of 1000 images. The model achieved 77% accuracy, with a recall of 0.65, specificity of 0.89, and negative predictive value of 0.718. At the selected operating point, 35 of 100 positive cases were not detected, while 35 of 124 negative predictions were false. These results indicate an exploratory-stage model and should not be interpreted as evidence of clinical readiness. To improve interpretability, Grad-CAM and LIME were applied to identify image regions contributing to the predictions. LIME produced more localized explanations than Grad-CAM, highlighting its potential for interpreting CNN-based classifications. Further validation using larger, independent, patient-level datasets is required before clinical application.**

***Index Terms*—Deep Learning, Explainable AI, Ultrasound Imaging, Venous Thrombosis.**

I. Introduction

Venous thrombosis is a medical condition characterized by the formation of blood clots within the veins, which can lead to serious complications such as pulmonary embolism and post-thrombotic syndrome [1], [2]. Early detection and accurate diagnosis of venous thrombosis are crucial for effective treatment and prevention of adverse outcomes. Ultrasound imaging is a widely used non-invasive technique for diagnosing venous thrombosis, providing real-time visualization of the veins and blood flow [3], [4].

The interpretation of ultrasound images for the diagnosis of venous thrombosis can be challenging due to the variability in image quality, anatomical structures, and the subtlety of thrombotic features. Traditional methods for analyzing ultrasound images rely heavily on the expertise of clinicians, which can lead to inter-observer variability and potential misdiagnosis [5], [6].

In recent years, Convolutional Neural Networks (CNNs) have shown great promise in medical image analysis, including the classification of ultrasound images for various conditions [7]–[10]. However, the black-box nature of CNNs can limit their adoption in clinical settings, as clinicians may be hesitant to trust predictions without understanding the underlying reasoning. To address this issue, explainable AI (Artificial Intelligence) methods have been developed to provide insights into the decision-making process of machine learning models. Some popular explainable AI methods for deep learning models include Grad-CAM (Gradient-weighted Class Activation Mapping) [11] and LIME (Local Interpretable Model-agnostic Explanations) [12], which can help visualize the regions of the input image that contribute most to the model's predictions.

There have been several studies that have explored the use of machine learning and deep learning techniques for the diagnosis of venous thrombosis [13]–[16]. However, there is still a need for further research to improve the accuracy and interpretability of these models, particularly in the context of ultrasound imaging. For instance, [13] proposed a machine learning-based system for the early diagnosis of Deep Vein Thrombosis (DVT). The study evaluated six classifiers, such as Decision Trees (DT), Extra Trees (ET), K-Nearest Neighbors (KNN), Random Forests (RF), Support Vector Machines (SVM), and Multi-Layer Perceptron Neural Networks (MLP-NN), using clinical features derived from the Wells criteria, age, and gender. Furthermore, the authors investigated the deployment of the models on a Raspberry Pi 4 edge device to develop a portable and low-cost diagnostic support system, with KNN achieving the highest diagnostic performance.

Differently, in the work [14], the authors employed the RetinaNet object detection architecture with ResNet50 and ResNet152 backbones for the detection of iliofemoral deep vein thrombosis (DVT) in lower-extremity computed tomography angiography (LECTA) images. Experimental results demonstrated that the proposed three-slice approach improved detection performance, achieving a sensitivity of 0.843 and a mean average precision (mAP) of 0.807 with the ResNet50 backbone, highlighting the effectiveness of incorporating clinically relevant contextual information into deep learning-based DVT detection.

In the manuscript [15], the authors proposed a novel Deep R-Belief Network for the automated diagnosis of DVT from

Duplex Ultrasound (DUS) images. Their methodology consists of a multi-stage pipeline that includes image denoising using a Gaussian filter, contrast enhancement through Contrast Limited Adaptive Histogram Equalization (CLAHE), and edge segmentation using a fuzzy-based thresholding algorithm to address intensity variations and ambiguous boundaries. Experimental results demonstrated the effectiveness of the proposed approach, achieving an accuracy of 98.63%, precision of 97.44%, specificity of 97.93%, recall of 97.55%, and F1-score of 98.13%.

In the study [16], the authors proposed a two-stage cascaded segmentation model with integrated attention mechanisms designed to handle multimodal inputs from CT, MRI, and ultrasound for automated detection of lower extremity deep vein thrombosis. The framework was evaluated on a dataset of 322 patients with lower extremity DVT covering CT, MRI, and ultrasound modalities.

Different from the aforementioned studies that do not focus on the interpretability of the model's predictions, the proposed work focuses on the binary classification of venous thrombosis in ultrasound images using a CNN architecture with emphasis on the interpretability of the model's predictions through the application of explainable AI methods, Grad-CAM, and LIME. Therefore, the main objective of this study is to develop a CNN-based model for the binary classification of venous thrombosis in ultrasound images and to provide insights into the model's decision-making process using explainable AI techniques.

This work is organized as follows: Section II describes the dataset and the methodology used for training the CNN and applying explainable AI methods. Section III presents the results of the classification performance and the insights gained from the explainable AI. Finally, Section IV concludes the study and discusses potential future directions for research in this area.

II. Methodology

This section describes the dataset used for training and evaluating the CNN model, the architecture of the CNN, and the explainable AI methods applied to interpret the model's predictions.

A. Dataset

The dataset used in this study is composed of ultrasound images labeled for the presence or absence of venous thrombosis. The images were extracted from venous ultrasound examinations and were derived from the ThrombUS+ dataset [4], [17], [18], a collection of ultrasound examinations acquired within the Horizon Europe ThrombUS+ project and distributed through Zenodo in DICOM format. The frame-level images employed in this work were downloaded from the publicly available Kaggle repository, Thrombus vs Non-Thrombus Dataset Images [19]. The repository contains ultrasound image frames from the ThrombUS+ dataset extracted from venous ultrasound examinations and labeled according to the presence or absence of thrombosis. The ultrasound images correspond to four anatomical regions of the lower limb veins: Popliteal Vein (PV), Common Femoral Vein (CFV), Great Saphenous Vein (GSV), and Femoral Vein (FV). Fig. 1 illustrates the anatomical locations of these veins in the lower limb. For more details about the dataset, please refer to the work [4].

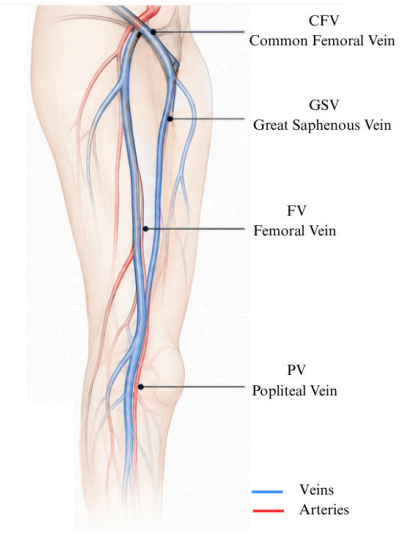

Fig. 1. Diagram of lower limb veins.

Fig. 2 shows examples of ultrasound images from the dataset used for training and evaluating the implemented method. The images in the dataset exhibit variations in terms of quality, contrast, and anatomical structures, which pose challenges for accurate classification.

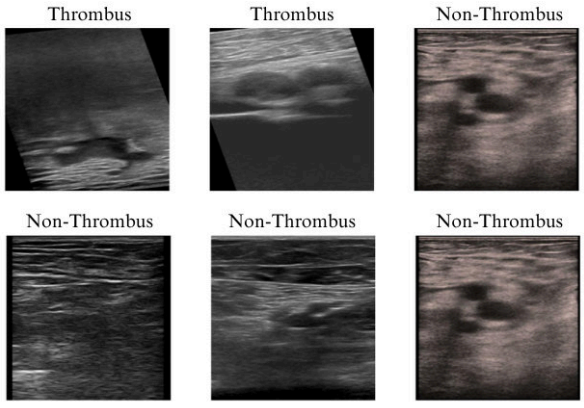

Fig. 2. Example of ultrasound images from the dataset used for training and evaluating the proposed method.

The selected dataset consists of a total of 1000 ultrasound images, with 800 images initially allocated for training and 200 images reserved for testing. The original dataset does not provide patient-level identifiers or metadata indicating whether the images correspond to individual patient examinations or to frames extracted from ultrasound examinations. Therefore, it was not possible to verify whether multiple images originated from the same patient. From the 800 images allocated to the

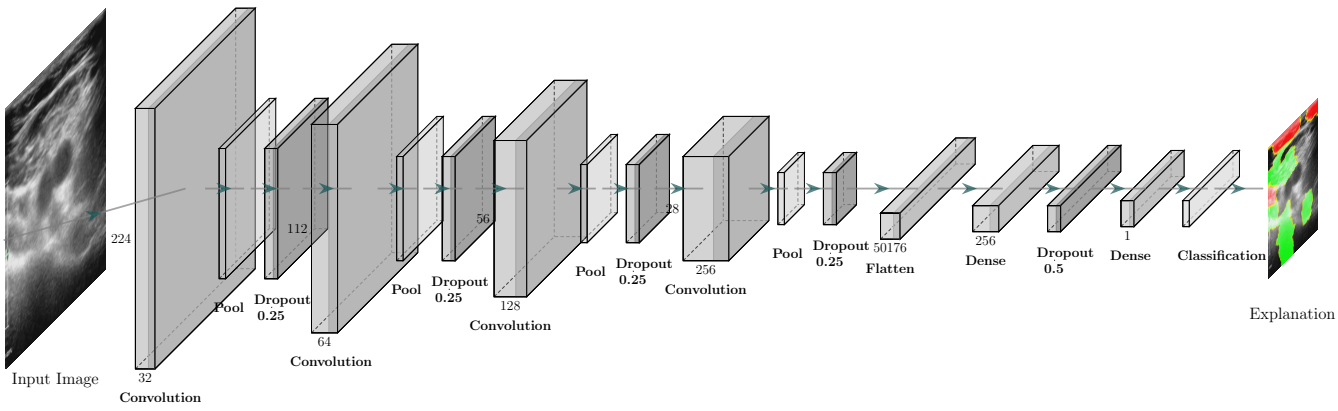

Fig. 3. Architecture of the proposed method for binary classification of venous thrombosis in ultrasound images.

training set, 20% were further separated for validation. Each image has a resolution of 224×224 pixels. The images were preprocessed by normalizing the pixel values to the range [0.0, 1.0].

B. Convolutional Neural Network

A CNN was implemented for the binary classification of venous ultrasound images into thrombus and non-thrombus categories. Fig. 3 illustrates the architecture of the proposed method. The model receives the ultrasound images as input and outputs a binary classification indicating the presence or absence of venous thrombosis. Moreover, after the classification, we apply explainable AI methods to interpret the model's decisions and identify the regions of the ultrasound images that contribute most to the classification results.

The architecture receives RGB images resized to 224×224 pixels as input and consists of four convolutional blocks. Each block comprises a 3×3 convolutional layer with ReLU activation and same padding, followed by batch normalization, a 2×2 max-pooling layer, and a dropout layer. The number of filters increases progressively from 32 to 64, 128, and 256, enabling the extraction of increasingly complex spatial features while reducing the spatial dimensions of the feature maps. The final layer consists of a single neuron with a sigmoid activation function given by:

$$\hat{y} = \frac{1}{1 + e^{-z}}, \tag{1}$$

where z is the output of the last fully connected layer. The sigmoid activation function maps the output to a probability value between 0 and 1. The output $\hat{y}$ represents the predicted probability of the positive class (thrombosis) for a given input image.

The network was trained using the Adam optimizer with a learning rate of 1×10^{-4} and the binary cross-entropy loss function given by:

$$\mathcal{L} = -\frac{1}{N} \sum_{i=1}^{N} \left[y_i \log(\hat{y}_i) + (1 - y_i) \log(1 - \hat{y}_i) \right], \tag{2}$$

where N is the number of samples, y_i is the true label for the i-th sample, and $\hat{y}_i$ is the predicted probability of the positive class for the i-th sample. The model was trained for 100 epochs with a batch size of 32. To prevent overfitting, early stopping was implemented with a patience of 15 epochs.

C. Explainable AI methods

To interpret the model's decisions and identify the regions of the ultrasound images that contribute most to the classification results, we applied two explainable AI methods: Grad-CAM and LIME. The following subsections describe each method in detail.

1) GRAD-CAM: is an explainability technique that highlights the image regions that most influence a CNN's prediction. Given an input image and a target class c, Grad-CAM computes the importance of each feature map in the last convolutional layer by analyzing the gradients of the class score with respect to the feature activations [11].

Let $A^k \in \mathbb{R}^{H \times W}$ denote the k-th feature map of the final convolutional layer, and let y^c represent the score associated with class c. The importance weight α_k^c of feature map A^k is obtained through global average pooling of the gradients:

$$\alpha_k^c = \frac{1}{Z} \sum_i \sum_j \frac{\partial y^c}{\partial A_{ij}^k}, \tag{3}$$

where $Z = H \times W$ corresponds to the total number of spatial locations in the feature map. The weight α_k^c measures how strongly the feature map A^k contributes to the prediction of class c. Positive values indicate that increasing the activation of the feature map tends to increase the class score.

The class-discriminative localization map is then computed as a weighted combination of all feature maps:

$$L_{\text{Grad-CAM}}^c = \text{ReLU}\left(\sum_k \alpha_k^c A^k \right), \tag{4}$$

where ReLU removes negative contributions and retains only the features that positively influence the prediction [11].

The resulting heatmap $L^c_{\text{Grad-CAM}}$ is subsequently resized to the original image dimensions and overlaid on the input image. Regions with higher activation values correspond to areas that contributed most strongly to the network's decision for class c, providing visual evidence of the model's reasoning process.

2) LIME: is an explainability technique that explains individual predictions by approximating the behavior of a complex model with a simpler and interpretable model [12]. Unlike Grad-CAM, LIME is model-agnostic and can be applied to any classifier without requiring access to its internal architecture or gradients.

Given an input image x and a trained classifier $f(\cdot)$, LIME first partitions the image into a set of interpretable components, called superpixels. Let

$$x' = [x'_1, x'_2, \ldots, x'_M] \tag{5}$$

denote the binary representation of the image, where $x'_m = 1$ indicates that the m-th superpixel is present and $x'_m = 0$ indicates that it is masked. A set of perturbed samples is generated by randomly turning superpixels on or off. For each perturbed image z', the original classifier produces a prediction $f(z')$.

LIME then assigns a proximity weight to each perturbed sample according to its similarity to the original image:

$$\pi_x(z) = \exp\left(-\frac{D(x,z)^2}{\sigma^2}\right), \tag{6}$$

where $D(x, z)$ is a distance metric between the original image and the perturbed sample, and σ controls the neighborhood size. The explanation is obtained by fitting a simple interpretable model $g \in G$, typically a sparse linear model, that minimizes the objective

$$\xi(x) = \arg\min_{g \in G} \left[L(f, g, \pi_x) + \Omega(g)\right], \tag{7}$$

where $L(f, g, \pi_x)$ measures how closely the surrogate model approximates the predictions of the original classifier in the local neighborhood of x, and $\Omega(g)$ penalizes model complexity to maintain interpretability.

For a linear surrogate model, the explanation takes the form

$$g(z') = w_0 + \sum_{m=1}^{M} w_m z'_m, \tag{8}$$

where w_m quantifies the contribution of the m-th superpixel to the prediction. Positive coefficients indicate regions that support the predicted class, whereas negative coefficients indicate regions that oppose it [12].

Although both Grad-CAM and LIME aim to explain CNN predictions, they operate differently. Grad-CAM exploits the internal gradients and feature maps of a CNN to generate a class-discriminative heatmap. Consequently, it requires access to the network architecture and differentiable layers. In contrast, LIME treats the model as a black box and explains predictions by observing how the output changes when interpretable image regions are perturbed [20]. LIME estimates feature importance by fitting a local surrogate model whose coefficients directly indicate the contribution of each superpixel.

III. Results and Discussion

The proposed CNN model was evaluated on an independent test set comprising 200 ultrasound images using an classification threshold of 0.756. The classification threshold of 0.756 was selected using the validation set by maximizing the Youden index, defined as $J = \text{Sensitivity} + \text{Specificity} - 1$. Thus, the selected threshold represents a statistical operating point that balances sensitivity and specificity. Performance metrics were estimated together with 95% confidence intervals (CI) obtained through bootstrap resampling with 2,000 iterations.

Table I summarizes the performance of the CNN model on the test set, including sensitivity (recall), specificity, precision, negative predictive value (NPV), Area Under the Receiver Operating Characteristic Curve (AUC-ROC), AUC-PR Area Under the Precision-Recall Curve (AUC-PR), Matthews Correlation Coefficient (MCC), F1-score, positive likelihood ratio (LR+), negative likelihood ratio (LR–), and accuracy.

TABLE I
Performance of the CNN Model on the Test Set ($n = 200$)

Metric	Value	95% CI
Recall	0.6500	[0.5556, 0.7423]
Specificity	0.8900	[0.8229, 0.9490]
Precision	0.8553	[0.7733, 0.9325]
NPV	0.7177	[0.6339, 0.7953]
AUC-ROC	0.8608	[0.8041, 0.9114]
AUC-PR	0.8572	[0.7852, 0.9195]
MCC	0.5563	[0.4321, 0.6649]
F1-Score	0.7386	–
LR+	5.9091	–
LR–	0.3933	–
Brier Score	0.1794	–
Accuracy	0.7700	–

The MCC value of 0.556 further suggests a moderate positive correlation between the predicted and true labels, supporting the model's overall discriminative capability. The positive predictive value was 85.5%, meaning that when the model predicts thrombosis, the prediction is correct in most cases. Conversely, the NPV was 71.8%, indicating that approximately seven out of ten negative predictions correspond to true non-thrombotic examinations.

Fig. 4 shows the calibration curve, which compares the predicted probabilities of thrombosis with the observed frequencies. The reliability analysis revealed moderate calibration errors with an expected calibration error (ECE) of 0.171, indicating that the predicted probabilities do not perfectly reflect the true occurrence frequencies. The calibration assessment is further supported by the Brier Score of 0.179, which indicates moderate probabilistic accuracy. Nevertheless, the confidence distributions show a reasonable separation between thrombus and non-thrombus cases, suggesting that the CNN achieves modest discriminative ability.

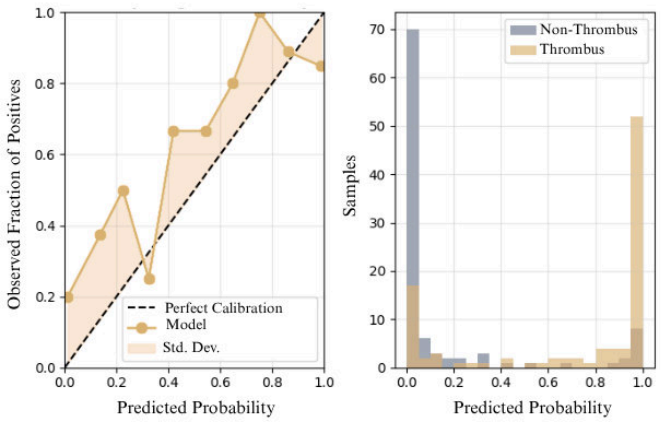

Fig. 4. Calibration curve with ECE of 0.171 and confidence distributions achieved by the CNN model.

Fig. 5 illustrates the AUC-ROC and AUC-PR curves. The AUC-ROC of 0.8608 indicates reasonable overall performance, while the AUC-PR of 0.8572 suggests that the model maintains good precision across a range of recall values.

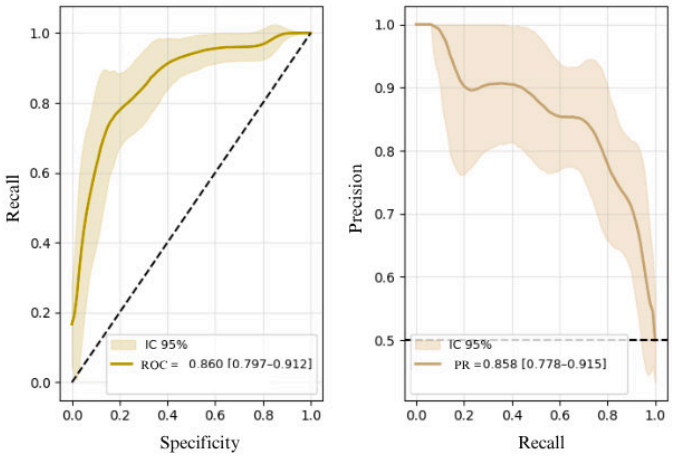

Fig. 5. AUC-ROC and AUC-PR curves for the CNN model on the test set.

Fig. 6 shows the confusion matrix. The model correctly classified 65 thrombotic cases and 89 non-thrombotic cases, while it misclassified 11 non-thrombotic cases as thrombotic and 35 thrombotic cases as non-thrombotic.

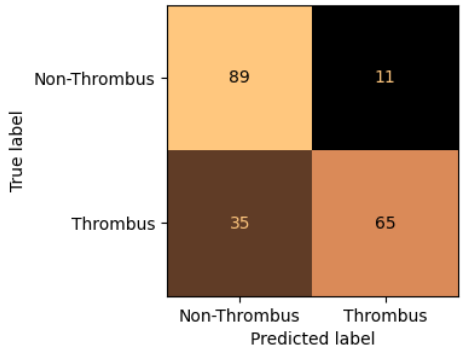

Fig. 6. Confusion matrix for the CNN model on the test set.

To explain the model's decisions and identify the regions of the ultrasound images that contribute most to the classification results, we applied the Grad-CAM and LIME techniques. Fig. 7 shows an example of a Grad-CAM visualization for a correctly classified thrombotic case. The heatmap indicates that the model focuses on specific regions of the ultrasound image. These regions may be associated with visual characteristics of venous thrombosis. In this example, the model predicted the presence of thrombus with $P(Y) = 0.984$, where Y denotes the presence of thrombus.

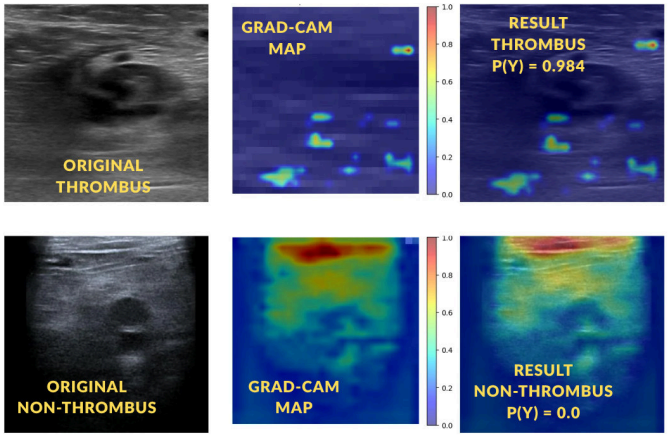

Fig. 7. Grad-CAM visualization of the proposed method. The heatmap highlights the regions that contribute most to the classification decision.

Fig. 8 presents representative misclassification cases together with their Grad-CAM visualizations. In the false-positive example, the network incorrectly classified a non-thrombotic image as thrombus with $P(Y) = 0.893$. The Grad-CAM visualization shows attention distributed across multiple heterogeneous regions rather than a clearly localized vascular structure.

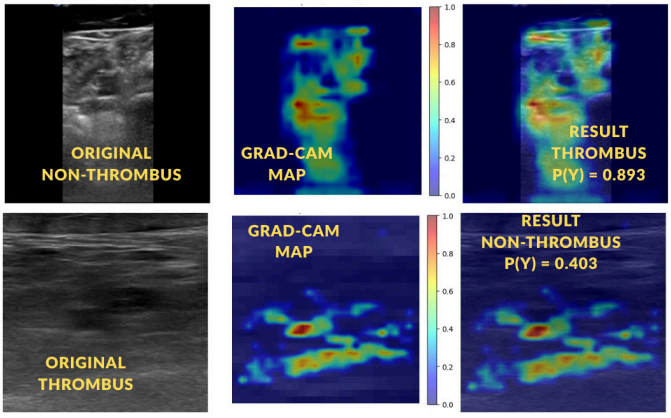

Fig. 8. Grad-CAM visualization with false positive and false negative cases. The heatmaps indicate the regions of the ultrasound images that influenced the model's incorrect predictions.

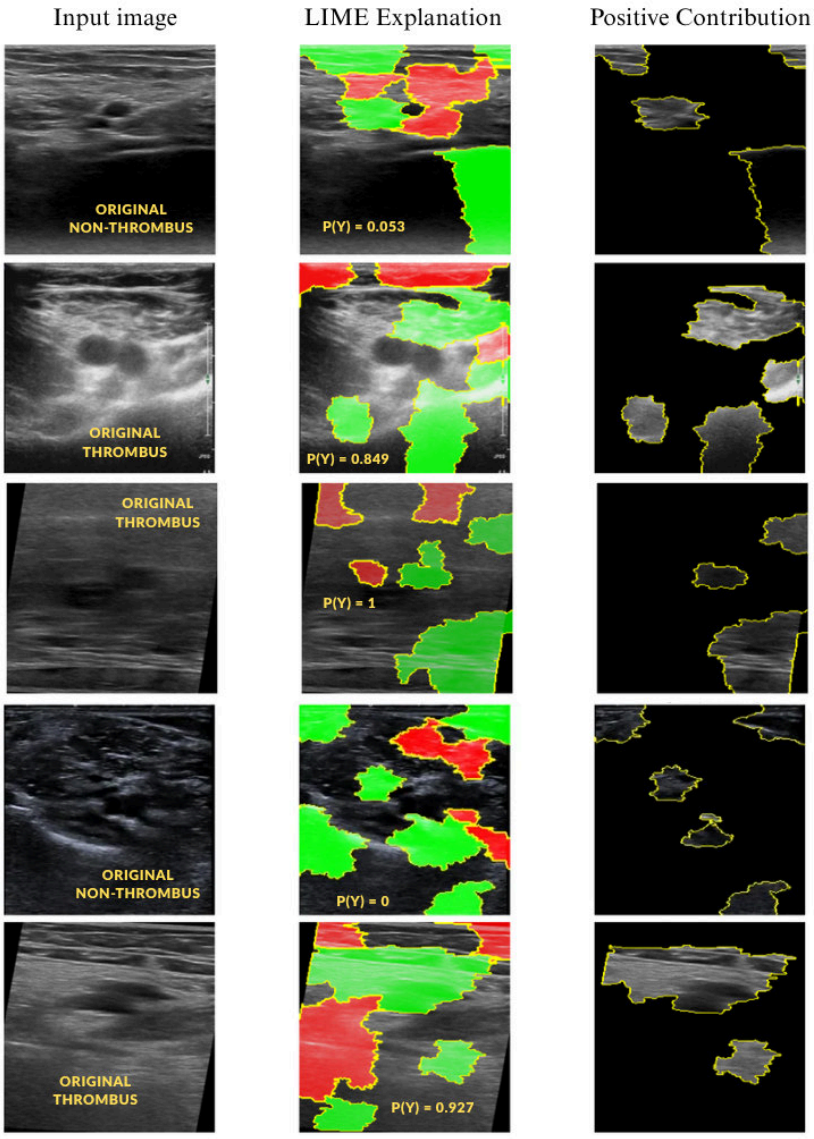

Fig. 9. LIME visualization of the proposed method. The highlighted areas indicate the regions of the ultrasound image that are most influential in the model's prediction.

Conversely, in the false-negative example, the model failed to assign sufficient importance to the thrombus region with only $P(Y) = 0.403$, resulting in a non-thrombus prediction. The Grad-CAM maps indicate that the CNN relies on broader contextual ultrasound patterns, which may contribute to classification errors when these patterns resemble features associated with thrombosis.

Fig. 9 depicts representative LIME explanations for correctly classified thrombus and non-thrombus ultrasound images.

Green regions indicate positive contributions toward the thrombus class, whereas red regions represent features associated with a prediction against the thrombus class. In the thrombus cases, positive superpixels were frequently observed around vascular structures and regions with visual patterns associated with thrombosis. Conversely, non-thrombus cases generally showed less positive evidence for the thrombus class and larger regions associated with predictions against it. These observations provide a qualitative indication of the image regions associated with the model's predictions.

Although the exact anatomical correspondence between the highlighted superpixels and thrombus locations cannot be confirmed without expert annotations, the LIME results suggest that localized image features may be associated with the CNN's predictions. In the examples analyzed, LIME produced more focused explanations than the Grad-CAM visualizations, which often showed broader activation regions. This difference is reported as an exploratory qualitative observation and should not be interpreted as evidence of the superiority of LIME over Grad-CAM. A quantitative assessment involving expert evaluation, anatomical annotations, or explanation-fidelity metrics

would be required to establish a definitive comparison.

IV. Conclusion

This study presented a CNN-based approach for the binary classification of venous thrombosis in ultrasound images, achieving an accuracy of 77% and an AUC-ROC of 0.86 on the test set. Beyond predictive performance, the study investigated the interpretability of the model through two widely used explainable artificial intelligence techniques. The explainability analysis revealed differences between the methods. Grad-CAM provided a global visualization of the regions influencing the network's predictions, but the resulting activation maps were often diffuse and extended beyond the most relevant anatomical structures. In contrast, LIME produced visually more localized maps in the examples examined by highlighting specific image regions that positively or negatively contributed to the classification outcome. The qualitative analysis suggested that LIME offered more focused explanations, facilitating the identification of discriminative image patterns associated with thrombus and non-thrombus cases. Overall, the results demonstrate that combining CNNs with explainable AI techniques can improve the transparency of thrombosis detection systems.

Although the proposed CNN demonstrated good discriminative ability, the calibration analysis revealed that the predicted probabilities do not perfectly reflect the true occurrence frequencies of thrombosis. Therefore, future studies will investigate probability calibration approaches, such as temperature scaling and isotonic regression, to improve the reliability of confidence estimates while preserving classification performance. Furthermore, since the current approach analyzes individual ultrasound frames independently, future work will explore temporal deep learning models capable of capturing the sequential dependencies between consecutive frames. Incorporating temporal information from ultrasound videos may provide richer contextual information and improve the robustness and accuracy of thrombosis detection, particularly in challenging cases where diagnostic evidence is distributed across multiple frames.

***Abstract*—X-Pan, a dataset of 1,566 de-identified panoramic radiographs (OPGs), is presented and tested for forensic dental age and sex estimation. Each instance contains associated tabular demographic and clinical attributes. The dataset was curated through an eligibility-driven sampling process from institutional records, with expert-supported labeling and structured documentation following the Datasheets for Datasets framework. Preprocessing includes privacy-preserving de-identification via manual cropping to remove identifying non-anatomical content, followed by dataset cleaning and label assignment according to predefined guidelines. To validate its usability, the dataset was employed in two baseline experiments: age estimation applying publicly available zero-shot weights, which achieved an MAE of 1.04 years (model 912, ages 1–24), and sex estimation fine-tuning three ImageNet-pretrained backbones, which achieved a best F1-score of 78.08% and AUC of 0.841 with ResNet50. To support reproducibility, dataset releases follow semantic versioning and all materials — including model weights, code, and the complete datasheet — are available at the project repository.**

***Index Terms*—orthopantomography dataset, forensic odontology, age estimation, sex estimation**

I. Introduction

Age estimation in living or deceased individuals is a core issue in forensic science, with applications ranging from criminal and civil proceedings to the identification of disaster victims and undocumented individuals. Forensic odontology plays a key role in this process because teeth are among the most durable tissues in the human body, remaining preserved even under extreme conditions such as charring, and because dental development follows a predictable chronology that enables age estimation from the formation and mineralization of crowns and roots visible in radiographic examinations [1]–[3].

Among radiographic modalities, panoramic radiographs (orthopantomographs, OPGs) are particularly suited to this task because a single image provides a comprehensive view of all teeth, the mandible, the maxilla, and the temporomandibular joint, permitting simultaneous analysis of eruption chronology and corono-radicular mineralization across the full dentition [4]. As a result, OPGs are the predominant image type in machine learning studies on forensic age estimation; alternatives such as cone-beam computed tomography are less common, in part due to their higher cost and more limited clinical availability [5].

The advancement of artificial intelligence (AI), and deep learning in particular, is closely tied to data availability [6], making large, well-documented datasets a prerequisite for effective models [7]. AI systems have been applied to forensic dentistry for over 20 years, with an approximately fivefold increase in publications across the periods 2011–2015 (2 articles), 2016–2020 (11 articles), and 2021–2023 (49 articles) [8, p. 89, 90]. Of the studies reviewed by Anees et al. [8, p. 89, 90], 46.27% (31 articles) focus on age estimation, while the remaining literature addresses human identification and estimates related to sex, dental characteristics, and implants.

However, the reproducibility of this body of work is limited. Representative examples of studies that use panoramic radiographs for machine learning tasks and provide limited or no access to their source code and model weights, and no instructions on how to obtain their datasets include [9]–[13]. Furthermore, none of the analyzed studies combine a detailed dataset description with instructions for acquiring the data for subsequent research.

To address this gap, this paper presents X-Pan, an annotated dataset of 1,566 OPGs (ethics committee approval: protocol No. 7.560.465; Instituto de Ciência e Tecnologia de São José dos Campos) documented following the Datasheets for Datasets framework [14], which includes extensive in-

formation on the dataset's motivation, composition, collection, preprocessing, cleaning, labeling, usage, distribution, and maintenance. These details will be summarized in the coming sections. To validate the dataset's usability, two baseline experiments are reported: age estimation using publicly available model weights from Heinrich et al. [15] and Koch et al. [16], and sex estimation through fine-tuning of three ImageNet-pretrained backbones.

II. Motivation

X-Pan was created primarily to support the development of deep learning models for automated dental age estimation, addressing the reproducibility gap identified in the Introduction: the lack of documented, accessible OPG datasets for subsequent research. Its construction was also designed to support a wider range of dental imaging studies, including sex estimation and population analyses. Detection of clinical interventions is a longer-term goal contingent on targeted expansion of the relevant classes (Section VI).

For the development of effective models in these tasks, large, diverse, and high-quality data are essential [7]. X-Pan aims to contribute to this need by providing a structured, standardized dataset with documented metadata, expert-supported labeling, and semantic versioning to facilitate reproducibility and reuse.

The dataset was created by the authors of this paper, affiliated with the Departments of Diagnostics and Surgery and of Social Dentistry and Pediatric Clinic at São Paulo State University, and the Departments of Electronics and of Informatics at the Federal University of Technology – Paraná. No grant was involved in its creation.

III. Composition

The dataset is composed of 1,566 panoramic radiographs, each corresponding to a single patient. Each instance is accompanied by the tabular attributes described in Table I, stored in a CSV file. The primary targets for supervised learning tasks are the `age` and `sex` fields.

Fig. 1 shows the age pyramid, stratifying the age distribution by sex. The dataset contains significantly more images from minors than from adults, a skew that prospective users should account for when designing experiments.

Table II shows the sex distribution. Sex is nearly balanced, with male patients accounting for 50.57% of instances.

The acquisition device is also recorded for each image (Table I): 1,091 instances (69.67%) captured with OP300 and 475 (30.33%) with Orthophos XG.

Table III shows the distribution of categorical attributes. The *pathol* attribute comprises the categories bone fracture, furcation lesion, endodontic-periodontal lesion (EPL), bone pathology, periapical lesion, and none. The *findings* attribute comprises the categories anomaly, foreign body, calcification, and none. For *braces*, *retainer*, and *orthog*, the allowed values are S (superior arch), I (inferior arch), SI (both arches), and N (none). The combined value SI is used in place of separate S and I entries to avoid ordering ambiguity in multi-value fields.

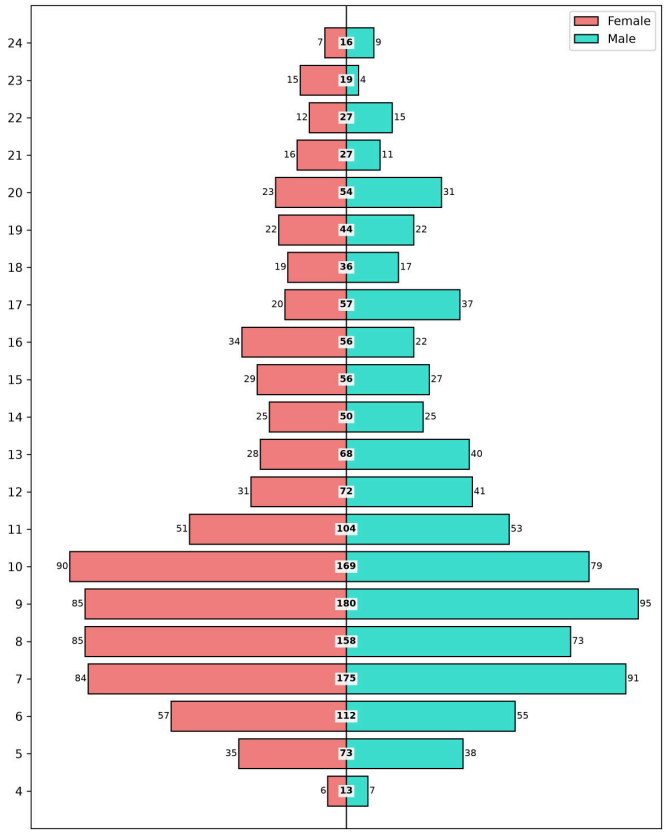

Fig. 1. Age distribution stratified by sex (pink: female; teal: male). Horizontal axis: number of images; vertical axis: age in years. The centered number represents the total number of images for the corresponding age.

Tables IV and V show the distributions for the numeric and pathology/findings attributes, respectively.

During the early phases of data collection, panoramic radiographs presenting orthodontic appliances (e.g., braces and retainers), foreign bodies, calcifications, signs of endodontic treatment, orthognathic surgery-related features, pathological findings, or absence of teeth were excluded. These criteria were later revised to admit the aforementioned cases, thereby increasing clinical diversity. Consequently, the prevalence of these characteristics in the final dataset is relatively low, reflecting their partial exclusion during the initial collection phase.

After revision, the remaining criteria were that images were required to contain age and sex records, be sharp and display adequate image quality, and allow complete visualization of the dental and osseous structures under study. Only images from patients ranging from 4 to 24 years of age were collected. All retained instances are complete – no metadata fields are missing.

The dataset is a non-probabilistic, consecutive sample drawn from a larger institutional database. A minimum sample size was determined using the standard finite-population proportion estimator:

TABLE I
ATTRIBUTES STORED IN THE X-PAN CSV METADATA FILE FOR EACH INSTANCE, INCLUDING THEIR DATA TYPES, ALLOWED VALUES, AND DESCRIPTIONS.

Field	Type	Allowed values / units	Description
image_name	string	filename / ID	Associates CSV row with image file
device	categorical	OP300, Orthophos XG	Radiograph acquisition device
month_of_capture	date	MM/YYYY; e.g., 04/2010	Month and year the radiograph was captured
age	integer	months	Patient's age in months
sex	categorical	M (male) , F (female)	Patient's biological sex
braces	categorical	S (superior), I (inferior), SI (both), N (none)	Presence/location of braces
retainer	categorical	S (superior), I (inferior), SI (both), N (none)	Presence/location of retainer
orthog	categorical	S (superior), I (inferior), SI (both), N (none)	Presence/location of orthognathic surgery indicators
endo	integer	0,1,2,...	Number of endodontic treatments visible
implan	integer	0,1,2,...	Number of dental implants visible
pathol	list / categorical	comma-separated terms	Pathologies present (e.g., periapical_lesion)
findings	list / categorical	comma-separated terms	Radiologist findings (e.g., foreign_body)

TABLE II
DISTRIBUTION OF PATIENT SEX

Sex	Count	%
Male	792	50.57
Female	774	49.43

TABLE III
DISTRIBUTION OF CATEGORICAL ATTRIBUTES. "SUPERIOR" AND "INFERIOR" REFER TO THE JAW IN WHICH THE APPLIANCE OR FEATURE IS PRESENT. "BOTH" CORRESPONDS TO THE "SI" VALUE IN THE CSV. "NONE" INDICATES ABSENCE.

	Superior		Inferior		Both		None	
Attribute	Count	%	Count	%	Count	%	Count	%
Braces	29	1.9	15	1.0	86	5.5	1,436	91.7
Retainer	0	0	52	3.4	4	0.3	1,510	96.4
Orthog	0	0	0	0	0	0	1,566	100.0

$$n = \frac{Z^2\, p(1-p)}{c^2} \tag{1}$$

where n is the target sample size, Z is the normal quantile associated with the specified confidence level, p is the anticipated population proportion, and c is the tolerable margin of error in proportion units. Applied to the Brazilian population aged 5 to 24 years (57,266,806 inhabitants [17]), with a 99% confidence level, a 5% margin of error, and $p = 0.5$ (maximizing the Bernoulli variance and yielding the most conservative estimate), the formula gives a minimum of 664 images. The present dataset contains 1,553 instances within this age range, exceeding that threshold by a factor of approximately 2.4. Representativeness relative to the broader source population was not formally validated beyond this criterion.

Each image is treated as an independent instance: there is no longitudinal connection between records, and each patient appears only once. The dataset is self-contained and does not depend on external resources.

All image-derived attributes (`braces`, `retainer`, `orthog`, `endo`, `implan`, `pathol`, `findings`) were independently labeled by three annotators following a written guideline, with the final value for each field determined by majority vote among the three assessments. No train-test-validation split is currently recommended by the authors.

All personally identifying information was previously anonymized, making it impossible to directly identify individuals included in the dataset.

The original radiographs constitute medical records protected by patient confidentiality. They were obtained for diagnostic and clinical purposes, archived in an institutional database authorized for scientific use, and de-identified prior to researcher access. Participants authorized use of their data by signing an Informed Consent Form. Additional data protection measures include restricted access control and removal of all direct identifiers. Given that no direct identifiers remain and the dataset is not linked to any external database, re-identification of individuals is considered infeasible; authorized users are nonetheless contractually prohibited from attempting it.

The dataset contains medical radiographic images, which may be distressing in a clinical context but do not depict graphic content.

IV. COLLECTION PROCESS

A. Data source and setting

Panoramic radiographs and associated clinical records were obtained directly from the partner institution's radiographic database, where they are stored in a Picture Archiving and Communication System (PACS). Images were not sourced from public websites or third parties. Patient age was derived from dates of birth and exam dates extracted from both physical and digital medical records, and was verified against source documents by the research team.

B. Time frame and sampling

Dataset construction took place between 2025 and 2026, through retrospective selection of images from a larger institutional archive whose records predate this period, spanning April 2010 to December 2025 (month and year of capture are recorded in the metadata). A non-probabilistic convenience/consecutive sampling was used: images were selected

TABLE IV
DISTRIBUTION OF NUMERICAL ATTRIBUTES

	0		1		2		≥ 3	
Attribute	Count	%	Count	%	Count	%	Count	%
Endodontic treatments	1,539	98.3	22	1.4	4	0.2	1	0.1
Dental implants	1,565	99.9	1	0.1	0	0	0	0

TABLE V
DISTRIBUTION OF PATHOLOGY AND FINDINGS CATEGORIES

Attribute	Category	Count	%
Pathol	Bone fracture	0	0
	Furcation lesion	0	0
	EPL	0	0
	Bone pathology	0	0
	Periapical lesion	1	0.1
	None	1,565	99.9
Findings	Anomaly	2	0.1
	Foreign body	0	0
	Calcification	0	0
	None	1564	99.9

based on availability and eligibility per inclusion/exclusion criteria, as detailed in Sec. III, with the aim of preserving demographic and radiographic variability (age ranges, biological sex, imaging patterns).

C. Data types and capture

Each instance comprises a panoramic radiograph and associated demographic metadata (biological sex, chronological age) recorded at patient intake prior to imaging. Radiographs were captured using one of two devices: Orthophos XG (Sirona Dental Systems, Germany) or OP300 (Instrumentarium, Finland). The specific capture device is stored as image metadata (Table I), and its distribution is described in Section III.

D. Data provenance, verification, and access

Clinical records and images originate from the institution's database to which the research group has authorized scientific access. Extracted metadata were verified by the research team for consistency and eligibility against study criteria. No remuneration beyond regular institutional salaries was paid to students, radiologists, or staff involved in data collection.

E. Ethics, consent, and anonymization

The study received approval from the Research Ethics Committees of both participating institutions — the Institute of Science and Technology of São Paulo State University (ICT/UNESP) and the Federal University of Technology – Paraná (UTFPR). Approval documents and committee reference numbers are archived and available upon institutional or editorial request. Patients were informed, as part of routine clinical care, that their clinical data and imaging exams may be used for academic and scientific purposes, and provided written consent via an Informed Consent Form. All data were de-identified prior to any experiments. Minimization measures were applied, including removal of direct identifiers and restricted access control.

F. Withdrawal and retraction

Once de-identified and incorporated into the dataset, images cannot be retroactively removed through any technical mechanism. However, patients may oppose future use of their data for research in accordance with applicable institutional policies.

V. PREPROCESSING, CLEANING, AND LABELING

Patient-identifying regions were removed by cropping, performed manually using Microsoft Photos (Windows 11). Images with missing age or sex metadata were excluded. Labels correspond to the attributes described in Table I.

The original unprocessed images and raw metadata were retained for traceability, stored separately on an access-restricted device.

Image-derived labels were assigned by majority-vote consensus among three independent annotators following a predefined written guideline, as described in Sec. III.

All scripted processing steps are archived in the project repository at https://github.com/Nickalverst/X-Pan with versioned filenames; all software and tool versions are recorded.

VI. USAGE

X-Pan has been used in the two baseline validation experiments reported in this paper: age estimation using publicly available model weights, and sex estimation through fine-tuning of three ImageNet-pretrained backbones (Section IX). All subsequent papers and systems that make use of X-Pan will be compiled, along with the up-to-date datasheet and the present paper, in the project repository.

The dataset is suitable for tasks inherent to panoramic radiographic analysis [18], including age and sex estimation and population-level dental imaging studies. Detection of clinical interventions (e.g., endodontic treatments, orthodontic appliances) is not currently supported by the dataset's composition; see the limitation below.

Several compositional factors may affect the performance and generalizability of models trained on X-Pan. First, all images originate from a single Brazilian institutional database and were captured using one of two specific devices; models may therefore underperform when applied to images from other institutions, regions, or equipment [19]–[21]. Second, sex distribution is nearly balanced (50.57% male), but age distribution is not: the dataset contains significantly more images of minors than of adults, as shown in Fig. 1. Models

trained on X-Pan should be expected to perform less reliably in adult age ranges. Third, clinical findings such as pathologies, endodontic treatments, and orthodontic appliances have low prevalence due to their partial exclusion during early collection. The current composition does not support such studies, which remain future work pending targeted class expansion.

The dataset should not be used for clinical diagnosis without independent validation on the target population and imaging equipment. Any attempt to re-identify individuals from the dataset is prohibited under the terms of use, which are available as an appendix to the datasheet.

VII. Distribution

The dataset is attainable by third parties exclusively for academic, scientific, or technological research, upon formal request to the dataset custodian (a.barbieri@unesp.br) and subsequent approval by the ethics committee. Access requires submission of signed agreement with the dataset's terms of use, confidentiality, and data protection requirements. Access requests may be submitted from the date of publication of this paper.

When approved, data will be shared via electronic transfer; no unrestricted public release is planned. The dataset is not issued under an open public license and has no associated access fees. A terms-of-use document governing authorized access is available through the project repository. The dataset currently has no DOI.

No third-party intellectual property restrictions are known to apply to the de-identified images. The original radiographs are held by the source institution, which has authorized their use for scientific purposes as described in Section IV.

VIII. Maintenance

The dataset is hosted and maintained by the lead researcher for programming and computational development (nicolasbarbierisousa@gmail.com), under supervision of the project research team. Dataset-related enquiries and access requests may also be directed to the dataset curator (a.barbieri@unesp.br). Data storage takes place in a controlled-access environment with security measures appropriate for anonymized radiographic data. There is currently no erratum.

A. Updates and versioning

The dataset will be reviewed and updated semiannually to add eligible new instances and, where necessary, correct labeling errors, standardize data, or remove inconsistent records. All changes will be documented and version-controlled; previous versions of the documentation will be retained and remain accessible through the project repository so that published experiments can be reproduced. Releases follow semantic versioning (MAJOR.MINOR.PATCH), where MAJOR denotes breaking changes, MINOR denotes backward-compatible additions, and PATCH denotes backward-compatible corrections. Updates and version history will be communicated via the repository.

No fixed data retention period was communicated to participants at the time of consent. Data will be retained indefinitely under the controlled-access conditions described in Section VII, subject to any future changes in applicable legislation or institutional policy.

B. Contributions and curation

There is no public contribution pipeline at present. External researchers may propose contributions by contacting the dataset curator at a.barbieri@unesp.br. Proposed additions will be reviewed by the research team for methodological compatibility, data quality, image standardization, and ethical compliance before incorporation. Accepted contributions will be integrated, documented under the appropriate version tag, and announced through the project repository.

IX. Validation

To illustrate the complete pipeline described in this paper, Fig. 2 shows an overview of the process, from data acquisition to validation results. The experiments and their results are described below.

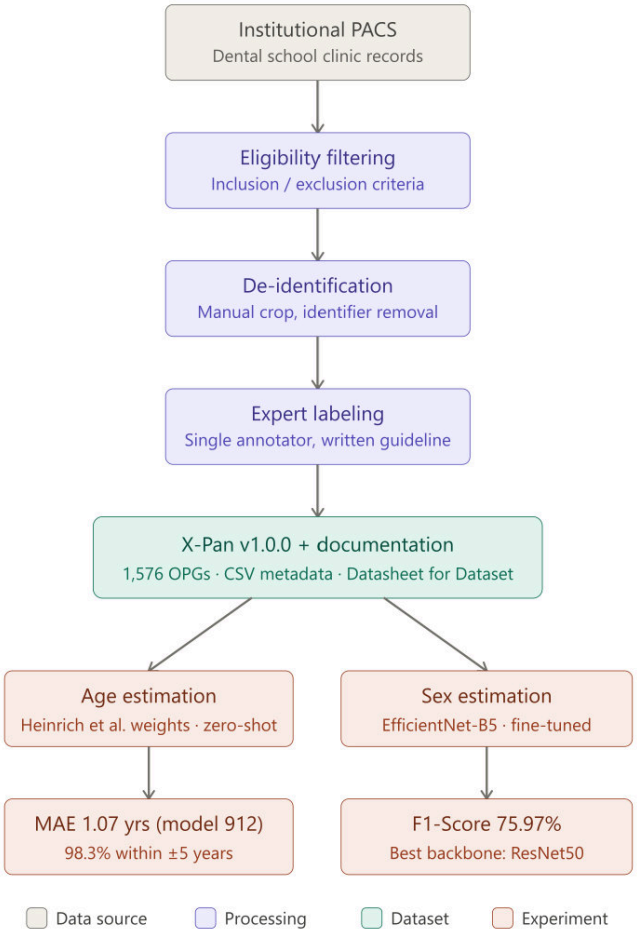

Fig. 2. Dataset construction and validation pipeline, from institutional data acquisition to the X-Pan v1.0.0 release and baseline validation experiments.

To demonstrate the usability of X-Pan with machine learning algorithms, two experiments were carried out. The first consisted of applying pre-trained weights from Heinrich et al. [15] (model 2216, for ages 2–89 years) and Koch et al. [16] (model 912, for ages 1–24 years) to estimate subject age. The second focused on sex estimation, in which three ImageNet-pretrained backbones — EfficientNet-B0, EfficientNet-B5, and ResNet50 — were fine-tuned on X-Pan as baseline experiments, using [22] as a reference for methodology and comparison.

A. Age estimation

For age estimation, the code from [15] was adapted to preprocess JPG instead of DICOM images. Both models were applied to all 1,566 instances. The results are shown in Table VI.

Model 912 achieved a 0.57-year (approx. 35.4%) lower overall MAE than model 2216, which is expected given that its training population (ages 1–24 years) closely matches the demographic distribution of X-Pan.

Grad-CAM activations represent the regions that most influenced the model's inference and should not be interpreted as evidence that a single anatomical structure determined the prediction.

Grad-CAMs generated by model 2216 are shown in Fig. 3. In panel A (ages 4–9), primary activations are anatomically compatible with the right maxillary tuberosity and posterior alveolar process in the area of upper first permanent molar root formation, the right mandibular ramus and mandibular angle, the left coronoid process, and the left mandibular ramus in the region corresponding to developing lower premolars. Secondary activations in the nasal cavity and maxillary sinuses may reflect craniofacial growth patterns, while notable activations anatomically compatible with the cervical vertebrae suggest the model draws on skeletal maturation cues beyond dental development alone. In panel B (ages 10–19), activations shift toward the maxillary tuberosity and the second permanent molar and upper third molar germ region, the right mandibular ramus and retromolar area corresponding to the developing lower third molar, the mandibular angle, and the left mandibular incisure; discrete activations persist along the mandibular body and in regions compatible with the cervical vertebrae and skull base. In panel C (ages 20–24), the pattern is more diffuse: primary foci are the right lower premolar region and the nasal cavity floor, with discrete activations near the lower third molar roots and mandibular body, and small activations near the mandibular condyles and superior image edges possibly related to the skull base or structural superposition. This reduced specificity is consistent with the diminishing discriminability of radiographic age markers in adulthood and with the wider confidence intervals observed for this group in Table VI.

B. Sex estimation

EfficientNet-B5, EfficientNet-B0 [23], and ResNet50 [24] backbones pretrained on ImageNet were fine-tuned on X-Pan

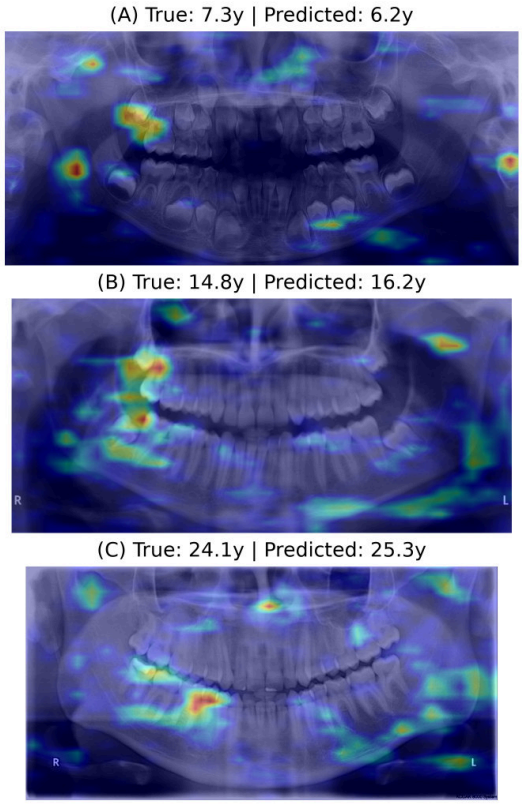

Fig. 3. Grad-CAM overlays produced by model 2216 for representative OPGs from three age bins: (A) 4–9 years, (B) 10–19 years, (C) 20–24 years. Each image was selected as the instance closest to the median absolute error within its bin. Warmer colours indicate regions of higher model attention.

using binary cross-entropy loss, AdamW optimization with learning rate of 1×10^{-4} and cosine annealing scheduling over a maximum of 12 epochs with early stopping (patience = 5). Training used 80% of the dataset and validation the remaining 20%. This constitutes a baseline experiment intended to demonstrate dataset usability rather than a reproduction of Bu et al. [22], whose dual-stream TResNet+CoAtNet-4 architecture and ROI preprocessing pipeline were not implemented. A faithful reproduction of their architecture is left for future work.

All three backbones were evaluated on accuracy, precision, recall, F1-score, and AUC. The results are shown in Table VII. ResNet50 achieved the highest F1-score (78.08%) and AUC of 0.841, surpassing EfficientNet-B0 (the second-best backbone) by 3.48 percentage points in F1. These results are substantially below Bu et al.'s reported accuracy of 86.79%, which is expected given the considerably smaller training set (1,253 versus 8,562 images) and simpler single-backbone architecture employed here.

Grad-CAMs generated by ResNet50 are shown in Fig. 4. Overall, activations are concentrated in the anterior dentoalveolar region of the mandible, with secondary activations in the posterior mandible and cranial regions. In panel A (correctly classified female), activation is anatomically compatible

TABLE VI

RESULTS OF APPLYING THE MODELS WEIGHTS PROVIDED BY [15] AND [16]. THE MEAN ABSOLUTE ERROR (MAE) GIVES THE MAGNITUDE OF THE DEVIATION BETWEEN THE ACTUAL AGE AND THE PREDICTED AGE. THE MAE WAS REPORTED ALONG WITH THE STANDARD DEVIATION (SD), STANDARD ERROR (SE), AND 95% CONFIDENCE INTERVAL (CI). THE SUCCESS RATE DESCRIBES THE PERCENTAGE OF OPGS IN WHICH THE AGE PREDICTION WAS CORRECT, WITH AN ACCEPTABLE ERROR RANGE OF $\pm$ 5, AND $\pm$ 10 YEARS.

		Absolute error (years)				Success rate (%)		
Model	**Age (years)**	**OPGs**	**MAE**	**SD**	**SE**	**95% CI**	**±5 years**	**±10 years**
912	4–9	554	0.72	0.94	0.04	0.64-0.80	99.6	99.6
	10–19	668	1.25	1.48	0.06	1.14-1.36	97.8	99.6

TABLE VII

SEX ESTIMATION RESULTS BY BACKBONE ON THE VALIDATION SET (20% STRATIFIED SPLIT).

Backbone-model	Precision (%)	Recall (%)	Accuracy (%)	F1 (%)	AUC (%)
EfficientNetB0 [23]	76.32	72.96	74.84	74.60	81.39
EfficientNetB5 [23]	73.03	69.81	71.66	71.38	81.17
ResNet50 [24]	74.71	81.76	76.75	78.08	84.10

with the right upper and lower molar region. In panel B (correctly classified female), activation concentrates on the right mandibular angle and the region corresponding to the lower third molar. In panels D and E (correctly classified males), the model consistently attends to the anterior region: panel D shows primary activation over the upper and lower incisors and the anterior mandibular and maxillary alveolar process, with secondary activation in the left lower premolar region; panel E shows activation over the upper and lower incisors and lower canines. This anterior dentoalveolar focus is consistent with the known sexual dimorphism of the anterior mandibular arch and alveolar morphology [22]. In panel C (misclassified female), activation concentrates on the upper and lower incisor region and the anterior mandibular alveolar process, as well as bilaterally in the lower canine and premolar region; the anatomically coherent but ambiguous pattern suggests morphological overlap between this individual's anterior arch and male-typical features. Panel F (misclassified male) shows activation in the left mandibular ramus and coronoid process, the right lower molar region, and areas compatible with the skull base, rather than the discriminative anterior dentoalveolar region; this failure to localise to the key features is consistent with the misclassification. Taken together, the Grad-CAM patterns reveal a more anatomically coherent and consistent representation than previously reported, with the anterior dentoalveolar region emerging as the primary discriminative area.

X. FUTURE WORK

Several directions for extending X-Pan and the baseline experiments presented here are identified.

Regarding the dataset, the most pressing limitation is the age imbalance: future collection cycles should prioritise adult images to improve coverage of the 20–89 year range. Expanding the dataset to include OPGs from multiple institutions and imaging devices would also improve generalizability and reduce the domain shift risk described in Section VI, but is among the most challenging advancements proposed.

For age estimation, the baseline experiments reported here applied pre-trained weights in a zero-shot setting. Fine-tuning, transfer learning, or training models directly on X-Pan are natural next steps.

For sex estimation, a faithful reproduction of the dual-stream TResNet+CoAtNet-4 architecture proposed by Bu et al. [22] is left for future work, as mentioned in Section IX.

Finally, detection of clinical interventions remains future work for X-Pan, contingent on targeted collection to increase the prevalence of pathologies, implants, and endodontic treatments (Section VI). Population-level analyses, already supported by the current composition, remain unexplored.

XI. HARDWARE AND TOOLS

All experiments were conducted on an NVIDIA GeForce RTX 3060 GPU under Linux (kernel 6.6.87.2-microsoft-standard-WSL2). Age estimation used TensorFlow 2.21.0 with CUDA 12.5.1 and cuDNN 9.0. Sex estimation used PyTorch 2.4.1 with CUDA 12.1 and cuDNN 9.1.0.

***Abstract*—Diabetic Retinopathy (DR) is an ocular disease caused by diabetes mellitus. In its later stages, DR can cause permanent damage to visual acuity, and an early diagnosis is essential to prevent vision loss. DR can be detected by analyzing a fundoscopy image, where specialists look for characteristic lesions in the retina, but ophthalmologists face several difficulties in the manual diagnosis of the disease. Computer-aided diagnosis assistance is a viable method to help experts overcome these difficulties. Therefor, this work evaluates and compares the YOLO11 and YOLO26 deep learning models in the task of segmenting DR lesions in fundoscopy images. The DDR dataset was used for training, validation and testing, and the IDRiD dataset was used as an external testing set to evaluate the models' generalization capabilities. Both dice score, intersection-over-union and inference time metrics were used to quantitatively analyze the results. The YOLO26 model obtained the best overall results, achieving 44.06% mean dice, 30.11% mean intersection-over-union and 49.88 ms mean inference time on the DDR dataset, as well as 51.78% dice, 42.66% intersection-over-union and 61.98 ms inference time on the IDRiD dataset. Microaneurysms were by far the hardest lesion for all models to segment. The models obtained higher dice and intersection-over-union metrics in the IDRiD dataset compared to DDR, even though IDRiD was used only for external testing, indicating that IDRiD is an easier dataset for segmentation an that the models exhibit good cross-dataset generalization capabilities. Thus, the proposed method has potential to assist ophthalmologists in DR screening and diagnosis, contributing as an accessible and efficient approach to DR screening.**

***Index Terms*—diabetic retinopathy, image segmentation, YOLO11, YOLO26, deep learning**

The authors would like to thank the Brazilian National Council for Scientific and Technological Development (CNPq) under Grant No. 315447/2023-0 and the Fundação Cearense de Apoio ao Desenvolvimento Científico e Tecnológico (FUNCAP) under Grant No. BMD-0008-00514.01.40/26 for the support to this research.

I. Introduction

Diabetic Retinopathy (DR) is a set of retinal and vitreous changes caused by diabetes, which in its later stages can cause permanent damage to the patient's vision. In early stages, DR is asymptomatic and usually causes no noticeable visual changes. However, as the disease progresses, DR can lead to loss of sight. Moreover, the progression of DR indicates a higher risk of vascular diseases, such as strokes, kidney problems and cardiovascular complications [1].

Among the most clinically significant DR lesions are microaneurysms, hemorrhages, hard exudates and soft exudates. Microaneurysms (MAs) are the earliest clinically detectable signs of DR and appear as small, round, red dots. Hemorrhages (HEs) occur when damaged retinal blood vessels rupture and appear as dot or blot red spots. Hard Exudates (EXs) are protein deposits that accumulate in the retina and appear as yellowish-white spots with well-defined margins. Soft Exudates (SEs) are retinal lesions caused by accumulation of axoplasmic material and appear as white, fluffy spots [2].

Due to loss of vision often being a late symptom of DR, many patients remain undiagnosed even when the disease is already causing severe retinal damage. DR can be detected by analyzing a fundoscopy screening image, where the presence of characteristic lesions indicate the disease. Fundus imaging is an initial and commonly employed diagnostic method due to being non-invasive, cost-efficient and portable [3].

According to the International Diabetes Federation [4], in 2024, it is estimated that 589 million adults aged 20-79 were living with diabetes, and the total number of people living with diabetes is projected to reach 853 million by 2050. Moreover, in the same year, Brazil was the 6th country with the most adults with diabetes.

For these reasons, regular ophthalmologic monitoring of people with diabetes is essential. However, ophthalmologists face several difficulties in the manual diagnosis of DR, such as a large number of retinal fundus images to be analyzed, which can cause abnormalities to be misinterpreted due to fatigue [5]. Furthermore, morphological changes in the retina are often subtle and small, making the analysis process time-consuming, and may cause observer variability [6].

Computer-aided diagnosis assistance to an expert is a viable method to help ophthalmologists overcome these daily difficulties, making fundoscopy image analysis process faster and DR diagnostic more accurate. By providing an initial assessment of the progression of the disease, the computational system enables the ophthalmologist to spend more time analyzing more severe cases, as well as to give faster diagnostics.

You Only Look Once (YOLO) from Ultralytics is a deep learning model for fast computer vision which provides a framework for several computer vision tasks, such as classification, object detection, segmentation and others. The YOLO11 version of YOLO has shown promising results in medical image classification [7], and the YOLO26 version outperforms YOLO11 in benchmark tests [8]. Therefore, this work applies the YOLO11 and YOLO26 deep learning models for the task of segmenting DR lesions.

II. Related Works

Automatic DR lesion segmentation has attracted considerable attention due to its potential at assisting ophthalmologists in early diagnosis and monitoring. Unlike image level DR classification, lesion segmentation aims to localize pathological regions at the pixel level, providing greater interpretability and enabling quantitative assessment of lesion areas.

Herrero *et at.* [9] proposed a deep decoder-focused U-Net model for segmenting DR lesions. By allocating more layers to the decoder, the model is able to gradually restore spatial details lost during down-sampling, mitigating over-compression and and enhancing fine-grained feature preservation. With this method, training on both the DDR and IDRiD datasets, a mean dice score of 52.24% and a mean intersection-over-union of 36.96% was obtained on the DDR test set, as well as 69.93% and 57.31% on the IDRiD test set, respectively.

Zhang, Xu and Zhai [10] proposed a method based on Fusion DenseNet and U-Net. By replacing the encoder part of U-Net with DenseNet and introducing Omni-Dimensional Dynamic Convolution to replace traditional convolutions, the model's adaptability and boundary recognition capabilities are improved. With this method, training on both the DDR and IDRiD datasets, a mean dice score of 46.03% and a mean intersection-over-union of 30.41% was obtained on the DDR test set, as well as 65.68% and 50.48% on the IDRiD test set, respectively.

Sivaz and Aykut [11] proposed a mamba-based dual-decoder adversarial network. A dual-decoder structure ensures consistency between predictions from the full-resolution and downscaled images, and two adversarial discriminators are employed to reduce feature distribution mismatches and align segmentation predictions across different scales. With this method, training on both the DDR and IDRiD datasets, a mean intersection-over-union of 33.85% was obtained on the DDR test set, as well as 53.08% on the IDRiD test set.

To our best knowledge, there has been no work in the literature using YOLO11 or YOLO26 for DR lesion segmentation. However, studies that used YOLO11 and YOLO26 for other segmentation tasks, including medical imaging, obtained satisfactory results. Ikram [12] used YOLO11 to brain tumor segmentation in MRI images, obtaining a mean average precision 91%. Nizar [13] used YOLO26 for multi-class fetal head ultrasound segmentation, obtaining a mean dice score of 92.53%. Thus, YOLO11 and YOLO26 show great potential in image segmentation, and testing its capabilities in further undeveloped areas is of utmost importance.

Therefore, motivated by the yet unexplored potential of YOLO11 and YOLO26 for DR lesion segmentation, this work proposed a comparative analysis of YOLO11 and YOLO26 with the goal of identifying the most suitable model for a high-precision and cost-efficient automated screening system.

III. Materials and Methods

For this study, the dataset images were first split into training, validation and test sets. Among the 757 DDR images, 383 were used for training, 149 for validation and 225 for testing. This split is the standard recommended by DDR creators, to facilitate comparisons between different experiments. Moreover, all 81 IDRiD images were used for testing, to evaluate the generalization capabilities of the models. Then, the models were trained with the training and validation sets. After training, the models' predictions on the DDR and IDRiD test sets were taken, and the evaluation metrics were calculated. This work's overall workflow diagram is presented in Figure 1.

All the model training and evaluation process was executed on a Windows 10 computer with the following hardware: AMD Ryzen 5 7600 6-core processor, 16 GB of RAM, NVIDIA GeForce GTX 1650 (4 GB) graphics card and 447 GB SSD Kingston SA400S37480G storage device.

During the training, the standard data augmentation implemented in the Ultralytics framework was used, which includes several methods such as hue, saturation and brightness adjustments, geometric transformations, and random erasing. This way, the relatively low number of images and class imbalance could not severely impair model performance.

Ultralytics provides YOLO segmentation models pretrained in the ImageNet dataset. When performing further training on pretrained models, the backbone and neck of the models have their weight values fixed, such that only the head of the architecture uptades during the training. This way, the model can inherit the feature extraction capabilities of the previous training, saving computational costs. This work used the pretrained YOLO11 and YOLO26 provided by Ultralytics.

A. Datasets

Two datasets were used in this study, both widely used in the literature for DR lesion segmentation: The Diabetic

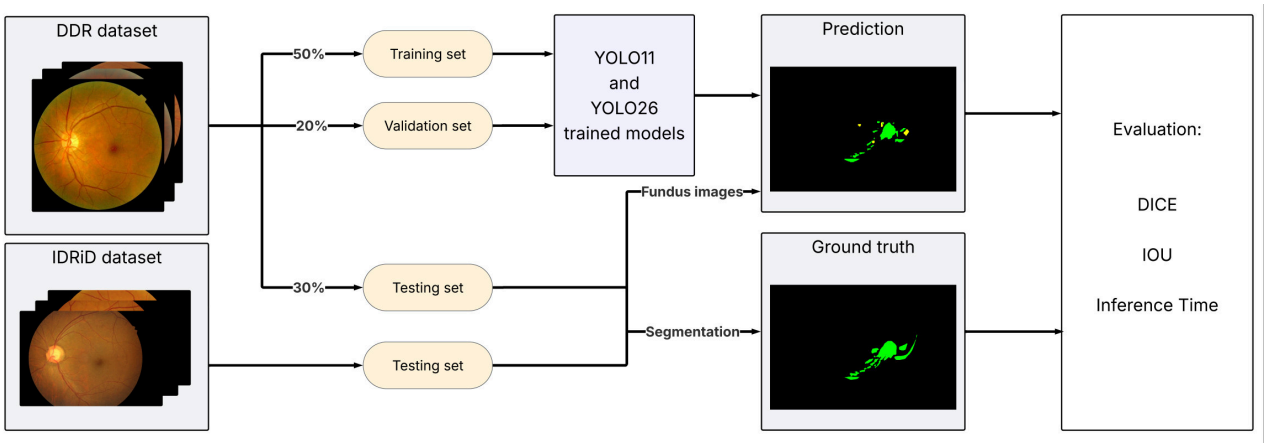

Fig. 1: Diagram of overall workflow process.

Retinopathy Database (DDR) for model training and testing and the Indian Diabetic Retinopathy Image Dataset (IDRiD) for external validation of the models.

1) DDR: The DDR [14] segmentation dataset contains 757 images obtained from hospitals in China. Image sizes range from 1088 $\times$ 1920 to 3456 $\times$ 5184 pixels. From the 757 total images, 601 contain HEs, 570 contain MAs, 486 contain SEs and 239 contain EXs. The original train, validation and test sets division proposed from the dataset creators was used in this study.

2) IDRiD: The IDRiD [15] dataset contains 81 images obtained from indian hospitals. All images are sized at 4288 $\times$ 2848 pixels. From the 81 total images, 80 images contain HEs, 40 SEs and all images contain MAs and EXs.

B. YOLO11

YOLO11 [16], released on september 10, 2024, is one of the most recent versions of the YOLO family of models, focused on optimizing performance and computational efficiency. One of the main innovations of this model is the C3k2 block, which performs several simultaneous convolutions that reduce the number of feature maps and concatenates the outputs, increasing the number of channels while the resolution remains constant, allowing for the capture of more complex features. YOLO11 also introduces the C2PSA block, which performs convolutions as well as employ an attention module and a fedd forward network, allowing the model to focus on the most relevant information of the image [18].

C. YOLO26

YOLO26 [17], released on january 14, 2026, is the current most recent version of the YOLO family of models. It introduces end-to-end inference, a lighter detection head, and task-specific heads for detection, segmentation, pose estimation, classification, and oriented detection. These changes make YOLO26 faster and more accurate than its predecessors, as well as more specialized in each of its available tasks.

D. Evaluation Metrics

To quantitatively analyze the experimental results, the DICE coefficient (DICE), intersection-over-union (IOU) and inference time (IT) performance metrics were adopted to evaluate the segmenting of DR lesions. The metrics of each prediction were calculated, and the mean and 95% confidence interval were taken for each model to analyze model performance. To calculate the metrics, the true positive (TP), false positive (FP) and false negative (FN) area of each lesion in each image was first calculated. The true positive refers to the intersection of the true lesion area and predicted lesion area, the false positive refers to the intersection of the true background area and predicted lesion area and the false negative refers to the intersection of the true lesion area and predicted background area. The relations of the DICE and IOU metrics to TP, FP and FN are shown in equations (1) and (2).

$$DICE = \frac{2TP}{2TP + FP + FN}, \tag{1}$$

$$IOU = \frac{TP}{TP + FP + FN}, \tag{2}$$

The IOU metric provides an intuitive assessment of the segmentation performance, as it directly compares the number of overlapping pixels between the ground truth and the predicted segmentation. The DICE metric, on the other hand, doubles the weight of true positives, effectively reducing the penalty of the model's FP and FN predictions.

IV. Results and Discussion

On the DDR dataset, YOLO26 consistently outperformed YOLO11 across all lesion categories. The mean DICE increased from 38.76% to 44.06%, an absolute improvement of 5.30%, while the mean IOU improved from 26.24% to 30.11%, an improvement of 3.87%. The models achieved the highest segmentation performance on EX lesions, with DICE scores of 49.83% for YOLO11 and 55.51% for YOLO26, followed by SEs, HEs and MAs. Among all lesion types,

TABLE I: Segmentation results on DDR

	YOLO11			YOLO26		
Lesion	DICE (%)	IOU (%)	IT (ms)	DICE (%)	IOU (%)	IT (ms)
Microaneurysm	21.66±17.42	14.55±15.83	-	24.52±14.67	18.50±16.21	-
Hemorrhage	37.24±20.15	25.83±18.74	-	44.18±12.92	28.35±14.56	-
Soft Exudate	46.31±18.68	30.46±21.37	-	52.03±17.43	35.17±14.85	-
Hard Exudate	49.83±22.61	34.12±19.29	-	55.51±14.74	38.42±15.93	-
Mean	38.76	26.24	114.04±32.18	44.06	30.11	49.88±23.72

TABLE II: Segmentation results on IDRiD

	YOLO11			YOLO26		
Lesion	DICE (%)	IOU (%)	IT (ms)	DICE (%)	IOU (%)	IT (ms)
Microaneurysm	27.93±12.37	22.90±11.82	-	35.73±9.64	27.38±12.51	-
Hemorrhage	43.18±13.25	38.41±10.47	-	51.12±12.73	43.27±8.91	-
Soft Exudate	50.65±9.76	42.57±12.34	-	58.74±11.28	48.15±14.62	-
Hard Exudate	54.76±12.83	46.32±15.57	-	61.53±7.45	51.84±10.36	-
Mean	44.13	37.55	120.34±40.42	51.78	42.66	61.98±16.64

MAs remained the most challeging to segment, obtaining the lowest DICE and IOU scores. In addition tot he accuracy improvementes, YOLO26 also substantially reduced the average inference time from 114.04 ms to 49.88 ms, more than halving the overall inference time. The segmentation results on the DDR test set are presented in Table I.

A similar trend was observed on the IDRiD external dataset, where YOLO26 achieved higher performance for every lesion class. The mean DICE increased from 44.13% to 51.78%, while the mean IOU increased from 37.55% to 42.66%, corresponding to absolute gains of 7.65% and 5.11% respectively. As in the DDR dataset, EXs exhibited the highest segmentation accuracy, reaching a DICE of 61.53%, whereas MAs remained the most difficult lesion to detect, with a DICE of 35.73%. YOLO26 also, again, demonstrated a considerably lower inference time, decreasing the average processing time from 120.34 ms to 61.98 ms, an improvement of 48.5%. The segmentation results on the IDRiD external test set are presented in Table II.

Although the models were trained exclusively on the DDR dataset and the IDRiD datset was used solely for external testing, the segmentation performance on IDRiD was consistently higher across all lesion categories. This behavior suggests that, despite serving as an unseen external dataset, IDRiD may present more favorable imaging characteristics for lesion segmentation, such as higher image quality, more consistent acquisition conditions, improved lesion visibility, or more homogeneous annotations. In contrast, the larger and more heterogeneous DDR dataset contains a wider range of lesion appearances, making it easier for the models to confuse lesions with one another, and making it a more challenging benchmark for pixel-level segmentation. For example, Figure 2 shows a case in which the original image from the DDR test set contained only an HE lesion, however, both models mistook part of the HE area for an SE lesion, and the YOLO11 model also segmented a small area as EX. These findings could also indicate that the trained models exhibit good cross-dataset generalization capabilities, since the learned parameters were able to produce good segmentations in very different scenarios, but further testing in more datasets and scenarios would be necessary to ascertain these capabilities. Moreover, these findings indicate that ophthalmologists segment DR lesions in standardized ways even in very different locations and clinical settings, since models only trained on DDR could also segment

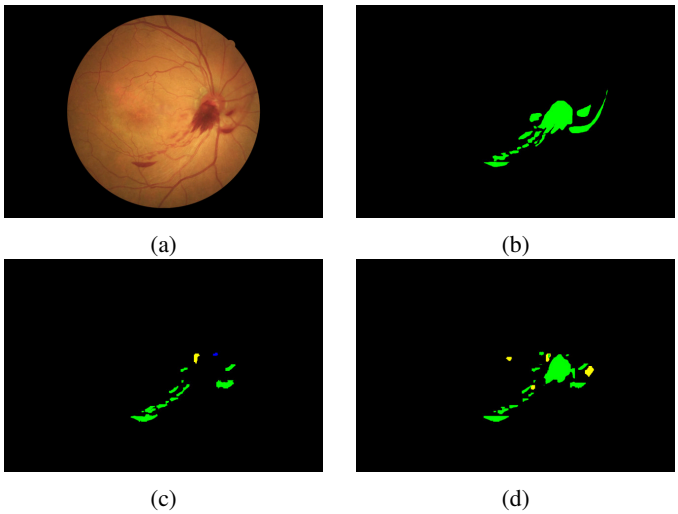

Fig. 2: Segmentation result sample on the DDR test set. The masks are presented using a lesion-specific color map: blue (EX), green (HE), and yellow (SE). (a) Original image. (b) Ground truth. (c) YOLO11. (d) YOLO26.

lesions in IDRiD.

Even though the IDRiD dataset was used solely for testing, both models obtained overall smaller 95% confidence intervals for all lesions in IDRiD compared to DDR, which further supports the possibility of IDRiD having more favorable imaging characteristics for consistent lesion segmentation. Moreover, MAs presented the relatively widest confidence interval in both datasets between all lesions, which indicates that, in addition to being the most challenging lesion to segment, MAs also present the most inconsistent segmentation results. This behavior could be likely related to the small size and low contrast of MAs compared with the more visually distinguishable exudative lesions. Furthermore, the confidence intervals of all lesions were considerably high, at a minimum of 8.91% YOLO26 HE IOU in IDRiD, which suggests that variability in image acquisition, lesion visibility or annotation method could be leading to inconsistent segmentations between images.

Overall, the experimental results show that YOLO26 provides consistent improvements over YOLO11 in both segmentation accuracy and computational efficiency. The largest performance gains were observed for HEs and exudates, while MAs continued to present the greatest segmentation challenge due to their small size and subtle appearance on the retina. YOLO26, compared to state-of-the-art methods, also obtained competitive results in the DDR dataset. Moreover, the relative drop in performance in the IDRiD dataset was comparatively small compared to state-of-the-art methods, even though other methods mostly used IDRiD for testing and training, instead of only for external testing. Furthermore, the low inference time achieved by YOLO26 indicates that the improved segmentation performance is accompanied by faster execution, making it more suitable for real-time or large-scale DR screening applications, as well as using the models on low computational power scenarios.

V. Conclusion

This study proposes a comparative analysis between YOLO11 and YOLO26 deep learning models in the task of segmenting diabetic retinopathy lesions in fundus images. The dice, intersection-over-union and inference time metrics were used to quantitatively evaluate the models. The DDR public dataset was used for training and validation, and the IDRiD dataset for external testing, allowing for an evaluation of the models' generalization capabilities.

Overall, the YOLO26 model obtained the best results in all lesions as well as in both datasets, achieving 44.06% mean dice, 30.11% mean intersection- over-union and 49.88 ms mean inference time on the DDR dataset, as well as 51.78% mean dice, 42.66% mean intersection-over-union and 61.98 ms mean inference time on the IDRiD dataset. Microaneurysms were by far the hardest lesion for all models to segment, such that the YOLO26 model obtained 24,52% dice and 18.50% intersection-over-union segmenting the lesion on the DDR dataset.

The results indicate that YOLO26 offers great potential in medical image processing applications, especially in large-scale and real-time scenarios, as it obtained competitive results to state-of-the-art methods. Moreover, both models demonstrated potential to have good generalization capabilities to unseen scenarios, but further research in different datasets and scenarios is necessary to ascertain these capabilities. Therefore, the presented method could help assist ophthalmologists in screening and diagnosing diabetic retinopathy by segmenting the characteristic lesions of the disease with high speed and moderate accuracy, especially in hardware-constrained scenarios.

Future works could use additional methods, such as more specialized data augmentation methods, to improve segmentation performance on difficult lesions, such as microaneurysms. Other datasets could also be used to further improve model generalization capabilities. Furthermore, the YOLO26 architecture could also be modified to improve feature extraction and learning capabilities on fundoscopy images and diabetic retinopathy lesions.

***Abstract*—**Microscopic examination of stained blood smears remains the reference method for detecting morphological abnormalities of leukocytes, erythrocytes, and platelets in veterinary hematology, but it is labor-intensive and expertise-dependent. This study evaluated the feasibility of a low-cost, YOLOv8-based deep learning framework for automated detection and classification of hematological elements in canine and feline blood smears acquired with conventional optical microscopy. A total of 8,855 hematological elements across thirteen classes were manually annotated and evaluated using blood-smear-level five-fold cross-validation. The model achieved a mean accuracy of 70.5%, mean specificity of 96.7%, and mean macro-averaged F1-score of 0.325. Performance was strongly class-dependent: segmented neutrophils (F1 = 0.914), eosinophils (F1 = 0.830), and lymphocytes (F1 = 0.762) were detected reliably, whereas band neutrophils, toxic neutrophils, and several rare classes performed poorly. Error analysis indicated that object-versus-background discrimination, rather than confusion between cell types, was the dominant source of error. These findings support the feasibility of conventional-microscopy-based AI screening as a triage aid for veterinary hematology, though current sensitivity is insufficient for autonomous diagnostic use.

I. INTRODUCTION

Hematological examination is among the most frequently requested diagnostic procedures in veterinary medicine, playing a fundamental role in the evaluation of infectious, inflammatory, parasitic, immune-mediated, and hematopoietic disorders[1]. The complete blood count provides quantitative and qualitative information on erythrocytes, leukocytes, and platelets, and the interpretation of specific elements (segmented and band neutrophils, lymphocytes, eosinophils, monocytes, and platelet abnormalities) frequently informs clinical decision-making and therapeutic monitoring in canine and feline patients[1].

Although automated hematology analyzers have substantially improved laboratory efficiency, important limitations remain regarding morphological assessment. Impedance and flow-cytometry-based systems estimate cellular counts with high precision but are frequently unable to reliably identify subtle morphological abnormalities, atypical or reactive leukocyte populations, platelet aggregates, or hemoparasites [2]–[4]. Microscopic examination of stained blood smears therefore continues to be considered an essential, reference-standard component of veterinary hematological evaluation, despite being labor-intensive and dependent on operator expertise[5], [6]. Increased band-neutrophil counts and toxic morphological change are historically used as indicators of a left shift and disease severity, although both findings carry well-documented inter-observer and analytic variability even among trained personnel [2], [7], [8]; platelet aggregates and related sample-handling artifacts can likewise complicate manual and automated platelet assessment alike [3], [9].

Convolutional neural networks and one-stage object-detection architectures of the You Only Look Once (YOLO) family [10], [11] have achieved promising results for the detection and classification of human leukocytes, including hybrid YOLO-classification pipelines and vision-transformer combinations [12], single-shot detector and YOLO comparisons trained on thousands of annotated leukocytes [13], convolutional networks trained via transfer learning [14], and networks augmented with dual-attention mechanisms [15] or applied to immature-versus-mature neutrophil discrimination [16]. A global scoping review covering 136 primary studies on machine- and deep-learning-based white blood cell classification confirmed a clear shift toward convolutional architectures over the past decade, alongside a persistent dependency of model accuracy on dataset size and balance [17]. Almost all of this evidence base, however, concerns human hematology under comparatively curated imaging conditions.

In veterinary medicine, AI-assisted hematology remains comparatively unexplored. A recent multicenter evaluation of a commercial point-of-care platform integrating convolutional neural network algorithms for canine and feline blood smear screening reported leukocyte differential agreement above 90% with board-certified clinical pathologists, illustrating the potential clinical value of such systems under controlled, well-resourced conditions [18]. However, most veterinary clinics

and small diagnostic laboratories lack access to such proprietary platforms or dedicated digital pathology scanners, motivating interest in low-cost approaches that pair conventional optical microscopes with affordable digital cameras.

From a computer-vision standpoint, blood smear analysis combines challenges rarely encountered jointly in other detection domains: individual hematological elements occupy a very small fraction of total image area, the morphological boundary between adjacent classes (e.g., band versus segmented neutrophils) can be genuinely continuous rather than discrete, and class prevalence in a clinical sample is, by definition, highly imbalanced rather than curated for machine learning. Strategies such as targeted data augmentation and synthetic oversampling have shown promise for related small-sample, imbalanced cell-classification problems [19], but their effectiveness for multi-class hematological detection in non-curated veterinary samples remains unestablished.

Outside hematology, YOLO-based detectors have been applied across a markedly diverse range of medical-imaging domains, illustrating both the maturity and cross-specialty transferability of the architecture: polyp detection in colonoscopy [20], dermoscopic and smartphone-based skin/nail lesion analysis [21], recognition of anatomical landmarks and instruments in laparoscopic surgery [22], detection of diabetic-retinopathy-related fundus lesions [23], multi-scale detection of pediatric wrist fractures in radiographs [24], grading of rib fractures on computed tomography [25], and identification of helminth eggs in stool microscopy [26], the latter a particularly close analogue, given that it likewise applies YOLO-based detection to small, morphologically variable biological objects in conventional brightfield microscopy images. Despite this breadth of cross-domain adoption, a systematic application of YOLO-based detection to the simultaneous, multi-class identification of hematological elements directly from canine and feline blood smears has not been identified in the reviewed literature.

The aim of this study was therefore to evaluate the feasibility of a low-cost, AI-assisted hematological screening approach based on conventional microscopy and a YOLOv8 object detection framework [10], [11], trained and evaluated on canine and feline blood smear images containing thirteen classes of hematological elements, using blood-smear-level five-fold cross-validation to characterize its strengths and limitations under realistic, imbalanced clinical conditions.

II. MATERIALS AND METHODS

Fig. 1 summarizes the overall experimental workflow, comprising sample collection, blood smear preparation, conventional-microscopy image acquisition, expert annotation, and YOLOv8-based training and evaluation, each described in detail in the subsections below.

A. Ethics Statement

All blood samples were residual material obtained during routine diagnostic hematological procedures performed for clinical purposes, independent of and prior to this research; no animals were sedated, sampled, or otherwise manipulated specifically for this study.

B. Dataset Acquisition

Peripheral blood smears from canine and feline patients were obtained through a collaboration with Diagnovet, a veterinary diagnostic laboratory in São José dos Campos, Brazil; case selection and identification validation were supervised by Fábio H. M. Jardini, a veterinary clinical pathologist and the laboratory's technical director.

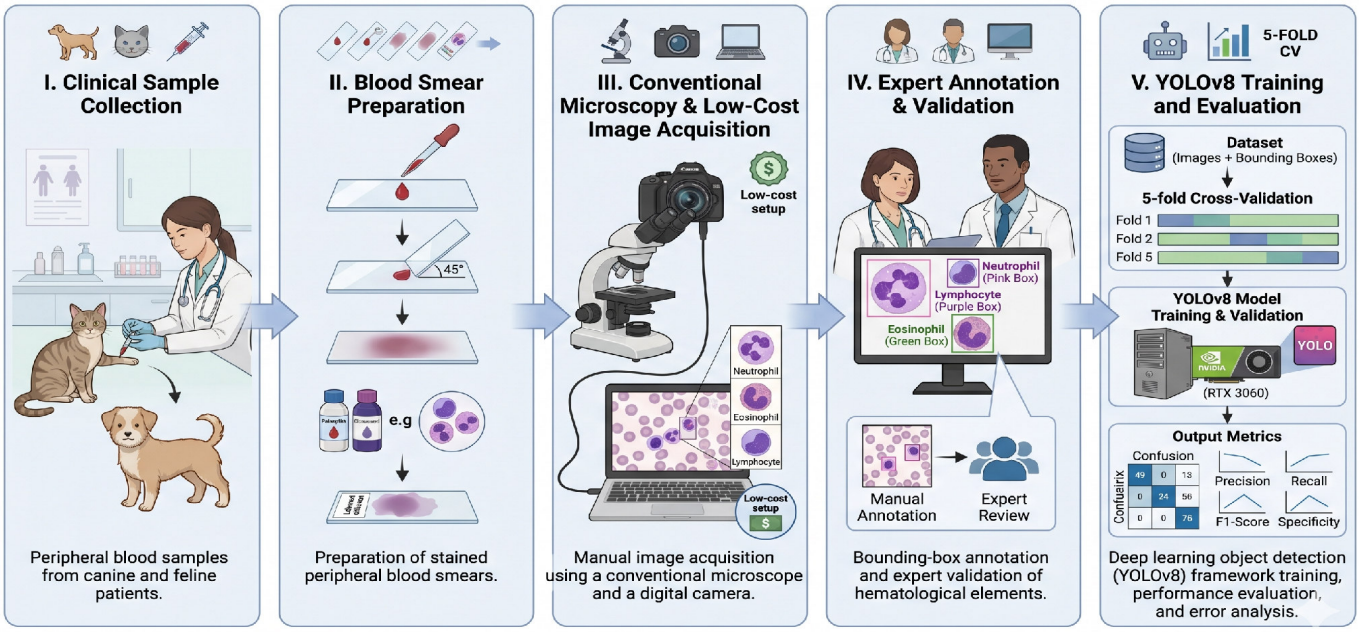

Fig. 1. Overview of the experimental workflow: peripheral blood smear sample collection, slide preparation, conventional optical microscopy and image acquisition, expert annotation of hematological elements, and YOLOv8-based model training and evaluation.

A total of 35 blood smear slides were analyzed, divided among 15 female dogs, 17 male dogs, 2 female cats, and 1 male cats. From a morphological and physiological standpoint, combining canine and feline samples within a single dataset is highly justified due to the structural analogy of their hematological elements. From a computer vision perspective, however, this deliberate pooling intentionally increases biological variability, presenting a more rigorous and realistic multi-species detection challenge for the model while simulating a diverse, low-cost clinical screening environment. Samples were processed using standard hematological protocols and stained with a panoptic (Romanowsky-type) protocol. Digital images were obtained by manual photography of stained smears under conventional optical microscopy: the responsible researcher visually scanned each slide and selectively photographed fields containing elements of interest, rather than exhaustively digitizing whole slides; reported class frequencies therefore describe the photographed fields rather than a uniform random sample of whole-slide cellularity. The images were obtained using a Canon Rebel T3i camera attached to a Motic BA210E microscope equipped with a 100x oil immersion objective and 10x eyepieces, yielding a total magnification of 1000x. Although the camera setup is capable of capturing 16-bit raw data, images were processed and evaluated as standard 8-bit JPEG files to maintain alignment with the computational restrictions of a low-cost diagnostic workflow.

C. Image Annotation

All images were manually annotated with bounding boxes by a veterinary researcher with clinical-pathology experience, with labels subsequently reviewed and validated by an experienced veterinary clinical pathologist. Thirteen classes were defined: segmented, band, and toxic neutrophils, eosinophils, lymphocytes, reactive lymphocytes, monocytes, an aggregate class, macroplatelets, Howell-Jolly-body-containing erythrocytes, Barr bodies, and background.

The final composed dataset comprised 8,855 annotated hematological elements (Table I), with marked natural class imbalance reflecting the prevalence of structures encountered during routine clinical examination. Segmented neutrophils were most prevalent (40.6%), followed by the aggregate class (16.0%, see flagged note in Section II-C), background (13.9%), and lymphocytes (11.0%). Three classes were represented by thirteen or fewer combined ground-truth instances (Howell-Jolly-body erythrocytes, macroplatelets); Barr bodies and toxic neutrophils, by contrast, had moderate instance counts (81 and 70, respectively), a distinction that becomes relevant in Section IV, since these two classes did not perform as their instance counts alone would predict.

D. YOLOv8 Architecture and Training

Object detection and instance segmentation were performed using the YOLOv8 architecture [10], [11], a one-stage framework that enables simultaneous localization and multi-class classification [10], [11]. This architecture was selected for its high computational efficiency and proven robustness across a diverse range of biomedical microscopy applications [12], [13], [15], [17], [20]–[26]. To evaluate the feasibility of the proposed approach under conditions realistically available to small veterinary diagnostic laboratories rather than dedicated research computing clusters [1], training was conducted on a deliberately modest, non-specialized workstation equipped with an Intel Core i7-4770 CPU (3.4–3.9 GHz, 8 threads), 32 GB DDR3 RAM, a 2 TB SSD, and a single NVIDIA GeForce RTX 3060 GPU with 12 GB GDDR6 [1].The pipeline was implemented using the default Ultralytics framework without architectural modifications, utilizing the nano variant for segmentation (YOLOv8n-seg) initialized with pretrained weights (yolov8n-seg.pt) [1], [11]. Training was embedded within a 5-fold cross-validation scheme and executed over 50 epochs per fold, using a batch size of 8 and an input image resolution of 640 x 640 pixels [1]. The optimization process was governed by the Ultralytics automatic configuration, which automatically selected the AdamW optimizer with a learning rate of 0.000625 and a momentum of 0.9 [1]. To optimize computational efficiency and prevent overfitting, automatic mixed precision (AMP) training was enabled, and early stopping was enforced with a patience threshold set to 10 epochs [1].

TABLE I. DISTRIBUTION OF ANNOTATED HEMATOLOGICAL ELEMENTS (N = 8,855)

Class	n	%
Segmented neutrophil	3,592	40.6
Aggregate *	1,416	16.0
Background	1,234	13.9
Lymphocyte	970	11.0
Eosinophil	597	6.7
Band neutrophil	339	3.8
Reactive lymphocyte	317	3.6
Monocyte	223	2.5
Barr body	81	0.9
Toxic neutrophil	70	0.8
Other rare classes†	13	0.15

**Biological identity pending confirmation (Sec. II-C). †Howell-Jolly-body erythrocytes (n=10), macroplatelets (n=2), abnormal erythrocytes (n=1), combined for brevity; class-wise totals differ from the nominal dataset total by <0.1% due to rounding.*

E. Cross-Validation and Evaluation Metrics

A five-fold cross-validation strategy, partitioned at the blood-smear level to prevent data leakage between training and validation partitions, was used: all elements from a given smear were assigned to a single fold (fold sizes: 1,854; 1,696; 2,133; 1,248; 1,924 elements). For each fold, precision, recall (sensitivity), specificity, and F1-score were computed per class from the resulting confusion matrix as:

Precision = TP/(TP+FP);

Recall = TP/(TP+FN);

Specificity = TN/(TN+FP);

F1 = 2 x (Precision x Recall)/(Precision+Recall),

where TP, FP, TN, and FN denote, respectively, true positives, false positives, true negatives, and false negatives for a given class. Macro-averaging across the thirteen classes was used to give equal weight to rare and frequent classes rather than allowing performance to be dominated by the majority class. Results are reported throughout as mean ± SD across the five folds; no formal inferential statistical testing across classes or folds was performed, and reported differences between classes or folds should accordingly be interpreted descriptively.

III. RESULTS

A. Dataset Composition

The resulting class-imbalance ratio showed in Table I (most-frequent class, segmented neutrophil, n = 3,592, versus least-frequent class) exceeds 3,500:1, substantially wider than the imbalance typically reported in curated human-hematology benchmarks and a likely contributor to the macro-averaged performance gap discussed in Section IV-A.

B. Cross-Validation Performance

Across folds, the model achieved mean accuracy 70.5% (range 64.3–73.9%), mean specificity 96.7% (range 96.4–96.9%), mean macro-averaged precision 31.4%, mean macro recall 34.2%, and mean macro F1 0.325 (range 0.281–0.361). The remarkably narrow range of macro specificity across folds indicates that the model consistently rejected non-target regions regardless of fold composition, whereas macro precision and recall, and therefore F1, were comparatively more sensitive to which blood smears were assigned to a given fold. Table II summarizes macro-level and representative class-wise performance; full results for every class are reported in the corresponding extended manuscript.

TABLE II. PERFORMANCE BY CLASS (MEAN ± SD ACROSS 5 FOLDS)

Class	Recall	Prec.	Spec.	F1
Overall (macro, 13 cls.)	.342±.038	.314±.024	.967±.002	.325±.029
Segmented neutrophil	**.923±.035**	**.906±.024**	**.951±.010**	**.914±.027**
Eosinophil	**.856±.023**	**.777±.097**	**.988±.004**	**.830±.062**
Lymphocyte	**.782±.108**	**.767±.112**	**.952±.019**	**.762±.042**
Aggregate	.571±.168	.436±.215	.937±.022	.468±.213
Monocyte	.474±.153	.449±.089	.975±.008	.455±.110
Reactive lymphocyte	.308±.107	.292±.055	.984±.002	.297±.081
Band neutrophil	.242±.353	.145±.226	.994±.005	.177±.277
Toxic neutrophil	.119±.108	.118±.091	.998±.001	.103±.067
Barr body	.000	.000	.998±.001	.000
Other rare classes†	.000	.000	.999–.000	.000

†Howell-Jolly body, macroplatelet, and abnormal erythrocyte classes, combined; "Overall" row reflects macro-averaging across all 13 originally annotated classes (Sec. III-A), not only the rows shown.

C. Error Analysis

The aggregated confusion matrices (Figs. 2-3) show that most classification errors involved object-versus-background discrimination rather than confusion among morphologically distinct cell types. Aggregates were correctly identified in only 56.9% of instances, with 42.4% misclassified as background and, conversely, 41.0% of true background misclassified as aggregates, the single largest error pathway in the matrix. Howell-Jolly-body-containing erythrocytes (n = 10) were misclassified as background in 100% of instances. Band neutrophils were correctly classified in only 4.4% of instances, with 81.7% misclassified as segmented neutrophils, mirroring the well-documented morphological continuum and inter-observer variability between these two forms [7], [8]. Toxic neutrophils were similarly unstable, correctly identified in only 8.6% of cases and otherwise distributed across background (21.4%), segmented neutrophils (18.6%), monocytes (17.1%), lymphocytes (11.4%), and eosinophils (10.0%); reactive lymphocytes were correctly classified in 30.9% of instances, most often confused with conventional lymphocytes (45.4%), a confusion that was symmetric (11.0% of true lymphocytes were misclassified as reactive lymphocytes). In contrast, segmented neutrophils and eosinophils showed minimal leakage to other classes (91.8% and 85.6% correctly classified, respectively), with residual error directed mostly toward background rather than toward another cellular class.

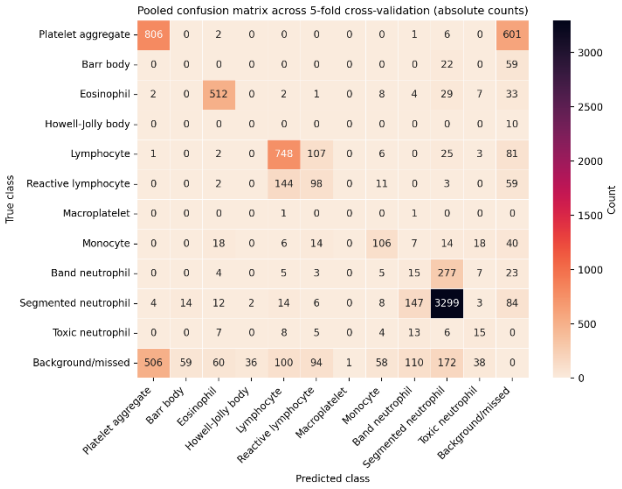

Fig. 2. Aggregated confusion matrix across the five cross-validation folds, absolute instance counts.

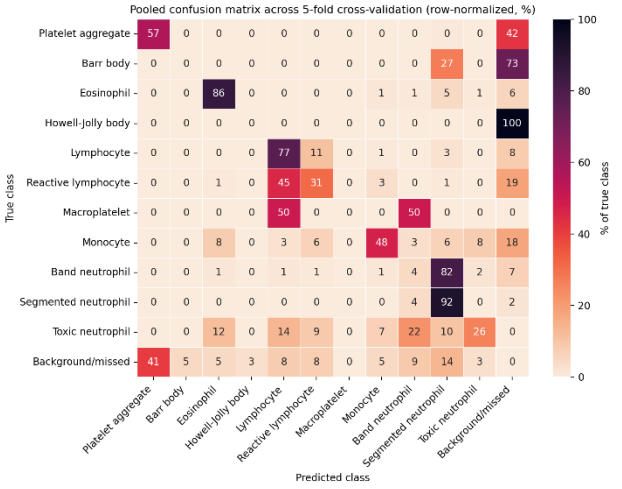

Fig. 3. Aggregated confusion matrix across the five cross-validation folds, row-normalized (each row sums to 100% of ground-truth instances of that class).

D. Variability and Qualitative Assessment

Class-level variability (Fig. 4) exceeded fold-level variability, indicating that class identity, rather than the specific smears assigned to a fold, was the dominant determinant of performance. Classes with very few instances showed essentially no dispersion because performance was near zero in every fold, whereas intermediate-frequency classes such as aggregates and band neutrophils showed the widest dispersion, consistent with their large standard deviations in Table II.

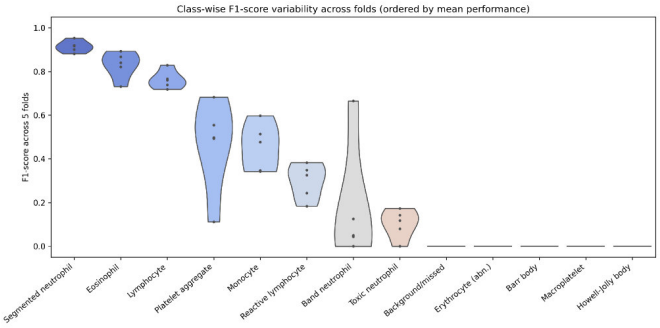

Fig. 4. Distribution of per-class of F1-score across the five cross-validation folds, illustrating heterogeneity of detection performance among the thirteen hematological classes.

A qualitative comparison between ground-truth annotations and model predictions on representative validation fields (Fig. 5) corroborated these quantitative patterns: dominant, morphologically distinct classes such as segmented neutrophils and eosinophils were consistently and accurately localized and classified, whereas aggregates and band neutrophils showed visible instances of missed detection or misclassification as segmented neutrophils, and the rarest classes were largely absent from the model's predictions even when present in the ground-truth annotation.

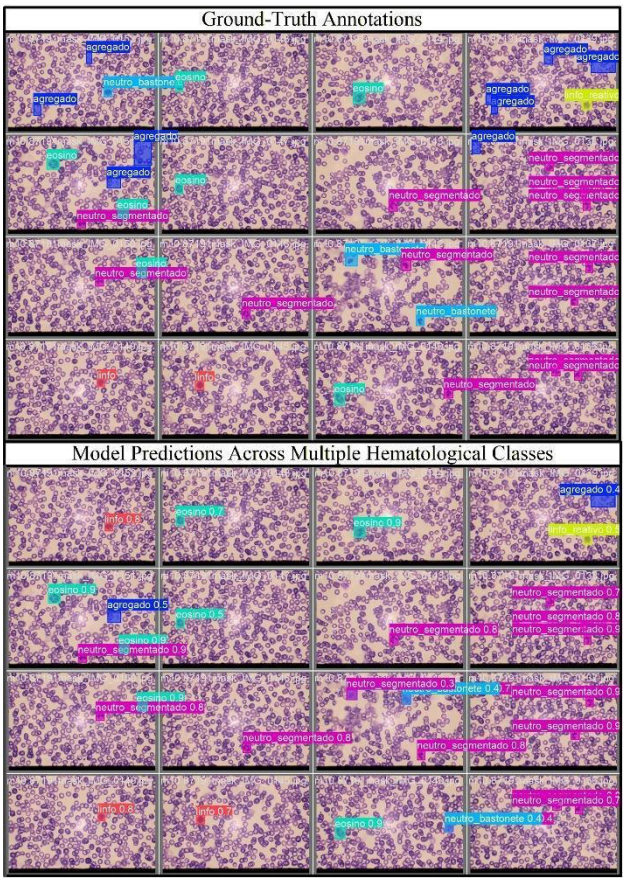

Fig. 5. Representative validation image fields comparing ground-truth annotations with model predictions across multiple hematological classes.

E. Synthesis of Quantitative Findings

Considered jointly, Tables I-II and Figs. 2-5 point to a consistent overall pattern: detection performance was strongly and predictably associated with the number of available training instances for a given class, with a secondary, independent contribution from the intrinsic morphological distinctiveness of that class. Segmented neutrophils and eosinophils combined high instance counts with comparatively distinctive morphology and accordingly achieved the highest and most stable F1-scores. Band and toxic neutrophils, despite moderate instance counts, achieved markedly lower performance than instance count alone would predict, reflecting their well-documented morphological continuity with segmented neutrophils. The aggregate class , despite being the second most frequent class overall, showed the largest variance in performance across folds, consistent with an amorphous and visually heterogeneous appearance. This pattern suggests that future efforts to improve performance should be differentially prioritized: increasing instance counts is likely to yield the greatest benefit for the rarest classes, whereas band/toxic neutrophils and the aggregate class may additionally require dedicated feature-engineering strategies targeting fine-grained morphological discrimination rather than instance count alone.

IV. DISCUSSION

A. Performance Patterns and Comparison with Prior Work

Strong, consistent performance for segmented neutrophils, eosinophils, and lymphocytes (together about 58% of annotated elements) likely reflects their relatively large size, distinctive staining characteristics, and low intra-class morphological variability, consistent with prior human-hematology reports [12], [13], [16]. The overall macro-averaged performance achieved here (F1 = 0.325) is considerably lower than the accuracies typically reported for human leukocyte detection, several exceeding F1 = 0.90 [12]–[16], [27]; this gap likely reflects a smaller, more class-imbalanced dataset (8,855 elements across thirteen classes, several with fewer than one hundred instances, versus datasets of several thousand to tens of thousands of relatively balanced images in many human-hematology studies), non-standardized conventional-microscopy acquisition rather than calibrated digital pathology scanners, and a broader taxonomy spanning leukocyte, platelet, and erythrocyte abnormalities plus an explicit background class. A global scoping review of 136 white-blood-cell-classification studies similarly concluded that accuracy in this domain remains strongly dataset-size- and balance-dependent [17], consistent with the present finding rather than representing an isolated negative result. The only directly comparable veterinary system, a commercial point-of-care CNN platform, reported >90% agreement with clinical pathologists [18], but was developed with substantially larger curated datasets and dedicated capture hardware integrated into the point-of-care device, unlike the explicitly low-cost, conventional-microscopy design objective adopted here.

The cross-domain YOLO literature surveyed in Section I [20]–[26], [28] offers a useful frame for interpreting these results. Several of these applications, including colonic polyp detection [20], helminth-egg identification in stool microscopy

[26], and pediatric wrist-fracture detection [24], likewise involve small, morphologically variable targets embedded in heterogeneous backgrounds, and generally report higher detection metrics than obtained here for the rarest hematological classes; in most cases, however, those studies were trained on datasets that were either explicitly curated for class balance or several-fold larger than the 8,855-element dataset used in the present study. This reinforces the broader conclusion of the scoping review by Asghar et al. [17]: across medical-imaging domains, YOLO-family detectors are architecturally capable of strong small-object performance, but realizing that capability for any individual class is conditional on adequate, reasonably balanced training data for that class-a condition that routine veterinary clinical sampling, by its nature, does not guarantee.

B. Sources of Error

A key finding was that the majority of misclassifications involved confusion between a true hematological element and background, rather than confusion between two distinct cell types: the aggregate-background error pathway alone accounted for the single largest source of error in the entire confusion matrix, and toxic neutrophils were likewise most frequently confused with background rather than with any single alternative leukocyte class. This suggests that the principal bottleneck lies in the object-detection (localization, object-versus-background discrimination) stage rather than in downstream classification of already-localized elements. Classes with ten or fewer combined instances (Howell-Jolly bodies, macroplatelets, abnormal erythrocytes) showed near-zero F1 in every fold, an expected consequence of insufficient training examples rather than fundamental model incapacity [19]. Band and toxic neutrophils, despite moderate instance counts (n = 339 and n = 70), also performed poorly, reflecting the genuinely continuous, subjective morphological boundary with segmented neutrophils that drives substantial inter-observer disagreement even among trained morphologists [7], [8]. Barr bodies (n = 81) likewise achieved near-zero F1 despite an instance count comparable to toxic neutrophils, a pattern that, unlike the truly rare classes above, is not fully explained by data scarcity alone and may instead reflect intrinsically low visual distinctiveness of this structure under conventional microscopy; this discrepancy was identified during internal stats-checking of the present draft and is highlighted here as a result that should be discussed explicitly rather than grouped with the data-scarcity explanation used for the other rare classes. If the “agregado” class is confirmed to represent platelet aggregates, it would constitute an inherently ambiguous detection target: amorphous, variable in density, and prone to blend with debris or out-of-focus regions, consistent with the well-documented phenomenon of in vitro platelet clumping that complicates both manual and automated platelet assessment [3], [9].

C. Clinical Implications

Taken together, these findings suggest that a low-cost, YOLOv8-based framework operating on conventional microscopy images can already provide clinically meaningful support for detecting the most common hematological elements (segmented neutrophils, eosinophils, and lymphocytes), which together represent the majority of diagnostically relevant decisions in routine canine and feline blood smear evaluation. However, the framework cannot presently be relied upon for independent detection of band neutrophils, toxic neutrophils, the aggregate class, or rare erythrocyte and platelet abnormalities, several of which carry direct clinical significance for recognizing inflammatory left shift, sepsis-associated toxic change, pseudothrombocytopenia, or regenerative anemia [2], [3], [7], [9]. Given the consistently high specificity observed across classes (96.4–96.9% macro-averaged), the framework is best positioned, at its current stage, as a triage aid flagging fields or smears for focused human review rather than as a stand-alone diagnostic substitute for microscopic evaluation by a trained veterinary professional.

In practical terms, a triage-oriented deployment could flag image fields or whole smears containing predicted segmented neutrophils, eosinophils, or lymphocytes for streamlined confirmation, while explicitly routing fields with predicted or suspected band/toxic neutrophils, aggregates, or rare erythrocyte/platelet findings for mandatory full manual review rather than automated acceptance or rejection. Such a tiered workflow would concentrate clinician attention on the classes where the present model is least reliable, rather than asking the model to make an autonomous call on findings most likely to be clinically decisive, such as toxic change or platelet aggregation.

D. Limitations and Future Directions

This study has several limitations that should be considered when interpreting its findings. First, the dataset was derived from approximately 50 blood smear slides obtained from a single veterinary diagnostic laboratory using a single conventional-microscopy acquisition setup; this limited and geographically concentrated sampling may restrict generalizability to other laboratories, staining protocols, microscope models, or camera systems, and external multi-center validation was not performed.

Second, several clinically relevant classes (Howell-Jolly bodies, macroplatelets, abnormal erythrocytes) were represented by ten or fewer ground-truth instances; the near-zero performance observed for these classes reflects insufficient training examples rather than fundamental model incapacity, and corresponding macro-averaged metrics should be interpreted with this caveat in mind. Barr bodies, with a moderate instance count (n = 81) but likewise near-zero F1, are a partial exception to this explanation, as discussed in Section IV-B.

Third, image annotation was performed by a single primary veterinary researcher with subsequent review by one experienced clinical pathologist; a fully independent multi-rater design with formal inter-observer agreement statistics was not implemented, which limits the ability to disentangle model error from possible annotation variability, particularly for morphologically ambiguous classes such as band and toxic neutrophils.

Fourth, several acquisition and training specifications flagged in Section II are not yet finalized in this draft; their absence does not affect the validity of the reported cross-

validation metrics, which were computed directly from model outputs, but does limit independent reproducibility until completed. Fifth, only descriptive statistics (mean ± SD across folds) were used; no formal inferential testing was performed, so claims of statistically significant differences between classes or folds cannot be made from this study alone. Finally, this study evaluated detection performance in isolation from downstream clinical workflows; the impact of integrating this framework into actual veterinary practice was not assessed.

Because the dominant error pathway was object-versus-background discrimination rather than inter-class confusion, improving detector sensitivity for small, low-contrast, or morphologically diffuse objects is likely to yield disproportionate gains relative to classification-only refinements. Targeted oversampling or synthetic augmentation for rare classes [19], explicit ordinal/hierarchical modeling of continuous morphological distinctions (e.g., band-to-segmented neutrophil, lymphocyte-to-reactive-lymphocyte), and prospective multi-laboratory validation with varied microscopy and staining equipment represent concrete next steps toward clinical deployment.

V. CONCLUSION

This study evaluated the feasibility of a low-cost, YOLOv8-based framework for automated detection and classification of thirteen classes of hematological elements in canine and feline blood smears acquired with conventional optical microscopy. Using blood-smear-level five-fold cross-validation on 8,855 annotated elements, the framework achieved mean accuracy 70.5% and mean specificity 96.7%, with reliable detection of the most clinically common cell types but substantially reduced sensitivity for band/toxic neutrophils, the aggregate class , Barr bodies, and rare erythrocyte/platelet abnormalities. Error analysis indicated that object-versus-background discrimination, rather than inter-class confusion, was the dominant source of error.

These findings support the feasibility of affordable, conventional-microscopy-based deep learning as a veterinary hematology screening aid, though current performance does not support fully autonomous diagnostic use. Given that most prior YOLO-based medical-imaging successes [20]–[26], [28] relied on larger or better-balanced datasets than the one used here, the present results should be read as a proof-of-concept lower bound rather than an upper bound on what this class of architecture can achieve in veterinary hematology. Future work should prioritize expanding underrepresented classes through multi-center data collection, refining small-object detection, and prospective clinical validation to determine the framework's practical value as a triage tool within real-world veterinary diagnostic workflows.

The main contributions of this study are threefold: (1) a quantitative feasibility assessment of YOLOv8-based detection across thirteen classes of canine and feline hematological elements using images acquired with conventional, non-specialized optical microscopy; (2) a blood-smear-level five-fold cross-validation protocol that avoids data leakage between training and evaluation partitions, providing a more conservative and clinically realistic performance estimate than image-level splitting; and (3) an explicit, class-by-class error analysis identifying object-versus-background discrimination-rather than inter-class confusion-as the dominant error source, which directly informs where future modeling effort should be concentrated.

ACKNOWLEDGMENT

This study was supported by the Brazilian Ministry of Health (MS) and the National Program for Genomics and Precision Health (Genomas Brasil); by the National Council for Scientific and Technological Development (CNPq), grants 406947/2023-6 and 443992/2023-1; and by the Coordination for the Improvement of Higher Education Personnel (CAPES). ***Resumo*—A tecnologia assistiva desempenha um papel fundamental na promoção da mobilidade, da autonomia e da qualidade de vida das pessoas com deficiência, sendo as cadeiras de rodas um dos principais recursos utilizados para esse fim. Entretanto, o elevado custo de componentes comerciais e a necessidade de adaptação às demandas específicas dos usuários representam desafios para sua viabilidade. Nesse contexto, o presente trabalho teve como objetivo desenvolver e aperfeiçoar uma roda para cadeira de rodas por meio da tecnologia de impressão 3D, visando à obtenção de uma solução funcional e de baixo custo. Inicialmente, foram avaliadas rodas comerciais de etileno-vinil-acetato (EVA) e rodas pneumáticas com câmara de ar, cujas limitações econômicas e de manutenção motivaram o desenvolvimento de um modelo próprio. O processo de prototipagem envolveu sucessivas modificações estruturais, passando de modelos segmentados em oito e quatro partes até a obtenção de uma roda em peça única, além da implementação de um aro de propulsão para maior conforto e ergonomia. Para a fabricação dos protótipos, foram utilizados filamentos de poliuretano termoplástico (TPU), acrilonitrila butadieno-estireno (ABS) e polietileno tereftalato glicol (PETG) reforçado com fibra de carbono, selecionados em função de suas propriedades mecânicas e funcionais. Os resultados demonstram a viabilidade técnica de um processo iterativo de desenvolvimento baseado em manufatura aditiva para a fabricação de rodas personalizadas de baixo custo, evidenciando o potencial dessa abordagem para reduzir a dependência de componentes comerciais e ampliar a flexibilidade no projeto de cadeiras de rodas infantis.**

***Palavras-chave*—tecnologia assistiva; cadeira de rodas; rodas; impressão 3D.**

I. INTRODUÇÃO

De acordo com a Organização Mundial da Saúde (OMS), a tecnologia assistiva engloba produtos, sistemas e serviços destinados a manter ou melhorar a funcionalidade e a independência dos indivíduos. Esses recursos, como cadeiras de rodas, desempenham um papel fundamental na promoção da autonomia, da inclusão social e da qualidade de vida, especialmente para pessoas com deficiência. Apesar dos benefícios reconhecidos, a OMS destaca que o acesso aos produtos assistivos ainda é limitado em diversas regiões, evidenciando a necessidade de ampliar sua disponibilidade e adoção em larga escala [1].

As cadeiras de rodas desempenham um papel essencial na reabilitação, promovendo a mobilidade, a autonomia e a participação social dos usuários. Além disso, a capacidade de utilizá-las está diretamente relacionada à inclusão e à melhoria da qualidade de vida [2].

Nesse contexto, o Laboratório xx, da Universidade YY, atua no desenvolvimento de soluções inovadoras em tecnologia assistiva, buscando criar dispositivos que atendam às necessidades específicas dos usuários por meio da integração entre pesquisa, ensino e extensão. O laboratório tem como missão desenvolver recursos acessíveis que promovam funcionalidade, autonomia e inclusão, aproximando o conhecimento científico das demandas reais da comunidade.

Entre os projetos desenvolvidos pelo laboratório, destaca-se a construção de cadeiras de rodas infantis destinadas a crianças de um a cinco anos de idade. Inicialmente, a estrutura desse equipamento era confeccionada em MDF (placa de fibra de média densidade); posteriormente, o projeto evoluiu para a utilização de chapas de tampinhas plásticas recicladas, proporcionando maior resistência, durabilidade e segurança ao equipamento. A proposta inicial consistia na utilização de rodas comerciais para a fabricação de bicicletas infantis, adaptando-as para a aplicação nas cadeiras de rodas. Contudo, durante o

desenvolvimento, observou-se que essa alternativa apresenta limitações relacionadas ao desempenho, à adaptação e ao custo, motivando a busca por uma solução própria.

Nesse contexto, a impressão 3D possibilita o desenvolvimento de dispositivos personalizados, adequados às necessidades individuais dos usuários de menor custo [3]. Dessa forma, iniciou-se o desenvolvimento de uma roda específica para essas cadeiras de mobilidade infantis utilizando manufatura aditiva por impressão 3D, visando obter um componente funcional, resistente, de baixo custo e passível de personalização conforme as necessidades dos usuários.

Embora a manufatura aditiva esteja sendo amplamente empregada no desenvolvimento de dispositivos de tecnologia assistiva, ainda não há estudos que descrevam processos sistemáticos para o desenvolvimento de rodas destinadas especificamente a cadeiras de rodas infantis. Considerando que esse componente influencia diretamente a mobilidade, a estabilidade, a ergonomia e o desempenho global do equipamento, sua otimização representa um desafio relevante para a engenharia aplicada à tecnologia assistiva.

Este trabalho tem como objetivo desenvolver um processo iterativo de projeto para rodas personalizadas destinadas a cadeiras de rodas infantis utilizando manufatura aditiva, descrevendo as sucessivas modificações estruturais implementadas durante o desenvolvimento e sua contribuição para o aprimoramento funcional do componente.

II. METODOLOGIA

Inicialmente, foram adquiridas rodas de etileno-vinil-acetato (EVA) comercialmente disponíveis, com aro 12, como apresentado na figura 1, utilizadas nas cadeiras de rodas produzidas pelo laboratório. Entretanto, verificou-se a necessidade de rodas com aro 14, ilustrado na figura 2, para atender adequadamente crianças maiores. O custo aproximado deste novo modelo, cerca de R$120,00 por unidade, tornava a aquisição economicamente inviável.

Fig. 1. Roda de EVA comercialmente disponível.

Foram testadas rodas pneumáticas de borracha com câmara de ar, compatíveis com o aro 14, conforme a imagem 3 mostra o pneu. No entanto, além do custo adicional referente às câmaras de ar (aproximadamente R$15,00 por unidade), a necessidade de manutenção periódica decorrente da perda de pressão comprometeu sua viabilidade de uso.

Fig. 2. Roda de Aro 14.

Fig. 3. Pneu de borracha, comercialmente disponível.

Diante dessas limitações, o desenvolvimento foi conduzido segundo uma abordagem iterativa de engenharia, na qual cada protótipo foi analisado quanto às limitações observadas durante sua utilização. Os resultados dessa avaliação orientaram sucessivos ciclos de redesenho, seleção de materiais e aperfeiçoamento estrutural, até a obtenção da configuração final, expressa pela figura 4. Em um primeiro momento, devido às limitações dimensionais da impressora utilizada (Creality K1 Max), o aro da roda foi projetado em quatro segmentos interligados, como observado na figura 5, produzidos em filamento polietileno tereftalato glicol (PETG) reforçado com fibra de carbono (PETG+CF). Embora funcional, essa configuração segmentada apresentava complexidade de montagem e compromete a integridade estrutural da peça.

A divisão do aro em segmentos representou uma solução transitória imposta pelas limitações dimensionais da impressora disponível naquele momento. Entretanto, a presença de múltiplas interfaces de união aumentava a complexidade da montagem e introduziu potenciais pontos de concentração de tensões mecânicas.

Com a aquisição da Creality Ender 5 Max, tornou possível a impressão do aro em peça única, como demonstra a figura 6, eliminando as junções entre segmentos e conferindo maior robustez ao componente.

Fig. 4. Modelo 3D da roda completa.

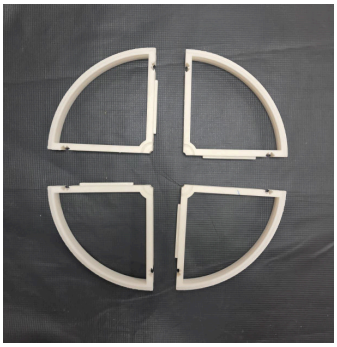

Fig. 5. Aro de impressão 3D dividida em 4 partes. Posteriormente, com a aquisição da impressora 3D.

O pneu foi projetado em oito segmentos independentes, indicado pela figura 7, acoplados posteriormente à estrutura da roda e impressos a partir do filamento de poliuretano termoplástico (TPU), material selecionado por sua elevada flexibilidade e capacidade de absorção de impactos. Adicionalmente, foi incorporado um aro de propulsão, também impresso em PETG reforçado com fibra de carbono, destinado a facilitar o manuseio da cadeira e proporcionar maior conforto ao usuário. A roda completa é resultado da montagem integrada desses três componentes produzidos separadamente, como ilustrado na figura 8.

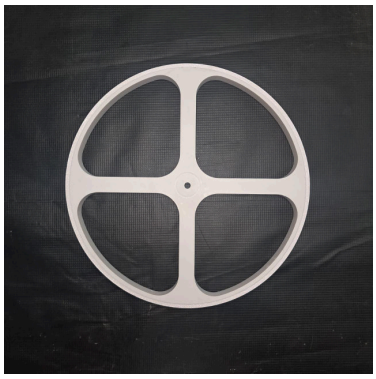

Fig. 6. Aro de impressão 3D peça única.

Fig. 7. Segmento de pneu sendo impresso. Pneu composto por oito partes.

Fig. 8. Roda completa, com aro de quatro partes, pneu e aro de propulsão

A. Materiais Utilizados

As rodas constituem um dos principais componentes das cadeiras de rodas, influenciando diretamente a mobilidade, a estabilidade, a manobrabilidade e o conforto dos usuários. Dessa forma, características como dimensões, materiais e configuração podem impactar significativamente o desempenho funcional da cadeira de rodas e, consequentemente, a independência e a participação social dos indivíduos [4].

O acrilonitrila butadieno-estireno (ABS) foi utilizado inicialmente na impressão dos aros devido à sua boa resistência ao impacto, rigidez e estabilidade dimensional. Além disso, apresenta boa processabilidade e durabilidade, características que favorecem a fabricação de componentes estruturais submetidos a esforços mecânicos. [6] Para a fabricação dos protótipos utilizou-se o filamento Hyper ABS na cor branca, com diâmetro de 1,75 mm e massa líquida de 1,0 kg. O processo de impressão foi realizado em temperaturas variando entre 230 °C e 270 °C, conforme as especificações do fabricante.

O PETG reforçado com fibras de carbono (PETG+CF) teve sua utilização concentrada nos componentes estruturais da roda devido à necessidade de elevada rigidez e estabilidade dimensional, características importantes para suportar os esforços mecânicos gerados durante o deslocamento da cadeira e, posteriormente, como substituto do ABS, dada a sua elevada resistência mecânica, maior rigidez e boa estabilidade térmica. Além disso, mantém boa

resistência ao impacto, tornando-se adequado para a fabricação de componentes submetidos a cargas e esforços mecânicos [7]. Dessa forma, na fabricação dos componentes da roda utilizou-se filamento PETG reforçado com fibra de carbono (PETG+CF), da marca Apex 3D (Carbon), na cor branca. O material apresenta diâmetro de 1,75 mm e foi processado em temperaturas de extrusão entre 260 °C e 300 °C, com temperatura da mesa aquecida variando entre 40 °C e 90 °C. O filamento foi fornecido em bobinas com massa líquida de 1 kg.

O poliuretano termoplástico (TPU) foi empregado exclusivamente na região correspondente ao pneu, explorando suas propriedades elastoméricas para promover absorção de impactos, aumento da aderência e maior conforto durante a movimentação, resistência ao desgaste e capacidade além de resistência ao desgaste. Além disso, apresenta alta resistência mecânica e boa durabilidade, características que favorecem sua aplicação em componentes sujeitos a cargas e atritos, como rodas e elementos de amortecimento [5]. Foi utilizado o filamento Rapid TPU 95A, da marca ELEGOO, na cor preta, com diâmetro de 1,75 mm e massa líquida de 1,0 kg. O material foi processado a uma temperatura de impressão de 200 °C a 230 °C, sendo recomendada a secagem prévia a 70 °C por 6 horas, conforme especificações do fabricante.

B. Aspectos éticos

A pesquisa foi submetida e aprovada pelo Comitê de Ética em Pesquisa pela Universidade Federal de Goiás, sob o parecer nº7.688.714, respeitando os princípios éticos aplicáveis às pesquisas envolvendo seres humanos.

III. RESULTADOS

O processo de desenvolvimento resultou em uma evolução progressiva das rodas infantis produzidas no laboratório, passando de soluções comerciais para um produto produzido internamente por meio da manufatura aditiva, à medida que surgiam limitações a cada alternativa avaliada.

A adoção da manufatura aditiva permitiu superar as limitações observadas nas rodas comerciais. A primeira versão, segmentada em quatro partes, embora funcional, apresentava maior complexidade na montagem e limitações estruturais. Além da obtenção do aro em peça única, a substituição do filamento ABS pelo PETG+CF também contribuiu para a resistência estrutural ao componente.

O aro em peça única consome 180g de filamento, dos quais 30g correspondem ao material de suporte, que são removidos após a impressão. Os oito segmentos de pneu consomem 24 g cada, de modo que a peça completa resulta em 192g. Por fim, o aro de propulsão consome aproximadamente 204g (sendo 15g de material de suporte). Portanto, a roda final completa utiliza, em média, 576g de filamento.

O tempo total de impressão de uma roda completa é de aproximadamente 18 horas e 40 minutos, distribuídas entre seus três componentes: a roda demanda 8 horas, o conjunto do pneu (oito segmentos), 6 horas e o aro de propulsão, 4 horas e 40 minutos. Os custos estimados de produção por roda, considerando o preço de mercado dos filamentos utilizados e a quantidade de material consumido, estão detalhados na Tabela 1.

TABELA I
Estimativa de custo de produção.

Estrutura	Filamento utilizado	Valor do filamento (R$/Kg)	Quantidade (g)	Custo estimado (R$)
Aro da roda	PETG+CF	189,00	180 g	28,35
Pneu	TPU	169,00	192 g	32,45
Aro de propulsão	PETG+CF	189,00	204 g	38,55
TOTAL	-	-	576 g	105,02

Observa-se que aproximadamente 60% do custo total se concentra nos componentes estruturais produzidos em PETG reforçado com fibra de carbono, enquanto o pneu em TPU representa cerca de um terço do custo final. Essa distribuição evidencia que futuras otimizações do projeto poderão se concentrar principalmente na redução do consumo de material estrutural.

Além da vantagem econômica, a solução desenvolvida apresentou menor valor de produção comparado às alternativas comerciais. O custo estimado para a fabricação de uma roda foi de R$105,02, totalizando R$210,04 para um par. Em comparação, as rodas comerciais apresentaram custo aproximado de R$120,00 por unidade, acrescido de R$15,00 referente à câmara de ar, resultando em aproximadamente R$270,00 para o par. Dessa forma, a solução desenvolvida representa uma redução de aproximadamente 22,2% no custo do par de rodas. Além da vantagem econômica, o modelo apresenta versatilidade dimensional, podendo ser redimensionado digitalmente para produzir rodas maiores ou menores conforme o porte físico da criança, sem a necessidade de novos moldes ou da aquisição de componentes adicionais.

As rodas na versão final foram aplicadas nas cadeiras de rodas infantis e submetidas a uso real por crianças de um a cinco anos de idade [Fig. 9]. Até o momento, os componentes apresentaram desempenho satisfatório, sem registro de falhas

estruturais ou necessidade de manutenção.

IV. DISCUSSÃO

O principal resultado deste estudo foi a demonstração da viabilidade de um processo iterativo de desenvolvimento aplicado à fabricação de rodas para cadeiras de rodas infantis por manufatura aditiva. O desenvolvimento foi conduzido de forma iterativa, com sucessivas modificações estruturais orientadas pelas limitações identificadas em cada etapa, contribuindo para o aprimoramento progressivo do componente. Esses aspectos reforçam um dos principais desafios apontados pela literatura: ampliar o acesso a tecnologias assistivas por meio de soluções acessíveis e adaptáveis [1,3].

Fig. 9. Criança testando a cadeira de rodas com a Roda completa, composta por um aro de quatro partes, pneu e aro de propulsão.

A evolução dos protótipos evidenciou a importância do processo de desenvolvimento iterativo. A impressão do aro em peça única eliminou as junções presentes na versão segmentada, reduzindo possíveis pontos de falha e aumentando a resistência estrutural do componente. Além disso, a substituição do filamento ABS pelo PETG reforçado com fibra de carbono proporcionou maior rigidez e resistência mecânica ao aro, enquanto o TPU apresentou desempenho compatível com a função de pneu, devido à sua flexibilidade e capacidade de absorção de impactos. A combinação desses materiais contribuiu para a obtenção de uma roda mais robusta e adequada à aplicação.

Outro aspecto relevante foi a possibilidade de personalização proporcionada pela manufatura aditiva. O modelo digital pode ser facilmente redimensionado para diferentes tamanhos de roda, permitindo sua adaptação às necessidades de crianças com diferentes características físicas, sem a necessidade de novos moldes ou componentes específicos. A possibilidade de redimensionamento digital do modelo amplia significativamente seu potencial de aplicação clínica, permitindo adequações rápidas às diferentes faixas etárias sem necessidade de fabricação de novos moldes ou aquisição de componentes específicos. Essa característica representa uma vantagem particularmente relevante em dispositivos destinados ao público pediátrico, cujas necessidades dimensionais se modificam rapidamente em função do crescimento. [8]

A aplicação das rodas nas cadeiras de rodas infantis demonstrou desempenho satisfatório durante o uso, sem ocorrência de falhas estruturais. Entretanto, o estudo atual apresenta como limitação a ausência de ensaios mecânicos padronizados. Dessa forma, estudos futuros são necessários para avaliar parâmetros como resistência mecânica, durabilidade, fadiga, desgaste e desempenho em diferentes condições de uso, além de comparações com rodas comerciais. Essas avaliações poderão fornecer evidências mais robustas sobre a confiabilidade e a aplicabilidade da solução desenvolvida.

De modo geral, os resultados reforçam o potencial da impressão 3D para o desenvolvimento de dispositivos de tecnologia assistiva de baixo custo, favorecendo a ampliação do acesso a recursos que promovam a mobilidade, autonomia e inclusão social.

Durante o desenvolvimento do protótipo, foram identificadas algumas dificuldades relacionadas às limitações dimensionais das impressoras 3D disponíveis. Ainda é necessário, trabalhos futuros, para realizar ensaios mecânicos padronizados para avaliar a resistência, a durabilidade e o desgaste dos componentes, bem como acompanhar o desempenho das rodas por períodos mais prolongados e em diferentes condições de uso.

V. CONCLUSÃO

O presente estudo demonstrou a viabilidade técnica de um processo iterativo de desenvolvimento de rodas para cadeiras de rodas infantis utilizando manufatura aditiva. A evolução sucessiva dos protótipos permitiu superar limitações identificadas nas soluções anteriores, resultando em um componente funcional, personalizável e economicamente competitivo. Mais do que o desenvolvimento de uma nova roda, o estudo estabelece um modelo de projeto potencialmente replicável para fabricação de componentes personalizados destinados a dispositivos de tecnologia assistiva.

Abstract—Functional Electrical Stimulation (FES) cycling uses electrically induced muscle contractions to produce coordinated pedaling movements and support lower-limb rehabilitation. Since the neuromuscular response is a nonlinear, time-varying system affected by muscle fatigue and highly dependent on individual physiological characteristics, developing an efficient control system remains a challenging task. This paper presents a brief review of the main control strategies applied to FES cycling. The methods are organized into three groups: classical feedback and proportional-integral-derivative control; adaptive, optimized, and model-based control; and intelligent and learning-based control, including fuzzy logic, neural networks, and deep reinforcement learning. Their main advantages, limitations, implementation requirements, and potential roles are qualitatively compared. Conventional PID controllers remain attractive because of their simplicity and low computational cost, whereas adaptive and model-based strategies offer greater personalization at the cost of increased complexity. Fuzzy logic and learning-based methods provide alternatives for handling nonlinear behavior and variability. The reviewed literature suggests that hybrid architectures combining classical feedback with adaptive or intelligent methods represent a promising direction for reliable and personalized FES cycling.

Keywords—Functional electrical stimulation, FES cycling, spinal cord injury, rehabilitation, closed-loop control, PID control, adaptive control.

I. INTRODUCTION

Functional Electrical Stimulation (FES) is a rehabilitation and assistance technique in which electrical pulses are applied to peripheral nerves to activate weakened or paralyzed muscles. When applied to the lower limbs, FES can produce functional movements such as standing, walking, and pedaling. In FES cycling, the stimulation of muscle groups, such as the quadriceps and hamstrings, is coordinated with the crank position to generate cyclic pedaling motion. Fig. 1 illustrates a typical FES cycling configuration.

This approach provides lower-limb exercise and has been studied in individuals with neurological impairments, particularly those resulting from stroke and spinal cord injury [1], [2]. Beyond restoring movement, FES cycling has been associated with improved lower-limb muscle health in adults with spinal cord injury, with lower certainty of evidence for gains in power output and aerobic fitness, and inconsistent findings for bone and cardiovascular outcomes [3]. Because these adaptations depend on sustained and repeated training, the duration and consistency of each session are clinically relevant, which motivates control strategies capable of maintaining stable pedaling as the muscles fatigue.

Fig. 1. FES cycling training session performed using a recumbent tricycle mounted on a stationary trainer. Surface electrodes positioned over the thigh muscles deliver stimulation synchronized with crank motion, producing cyclic pedaling. Orthopedic braces stabilize the lower limbs, constrain their movement primarily to the sagittal plane, and secure the feet to the pedals. The system also includes an LCD display, control buttons mounted on the handlebars, and a rear compartment housing the batteries, electrical stimulator, embedded computer, and sensor receiver.

Despite its rehabilitation potential, control loop design for FES cycling encounters significant barriers related to the time-varying parameters of muscles and fatigue. Many systems apply predefined stimulation patterns based on crank angle or trial-and-error procedures. These open-loop approaches are relatively simple, but fail to automatically compensate for changes in muscle response during exercise. The relationship between electrical stimulation and the resulting movement is non-linear and time-varying, while muscle fatigue, spasticity, electrode placement, external disturbances, and inter-subject variability can considerably affect cadence and performance during exercise [1], [4], [5].

Closed-loop control seeks to overcome some of these limitations through the use of feedback from encoders installed on the crank, inertial measurement units (IMUs), pedal force sensors, or mechanomyographic sensors. The measured movement is compared with a desired reference, such as cadence, crank velocity, or joint trajectory, and the stimulation parameters are adjusted according to the resulting error. Pulse width, current amplitude, and stimulation frequency are among the parameters that can be modified in real time to regulate movement and maintain the desired exercise condition [1], [4], [5].

Various control methods have been investigated for this purpose. Conventional proportional-integral-derivative (PID) control is widely used due to its simple structure, interpretability, and low computational cost, both in terms of

algorithm and hardware. However, its fixed parameters can become inadequate as fatigue increases [2].

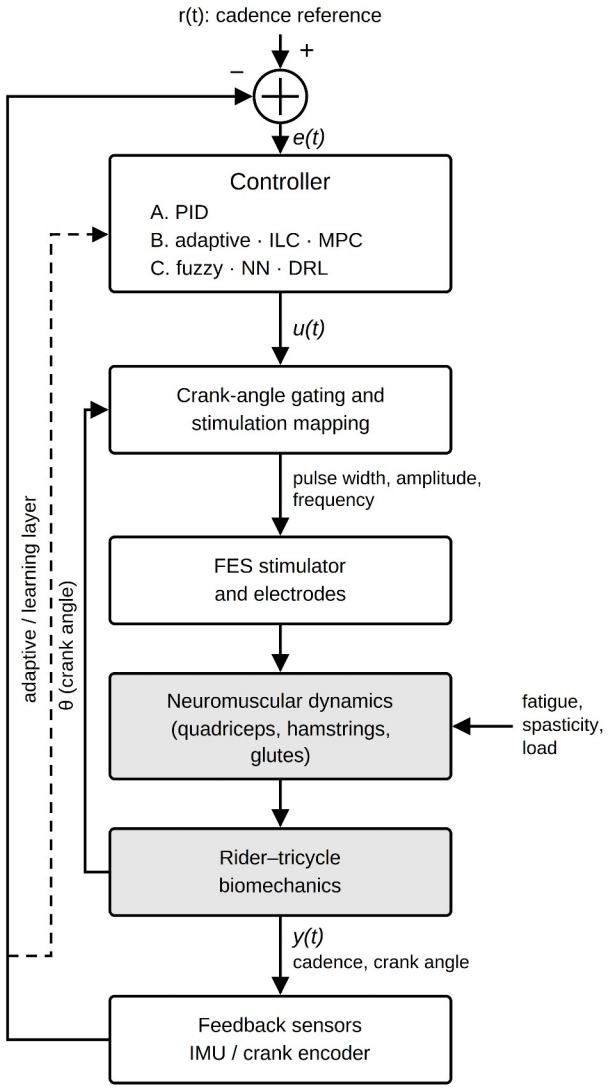

Fig. 2. Closed-loop architecture of an FES cycling system. Labels A, B, and C inside the controller block correspond to the three control families reviewed in Section II. Shaded blocks represent the physiological and mechanical plant. The dashed path represents an optional adaptation or learning mechanism that may update controller parameters, internal models, or stimulation policies depending on the adopted strategy.

Adaptive and optimized controllers seek to update stimulation commands or controller gains during operation, whereas model-based approaches use mathematical representations of the neuromuscular and biomechanical systems to predict their responses. Model Predictive Control (MPC) can additionally optimize future control actions while considering physiological and operational constraints. However, most available evidence on MPC pertains to FES-assisted motor tasks in general, rather than FES cycling specifically [6].

Intelligent control strategies offer alternative ways to deal with non-linearities and rider-specific behaviors. Fuzzy logic-based controllers represent the relationship between tracking errors and stimulation commands through linguistic rules, without requiring an exact mathematical model [7], [8]. Neural networks can learn non-linear mappings from experimental data and can be used to estimate muscle responses or adjust controller parameters [2], [5]. Another technique, deep reinforcement learning, has been studied as a method to learn stimulation parameters capable of improving cadence tracking while limiting unnecessary stimulation [9].

This paper presents a brief narrative review of representative control strategies applied to FES cycling. The selected studies were used to illustrate the main characteristics of each control family, rather than to perform a systematic comparison or meta-analysis. The search and selection procedure is described in Section II. Unlike existing reviews in [1], [2], and [6], this work organizes the strategies according to the point where each acts within the closed-loop architecture and presents the experimental validation associated with each, so that algorithm development and clinical evidence can be evaluated separately.

II. REVIEW METHODOLOGY

The aim was not to provide an exhaustive coverage of the field, but rather to select representative studies illustrating each control family and the level of experimental evidence associated with each. Therefore, the study was conducted as a narrative review with its search procedure documented.

A. Search Strategy

The literature search combined keyword searches with an analysis of the references from the articles identified. In addition, references that appeared in common among different studies were examined in order to identify other relevant works for the review. The search was conducted between April and June 2026 and considered studies published from 2016 onwards. Keyword searches were conducted in Google Scholar using at least four similar queries relating FES cycling to different control families, including, for example: "functional electrical stimulation"; "cycling closed-loop control"; "cycling closed-loop control" with bang-bang control; "FES cycling PID"; "FES cycling adaptive" OR "iterative learning" OR "model predictive" control; and "FES cycling fuzzy" OR "neural network" OR "reinforcement learning" control. The results of each search were analyzed in order of relevance. For the more specific queries, approximately the first 30 results were assessed, whereas for the broader queries, the screening extended to more than 100 results, which were analyzed in blocks. For these broader searches, the screening was progressively expanded until the additional results no longer yielded studies that met the inclusion criteria. Since Google Scholar provides only an estimated total number of results, the number of results actually screened in each search was recorded instead. Initially, the studies were assessed based on their title and abstract. Studies considered potentially relevant were subsequently examined based on their abstract, methodology, and conclusions. When a study remained consistent with the established criteria, the full text was then read and analyzed.

The keyword search was also complemented by citation network analysis using ResearchRabbit, based on four articles considered relevant to the topic [2], [3], [13], [16]. The references cited by these articles, the studies that cited them, and other related studies suggested by the platform were analyzed. The studies identified through this process were also checked in Google Scholar and evaluated according to the same eligibility criteria.

This step was intended to identify studies that were not found through the keyword searches, particularly studies that presented control strategies related to FES cycling but did not use the term "FES cycling" in the title or abstract.

B. Inclusion and Exclusion Criteria

Studies were included if they described a closed-loop control strategy applied to FES cycling or to an FES-assisted motor task directly related to cadence regulation. The studies were also required to describe the controller structure and the modulated stimulation parameter, as well as report quantitative performance results obtained through simulation, in able-bodied participants, or in participants with neurological impairment. Studies conducted by research teams participating in competitions, particularly those conducted following cycling-related competitions such as Cybathlon, were also considered. Studies were excluded if they did not describe a control law, focused exclusively on physiological or clinical outcomes, or did not report quantitative performance measures such as cadence, speed, or time. Extended abstracts and non-peer-reviewed materials were also excluded. Only studies published in English were included.

C. Selection Procedure

The studies were initially selected based on a review of their titles and abstracts. After this stage, 39 papers were selected for full-text reading and assessment according to the eligibility criteria. In the end, 16 studies were selected because they presented results considered relevant to the control families discussed in Section III. When selecting the studies, preference was given to papers that presented quantitative results, clearly described the stimulation parameters used, and included experimental validation. More recent studies were also preferred when papers with similar characteristics were available. References [10] and [11] were not part of the selected studies and were used only as references for the formal description of PID control.

D. Limitations of the Review

This review has some limitations. The search was conducted mainly through Google Scholar and complemented by citation network analysis. The number of results analyzed varied depending on the search, and no systematic or preregistered review protocol, such as PRISMA, was used. In addition, the studies were selected by a single author, with some guidance from the advisor, without a third independent assessment or a formal risk-of-bias analysis. A meta-analysis was also not performed. Therefore, the possibility of selection bias cannot be completely ruled out. For this reason, the comparison presented in Section IV should be understood as a qualitative analysis of representative studies rather than as evidence that one particular control strategy is superior to the others.

III. CONTROL STRATEGIES

Fig. 2 shows a representative closed-loop architecture adopted in FES cycling systems. The controller generates a control command based on the measured error. This command is synchronized with the crank angle and converted into stimulation parameters applied to the quadriceps and hamstrings, while the resulting movement is measured and fed back to the comparator. Muscle fatigue acts as a disturbance within the control loop rather than on the reference signal, as commonly represented in the literature. Therefore, this muscular fatigue helps explain why fixed controller parameters may become inadequate over the course of a training session. Accordingly, the reviewed strategies differ mainly in the implementation of the controller block and, in some methods, in the presence of adaptation or learning mechanisms capable of modifying gains, internal models, or stimulation parameters. The three control families discussed in the following subsections are indicated within the controller block: classical feedback and PID control (A); adaptive, optimized, and model-based control (B); and intelligent and learning-based control (C).

A. Classical Feedback and PID Control

The proportional-integral-derivative (PID) controller is one of the most popular feedback control techniques in engineering. The controller combines information related to the present, the past, and the expected trend of the tracking error through the proportional, integral, and derivative terms, respectively [1], [2]. The control signal can be represented as:

$$u(t) = K_p e(t) + K_i \int e(\tau)\, d\tau + K_d \frac{de(t)}{dt} \quad (1)$$

In (1) $e(t) = r(t) - y(t)$ is the difference between the desired reference $r(t)$and the measured output of the system $y(t)$ [10], [11].

In FES cycling, the reference signal may represent the desired pedaling cadence range, pedal speed, knee angle, or joint trajectory. The measured variable is obtained through sensors such as encoders or inertial measurement units (IMUs). Based on the difference between the desired and measured values, the PID controller modifies an electrical stimulation parameter, usually pulse width, current, or stimulation amplitude. For this purpose, it is necessary to select which parameter will be modulated while the others remain fixed. When the measured cadence is below the reference value, the controller increases the stimulation command to generate a stronger muscle contraction. Conversely, when the cadence exceeds the desired value, the stimulation command is reduced. This feedback structure allows the system to continuously regulate stimulation rather than applying a predefined and constant stimulation pattern [2], [4], [12].

The use of feedback is important in FES cycling because the muscular response cannot be clearly and accurately predicted solely from the applied stimulation signal. Open-loop systems generally use stimulation patterns determined through clinical experience, visual observation, or trial-and-error procedures. However, their performance may deteriorate when the muscular response changes due to fatigue, external disturbances, electrode positioning, or differences among users.

Closed-loop PID control seeks to partially compensate for these variations by continuously monitoring the movement and correcting the stimulation parameters according to the observed error. Closed-loop feedback can improve cadence regulation and trajectory tracking compared with fixed-stimulation approaches, although its performance de-

pends on the controller design, tuning procedure, and experimental conditions [2], [4], [12].

Fonseca et al. evaluated cadence tracking and disturbance rejection in a participant with complete spinal cord injury using an FES-controlled tricycle. The system modulated the stimulation pulse width according to cadence feedback obtained from an IMU. The control strategy was able to track a varying cadence reference when the cadence remained above approximately 25 rpm using quadriceps stimulation alone. However, disturbance loads reduced the cadence, and the addition of hamstring and gluteal stimulation was associated with increased oscillations and spasticity. Because the investigation was a single-participant case study, its results should not be generalized to the entire population of FES-cycling users [12]. The same tricycle platform, in a mobile configuration and with the same stimulation and crank-sensing architecture, was later used in the Cybathlon 2016 FES bike race, where pilot-defined stimulation intensity was adopted in place of automatic cadence regulation [13]. This contrast illustrates that closed-loop cadence control and practical operation by the user may impose competing requirements.

Despite these advantages, conventional PID control presents important limitations in FES cycling. The relationship between electrical stimulation and the resulting muscle force is nonlinear, time-varying, and strongly dependent on the physiological condition of the user. Muscle fatigue progressively modifies this relationship during exercise. This means that a set of fixed controller gains may provide satisfactory performance at the beginning of a training session but become inadequate over time. Because FES cycling involves a complex biological system, several dynamic factors affect pedaling performance, with fatigue being one of the most important [1], [2], [5]. Other difficulties include overshoot, long settling times, and sensitivity to disturbances. Individual differences in muscle recruitment, electrode positioning, neurological impairment, and fatigue resistance also reduce the possibility of using the same fixed PID gains for all participants. Consequently, conventional PID controllers generally require experimental tuning for each user and operating condition. Although fixed-gain PID control may outperform open-loop stimulation, it may not ensure consistent performance throughout prolonged rehabilitation sessions [2], [4], [11], [12].

Therefore, PID control remains an important reference strategy for FES cycling because of its simplicity, interpretability, low implementation cost, and established use in feedback systems. However, its performance when used alone may be limited under nonlinear and time-varying operating conditions. Consequently, conventional PID is particularly useful as a baseline controller, whereas adaptive or hybrid PID structures appear more suitable for personalized and long-duration FES-cycling applications.

B. Adaptive, Optimized, and Model-Based Control

Muscle response varies among FES users; therefore, adaptive control is a promising tool for FES cycling. Adaptive strategies use feedback information to update the stimulation command or controller parameters according to the observed system response. Variables such as cadence, crank angle, resistance, and tracking error can be used to adjust the stimulation intensity through pulse width, current amplitude, or stimulation frequency. This allows the controller to compensate, at least partially, for changes caused by muscle fatigue [2].

The repetitive and predictable nature of pedaling also makes FES cycling suitable for iterative learning control (ILC) and repetitive learning control (RLC). Both use information recorded during previous cycles or trials to correct the stimulation command applied in subsequent cycles, so that systematic tracking errors are progressively reduced without requiring the complete system dynamics to be known in advance. The two formulations differ in their operating assumptions. ILC is applied to tasks performed over a finite interval, with the initial conditions reset at the beginning of each trial, whereas RLC is intended for continuous operation without resetting [14].

Ghanbari et al. applied ILC to a motorized FES cycle-rider system within a passivity-based framework. The closed-loop switched system was shown to be output strictly passive, and an Arimoto-type learning update law was then used to guarantee convergence of the cadence tracking error in the L2 sense. In experiments with seven able-bodied participants stimulated only over the quadriceps, the mean cadence tracking error was 0.00 ± 2.47 rpm for a 50 rpm reference. The authors ascribed the remaining error to unaccounted factors like electromechanical delay and muscle fatigue, noting that participants with neurological conditions had not yet been assessed [15].

Duenas et al. developed a switched RLC in which stimulation was distributed among six lower-limb muscle groups according to the crank angle, while an electric motor provided assistance in the regions of low torque transfer. Asymptotic cadence tracking was established through a Lyapunov-based analysis for nonsmooth switched systems. The controller was evaluated in five able-bodied participants and three participants with neurological conditions. Trials performed with the learning feedforward term active yielded a lower root-mean-squared cadence error than trials in which it was disabled, with mean values of 3.68 rpm against 4.20 rpm for the able-bodied group and 3.17 rpm against 3.49 rpm for the impaired group [14].

These findings imply that cadence control in FES cycling can be enhanced by learning-based feedforward terms. Two restrictions should be taken into account, though. First, the reported tracking performance cannot be solely attributable to electrical stimulation because the learning-based controller in both cases worked in tandem with an electric motor. Second, whereas muscle fatigue is a nonperiodic disturbance that builds up during the session and is not immediately addressed by the learning term, learning control makes up for the periodic component of the system dynamics [14], [15]. Therefore, the consistency of the pedaling task and the accuracy of the feedback readings determine how effective these strategies are [2].

Optimization and adaptation are related but are not identical. Optimized PID structures represent another approach for improving conventional feedback control. Optimization searches for controller parameters or stimulation patterns that minimize a predefined performance criterion, whereas adaptation modifies these parameters in response to changes observed during operation [5].

Backpropagation (BP) is an algorithm used to train a neural network by adjusting the weights between its layers according to the error between the obtained and desired outputs. In a BP-PID controller, the three neurons in the output layer correspond to the proportional, integral, and derivative

gains, respectively. Therefore, the learning capability of the neural network allows the values of Kp, Ki, and Kd to be updated according to the system behavior. In the complete structure, Particle Swarm Optimization (PSO) improves the search and optimization process, the BP neural network adjusts the controller parameters, and the PID controller generates the command responsible for modifying the electrical stimulation pulse width [5].

Model-based control uses mathematical representations to predict how stimulation parameters affect muscle activation, joint torque, lower-limb movement, and user performance. Patient-specific characteristics, such as limb dimensions, range of motion, and nonlinear force–length and force–velocity relationships, can also be incorporated into a biomechanical model [5], [6]. An important example of an optimized and model-based approach is Model Predictive Control (MPC). MPC calculates stimulation commands that minimize a cost function while satisfying constraints related to stimulation intensity, joint movement, muscle activation, or the contribution of assistive devices. To do so, the controller predicts the future response of the system over a finite horizon. When new measurements become available, the optimization process is repeated, but only the first calculated control command is applied [6].

However, the evaluated studies primarily comprised movements with a limited number of degrees of freedom and covered a variety of upper- and lower-limb FES tasks. As a result, the evidence was not limited to cycling. Therefore, rather than being a proven cycling solution, MPC should be considered a promising model-based approach for future FES-cycling systems [6].

The challenges of finding precise patient-specific models, the computational costs of real-time optimization, and differences between theoretical predictions and actual muscular responses are the primary drawbacks of optimal and model-based controllers [6]. In general, model-based, optimal, and adaptive techniques are more robust and personalized than fixed-gain control. However, dependable sensors, computationally effective algorithms, and models that can be updated in response to changes in the user's muscular reaction are necessary for their practical use in FES cycling [1], [2], [5], [6].

C. Intelligent and Data-Driven Control

Fuzzy Logic Control (FLC) represents the relationship between system inputs and stimulation commands through membership functions and rules expressed in linguistic terms. The inputs commonly include the tracking error and its rate of change, while the output may represent a variation in stimulation amplitude or pulse width. The fuzzy inference mechanism combines the activated rules and converts the resulting fuzzy output into a numerical stimulation command [2], [7], [8].

Watanabe and Tadano developed a continuous-time fuzzy FES controller that used knee-angle error and its derivative to modify the stimulation pulse amplitude. The controller was compared with a PID controller in knee-extension experiments involving three healthy participants. Although the fuzzy controller generally presented favorable tracking performance, the study did not directly test FES cycling. It was conducted as a preliminary evaluation before the controller's intended application to cycling-speed regulation [7].

A fuzzy controller was studied in FES cycling by Ahmad et al. The system used phase-angle information and adjusted the stimulation pulse width between 50 and 200 μs while maintaining a frequency of 35 Hz. Three healthy participants and one with post-stroke hemiplegia participated in the experiments. The hemiplegic individual had a higher fatigue index than the healthy participants, despite the controller producing comparatively minimal trajectory errors. Further validation and patient-specific adaptation are required, as evidenced by the small sample size and the inclusion of only one participant with neurological impairment [8].

Neural networks provide a different approach by learning nonlinear mappings between measured variables, stimulation inputs, and the resulting movement. Once trained, a neural network can estimate stimulation parameters, predict muscular responses, or adjust the gains of another controller, such as a BP-PID controller. Therefore, neural networks can improve personalization and reduce dependence on fixed controller parameters. However, their performance depends on the quantity and quality of the training data, and their computational requirements may hinder real-time implementation [2], [5].

Deep Reinforcement Learning (DRL) allows the controller to learn a stimulation policy through interaction with a simulated or physical environment. In reinforcement learning, the controller applies a control action after receiving information about the current state. Depending on the quality of the resulting movement, the controller receives a numerical reward. The controller learns to create stimulation patterns that enhance cadence tracking while reducing unnecessary stimulation by optimizing the total reward [9].

Wannawas et al. developed a neuromechanics-based DRL controller trained using a personalized musculoskeletal model that incorporated a model of muscle fatigue. Two agents were employed: a Starter agent initiated the cycling movement, whereas a Tracker agent regulated the desired cadence. In simulation, the DRL controller achieved lower tracking errors and shorter response times than the implemented PID and fuzzy controllers. However, the DRL controller had direct access to simulated fatigue information that was unavailable to the conventional controllers, which limits the fairness of a direct comparison [9]. Moreover, the complete adaptive controller was not transferred to real-time patient operation, and the authors stated that real-world fatigue estimation and the amount of required training data remained important limitations. As a result, while the results show viability, they do not yet represent thorough clinical validation [9].

Overall, fuzzy logic is a comparatively straightforward and comprehensible method for managing nonlinear behavior without the need for a precise system description [2], [7], [8]. Increased learning and personalization capabilities, such as the ability to automatically recognize stimulation patterns and adjust to muscle fatigue, are provided by neural networks and reinforcement learning [2], [5], [9]. However, these advantages are accompanied by greater computational complexity, dependence on training data or simulation models, and the need for more rigorous clinical validation [1], [6], [8], [9]. Therefore, intelligent and learning-based methods are promising for personalized FES cycling, but their reliability and safety must be demonstrated through more robust studies.

D. Fatigue Measurement and Estimation

Muscle fatigue appears throughout this review as

one of the main factors that reduce FES cycling performance during a session. Therefore, it is important to examine how fatigue was measured or estimated in the reviewed studies. In some cases, fatigue is only compensated for by the controller, while in others it is estimated or explicitly included in the model. Overall, three approaches were identified.

The first, and most common, approach is not to measure fatigue directly. In this case, fatigue is indirectly compensated for through the cadence error: as the muscle response decreases, cadence drops, the tracking error increases, and the controller increases the stimulation. This approach was used in [4], [7], [12], [14], and [15]. In these studies, fatigue is recognized as a limitation and, in [14] and [15], is described as a non-periodic disturbance that cannot be compensated for by the learning term. However, no fatigue-related variable is directly included in the control loop. An intermediate case is reported in [4], in which mechanomyographic sensors were used to record muscle activity, but their signals were not incorporated into the closed-loop control algorithm due to real-time processing limitations. This suggests that the limitation was more related to implementation than to the availability of sensing technology.

The second approach uses fatigue indicators derived from signals already available in the control system [8], [5]. These indicators are useful, but they are still based on tracking error or task interruption rather than on a direct physiological measure of muscle state.

The third approach considers fatigue as an explicit state of the system. In the deep reinforcement learning (DRL)-based controller presented in [9], the personalized musculoskeletal model included a fatigue model, allowing its state to be directly used by the learning agent. However, this state was simulated rather than experimentally measured. In addition, it was not available to the PID and fuzzy controllers used for comparison, which limits the equivalence between the evaluated strategies.

Outside closed-loop FES cycling control, muscle fatigue has also been directly assessed using force-based metrics. Time to fatigue and the force–time integral were used as measures, and the authors observed that the advantage of distributed stimulation decreased significantly at high stimulation intensities [16]. These results were obtained under isometric and open-loop conditions, showing that fatigue reduction in FES has mainly been addressed through the stimulation strategy rather than directly through the controller. Overall, none of the reviewed FES cycling studies used a physiological indicator of muscle fatigue as a feedback signal in closed loop. Fatigue is frequently identified as one of the main disturbances affecting the system, but it remains either unmeasured or estimated from the same error signal already used by the controller. This is an important limitation because a controller that only compensates for a decrease in cadence cannot distinguish whether it was caused by muscle fatigue or by an external load. Therefore, it cannot adapt the stimulation specifically to the muscle's fatigue state.

The three categories mentioned above, fixed structure and fixed gains, explicit adaptation or prediction, and data-driven learning, address the same control problem from different angles, but the studies supporting them were conducted under markedly different conditions. Table I summarizes the experimental characterization of each representative study, including the number and profile of participants, stimulated muscles and stimulation parameters, reported error metrics, the presence of motorized assistance, and level of evidence associated with each result. The heterogeneity shown in Table I is substantial, and the reported errors are not directly comparable across studies, since they were obtained under different references, modulated variables, and populations. The following section compares the strategies in terms of the trade-offs that determine their applicability.

Table I—Experimental characterization of the reviewed FES control studies

Study	Participants	Muscles / FES parameters	Error metric (reported result)	Motor assist	Level of evidence
Fonseca [12]	1 male, complete SCI T9	Quadriceps (± hamstrings, glutei); 40 mA, 50 Hz; PW 0–500 μs	Absolute mean error 1.9–10 % (quadriceps only)	No	Single-participant case study
Woods [4]	1 able-bodied	Quadriceps, hamstrings, glutei; 40 Hz; PW 200–250 μs; % current modulated	No convergence above 60 rpm	No	Proof of concept, able-bodied
Ghanbari [15]	7 able-bodied	Quadriceps only; 60 Hz; 90 mA; PW modulated	0.00 ± 2.47 rpm at 50 rpm	Yes	Controlled exp., AB, motor-assisted
Duenas [14]	5 able-bodied + 3 neurological	6 muscle groups; 60 Hz; 70–90 mA; PW modulated	RMS 3.68 vs 4.20 rpm (AB); 3.17 vs 3.49 (NC)	Yes	Controlled exp., AB & neuro., motor-assisted
Sun [5]	6: 1 healthy, 3 SCI, 2 stroke	6: 1 healthy, 3 SCI, 2 stroke	RMSE not consistently reduced; gain in cycling time	No	Small mixed clinical sample
Watanabe [7]	3 able-bodied	Rectus femoris, vastus lateralis; 30 Hz; PW 300 μs; amplitude modulated	MAE lower than PID ($p < 0.05$) 0.05)	No	Preliminary, non-cycling task
Ahmad [8]	3 able-bodied + 1 stroke	Quadriceps only; 35 Hz; PW 50–200 μs	Trajectory error 2.69–3.46°; fatigue index 0.046–0.230	No	Small sample, one patient
Wannawas [9]	None (simulation)	Simulated model	Lower RMSE than PID and fuzzy, with access to fatigue state	N/A	Simulation only

SMA: single muscle activation; MMA: multiple muscle activation; PW: pulse width. Values are reported as in the original publications. Watanabe and Tadano [7] evaluated knee extension rather than cycling. The number of participants reported in the text of [5] differs from the value given in its Table 1.

Table II—Proposed comparison criteria for FES cycling controllers

Criterion	Operational definition	Unit
Cadence tracking error	RMS of the difference between reference and measured cadence over a declared steady-state window; the reference value and window must be reported	rpm (and % of reference)
Response time	Time from a step change in the reference until the cadence enters and remains within a declared tolerance band	s
Mechanical output	Integral of crank torque times angular velocity over the session; mean power when session durations differ	J (or W)
Stimulation charge	Sum over channels of current × pulse width × frequency × active time; normalized by mechanical work to express stimulation cost	mC (and mC/J)
Fatigue index	Decline of a declared physiological or mechanical quantity between the initial and final portions of the session, or time until that quantity falls below a stated fraction of its initial value	dimensionless (or s)
Computational cost	Controller execution time per iteration relative to the control period, together with the hardware class used	ms / % of period
Safety	Declared current and pulse-width limits, number of saturation events, and adverse occurrences such as spasms, discomfort, or session interruption	counts

IV. COMPARATIVE DISCUSSION

The reviewed strategies differ mainly in how they trade simplicity and interpretability against adaptability. Conventional PID and fuzzy controllers remain attractive when low implementation cost and transparent behavior are priorities, whereas adaptive, learning-based, and model-based approaches offer greater personalization at the cost of modeling effort, data requirements, or computational load [1], [2], [5], [6], [12].

The experimental basis of the reviewed strategies is markedly uneven. Among the representative studies selected in this review, direct experimental evidence for fixed-gain PID includes small-scale investigations [12], whereas iterative and repetitive learning controllers have been evaluated in both able-bodied participants and individuals with neurological impairments [14], [15]. The PSO-BP-PID approach reported in [5] was experimentally evaluated with six participants, although the sample remained small. In contrast, the DRL approach in [9] was evaluated primarily in simulation, while the available MPC evidence is dominated by non-cycling FES tasks [6]. Therefore, experimental maturity and algorithmic sophistication remain uneven across the reviewed control strategies.

The reviewed evidence does not indicate a universally superior control strategy for FES cycling. The rehabilitation goal, available sensors, processing power, necessary degree of customization, and safety restrictions all influence the best option.

The development of hybrid architectures that combine adaptive, model-based, or learning-based methods with the reliability and interpretability of conventional feedback control represents a promising future direction. A logical division of tasks is suggested by the contrast between periodic and nonperiodic disturbances, where an adaptive term deals with the progressive effect of fatigue and a learning term compensates for cycle-to-cycle repeating dynamics [14], [15]. Standardized performance measurements, patient-specific models, reliable fatigue-related feedback, and validation with larger and more diverse populations are all necessary for further advancement [1], [2], [5], [9].

The main limitation of the comparison presented above is not the lack of results, but the absence of a common evaluation framework. The reviewed studies use different reference signals, control variables, session durations, and error metrics, making direct comparisons difficult.

Rather than proposing a new control structure, we suggest that the architecture in Fig. 2 be adopted as a reference instrumentation frame, in which four measurement points are defined explicitly. At the controller output, the stimulation parameters should be recorded for each channel, allowing the total delivered electrical charge to be calculated. At the stimulator–electrode interface, fixed and modulated parameters should be reported, making it clear which variable is used for control. At the plant output, kinematic and, when available, kinetic measures should be recorded, including crank angle, cadence, torque, and mechanical power. When motorized assistance is used, its contribution should also be measured separately from the muscle contribution.

As shown in Table I, the two studies that used learning-based feedforward terms [14], [15] included motorized assistance, but neither reported cadence tracking with the motor disabled. Separating these contributions does not require additional hardware, only independent recording of the two control inputs.

Table II summarizes seven quantities that can be used to characterize FES cycling controllers. The goal is not to establish fixed target values, which depend on the rehabilitation objective and the study population, but to facilitate comparisons across different studies. The stimulation charge normalized by the mechanical work produced expresses how much stimulation was required per unit of useful output, linking tracking accuracy to its physiological cost. Thus, reducing cadence error by increasing stimulation is not necessarily equivalent to achieving the same error with a lower delivered electrical charge. Safety should also be reported more consistently, since previous studies have described spasticity [12], discomfort limiting session duration [14], and stimulation levels limited by participant tolerance [4].

Finally, studies should report a minimum set of information, including the number and clinical profile of participants, the stimulated muscle groups, fixed and modulated stimulation parameters, the presence and contribution of motorized assistance, whether fatigue-related information was used in the control loop, and the order in which the experimental conditions were tested.

V. CONCLUSION

FES cycling is a promising rehabilitation technique, but its performance is strongly affected by muscle fatigue, nonlinear neuromuscular behavior, external disturbances, and user individuality. This review discussed three main groups of control methods: classical PID control; adaptive, optimized, and model-based control, including iterative and repetitive learning; and intelligent and learning-based control.

Conventional PID remains an important reference because of its simplicity, but fixed gains may not provide consistent performance when the muscular response changes over time. Adaptive, optimized, model-based, and learning-based approaches offer greater personalization at the cost of additional modeling, data, or computational requirements. A promising direction is therefore not the complete replacement of classical controllers, but their integration with these methods [2], [5], [9], [14], [15]. The existing evidence, however, remains heterogeneous: several advanced approaches have been evaluated primarily in simulations, in healthy participants, or in small clinical samples, and the strategies with the strongest theoretical guarantees are not those with the broadest experimental support. Progress therefore depends less on additional controller formulations than on the evidence required to choose among those that already exist. Four gaps follow directly from this review. First, no reviewed study used a physiological indicator of muscle fatigue as a closed-loop feedback signal, although fatigue is consistently identified as the dominant disturbance. Second, the studies reporting the strongest theoretical guarantees employed motorized assistance without isolating the contribution of stimulation. Third, the comparison favoring learning-based control was obtained in simulation and under unequal information conditions. Fourth, reported errors are not commensurable across studies. Addressing these gaps requires the reporting conventions proposed in Section IV, comparisons under equivalent information and assistance conditions, and validation in larger and clinically representative samples.

Acknowledgment: The authors thank Estevão Lopes for participating in the FES cycling session shown in Fig. 1 and the EMA/LARA team at the University of Brasília for providing the experimental infrastructure and technical support. During the preparation of this manuscript, the authors used Claude (Anthropic) to assist in translating text originally written in Portuguese into English and for minor language editing, including grammar and syntax corrections. All AI-assisted text was reviewed by the authors, who take full responsibility for the final content of the manuscript.

***Abstract*—** Functional assessment is an essential component of hospital cardiorespiratory rehabilitation; however, conventional assessment methods still rely on manual repetition counting, external timing devices, and direct supervision by healthcare professionals, limiting workflow efficiency and assessment standardization. This study presents the design, development, and preliminary technical verification of EX-REAB, a modular computational platform that integrates computer vision and non-immersive virtual reality for automated functional assessment in hospital rehabilitation. The platform was developed through an iterative user-centered software engineering process involving physiotherapists, biomedical engineers, computer scientists, and software developers. EX-REAB incorporates MediaPipe Pose-based markerless motion capture, automated movement recognition, standardized execution of the 2-Minute Step Test and the 30-Second Sit-to-Stand Test, real-time performance feedback, and structured clinical data management. The resulting architecture comprises six interconnected functional layers, enabling automatic motion analysis, computation of kinematic variables, and export of standardized performance metrics for subsequent clinical and research applications. The modular architecture also supports future integration with physiological monitoring systems, wearable sensors, sleep assessment technologies, artificial intelligence algorithms, and clinical decision-support tools. EX-REAB establishes a scalable computational framework for automated functional assessment and provides the technological foundation for next-generation intelligent rehabilitation systems in hospital environments.

I. Introduction

Patients hospitalized with cardiorespiratory disorders frequently experience a rapid decline in physical function due to the combined effects of the underlying disease, prolonged bed rest, systemic inflammation, and physical inactivity during hospitalization. This functional deterioration is associated with reduced exercise capacity, muscle weakness, prolonged hospital stays, increased dependency, and poorer clinical outcomes after discharge. Consequently, early mobilization and cardiorespiratory rehabilitation have become

fundamental components of hospital care and are strongly recommended by national and international clinical guidelines for medically stable patients because they preserve functional capacity, reduce hospital length of stay, decrease complications, and improve functional independence and quality of life [1]-[3].

Despite the well-established benefits of early rehabilitation, its implementation remains limited in routine clinical practice. Previous studies have reported that fewer than 10% of critically ill patients are mobilized beyond the bedside [4]. Multiple barriers contribute to this scenario, including patient-related factors such as low motivation, anxiety, and clinical instability; organizational barriers including limited staffing and insufficient professional training; and hospital infrastructure constraints. Moreover, rehabilitation programs still rely predominantly on conventional functional assessments based on manual repetition counting, external timing devices, and continuous supervision by healthcare professionals. These limitations increase the evaluator`s workload, introduce measurement variability, reduce protocol standardization, and hinder the personalization of rehabilitation according to each patient's functional status [5].

Recent advances in computer vision, artificial intelligence, and virtual reality have created new opportunities to develop intelligent rehabilitation technologies that automate functional assessment through markerless motion capture and real-time biomechanical analysis. Among these technologies, MediaPipe Pose enables accurate estimation of human body posture from conventional RGB cameras, eliminating the need for wearable sensors or optical marker systems. Nevertheless, few digital platforms integrate computer vision, non-immersive virtual reality, automated performance analysis, and structured clinical data management into a unified solution specifically designed for hospital cardiorespiratory rehabilitation. To the best of our knowledge, no previous platform has combined markerless computer vision, non-immersive virtual reality, automated functional assessment, and structured clinical data management into a single modular architecture specifically designed for hospital cardiorespiratory rehabilitation.

To address this technological gap, we developed EX-READ, a modular digital platform that combines computer vision and non-immersive virtual reality to automate functional assessment during hospital cardiorespiratory rehabilitation. The platform integrates standardized functional assessment protocols, real-time motion capture using MediaPipe Pose, automatic performance analysis, and structured clinical data management within a scalable architecture designed for future integration with physiological monitoring systems, wearable sensors, artificial intelligence algorithms, and clinical decision-support tools.

This study presents the design, development, modular architecture of the computational platform, and preliminary technical verification of EX-READ as a computer vision-based platform for automated functional assessment in hospital cardiorespiratory rehabilitation.

II. Materials and Methods

A. Study Design

This study is a technological development study focused on the design, implementation, and preliminary technical verification of EX-READ, a non-immersive virtual reality modular computational platform developed to support functional assessment during hospital cardiorespiratory rehabilitation. EX-READ implements two standardized functional assessment protocols through a modular execution engine capable of automatic motion processing, real-time performance analysis, and structured clinical data management. The modular computational platform was conceived as the first technological module of a broader digital rehabilitation ecosystem, enabling future integration with physiological monitoring systems, wearable sensors, artificial intelligence algorithms, and clinical decision-support tools.

B. Modular computational platform Development Process

The development of EX-READ was carried out by a multidisciplinary team comprising physiotherapists, biomedical engineers, computer scientists, and software developers, following an iterative, incremental software development process. The workflow included five sequential stages: (i) requirements analysis; (ii) system architecture design; (iii) modular computational platform implementation; (iv) integration and internal verification; and (v) iterative refinement of the final application.

The modular computational platform was developed using an iterative user-centered approach, enabling continuous refinement of the application across successive development cycles.

Initially, clinical and technical requirements were established based on current scientific evidence, hospital rehabilitation workflows, and the practical experience of healthcare professionals involved in cardiorespiratory rehabilitation. Functional requirements included patient registration, execution of standardized functional assessment protocols, automatic performance recording, audiovisual feedback, data storage, and report generation. Non-functional requirements included usability, reliability, interoperability, scalability, modular computational platform maintainability, and information security.

C. Motion Capture and Tracking Layer

The Motion Capture and Tracking Layer is responsible for acquiring, detecting, and processing human body movements throughout the functional assessment. This layer establishes the communication between the participant's physical movements and the computational modules of EX-READ, enabling automated assessment without the need for wearable sensors, external markers, or manual repetition counting.

Human motion capture is performed using MediaPipe Pose (Google LLC) [6], a real-time computer vision framework that estimates three-dimensional human body posture from RGB images. The framework detects 33 anatomical landmarks distributed across the head, trunk, upper

limbs, and lower limbs, allowing continuous tracking of body segments during exercise execution.

During each assessment, image frames are continuously acquired by a conventional RGB camera positioned in front of the participant. Each frame is processed in real time by the MediaPipe Pose model [7], which identifies the anatomical landmarks and estimates their spatial coordinates. These data are subsequently transferred to the EX-READ processing pipeline, where they are used to monitor body movement throughout the assessment.

To improve robustness, the tracking layer monitors confidence and temporal consistency between consecutive frames. The default confidence parameter is 0.5; frames with confidence ≤0.5 are ignored for joint-angle calculation and repetition-state transitions until confidence exceeds 0.5. Robustness under hospital conditions, including occlusion, lighting, clothing, medical devices, use of support, and out-of-plane movement, remains to be evaluated.

The extracted kinematic information is subsequently transmitted to the Functional Assessment Core Engine, where the anatomical landmarks are analyzed according to the selected assessment protocol. The processing pipeline automatically identifies movement cycles, estimates joint displacement, recognizes valid repetitions, and generates the performance variables required for each functional test.

The modular implementation of the Motion Capture and Tracking Layer enables the future incorporation of alternative motion-sensing technologies, including depth cameras, inertial measurement units (IMUs), wearable sensors, and multimodal physiological monitoring devices, without requiring modifications to the remaining modular computational platform architecture.

Based on these specifications, the modular computational platform architecture was designed using a modular structure to facilitate future expansion and integration with additional technological resources.

D. Internal Verification and Modular Computational Platform Refinement

Following platform implementation, the first functional prototype of EX-READ underwent internal technical verification by the multidisciplinary development team. This stage aimed to verify platform functionality, operational stability, interface consistency, navigation workflow, and correct execution of the programmed protocol logic under simulated operating conditions. No hospitalized participants were included, and the automated outputs were not compared with measurements obtained by an independent physiotherapist or a reference motion-capture system. Therefore, this stage was not designed to establish measurement error, agreement, repeatability, or clinical validity and should not be interpreted as a clinical or measurement-validation study.

The verification process comprised systematic execution of all modular computational platform functionalities, including configuration of assessment protocols, user interaction, motion tracking, timing control, automatic repetition counting, real-time audiovisual feedback, and data recording. Each software module was inspected and subsequently evaluated after full system integration to ensure proper communication among components and consistent behaviour of the modular computational platform during complete assessment sessions.

Based on the issues identified during internal verification, two iterative refinement cycles were performed. These refinement stages included optimizing the graphical user interface, improving navigation flow, adjusting motion-tracking parameters, refining exercise execution logic, enhancing timing synchronization, and optimizing real-time visual feedback. The modular computational platform was re-evaluated after each refinement cycle to verify the effectiveness of the implemented modifications and to ensure system stability.

This process produced the final functional version of EX-READ, providing a stable, standardized, and modular computational framework for functional assessment using non-immersive virtual reality. This version constitutes the technological basis for subsequent usability, feasibility, and clinical validation studies.

III. RESULTS

A. EX-READ Modular computational platform Architecture

The final version of EX-READ incorporates a complete computational framework for automated functional assessment, including patient registration, RGB camera configuration, MediaPipe Pose-based motion capture, automatic repetition counting, real-time timing control, joint angle estimation, standardized execution of the 2-Minute Step Test and 30-Second Sit-to-Stand Test, structured clinical data management, automatic export of assessment results to Microsoft Excel®, and generation of clinical performance reports. Together, these functionalities establish a comprehensive modular platform capable of supporting standardized functional assessment in hospital rehabilitation. (Fig. 1).

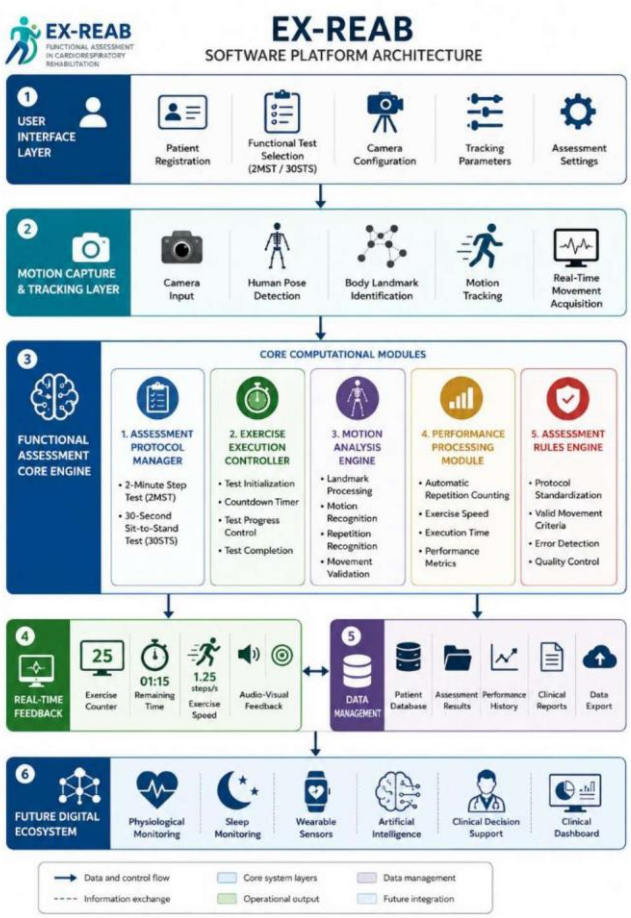

Fig. 1A. Overall architecture of the EX-READ modular computational platform. The system was designed as a modular digital platform comprising six functional layers: User Interface, Motion Capture and Tracking, Functional Assessment Core Engine, Real-Time Feedback, Data Management, and a Future Digital Ecosystem. The modular architecture enables standardized functional assessment through non-immersive virtual reality while supporting future integration with physiological monitoring systems, wearable sensors, artificial intelligence algorithms, and clinical decision-support tools.

The modular computational platform architecture was designed following a modular approach, enabling independent development and maintenance of each functional component while preserving communication among all modular computational platform layers. This architecture also allows future incorporation of additional digital health technologies without requiring substantial structural modifications (table I).

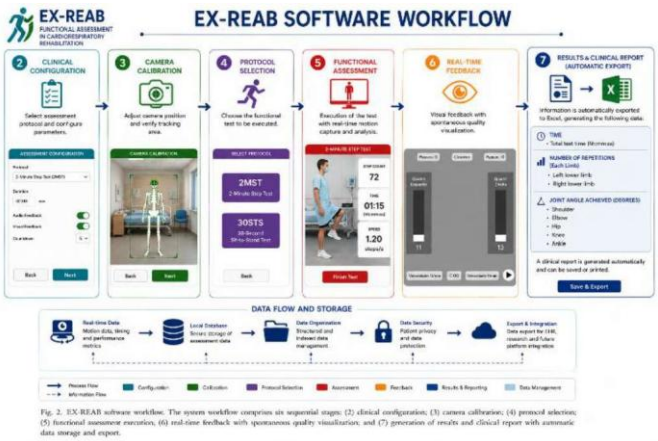

TABLE I. COMPONENTS AND FUNCTIONALS

Module	***Main Function***	***Output***
User Interface Layer	Patient registration, protocol selection, camera configuration, assessment setup	Configured assessment session
Motion Capture and Tracking Layer	RGB image acquisition, MediaPipe Pose processing, detection of 33 anatomical landmarks	Real-time body landmark coordinates
Motion Analysis Pipeline	Joint angle estimation, movement trajectory analysis, biomechanical threshold evaluation	Movement recognition and validated repetitions
Functional Assessment Core Engine	Protocol management, execution control, performance processing, assessment rules	Standardized functional assessment metrics
Real-Time Feedback Layer	Real-time visualization of timing, repetitions, movement status, and protocol progression	Immediate visual feedback to clinician and participant
Data Management Layer	Data Management Layer	Data Management Layer
Clinical Report Module	Automatic generation of standardized assessment reports	Clinical performance report
Future Digital Ecosystem	Integration with wearable sensors, physiological monitoring, sleep assessment, artificial intelligence, and clinical decision-support systems	Scalable digital rehabilitation ecosystem

Abbreviations: RGB, Red-Green-Blue; AI, Artificial Intelligence; EX-READ, Computer Vision and Non-Immersive Virtual Reality Platform for Automated Functional Assessment.

B. User Interface Layer

The user interface layer provides the interaction between healthcare professionals and the modular computational platform (Fig. 2). Before each assessment, users can configure the functional protocol, select the assessment duration, adjust camera parameters, and define tracking settings through an intuitive graphical interface.

The information is automatically exported to excel:total assessment time; number of repetitions; lower-limb movement counts; joint angle measurements; protocol identification; performance metrics generated during assessment.

C. Motion Analysis Pipeline (Fig. 3 and 4)

After landmark detection, the EX-REAB motion analysis pipeline processes MediaPipe Pose coordinates to identify movement cycles according to each functional protocol. For the 30STS, shoulder, hip, and knee landmarks are used to calculate the hip angle; for the 2MST, hip, knee, and ankle landmarks are used to calculate the knee angle. Repetitions are validated by protocol-specific state-transition rules derived from the literature [8], [9]. In the 2MST, the states are resting (<130°), transition (100°-130°), and reached (<100°), with a new step counted only after return to resting. In the 30STS, the states are resting (<120°), transition (120°-150°), and reached (>150°). Incomplete sequences are not counted, postural compensations are not independently classified, and threshold sensitivity was not evaluated at this development stage.

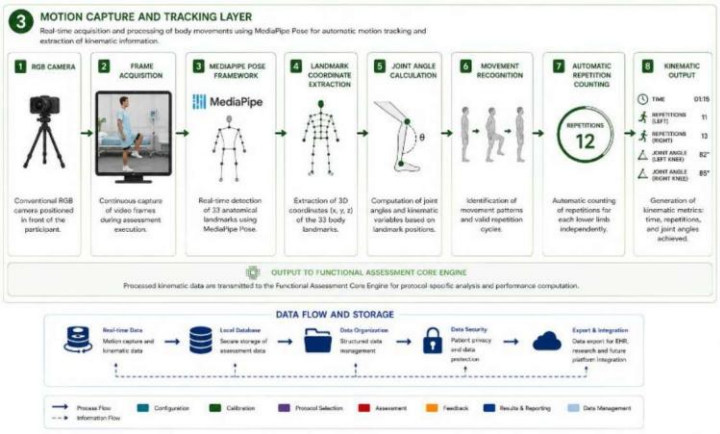

Fig. 3. Motion Capture and Tracking Layer workflow. The layer comprises eight sequential processes: (1) RGB camera; (2) frame acquisition; (3) MediaPipe Pose framework; (4) landmark coordinate extraction; (5) joint angle calculation; (6) movement recognition; (7) automatic repetition counting; and (8) generation of kinematic output. The processed data are transmitted to the Functional Assessment Core Engine for protocol-specific analysis and performance computation.

D. Functional Assessment Core Engine

The Functional Assessment Core Engine represents the central computational module of the EX-REAB platform, coordinating all processes required for automated functional assessment. This module receives the kinematic information generated by the Motion Capture and Tracking Layer and executes the computational routines responsible for protocol management, movement interpretation, performance analysis, and generation of assessment outcomes.

The Core Engine operates through five integrated computational components: Assessment Protocol Manager, Exercise Execution Controller, Motion Analysis Engine, Performance Processing Module, and Assessment Rules Engine (Fig. 3). Together, these components ensure standardized execution of functional assessment protocols while maintaining synchronization among all modular computational platform layers.

The Assessment Protocol Manager initializes the selected functional protocol, configures protocol-specific parameters, and controls the execution logic of the 2-Minute Step Test (2MST) and the 30-Second Sit-to-Stand Test (30STS). Once the protocol is initiated, the Exercise Execution Controller supervises test progression by managing countdown timing, exercise duration, protocol transitions, and test completion according to predefined assessment rules.

The Motion Analysis Engine continuously processes the anatomical landmarks provided by MediaPipe Pose to identify movement cycles, recognize valid repetitions, and

verify whether the participant's movements satisfy the biomechanical criteria established for each assessment protocol. Subsequently, the Performance Processing Module automatically computes clinically relevant variables, including repetition count, execution time, movement cadence, and protocol-specific performance indicators.

Finally, the Assessment Rules Engine applies predefined decision rules to ensure protocol standardization, identify execution errors, verify movement quality, and maintain consistency throughout the assessment. This modular organization enables independent maintenance and future expansion of each computational component while preserving seamless communication with the remaining modular computational platform layers.

E. Real-Time Feedback

The Real-Time Feedback Layer was designed to provide continuous visual information to both healthcare professionals and participants throughout the assessment process. By continuously receiving processed data from the Functional Assessment Core Engine, the system updates performance indicators instantaneously, allowing immediate monitoring of exercise execution.

During assessment, the graphical interface dynamically presents protocol progression, elapsed time, repetition count, exercise cadence, and task status. In addition, visual indicators representing lower-limb movement are continuously updated according to the detected joint displacement, enabling immediate identification of movement symmetry and execution quality.

This real-time interaction facilitates participant engagement while allowing clinicians to supervise protocol execution without manual counting or external timing devices. The feedback architecture may reduce operator workload and support standardized assessment procedures; however, these effects were not measured in the present study.

The modular implementation of the feedback layer enables future incorporation of additional visualization resources, including biomechanical indicators, physiological variables, performance dashboards, and adaptive feedback strategies based on artificial intelligence algorithms.

F. Data Management

The Data Management Layer is responsible for automatic storage, organization, and export of all information generated during functional assessment. Throughout test execution, performance variables produced by the Motion Analysis Pipeline and Functional Assessment Core Engine are continuously transferred to the local database without requiring user intervention.

Following completion of each assessment, EX-REAB automatically generates a structured dataset containing protocol identification, total assessment time, number of repetitions performed, lower-limb movement metrics, joint angle measurements, and protocol-specific performance indicators. These data are automatically exported to Microsoft Excel®, allowing subsequent statistical analysis and long-term monitoring of patient progression.

The generated datasets provide standardized quantitative information that can be integrated into clinical records, research databases, and future digital health platforms. The modular architecture also supports future interoperability with electronic health records (EHRs), cloud-based repositories, wearable monitoring systems, and clinical decision-support platforms.

G. Modular computational platform Capabilities

The final functional version of EX-REAB provides an implemented computational platform capable of performing the complete automated functional-assessment workflow, from patient registration and protocol configuration to motion capture, movement recognition, real-time performance analysis, data storage, and automatic export of clinical results. These functionalities demonstrate technical implementation and establish the technological basis for subsequent usability, feasibility, and clinical validation studies.

IV. DISCUSSION

The present study describes the design and development of EX-REAB, a modular digital platform that integrates computer vision, non-immersive virtual reality, automated motion analysis, and structured clinical data management for functional assessment during hospital cardiorespiratory rehabilitation. To the best of our knowledge, this is one of the first platforms specifically designed to combine these technologies within a unified architecture for hospital rehabilitation.

Beyond its technical implementation, EX-REAB was conceived to address practical barriers that limit routine functional assessment in hospital rehabilitation (Table II). EX-REAB may simplify workflow and reduce manual tasks, but effects on workload, staffing requirements, and evaluator variability were not measured in the present study. Contactless RGB-based capture may also offer potential biosafety advantages. Automatic export of assessment time, repetition count, joint angles, and performance metrics may facilitate clinical documentation, longitudinal follow-up, and future integration with digital health systems, although their validity and clinical impact require formal evaluation.

TABLE II. Potential Advantages of EX-READ Compared with Conventional Functional Assessment*

Conventional assessment	***EX-READ platform***
Manual repetition counting	Automatic repetition counting
External stopwatch	Automatic timing
Visual observation only	Computer vision-based motion analysis
Subjective movement evaluation	Algorithm-derived kinematic analysis*
Greater evaluator workload	Potential reduction in manual workload*
Possible need for two professionals in some situations	Potential to support assessment by a single trained evaluator*
Contact with shared assessment equipment	Contactless assessment using RGB camera
Manual data recording	Automatic data export to Excel

**Potential advantages were not measured and require confirmation in future clinical validation studies.

Another important contribution of EX-READ is its modular computational platform architecture, which was intentionally designed to support future technological expansion. Unlike standalone rehabilitation applications, the platform allows independent incorporation of additional computational modules without requiring substantial modifications to the existing framework. This design facilitates future integration with wearable physiological sensors, sleep monitoring systems, artificial intelligence algorithms, electronic health records, and clinical decision-support tools, supporting the evolution of EX-READ into a comprehensive digital ecosystem for precision rehabilitation.

The present work focused on modular computational platform development and preliminary technical verification and therefore does not establish validity, reliability, measurement error, agreement, repeatability, usability, or clinical effectiveness. Future studies should compare EX-READ-derived repetition counts, execution times, and joint-angle measurements with simultaneous measurements obtained by trained physiotherapists and/or a reference motion-capture system in participants with different mobility levels, including analyses of absolute error, agreement, and repeatability. Future validation should also evaluate threshold sensitivity and performance under representative hospital conditions.

In addition, future versions of EX-READ will incorporate continuous physiological monitoring, sleep assessment, wearable sensing technologies, and artificial intelligence-based predictive models to support personalized rehabilitation strategies in hospital environments.

Therefore, EX-READ establishes the technological foundation for intelligent and scalable digital rehabilitation systems and for future clinically validated applications in hospital rehabilitation settings.

V. CONCLUSION

EX-READ provides a computational framework for automated functional assessment in hospital rehabilitation by combining markerless computer vision, non-immersive virtual reality, standardized computational workflows, and structured digital data management. The present study demonstrates technological development and preliminary technical verification under simulated conditions. Clinical validity, reliability, error, agreement, repeatability, usability, and workflows, and structured digital data management within a unified modular architecture. This technological foundation has the potential to support the next generation of intelligent rehabilitation systems that deliver scalable, objective, and data-driven physiotherapy in hospital settings.

***Abstract*—Independent mobility is essential for individuals with severe motor impairments, although conventional wheelchair interfaces may not be suitable for users with limited upper-limb control. This work presents the initial development and pilot functional evaluation of a multimodal interface for assistive wheelchair control using electrooculography (EOG), capacitive sensing, and inertial sensing. EOG signals generate left and right commands, the capacitive sensor provides a forward command, and an inertial measurement unit monitors lateral neck inclination. Two ESP32 microcontrollers communicate through MQTT over Wi-Fi, and the received commands are converted into motor actuation through an H-bridge driver. Preliminary EOG acquisition and functional tests were performed by one of the authors as an initial pilot evaluation of the proposed architecture. The results were qualitatively analyzed to verify the functional integration and interaction among the sensing, processing, communication, and actuation modules. The preliminary findings support the feasibility of the proposed proof-of-concept architecture under controlled bench conditions, while quantitative evaluation of classification performance, communication characteristics, and system robustness is planned as part of future experimental stages. The present study does not constitute quantitative validation of wheelchair performance, usability, or safety.**

***Index Terms*—Assistive Technology, Electrooculography (EOG), Human–Machine Interface, Capacitive Sensing, Inertial Sensing**

I. Introduction

Mobility is a fundamental aspect of autonomy, social participation, and quality of life for people with motor disabilities. Partial or complete loss of locomotion compromises daily activities, reduces functional independence, and may lead to significant physical, emotional, and social impacts. This condition is observed in individuals with paraplegia, quadriplegia, spinal cord injuries, neuromuscular diseases, and other neuromotor disorders, which may present different degrees of impairment affecting upper- and lower-limb control [1], [3], [4].

In many of these cases, powered wheelchairs represent an important solution for increasing user independence. However, conventional control systems, typically based on joysticks, are not always suitable for individuals with severe upper-limb impairments. Users with reduced muscle strength, impaired fine motor coordination, or limited voluntary movements may experience difficulties operating these devices accurately and safely, highlighting the need for alternative control interfaces [2].

Given these limitations, several studies have investigated human–machine interfaces capable of exploiting preserved motor or physiological functions. Among these alternatives, electrooculography (EOG) has attracted considerable attention because it enables the detection of eye movements based on variations in the corneo-retinal potential. Since ocular control may remain preserved even in individuals with severe motor impairments, EOG represents a promising approach for generating commands in assistive mobility systems [3], [5].

Despite the potential of ocular control, relying on a single source of information may introduce challenges related to reliability, user adaptation, and operational safety. Involuntary eye movements, acquisition noise, blinks, and signal fluctuations may hinder command interpretation. Furthermore, users may exhibit different preserved motor abilities, making it advantageous to combine multiple input modalities. In this context, multimodal approaches have been investigated to integrate different signals and sensors into a unified control

strategy [2].

Residual body movements and complementary sensors can further expand the interaction possibilities of assistive systems. Capacitive sensors can serve as low-effort activation interfaces, while inertial sensors can contribute to postural monitoring and the detection of unsuitable operating conditions. Integrating these sources of information allows command generation and monitoring functions to be distributed across multiple inputs, resulting in an interface that is more adaptable to the user's functional capabilities.

Based on this motivation, this work presents the initial development and pilot functional evaluation of a multimodal human–machine interface for assistive wheelchair control. The proposed architecture integrates EOG for directional commands, capacitive sensing for forward movement, and inertial sensing for monitoring lateral neck inclination. The primary objective of this initial stage is to verify the functional integration of the sensing, processing, communication, and motor-actuation modules and to assess qualitatively whether the proposed interaction strategy operates as intended. Therefore, the present study is intentionally framed as a preliminary proof-of-concept investigation. Quantitative evaluation of classification performance, false activations, response time, communication reliability, and user-related performance is reserved for subsequent experimental stages and future work.

II. Materials and Methods

The proposed system was developed to integrate different sources of information related to the user's intentions and the operating conditions of the device, supporting command generation and postural monitoring within the prototype. The overall architecture of the proposed system is illustrated in Fig. 1.

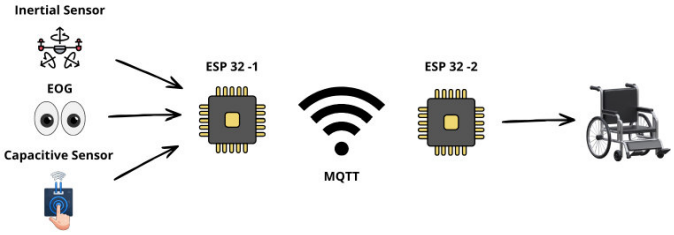

Fig. 1. Project schematic.

As illustrated in the schematic, the sensors acquire the information required for system operation. The acquired signals are transmitted to an ESP32 microcontroller, where data processing is performed, while a second ESP32 receives the generated commands and controls the actuators. Communication between the microcontrollers is established through the Message Queuing Telemetry Transport (MQTT) protocol over a Wi-Fi network.

The proposed architecture combines three input modalities. Horizontal eye movements generate LEFT and RIGHT commands, capacitive activation generates the FORWARD command, and the inertial sensor monitors lateral neck inclination. When no valid movement command is detected, or when the predefined interruption condition is reached, the system returns to the STOP state. The resulting command is then transmitted to the motor-control module.

A. Pilot Evaluation Scope

The experiments reported in this study correspond to an initial pilot stage of the proposed system development. The primary purpose of this stage was to verify the functional integration of the sensing, signal-processing, communication, and motor-actuation modules under controlled bench conditions. Accordingly, the evaluation was exploratory and qualitative rather than a quantitative performance assessment.

The preliminary EOG acquisition and classification tests were conducted with one author-participant, without external volunteers. The experiments were intended to verify whether intentional horizontal eye movements produced distinguishable signal patterns and whether these patterns resulted in the expected state transitions. Similarly, the multimodal integration, MQTT communication, and motor-actuation stages were evaluated by observing whether the implemented commands were correctly processed, transmitted, and translated into the expected prototype responses.

No statistical inference or generalized performance claim is intended from these experiments. The observations obtained in this phase were used to verify the expected qualitative behavior of the system and to identify aspects that require further investigation. Quantitative characterization, including classification accuracy, false-activation rate, response time, communication latency, packet loss, inertial-estimation error, and evaluation with multiple participants, is planned for subsequent stages of the project.

Table I summarizes the specific questions addressed by each pilot evaluation and distinguishes them from the quantitative questions reserved for future work.

B. Inertial Sensor

The MPU-9250 module, which integrates a three-axis accelerometer and a three-axis gyroscope, was employed to monitor the user's lateral neck inclination during prototype operation. The inertial sensor enables the detection of postures that exceed the predefined operational threshold, as illustrated in Fig. 2.

Figure 2 illustrates the inclination range adopted for user postural monitoring. Based on preliminary experiments, an angular threshold of $\pm 50^{\circ}$ relative to the neutral neck position was adopted as an operational criterion for the prototype. When the measured inclination remains within this range, movement commands are enabled; otherwise, motor actuation is interrupted. This threshold was selected for functional pilot testing and was not derived from a clinical or ergonomic safety assessment.

Data acquisition from the inertial sensor was performed through the Inter-Integrated Circuit (I^2C) communication protocol using an ESP32 microcontroller. Before operation, the gyroscope was calibrated to compensate for measurement

TABLE I
SCOPE OF THE PILOT FUNCTIONAL EVALUATION.

Module	Pilot question	Evidence collected	Not evaluated quantitatively
EOG	Whether horizontal gaze produced the expected signal patterns and state transitions.	Representative EOG trace and observed state-machine transitions.	Accuracy, sensitivity, false activations, robustness and generalization.
Capacitive sensor	Whether activation generated the intended forward command.	Qualitative activation and command response.	Repeatability, sensitivity and environmental robustness.
IMU	Whether inclination outside the prototype range triggered interruption logic.	Observed threshold-dependent state response.	Angular accuracy, drift and clinical/ergonomic validity.
MQTT	Whether commands could be transmitted and interpreted by the actuation module.	Published and received command messages.	Latency, jitter, packet loss, and security performance.
Motors	Whether received commands were mapped to the intended motor actions.	Bench observation of motor-command mapping.	Response time, trajectory, load behavior and navigation performance.

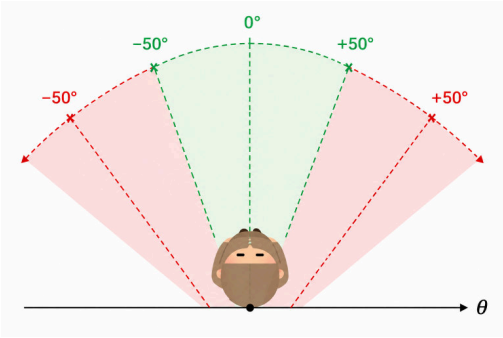

Fig. 2. Lateral neck inclination adopted for postural monitoring.

offsets, since inertial sensors based on Microelectromechanical Systems (MEMS) technology are susceptible to systematic errors, measurement noise, and angular drift, particularly when orientation is estimated through numerical integration [4], [5].

During the calibration procedure, the sensor was maintained at rest, and the average of 500 samples was computed to estimate the initial measurement offset [4]. After offset compensation, the angular velocity measurements were sampled at approximately 60 Hz and numerically integrated by the ESP32 to estimate the lateral neck inclination. The estimated inclination was then compared with the predefined operational threshold. Because the estimate is obtained by direct gyroscope integration, cumulative drift may occur over time and was not quantitatively characterized in the present pilot study.

C. Capacitive Sensor

The capacitive sensor was employed as an interface to detect the user's intention to initiate forward motion. In assistive mobility systems, individuals with paraplegia, quadriplegia, or other motor impairments may experience difficulties operating conventional interfaces, such as joysticks, thereby motivating the adoption of alternative activation methods that require minimal physical effort [2], [6].

Its operating principle is based on variations in capacitance produced by the proximity or contact of the human body with the sensor-sensitive surface. These variations are interpreted by the embedded system as an activation signal, enabling the detection of a voluntary command without requiring significant mechanical force [7], [8].

In the proposed architecture, the capacitive sensor is not used as a general wheelchair enable signal and does not interfere with the directional commands generated by the EOG module. Instead, it provides an independent command associated exclusively with forward movement. Thus, sensor activation is interpreted by the system as the user's intention to move the wheelchair forward.

Accordingly, each sensing modality performs a specific function within the multimodal interface. The capacitive sensor generates the forward command, the EOG module identifies the lateral directional commands, and the inertial measurement unit (IMU) monitors the user's postural inclination. This functional separation enables the different sensing modalities to operate in a complementary manner, increasing the flexibility of the proposed control strategy.

The sensor position should be adjusted according to the user's functional capabilities. For individuals with paraplegia, activation can be performed using body regions with greater preserved motor function, such as the hands or arms. For users with quadriplegia, the sensor may be positioned near the head, shoulder, chin, or another region with preserved voluntary control [9].

D. EOG

Figure 3 illustrates the functional architecture of the electrooculography (EOG) signal acquisition and conditioning module developed in this work. The module converts the electrical potentials generated by eye movements into signals compatible with embedded processing, allowing their use as one of the input modalities of the proposed multimodal assistive interface.

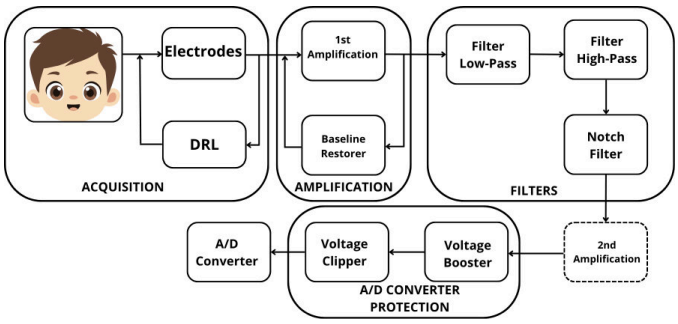

Fig. 3. Functional diagram of the EOG signal acquisition and conditioning module.

Electrooculography was employed because it enables the detection of horizontal eye movements through variations in the corneo-retinal potential. In this configuration, rightward and leftward eye movements produce voltage deflections with opposite polarities, allowing these events to be associated with directional commands. This characteristic makes EOG a suitable alternative for human–machine interfaces intended for users with severe motor impairments, since ocular control is frequently preserved even in conditions involving substantial upper-limb limitations [10], [11], [13], [14].

EOG signals were acquired using surface electrodes positioned around the eyes according to the direction of the ocular movements to be monitored. Because EOG signals exhibit low amplitudes and are susceptible to external interference, the acquired signal was initially processed by a differential amplification stage combined with a *Driven Right Leg* (DRL) active reference circuit. This configuration improves common-mode rejection and stabilizes the electrical reference during signal acquisition [10], [12].

Subsequently, the signal was processed by a baseline restoration stage and active filters. The baseline restorer compensates for slow DC-level variations, whereas second-order high-pass and low-pass filters implemented using the Sallen–Key topology define the frequency band of interest while preserving the components associated with voluntary eye movements. Additionally, a Notch filter was employed to attenuate the 60 Hz power-line interference commonly observed in biopotential acquisition systems.

The conditioned signal was then subjected to a second amplification stage to increase the amplitude of the useful EOG components. Before analog-to-digital conversion, a protection circuit shifted the signal to a positive voltage range and limited its amplitude to levels compatible with the analog input of the microcontroller, thereby protecting the embedded acquisition input.

For the prototype implementation, a printed circuit board (PCB) was designed and fabricated. Figure 4 presents the developed PCB for the EOG signal acquisition module.

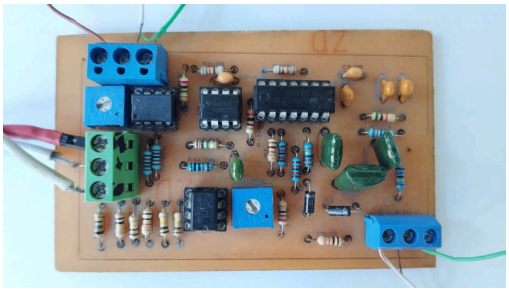

Fig. 4. Printed circuit board developed for the EOG signal acquisition and conditioning module.

For the acquisition of horizontal eye movements, surface electrodes were positioned in the periocular region to capture the potential variations associated with lateral gaze displacement [10]. The electrodes were placed near the outer canthi of the eyes, together with a reference electrode to stabilize the measurements. This configuration was adopted because it provides greater sensitivity to horizontal eye movements, which constitute the directional commands employed by the proposed assistive interface [11].

Figure 5 illustrates the electrode placement adopted during the acquisition experiments.

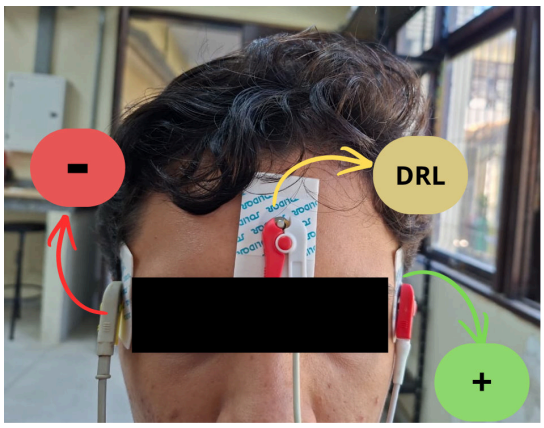

Fig. 5. Electrode placement adopted for horizontal EOG signal acquisition.

The conditioned EOG signal was digitized at approximately 60 Hz using an ADC with 12-bit resolution. The acquisition chain used an amplifier gain of approximately 66, high-pass and low-pass cutoff frequencies of 0.5 Hz and 12 Hz, respectively, and surface Ag/AgCl electrodes. Electrode–skin impedance was not quantitatively measured during the experiments. These parameters are reported to improve reproducibility of the prototype implementation, while the present study does not establish whether they are optimal for classification performance across users.

Preliminary EOG acquisition tests were performed by one of the authors of this study, with no external volunteers involved in the reported experiments. These tests constituted an initial pilot evaluation intended to verify the functionality of the EOG acquisition chain and the response of the state-machine-based classification algorithm. During the tests, the participant performed intentional leftward and rightward eye movements while the EOG signal and the corresponding state transitions were observed.

At this stage, the experiments were exploratory and were not designed for statistical characterization. The number of repetitions was therefore not systematically recorded for quantitative analysis. The observations obtained in this phase were used to verify the expected qualitative behavior of the signal and classification states and to identify aspects of the system that require further investigation.

The reported pilot tests were performed by one of the authors, and no external volunteers were recruited. The experiment was limited to preliminary prototype development and functional verification and did not involve clinical assessment. The authors recognize that the use or publication of identifiable participant images must comply with the applicable institutional and event requirements; therefore, any image used in

the final submission should be accompanied by the appropriate authorization or documentation when required.

E. State-machine-based EOG Classification Algorithm

After signal acquisition and analog conditioning, the digitized electrooculography (EOG) signal was processed by the ESP32 to identify horizontal eye movements and convert them into discrete navigation commands. A state-machine-based approach was adopted because EOG signals are characterized by temporal patterns rather than isolated voltage values.

Initially, the filtered signal was centered with respect to the baseline estimated during the calibration stage. During this procedure, the user maintained the gaze in the neutral position, allowing the reference value b_0 to be estimated. The centered signal was defined as

$$x[n] = v_f[n] - b_0, \tag{1}$$

where $v_f[n]$ denotes the filtered EOG signal and $x[n]$ represents the centered signal. This operation shifts the baseline to approximately zero, facilitating the identification of positive and negative deflections associated with eye movements.

EOG events were identified by analyzing the temporal evolution of the centered signal. To this end, the variation between consecutive samples was computed as

$$\Delta x[n] = x[n] - x[n-1], \tag{2}$$

This variation allows the detection of changes in the signal trend. A transition from an increasing to a decreasing trend characterizes a positive peak, whereas a transition from a decreasing to an increasing trend characterizes a negative peak. Consequently, eye-movement detection depends not only on the instantaneous signal amplitude but also on its temporal behavior.

Figure 6 presents the flowchart of the proposed classification algorithm. The process begins with EOG signal acquisition, followed by digital filtering, baseline centering, and validation of candidate peaks. Based on the polarity of the first detected peak, the movement is classified as either left or right. Subsequently, the algorithm searches for a peak with opposite polarity, which is interpreted as the return of the gaze to the neutral position.

The adopted strategy assumes that each horizontal eye movement consists of two sequential events: gaze displacement and gaze recentering. Accordingly, the first valid peak represents the user's directional intention. A positive peak is interpreted as a left command, whereas a negative peak corresponds to a right command. This convention reflects the electrode configuration adopted in the experiments and can be reversed if the signal polarity is inverted.

After detecting the first peak, the algorithm does not immediately accept a new command. Instead, the state machine enters a waiting state in which it searches for a peak of opposite polarity corresponding to gaze recentering. Once this second peak is detected, the state returns to the neutral condition. This strategy prevents the natural return of the eyes from being incorrectly interpreted as a new directional command.

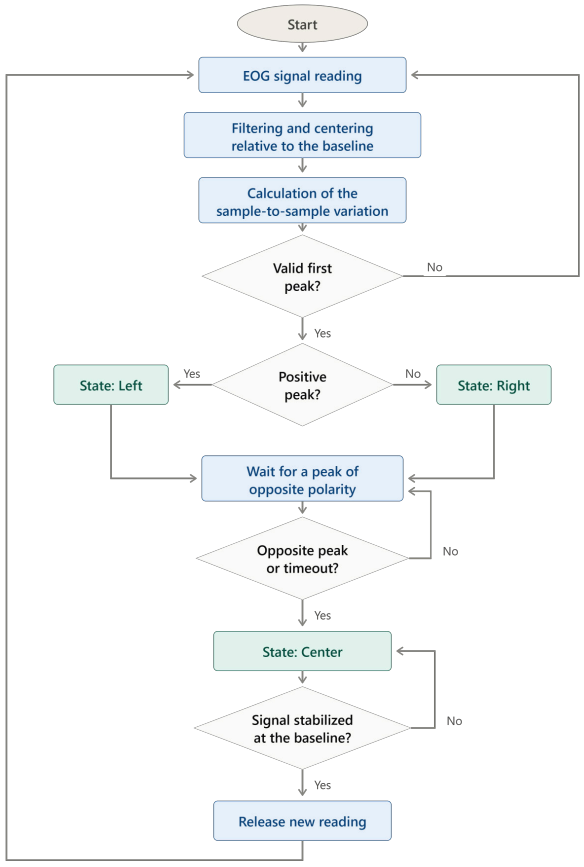

Fig. 6. Flowchart of the state-machine-based EOG classification algorithm.

To reduce false detections caused by noise or small signal fluctuations, amplitude thresholds were incorporated into the algorithm. The directional threshold, denoted by L_{dir}, validates the deflection associated with leftward or rightward gaze displacement, whereas the recentering threshold, denoted by L_{rec}, validates the opposite-polarity deflection corresponding to gaze recentering. Consequently, only significant signal variations are considered during the decision process.

The directional and recentering thresholds were selected empirically during preliminary pilot tests performed by one of the authors. The adopted values were $L_{dir} = 0.40$ and $L_{rec} = 0.15$. These thresholds correspond to the directional gaze displacement threshold and the opposite-polarity gaze recentering threshold, respectively. They were used for functional prototype testing and should not be interpreted as universally validated physiological limits.

Finally, after returning to the center state, the algorithm waits until the signal stabilizes around the baseline before enabling a new detection cycle. This condition reduces the likelihood that residual oscillations produced by the eye movement itself will be interpreted as additional commands.

F. Communication Between Modules Using MQTT

Communication between the embedded modules was required due to the functional partitioning of the system into two ESP32 microcontrollers. The first microcontroller is responsible for sensor data acquisition and processing, whereas the second controls the actuators. This partitioning improves the organization of the prototype architecture by isolating the sensing module from the power stage while facilitating the integration between signal processing and actuation.

Communication between the two modules was established using the MQTT (*Message Queuing Telemetry Transport*) protocol over a Wi-Fi network. MQTT adopts a publish/subscribe communication model in which clients exchange messages organized in topics through a server referred to as a *broker*. This architecture reduces the coupling between devices while requiring low computational and communication overhead, making it widely adopted in embedded systems and Internet of Things (IoT) applications [15]–[17].

In the proposed architecture, both ESP32 microcontrollers operate as MQTT clients. The acquisition module acts as the *publisher*, acquiring and processing the signals from the EOG module, the capacitive sensor, and the inertial measurement unit (IMU). Based on these inputs, the system generates a discrete command representing the current state of the interface.

Figure 7 illustrates the MQTT communication architecture adopted in the proposed system. The acquisition ESP32 processes the sensor data and publishes the generated command to the topic *prototype/wheelchair/command*. The MQTT *broker* forwards this message to the second ESP32, which operates as a *subscriber*. The actuation module then interprets the received command and generates the control signals required by the H-bridge and the drive motors.

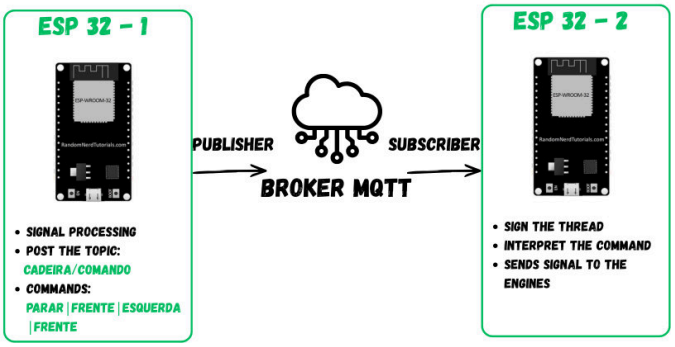

Fig. 7. MQTT communication architecture between the embedded modules.

The processing performed by the acquisition ESP32 results in one of four discrete motor commands: *STOP*, *FORWARD*, *LEFT*, or *RIGHT*. The *FORWARD* command is generated by activation of the capacitive sensor, whereas the *LEFT* and *RIGHT* commands are determined from the EOG signal classification. The *STOP* command is issued when no valid movement command is detected or when the IMU indicates that the predefined operational inclination range has been exceeded. The *CENTER* state used internally by the EOG classifier is not treated as a motor command. Simultaneous conflicting activation of the capacitive and EOG inputs was not systematically evaluated in the present pilot study.

The MQTT Quality of Service (QoS) level 0 was selected because it minimizes communication overhead and latency by eliminating message acknowledgment requirements [15]. Moreover, messages were configured as non-retained, preventing previously transmitted commands from being executed after a possible reconnection.

As a communication protection mechanism, the acquisition ESP32 periodically retransmits the current command, thereby acting as a heartbeat signal for the communication link. At the actuation module, if no valid message is received within the predefined timeout interval implemented in the firmware, the motors are automatically disabled. This behavior provides a functional interruption response to loss of command messages; however, its timing performance and safety effectiveness were not quantitatively validated in this pilot stage.

III. Results and Discussion

The experimental sequence was intentionally organized as a staged functional verification of the prototype. First, the EOG acquisition and state-machine behavior were examined; next, the three sensing modalities were integrated; subsequently, command transmission through MQTT was observed; and finally, the received commands were mapped to motor actuation. This sequence was selected to verify the main functional links of the proposed architecture before undertaking a structured quantitative evaluation.

The results presented in this section correspond to the initial pilot stage of the project and were therefore evaluated qualitatively. The purpose of the experiments was to verify the functional integration of the proposed sensing, processing, communication, and actuation chain under controlled bench conditions. The results should not be interpreted as quantitative estimates of classification accuracy, communication reliability, usability, or wheelchair safety.

A. Preliminary Qualitative Evaluation of Eye Movements

The initial functional evaluation was conducted as a qualitative pilot assessment of the EOG acquisition and classification stages. The purpose of this experiment was not to estimate classification accuracy, but rather to verify whether the proposed acquisition and state-machine strategy produced the expected responses to intentional horizontal eye movements.

After signal conditioning and digitization, lateral gaze displacements produced characteristic voltage variations, consisting of an initial peak associated with gaze displacement followed by an opposite-polarity deflection corresponding to gaze recentering. Figure 8 illustrates a representative EOG signal and the corresponding state transitions observed during the pilot test.

Under the tested condition, the algorithm generated the expected left, right, and center states according to the temporal

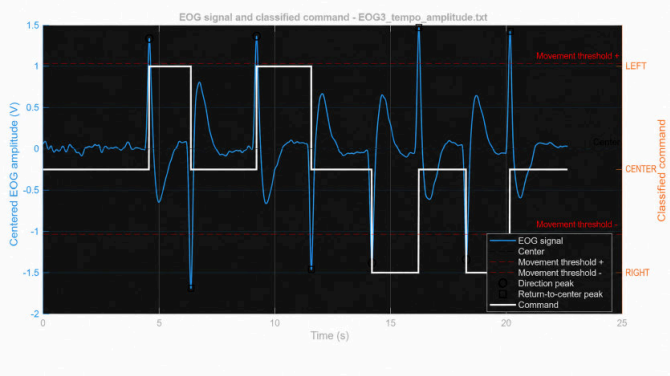

Fig. 8. Representative EOG signal and corresponding state-machine transitions during the preliminary functional test.

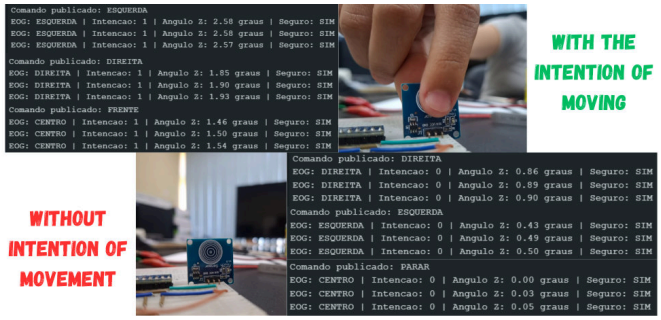

Fig. 9. ESP32 serial monitor during multimodal sensor integration, displaying the estimated IMU angle, the capacitive sensor state and the directional command identified from the EOG signal. In the monitor, *Comando publicado* corresponds to *Published command*, *Intencao* to *Intention*, *Angulo Z* to *Z angle*, and *graus* to *degrees*. The label *Seguro: SIM* indicates that the measured inclination is within the operational range adopted in the firmware. The commands *ESQUERDA*, *DIREITA*, *FRENTE*, *CENTRO*, and *PARAR* correspond to *LEFT*, *RIGHT*, *FORWARD*, *CENTER*, and *STOP*, respectively.

sequence of detected events. This observation provides preliminary qualitative evidence that the proposed state-machine strategy can distinguish the intended movement sequence under controlled conditions. However, because the present evaluation was exploratory and involved a single author-participant, these observations should not be interpreted as estimates of classification accuracy, robustness, or generalization to other users.

A quantitative evaluation involving repeated and labeled trials will be conducted in a subsequent stage of the project to characterize classification accuracy, false activations, response time, and robustness under different operating conditions.

B. Multimodal Sensor Integration

Following the functional evaluation of eye-movement identification, the sensing modalities were integrated to form the proposed multimodal interface. At this stage, the embedded system simultaneously processed three sources of information: the directional commands obtained from the EOG, the forward command generated by the capacitive sensor, and the postural inclination estimated by the inertial measurement unit (IMU).

Figure 9 shows the serial monitor during prototype operation, displaying the combined information processed by the embedded system. The monitored variables include the inclination angle estimated by the IMU, the activation state of the capacitive sensor, and the directional command identified from the EOG signal. The displayed data show concurrent processing of the three sensing modalities during the functional bench test.

The multimodal integration stage was evaluated qualitatively as part of the pilot development phase. The purpose was to verify whether the three sensing modalities could be acquired and processed concurrently within the embedded architecture and whether their respective functions remained distinguishable during operation.

During the experiments, the capacitive sensor operated as an independent input associated with forward movement. When activated, the embedded system interpreted this event as a forward navigation command. The EOG module remained responsible for the lateral directional commands, and the observed states were processed concurrently with the capacitive input during the bench tests.

Simultaneously, the IMU continuously estimated the user's postural inclination. Consequently, the proposed multimodal interface combines sensing modalities with distinct and complementary functions: the capacitive sensor generates the forward command, the EOG provides the lateral directional commands, and the IMU performs postural monitoring.

The serial-monitor observations show that the three sensing modalities were acquired and processed simultaneously by the ESP32. This stage demonstrates the functional integration of command generation and postural monitoring within a single embedded architecture, enabling subsequent evaluation of MQTT communication and motor actuation. It does not, however, establish quantitative performance under repeated or conflicting multimodal inputs.

C. MQTT Communication

The MQTT communication stage was evaluated qualitatively during the pilot phase to verify the functional transmission of commands between the acquisition and actuation modules. Communication between the modules was established using a public HiveMQ server operating as the *broker*. The ESP32 responsible for sensor acquisition and processing acted as the *publisher*, transmitting the commands generated by the multimodal interface to the topic *prototype/wheelchair/command*. The second ESP32, responsible for motor actuation, operated as the *subscriber*, remaining subscribed to the same topic to receive and interpret the transmitted commands.

Figure 10 shows the MQTT communication interface during the experiments, including the active connection to the *broker*, the subscribed topic, the QoS level set to 0, and the exchanged messages.

During the bench experiments, the published messages were received by the actuation module and translated into the corresponding motor commands. The *FORWARD*, *LEFT*, *RIGHT*,

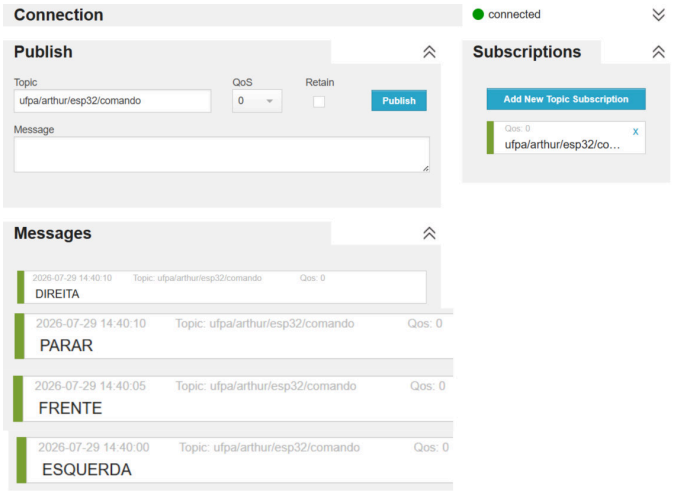

Fig. 10. MQTT communication interface showing QoS 0, active connection to the broker, and published navigation commands during the functional test.

and *STOP* messages produced the command interpretations defined in the firmware under the tested conditions.

The QoS 0 level was adopted because it minimizes communication overhead by eliminating message acknowledgment requirements [15]. Because QoS 0 does not guarantee message delivery, the present implementation should be interpreted as a proof-of-concept communication strategy. Latency, jitter, packet loss, reconnection time, and long-term communication reliability were not quantitatively evaluated in the pilot stage. These parameters will be characterized in subsequent experimental work.

D. Motor Actuation

Following the functional evaluation of MQTT communication, the motor actuation stage was evaluated qualitatively under bench conditions. The purpose of this stage was to verify whether the commands generated by the multimodal interface and transmitted through MQTT were correctly converted into the corresponding H-bridge control signals and motor responses.

Figure 11 illustrates the experimental setup adopted for motor actuation. The actuation ESP32 was connected to the H-bridge inputs, whereas the motors were connected to the corresponding outputs. Based on the received commands, the prototype executed the movements defined by the proposed multimodal control strategy. These tests were performed in a bench configuration and did not include a powered wheelchair under user load.

During the bench tests, the *FORWARD* command, generated when the capacitive sensor was activated and the IMU remained within the adopted operational range, resulted in simultaneous activation of both motors. For the *LEFT* command, the left motor remained disabled while the right motor was activated. Conversely, for the *RIGHT* command, the right motor remained disabled while the left motor was activated.

Whenever no valid command was detected or the IMU identified an inclination outside the adopted operational range, both motors remained disabled according to the implemented interruption logic. This behavior demonstrates the functional response of the motor-control stage to the predefined prototype conditions but does not constitute validation of wheelchair safety.

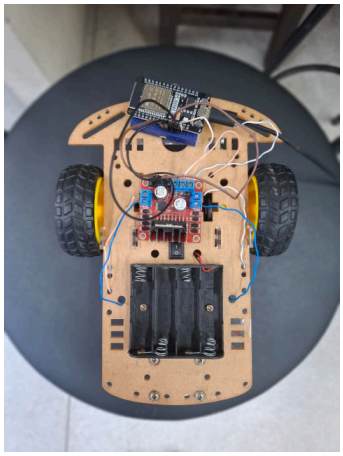

Fig. 11. Experimental setup used for functional bench evaluation of motor actuation through the ESP32 and the H-bridge.

Table II summarizes the motor response associated with each command observed during the experiments.

TABLE II
FUNCTIONAL MOTOR RESPONSE ACCORDING TO THE RECEIVED COMMAND.

Command	Left motor	Right motor	Movement
FORWARD	On	On	Forward movement
LEFT	Off	On	Left turn
RIGHT	On	Off	Right turn
STOP	Off	Off	Stop

Overall, the bench observations indicate that the actuation module converted the digital commands generated by the multimodal interface into the expected motor actions under the tested conditions. These observations demonstrate functional integration between sensing, communication, and actuation, but do not provide quantitative information regarding motor response time, acceleration, trajectory tracking, maneuverability, energy consumption, or performance under wheelchair load.

E. Discussion

The results obtained in this study should be interpreted within the scope of an initial pilot development stage. The primary objective was to verify the functional integration of the proposed multimodal architecture rather than to establish quantitative performance or clinical effectiveness.

Within this scope, the experiments demonstrated that the EOG acquisition and state-machine classification produced the expected qualitative responses to intentional horizontal eye movements, that the capacitive and inertial modalities could be processed concurrently with the EOG input, and that the generated commands could be transmitted through MQTT and

converted into the expected motor-control responses under bench conditions.

The obtained observations are consistent with previous studies that investigated alternative interfaces for assistive mobility, particularly considering the limitations of conventional joystick-based control for users with severe motor impairments [2]. Previous EOG-based approaches have demonstrated the feasibility of wheelchair control through eye movements [13], [14]; however, most of these systems rely on a single input modality for command generation.

The proposed methodology differs by adopting a multimodal interface in which complementary sensing modalities are integrated within a single embedded architecture. Rather than replacing unimodal approaches, the system distributes command generation and postural monitoring across different inputs. This organization is intended to support adaptation to users with different preserved motor abilities, although usability and comparative performance were not evaluated in the present pilot stage.

The present study has important limitations that are directly related to its exploratory scope. The EOG experiment involved only one author-participant and was not designed for statistical assessment of classification performance. Accuracy, confusion matrices, false-activation rates, and robustness against blinking or other physiological artifacts were not evaluated. In addition, gyroscope drift, communication latency, jitter, packet loss, reconnection behavior, and inertial-estimation error were not quantitatively characterized. The $\pm 50^{\circ}$ inclination limit was adopted only as an operational prototype threshold, and the experiments were performed under bench conditions rather than with a powered wheelchair in realistic navigation scenarios.

The simultaneous occurrence of potentially conflicting commands from the capacitive and EOG modalities was also not systematically evaluated. This aspect should be addressed in future experiments because multimodal systems require explicit command-priority and conflict-management rules under concurrent user inputs.

The integration of signal acquisition, embedded processing, MQTT communication, and motor actuation also aligns the proposed architecture with developments in embedded systems and Internet of Things (IoT) applications, where modularity, scalability, and low communication overhead are relevant design considerations [15]–[17]. Nevertheless, the use of wireless communication and a public broker should be considered a characteristic of the current proof-of-concept implementation rather than a validated architecture for safety-critical wheelchair operation.

F. Pilot Study Limitations and Future Quantitative Evaluation

The present study represents an initial pilot stage in the development of the proposed multimodal assistive interface. Accordingly, the experimental results should be interpreted as preliminary qualitative evidence of functional integration rather than as quantitative validation of system performance.

The main limitation of this stage is the absence of a systematic quantitative evaluation. The EOG experiments involved a single author-participant, and no statistical analysis of classification performance was performed. Similarly, communication latency, jitter, packet loss, reconnection behavior, inertial-estimation error, false activations, response time, and long-term system reliability were not quantitatively characterized. The motor-actuation experiments were conducted under bench conditions and did not reproduce the mechanical and environmental conditions of a powered wheelchair operating under user load.

The simultaneous occurrence of potentially conflicting commands from the capacitive and EOG modalities was also not systematically evaluated. This aspect should be addressed in future experiments because multimodal systems require explicit command-priority and conflict-management rules under concurrent user inputs. Debounce behavior, command duration, release conditions, and emergency-stop behavior likewise require dedicated evaluation.

The next experimental stage will quantify the performance of each functional link identified in the present pilot study. For the EOG modality, the planned protocol will include repeated labeled trials with predefined ground-truth commands and multiple participants, enabling the calculation of accuracy, sensitivity by direction, confusion matrices, false activations per unit time, missed commands, and response time. The influence of blinking, spontaneous eye movements, and signal artifacts will also be investigated.

For the inertial modality, future experiments will characterize angular drift and estimation error over time and will investigate the relationship between the selected operational threshold and user posture. If necessary, sensor-fusion methods combining gyroscope and accelerometer information will be evaluated. The adopted $\pm 50^{\circ}$ threshold will be treated as an experimentally adjustable parameter rather than as a clinically or ergonomically validated safety limit.

For the communication layer, future tests will measure end-to-end latency, jitter, packet loss, reconnection behavior, and effective stop time after communication interruption. Because the present prototype uses QoS 0 and a public broker only for proof-of-concept bench testing, future implementations will investigate local or authenticated communication, command expiration, sequence control, and additional fail-safe mechanisms appropriate to a motorized assistive device.

Finally, controlled experiments will progressively move from laboratory characterization to multi-participant evaluation and, subsequently, to tests of the integrated system under realistic wheelchair operating conditions. This staged approach is intended to provide increasingly strong evidence regarding robustness, usability, practical applicability, and safety without attributing conclusions to the current pilot study that the available data cannot support.

IV. Conclusion

This work presented the initial development and pilot functional evaluation of a multimodal human–machine interface for assistive wheelchair control based on electrooculography,

capacitive sensing, inertial sensing, MQTT communication, and H-bridge motor actuation.

The preliminary experiments demonstrated the functional integration of the sensing, processing, communication, and motor-actuation modules under controlled bench conditions. The results obtained in this stage were intentionally analyzed qualitatively, with the primary purpose of verifying the expected operation of the proposed architecture and identifying aspects requiring further experimental investigation.

Because the present study represents an initial pilot stage, the results should not be interpreted as quantitative validation of classification performance, usability, wheelchair navigation, or safety. The EOG evaluation involved a single author-participant, while communication performance, false-activation rates, response time, inertial-estimation error, and motor performance were not systematically quantified.

Future work will focus on the quantitative characterization of the proposed system through repeated labeled experiments, multiple participants, objective classification and false-activation metrics, response-time measurements, communication-performance analysis, inertial-estimation characterization, and controlled experiments under progressively more realistic wheelchair operating conditions. This staged approach is intended to progressively evaluate the robustness, usability, and practical applicability of the proposed multimodal interface.

***Abstract*—This study presents the design and proof-of-concept evaluation of a non-immersive virtual tour system integrated with a smart cycle ergometer for pulmonary rehabilitation of patients with chronic respiratory diseases (CRDs). The platform combines a retrofitted ergometer, a wireless pulse oximeter, and an ESP32-based embedded system to acquire mechanical (speed, distance, power) and physiological (heart rate, oxygen saturation) data, synchronizing them with a first-person virtual route displayed on an external screen. A dual Bluetooth architecture (BLE and HM-10) supports simultaneous acquisition and transmission, complemented by a fault-tolerance mechanism that preserves mechanical data streaming during sensor disconnections. A technical evaluation with healthy volunteers assessed data continuity, communication stability, and recovery after simulated sensor failures, showing reliable multimodal acquisition and stable synchronization. As an early-stage proof of concept with healthy participants, no clinical claims are made, but the results establish a technical foundation for future clinical validation of interactive rehabilitation systems for CRD patients.**

***Index Terms*—IoT, cyclo ergometer, proof-of-concept, pulmonary rehabilitation**

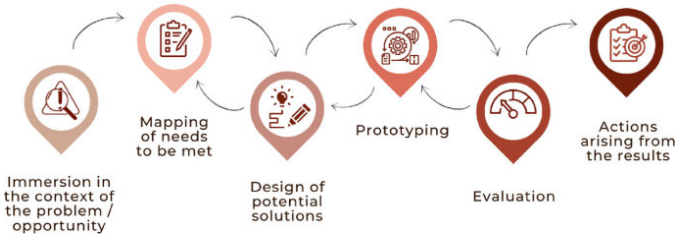
I. INTRODUCTION

Chronic respiratory diseases (CRDs), including chronic obstructive pulmonary disease (COPD), interstitial lung disease, bronchiectasis, and chronic asthma, represent leading causes of death and disability worldwide [1]. COPD alone is recognized as the third leading cause of death globally, with approximately 24% of patients dying within five years of diagnosis [2], [3]. These conditions progressively impair lung function, exercise tolerance, and quality of life, creating a substantial and growing healthcare burden [2], [4], [3]. This scenario has also motivated international initiatives focused on digital health solutions for chronic respiratory conditions. One example is MULTIPULM, a Horizon Europe-funded project that aims to implement an integrated digital care ecosystem for multimorbid patients with chronic respiratory conditions in Brazil, Serbia, and Türkiye [5]. Although the system proposed in this study was developed independently from MULTIPULM, part of the research group involved in this article also participates in the consortium, reinforcing the alignment of this work with broader international efforts in

remote monitoring, patient engagement, and digital support for respiratory care.

Pulmonary rehabilitation (PR) has been established as a cornerstone in the management of CRDs. There is robust evidence that well-structured PR programs incorporating aerobic exercise, muscular strength training, and respiratory techniques significantly improve exercise capacity, reduce dyspnea, and enhance health-related quality of life [6], [2], [1], [3]. Specifically, exercise modalities such as cycling on stationary ergometers have been widely employed as effective tools for endurance training within PR programs [7], [1], [8]. However, despite these well-documented benefits, PR programs face persistent challenges related to patient accessibility, adherence, and motivation, which remain major barriers to successful outcomes [1], [3]. Fear of activity-triggered breathlessness, monotony of conventional exercise routines, and limited access to rehabilitation facilities contribute to low participation and high dropout rates [4], [3].

In recent years, virtual reality (VR) technology has emerged as a promising complementary approach to address these challenges. VR can be broadly classified into two categories: immersive VR, which utilizes head-mounted displays (HMDs) to fully envelop the user in a virtual world, and non-immersive VR, which presents virtual environments on external displays such as computer screens or television monitors without fully isolating the user from the real world [9], [10], [11]. Both modalities offer the capacity to create engaging environments that can shift patients' attention away from negative sensations such as fatigue and dyspnea during physical activity [6], [2], [4]. Studies have demonstrated that VR-based interventions can enhance patient motivation, increase exercise enjoyment, and improve treatment compliance [2], [9], [4]. The integration of VR with exercise training has shown significant improvements in exercise tolerance, lung function parameters such as FEV1/FVC, and psychological outcomes including reduced anxiety and depression in patients with COPD [2], [3].



While immersive VR systems using HMDs have received considerable research attention, non-immersive approaches present distinct advantages for clinical rehabilitation populations. Immersive VR headsets generate noticeable heat during use, which, paired with physical exertion, can quickly become uncomfortable for participants [12]. Furthermore, immersive VR carries a significantly greater risk of simulator sickness, including nausea, headaches, and dizziness, compared to non-immersive alternatives [13], which may be particularly problematic for patients with CRDs who already experience respiratory distress. Non-immersive VR systems, which display virtual environments on television screens or projected displays positioned in front of the exercising patient, have demonstrated comparable benefits in terms of engagement and distraction while avoiding these adverse effects [10], [14], [15]. Historically, the combination of cycle ergometers with non-immersive virtual environments displayed on monitors has been explored since the mid-1990s, when early proof-of-concept systems used screens positioned in front of stationary bikes to present interactive virtual scenarios [10]. More recently, post-COVID-19 rehabilitation programs have successfully employed cycle ergometers synchronized with projected video simulations of outdoor cycling displayed on 75-inch television screens, with patients rating this modality among the highest-valued rehabilitation components [14], [7].

Despite these advances, the integration of smart cycle ergometers with virtual tour experiences specifically designed for non-immersive pulmonary rehabilitation of patients with CRDs remains underexplored. Most existing VR systems have focused on upper limb recovery, balance, or cognitive training, with cycling-based cardiorespiratory training receiving comparatively less attention [15]. This article presents the development and evaluation of a proof-of-concept system integrating a smart cycle ergometer with a non-immersive virtual tour application, displayed on a television screen and synchronized with the user's pedaling cadence. By combining real-time physiological monitoring, adaptive exercise parameters, and interactive virtual tours, the proposed architecture aims to mitigate well-documented drawbacks of head-mounted devices—such as cybersickness and thermal discomfort—while providing an accessible setup for pulmonary care. Therefore, this study focuses on the design, implementation, and engineering validation of the solution architecture, evaluating communication stability and integration among its core components.

II. METHODOLOGY

The project, from its conception to the production of this paper, was grounded in the Interdisciplinary Method for Technological Research Development with a Focus on Health (MIDTs), proposed by Vasconcelos et al. (2026). This methodology consists of six cyclical and iterative development steps, as described in Figure 1.

Fig. 1. MIDTs simplified flow

Source: Vasconcelos et al. (2026).

A. Problem Understanding

The first stage aimed to understand the rehabilitation context and identify opportunities for technological support in the care of patients with chronic respiratory diseases. This stage was based on discussions with physiotherapy professionals and a review of the literature on pulmonary rehabilitation, cycle ergometer-based exercise, patient adherence, and the use of virtual reality resources in rehabilitation.

The analysis indicated that stationary cycling is a widely used strategy in pulmonary rehabilitation because it supports controlled aerobic training and can be adapted to different functional capacities. However, conventional cycling sessions

may become repetitive and poorly engaging, which can negatively affect adherence and continuity of rehabilitation. Therefore, the use of a non-immersive virtual environment synchronized with pedaling cadence was defined as a strategy to increase engagement without exposing users to the discomfort and cybersickness risks associated with head-mounted displays.

In addition, the problem understanding stage highlighted the need for real-time physiological monitoring during exercise, especially for patients with respiratory limitations. Thus, the proposed system was designed to combine exercise interaction, visual feedback, and the acquisition of physiological and mechanical variables relevant to pulmonary rehabilitation.

B. Requirements

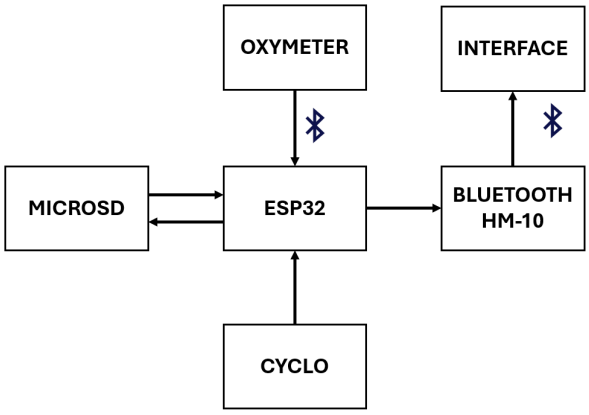
After defining the problem, the project requirements were established from three complementary perspectives: clinical monitoring, hardware integration, and interactive feedback. From the clinical perspective, the system should monitor variables commonly used during supervised exercise sessions, including peripheral oxygen saturation, heart rate, pedaling speed, exercise time, and estimated power.

From the hardware perspective, the system should acquire data from both the cycle ergometer and the pulse oximeter, process these signals through an embedded system, and transmit them wirelessly to the interactive interface. The prototype should also include local data storage to preserve session records and support future analysis.

From the software perspective, the interface should display the virtual tour and real-time exercise data in a clear and minimally disruptive way. The visual environment should progress according to the user's pedaling cadence, creating a direct relationship between physical effort and movement through the virtual route. The interface should also display physiological and mechanical indicators, allowing the user or supervising professional to monitor the activity without interrupting the exercise.

Based on these requirements, the proof of concept focused on four core functions: acquisition of physiological data, estimation of mechanical variables, wireless communication between hardware and interface, and synchronization between pedaling cadence and virtual tour progression.

C. System Design



The system architecture was designed to integrate three main components: an adapted cycle ergometer, a pulse oximeter for physiological monitoring, and a web-based non-immersive virtual tour interface. The ESP32 microcontroller was selected as the embedded processing unit due to its low cost, compact size, processing capacity, and native support for Bluetooth Low Energy communication.

A central design requirement was the need to handle two simultaneous Bluetooth-based communication flows. The first flow involved receiving physiological data from the pulse oximeter through BLE, including heart rate and peripheral oxygen saturation. The second flow involved transmitting the processed mechanical and physiological data from the embedded system to the web interface. To support this dual communication architecture, an additional HM-10 Bluetooth module was incorporated into the system. In this configuration, the ESP32 was responsible for communicating with the pulse oximeter via BLE, while the HM-10 module provided a dedicated Bluetooth communication channel between the embedded system and the interface.

The mechanical data acquisition subsystem was designed to estimate pedaling speed and power. A magnetic sensor was used to detect pedaling pulses and estimate angular velocity, serving as the basis for calculating speed and generated power. The sensor was also calibrated using a tachometer to improve the accuracy of the estimates. Torque was estimated through testing, and power was derived indirectly from the relationship between torque and speed. A low-cost methodology was employed to calculate these parameters [16].

The data flow was organized so that mechanical variables captured from the cycle ergometer and physiological variables received from the oximeter could be processed by the embedded system and transmitted to the web interface through the HM-10 communication channel. This architecture separated the acquisition and transmission tasks, reducing communication conflicts and supporting real-time visualization during exercise. The architecture also included a MicroSD module for local backup storage, allowing session data to be preserved even in the event of communication instability. The conceptual architecture of the proposed system is presented in Figure 2.

Fig. 2. System architecture and data flow between the cycle ergometer, oximeter, embedded system, HM-10 module, and web interface.

D. Prototype Development

The prototype was developed by integrating the embedded hardware, firmware, and interactive web interface. In the hardware module, the pulse oximeter was connected to the ESP32 through Bluetooth Low Energy to acquire oxygen saturation and heart rate data. The cycle ergometer was adapted with

a magnetic sensor to acquire pedaling information, allowing the estimation of speed and power. The power estimation method was based on a previous study developed by the research group, in which pedaling power was calculated from the relationship between angular velocity and torque in an adapted cycle ergometer [16].

The firmware was implemented to process the mechanical data from the cycle ergometer and combine them with the physiological data received from the oximeter. These data were organized into structured packets and transmitted to the web interface through the HM-10 Bluetooth module. A printed circuit board was also designed to organize the components, improve connection stability, and support more reliable testing.

The interface was developed using HTML5, CSS3, and JavaScript. Communication between the hardware and the browser-based interface was implemented using the Web Bluetooth API, enabling the direct reception of Bluetooth data packets by the web application. This approach was selected to reduce dependence on local network infrastructure and to minimize latency fluctuations that could affect the synchronization between pedaling and the visual experience.

The interactive interface was implemented to display a first-person non-immersive virtual tour and real-time indicators of exercise performance and physiological status. The estimated speed was used to control the progression of the virtual route, while power, oxygen saturation, heart rate, and elapsed time were organized as visual indicators on the exercise screen. Initially, two virtual routes were developed: one representing Fortaleza, Brazil, where the system was developed, and another representing Novi Sad, Serbia, a partner country in the MULTIPULM project. These routes were selected to demonstrate the flexibility of the system in incorporating different geographic and contextual scenarios into the rehabilitation experience. The developed interface and its operation are presented in the Results section.

E. Evaluation

The technical evaluation was conducted as a proof-of-concept test with six healthy participants, with a mean age of 21 ± 2 years. The evaluation aimed to verify the feasibility of the integrated system in terms of data acquisition, real-time visualization, communication stability, and fault tolerance, without assessing clinical or therapeutic outcomes.

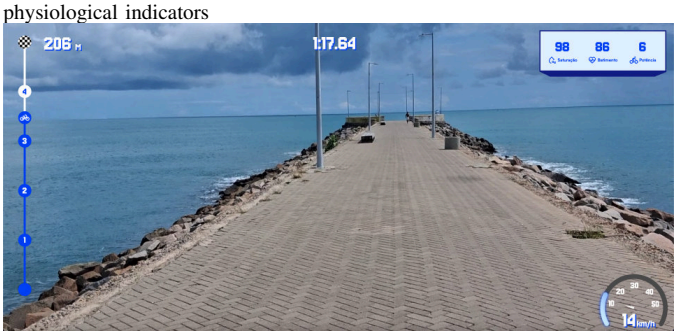
The web-based interface was developed as a localhost application, operating exclusively within a controlled local environment without external network dependencies. This architecture allowed for direct and predictable communication between the hardware and the interface throughout all testing sessions.

Each participant performed a standardized five-minute session on the adapted cycle ergometer while using a fingertip pulse oximeter, following a predetermined and identical virtual route across all participants. During the session, all participants were instructed to exercise at their maximum sustainable effort to ensure consistent exercise intensity throughout the testing protocol. Participants were informed of this objective before each session, and the interface continuously displayed their current speed to enable real-time monitoring of their performance. Since the objective was to evaluate the technical behavior of the system under standardized conditions, the route was not considered as an experimental variable, but rather as a controlled element to ensure reproducibility across all testing sessions.

During the sessions, the system collected mechanical variables from the cycle ergometer, including elapsed time, distance, speed, and estimated power, as well as physiological variables from the pulse oximeter, including peripheral oxygen saturation and heart rate. These data were transmitted to the web interface and displayed in real time. The oximeter readings were also manually checked throughout the tests and compared with the values shown on the platform to verify consistency between the source device and the interface.

Beyond the participant trials, three independent 15-minute tests were conducted strictly to monitor the hardware-interface connection stability and quantify data packet loss. Furthermore, the recorded sessions were analyzed for signal continuity, the presence of missing values, and possible communication interruptions between the cycle ergometer, the oximeter, and the interface.

Finally, an additional fault-tolerance test was performed by temporarily removing the pulse oximeter from the participant's finger and then repositioning it. This procedure simulated a transient disconnection of the physiological signal and was used to verify whether the system could detect the interruption, preserve the mechanical data stream, and automatically resume heart rate and oxygen saturation monitoring after reconnection without requiring a new session.



III. RESULTS

A. Presentation of the Integration

The proposed prototype is an integrated non-immersive virtual tour system connected to an adapted cycle ergometer and a pulse oximeter. It enables users to pedal while following a first-person virtual route displayed on an external screen, with the progression of the route synchronized with the pedaling speed estimated from the cycle ergometer.

Figure 3 presents the developed interface during the virtual tour. The central area of the screen displays the first-person route, while real-time indicators are arranged around the visual field to support continuous monitoring without interrupting the activity. The interface displays mechanical parameters, including elapsed time, estimated speed, distance, and pedaling power, together with physiological indicators, namely peripheral oxygen saturation (SpO_2) and heart rate. These elements satisfy the functional requirements previously established for the prototype, particularly the simultaneous visualization of exercise performance and physiological status.

Fig. 3. Non-immersive virtual tour interface with real-time mechanical and physiological indicators

Two initial virtual routes were implemented: one representing Brazil, where the system was developed, and another representing Serbia, a partner country in the MULTIPULM project. The interface also includes a random route selection option. These alternatives demonstrate the flexibility of the system to incorporate different geographic contexts into the rehabilitation experience. To ensure reliability during these sessions, the interface includes an alert system (Figure 4) that notifies users when sensor disconnections occur, allowing participants to remain aware of system status without interrupting their exercise.

Fig. 4. Non-immersive virtual tour interface with real-time mechanical and physiological indicators with component disconnection alerts

When a sensor disconnection occurs, the interface displays three warning indicators in the upper-right corner. Each orange icon signals the unavailability of a specific parameter: Saturação (SpO_2), Batimento (heart rate), and Potência (power output). When this happens, the system continues to record mechanical data normally. Physiological measurements are marked with a sentinel value (-1) until the sensor automatically reconnects.

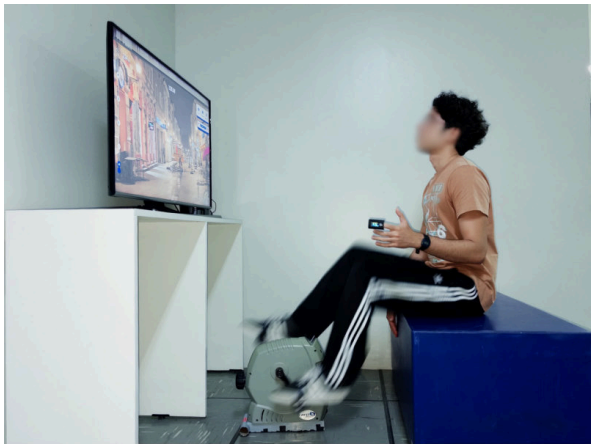


Figure 5 shows the prototype during the proof-of-concept evaluation. Panel (a) presents a focused side view of the participant pedaling while wearing the pulse oximeter, whereas panel (b) shows a broader view of the system and the interaction with non-immersive VR. Together, these views illustrate the intended use scenario, in which the participant remains physically engaged in the cycling activity while receiving real-time visual feedback from the simulated route.

The evaluation aimed to verify whether the prototype could operate as an integrated system under realistic conditions. The following analyses address real-time data acquisition, synchronization between mechanical and physiological measurements, communication stability, consistency of the acquired signals, and system behavior during a simulated temporary disconnection of the pulse oximeter.

Fig. 5. Prototype operation during the proof-of-concept test: (a) side view of the participant using the adapted cycle ergometer; (b) broader view showing the participant's interaction with the virtual tour interface.

(b)

B. Real-Time Data Acquisition and Synchronization

During the testing sessions, the system continuously recorded telemetry data from both the cycle ergometer and the pulse oximeter, enabling a practical evaluation of the integration between the hardware modules and the web interface. Table I presents a representative subset from one session on the Brazil route, which illustrates the structure of the transmitted data packets, while the final row summarizes the average values computed over the complete session.

TABLE I
REAL-TIME DATA COLLECTION SAMPLE AND AVERAGES

In addition to the sample presented above, the overall characteristics of the test sessions were quantified to evaluate the system under continuous operation. Table II summarizes the global and communication-related metrics observed across all five-minute sessions performed during the proof-of-concept evaluation, providing an overview of the robustness of the data acquisition pipeline.

TABLE II
QUANTITATIVE SUMMARY OF THE TEST SESSIONS

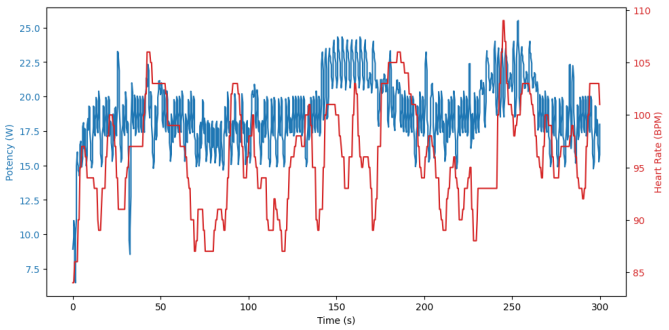
Metric	**Result**
Selected Routes	*brazil* and *servia*
Total Duration (per session)	5 minutes (5:00.00)
Local Packaging Cadence	∼120 ms (interface sampling tick)
BLE Telemetry Update Interval	∼508 ms (min. 468, max. 561 ms)
Total Data Records	12,503 records across 6 sessions (∼2,500 each)
Missing Physiological Values	288 records (∼2.3% of samples)
Successful Data Capture Rate	∼97.7% (mechanical stream: 100%)

Analysis of Simultaneous Recording

Across the six complete sessions, mechanical (speed, distance, and power) and physiological (oxygen saturation and heart rate) measurements were consistently recorded within the same integrated data packet, using a local sampling cadence of approximately 120 ms. Because both data streams are timestamped and merged before transmission to the interface, no temporal drift or synchronization offset was observed between them. These results demonstrate that the embedded architecture can process data from the cycle ergometer and the pulse oximeter concurrently, without one acquisition stream blocking or delaying the other.

Analysis of Transmission and Telemetry Gaps

Unlike the mechanical measurements, which were successfully captured in 100% of the records, the physiological measurements (SpO_2 and heart rate) exhibited brief, isolated gaps in two of the six sessions, accounting for approximately 2.3% of the total samples. These interruptions appeared as short sequences of zero-valued samples, consistent with transient signal loss from the fingertip pulse oximeter rather than a system-level failure, since the mechanical data stream remained uninterrupted throughout the same intervals. This behavior anticipates the fault-tolerance mechanism discussed later in the Reliability of the Data subsection, in which the application represents the temporary absence of physiological data using a sentinel value while preserving uninterrupted acquisition of the mechanical measurements.



Regarding communication timing, the local packaging interval remained stable at approximately 120 ms, whereas the BLE telemetry link updated every 508 ms on average (ranging from 468 to 561 ms), consistent with the communication stability analysis presented later in this section. No unexpected disconnections, packet losses, or processing delays capable of compromising the real-time visual feedback loop were observed beyond the isolated pulse oximeter dropouts described above. Overall, the system achieved a physiological data capture rate of approximately 97.7%, while maintaining uninterrupted acquisition of the mechanical data stream throughout all test sessions.

C. Consistency of Physiological and Mechanical Data

In addition to confirming the simultaneous acquisition of mechanical and physiological measurements, it is also important to evaluate whether the recorded signals exhibited behavior consistent with the exercise being performed. Figure 6 illustrates the relationship between the cycle ergometer's estimated power output and the participant's heart rate during a representative session. As expected, heart rate increased during periods of greater mechanical effort and decreased as the exercise intensity was reduced.

As the evaluation involved healthy volunteers performing a short, non-standardized exercise protocol, these observations should be interpreted solely as evidence that the proposed system can continuously acquire, synchronize, and display mechanical and physiological signals during exercise. They are not intended to demonstrate clinical effectiveness or improvements in cardiovascular performance.

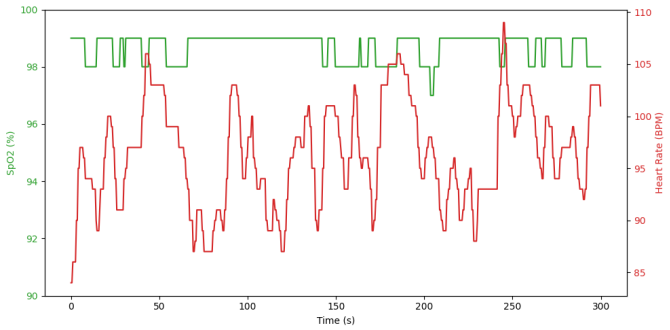


Fig. 6. Mechanical Effort vs. Physiological Response

To further demonstrate the continuity of the physiological data stream, Figure 7 presents the temporal evolution of SpO_2 and heart rate for a representative participant throughout the entire session. Oxygen saturation remained within a stable range during exercise, whereas heart rate varied continuously in response to pedaling effort, without abrupt jumps, prolonged flat segments, or discontinuities that would suggest stalled or

repeated measurements. These results indicate that the interface successfully captured and displayed the natural temporal variation of both physiological signals, rather than freezing or interpolating values during data acquisition.

Fig. 7. Temporal Evolution of SpO_2 and Heart Rate (BPM)

To ensure the reliability of the data displayed on the web interface, the researchers periodically compared these values with the pulse oximeter throughout the testing sessions. These manual comparisons consistently confirmed agreement between the displayed and source measurements in real time, with no discrepancies beyond the expected latency of the BLE communication. This evaluation demonstrates the technical fidelity of the data transmission pipeline; however, no claims are made regarding the clinical significance of the observed physiological responses, since the participants were healthy volunteers performing a short proof-of-concept evaluation rather than a clinical rehabilitation protocol.

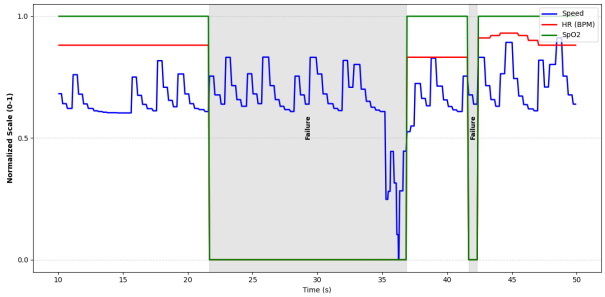
D. BLE Communication Latency

During the independent 15-minute extended stability tests, the system maintained a highly stable telemetry stream, successfully receiving 99.73% of the expected data packets (representing a minimal average packet loss of only 0.27%). Notably, two of the three extended sessions exhibited absolute continuity with 0% packet loss, with all minor disconnections isolated to a single session.

To evaluate the stability of the wireless communication, the inter-packet interval of the BLE telemetry was analyzed for the six participants who completed a full session. Table III summarizes the mean, standard deviation, minimum, and maximum latency observed for each participant, together with the aggregated results across all sessions.

The packets were received within a narrow interval around the nominal BLE update period of 500 ms for most of the participants, with maximum latencies not exceeding 561 ms and standard deviations below 15 ms. These results indicate a highly stable communication cadence, with no other evidences of packet loss or connection instability during normal operation apart from a single latency spike of 1030 ms, observed during DA's session. As discussed in the following subsection, this event coincided with the intentional temporary removal of the pulse oximeter and therefore does not represent a communication failure under normal operating conditions.

TABLE III
BLE Inter-Packet Latency by Participant



Participant	Packets	Mean (ms)	Std. Dev. (ms)	Min (ms)	Max (ms)
AN	591	508.6	11.1	459	551
ES	591	509.1	13.7	470	555
JV	590	509.1	13.8	471	541
DA	589	509.3	26.2	470	1030
VA	591	508.0	13.4	470	550
YA	591	507.9	14.1	468	561
Aggregated	**3537**	**508.7**	**16.1**	**459**	**1030**

The participants's names were ommited for privacy purposes.

E. Fault Tolerance During Simulated Oximeter Disconnection

To evaluate the fault tolerance of the proposed architecture, the pulse oximeter was intentionally removed from the participant's fingertip during one session and subsequently repositioned, simulating a temporary loss of the physiological signal. As illustrated in Figure 8, the application maintained normal operation throughout the event. As soon as valid oximeter readings became unavailable, the system automatically assigned a reserved sentinel value (-1) to the physiological variables while continuing to acquire and display the mechanical measurements (speed, distance, and power) without interruption or reduction in the sampling rate. Once the pulse oximeter was repositioned, SpO_2 and heart rate measurements resumed automatically, demonstrating that the system could recover autonomously without requiring user intervention or a restart of the exercise session.

Fig. 8. Behavior of Speed, HR, and SpO_2 During a Simulated Connection Failure

These results demonstrate that the proposed architecture remains operational during temporary physiological signal loss, an important requirement for pulmonary rehabilitation systems. As patients with chronic respiratory diseases frequently experience dyspnea and early fatigue [2], [4], unexpected monitoring interface interruptions could negatively affect exercise continuity and patient adherence. The adopted fault-tolerance strategy isolates communication failures by assigning a sentinel value (-1) to unavailable physiological measurements while preserving acquisition and visualization of the mechanical data stream. Consequently, the rehabilitation session proceeds normally until the physiological signal is restored, avoiding unnecessary exercise interruption due to temporary sensor disconnections.

It should be emphasized that the present evaluation focused exclusively on validating the technical reliability and integration of the proposed system using healthy participants. Clinical aspects, including adaptive adjustment of exercise intensity based on physiological feedback, patient-reported usability, comfort, and rehabilitation outcomes, were beyond the scope of this proof-of-concept study and should be investigated in future clinical trials involving individuals with chronic respiratory diseases.

IV. CONCLUSION

This study presents the design and proof-of-concept evaluation of an integrated system for pulmonary rehabilitation that combines an adapted cycle ergometer, a pulse oximeter, and a non-immersive virtual tour interface. By integrating mechanical and physiological monitoring into a single platform, the proposed architecture enables synchronized data acquisition and real-time visualization, providing an interactive environment to support rehabilitation sessions.

The technical evaluation demonstrated that the system could reliably acquire, synchronize, and transmit multimodal data throughout exercise while maintaining stable BLE communication and continuous visual feedback. Furthermore, the proposed fault-tolerance mechanism preserved uninterrupted acquisition and visualization of the mechanical data stream during temporary pulse oximeter disconnections and automatically resumed physiological monitoring once the sensor was repositioned, without requiring user intervention. These results demonstrate the technical feasibility and robustness of the proposed architecture, establishing a solid foundation for future pulmonary rehabilitation systems that combine real-time physiological monitoring with interactive virtual environments.

This study, however, represents a technical proof of concept. The evaluation was conducted exclusively with healthy volunteers and was not intended to assess clinical efficacy, patient adherence, or rehabilitation outcomes. Therefore, no conclusions can be drawn regarding the therapeutic benefits of the proposed system for individuals with chronic respiratory diseases.

Future work will focus on integrating cloud-based data storage to enable longitudinal monitoring, implementing remote supervision tools for physiotherapists, calibrating and comparing the system against standard cycle ergometers and oximeters, and conducting clinical studies involving patients with chronic respiratory diseases. These studies will investigate usability, patient engagement, safety, and the efficacy of the proposed system in real-world pulmonary rehabilitation programs.

ACKNOWLEDGMENT

The team would like to thank the University of Fortaleza (UNIFOR) and the Vortex Laboratory for the opportunity, and especially professors Natália Bitar da Cunha Olegario and Joel Sotero da Cunha Neto, as well as Jonatas Silva Pereira, for supervising the development of this project.

***Abstract*— Wheelchair prescription depends on functional, postural, and environmental analysis. A recurrent difficulty in this process is anticipating whether a wheelchair will be compatible with the patient's home before the device is delivered or adapted. This paper presents a visual-interactive prototype developed in Unreal Engine 5 to support environmental analysis during wheelchair prescription planning. The system allows physiotherapists to create simplified residential layouts, insert and reposition objects, switch between patient-centred and caregiver/conductor views, and navigate the environment using a simulated wheelchair. The prototype integrates wheelchair control, environment editing, object manipulation, and an inventory of furniture and structural elements. Initial requirements were guided by physiotherapy collaborators in the project team, and preliminary functional verification focused on navigation, object positioning, view switching, collision behavior, and interaction consistency. The current version does not replace clinical assessment and has not yet been validated in real homes or with patients. Rather, it demonstrates preliminary technical feasibility as a visual support tool for testing spatial configurations and observing possible environmental constraints during prescription planning.**

***Keywords*—** Wheelchair Prescription, Virtual Reality, Unreal Engine 5, Rehabilitation Engineering, Assistive Technology

I. INTRODUCTION

Wheelchair prescription is a multidisciplinary process that considers the user's physical condition, posture, mobility needs, and daily environment. The choice of an inadequate wheelchair can reduce comfort, independence, and accessibility, and may also contribute to secondary problems related to posture and mobility use [1-3]. For this reason, the prescription process cannot be limited to the device itself. It also requires attention to how the wheelchair will be used in the places where the patient performs daily activities.

A practical challenge in this process is the relation between the wheelchair and the patient's home. Door widths, corridors, furniture placement, turning areas, and circulation spaces can determine whether a wheelchair is usable in daily routines. These conditions are usually assessed through measurements, photographs, visits, or patient reports. Although these procedures are useful, they are mostly static. They may indicate that a corridor has a certain width, but they do not necessarily show how a wheelchair behaves while turning, entering a room, or avoiding furniture [2].

Virtual reality and real-time simulation have been used in rehabilitation and assistive technology because they allow interaction with controlled and repeatable scenarios [4], [5]. Wheelchair simulators have also been proposed for navigation training, driving assessment, and evaluation of user

This work was developed using resources obtained from the Financiadora de Estudos e Projetos (FINEP) – Ref. Finep nº 2174/22.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

performance [6-8]. These studies are important because they show that virtual environments can reproduce mobility tasks without exposing users to the same risks found in real environments.

However, many wheelchair simulation systems focus on the wheelchair user as the main participant. Their usual goal is to train driving skills, measure performance, or study interaction in immersive environments. The problem addressed in this work addresses a different problem. During prescription planning, the physiotherapist needs to reason about the relation between the device and the patient environment before final decisions are made. In this context, the system must support layout construction, object manipulation, and quick testing of different spatial configurations.

II. RELATED WORKS

Virtual environments have been widely explored for wheelchair training and mobility assessment. Vailland et al. [6] evaluated a VR-based power wheelchair simulator with regular users, while Bigras et al. [7] studied augmented feedback during powered wheelchair simulator training. These works show that simulation can be useful for safe practice and for analyzing aspects of wheelchair performance.

Other studies focused on realism, usability, and user experience. Riera et al. [8] developed a haptic virtual walker for wheelchair users in immersive environments. Chaar and Archambault [9] evaluated a low-cost virtual reality simulator for manual wheelchair training and emphasized usability issues that must be considered in this type of system. Salgado et al. [10] presented a multimodal dataset from an immersive wheelchair simulator, including physiological and questionnaire-based data. These works indicate that interaction quality and user comfort are relevant aspects when virtual simulators are applied to rehabilitation.

Some studies also move closer to accessibility evaluation. Monteiro et al. [11] proposed a virtual wheelchair accessibility evaluation tool capable of capturing trajectory and time metrics. Systematic reviews have discussed the use of virtual reality to complement wheelchair skills training and broader rehabilitation activities [12], [13]. These studies point to the value of simulation, but also show that validation protocols and clinical use cases are still developing.

The present work uses this literature as a technical reference, but targets a different use case. The objective is not to train the wheelchair user or to measure driving performance as the main outcome. The focus is to provide the physiotherapist with an editable environment that can represent the patient's home and support prescription planning. This difference guided the selection of the implemented features, especially the editing mode, inventory system, user-configurable obstacles, and the transition between patient-centered and caregiver/conductor views.

III. MATERIALS AND METHODS

A. Functional Requirements and Scope

The system was developed in Unreal Engine 5.5.1. The engine was selected because it supports real-time rendering, collision handling, view switching, and visual scripting through Blueprints. GitHub was used for version control and organization of implementation tasks. Blender was also used during asset preparation and 3D modeling activities.

The initial functional requirements were defined through iterative discussions within the development team and with the physiotherapy collaborators involved in the project. These discussions were used to identify the main environmental and interaction features considered important for the initial prototype.The requirements included the presence of walls, doors, windows, tables, chairs, cabinets, and a user-configurable object that could represent obstacles or other elements found in a patient's home.

Another requirement was the possibility of switching between the view of the wheelchair user and the view of the person conducting or assisting the patient. In the implementation, this mechanism was created using camera resources available in Unreal Engine 5, but in the clinical description of the system it is treated as user-type view switching. This distinction is important because the purpose is not to describe camera technology itself, but to provide different viewpoints for navigation, inspection, and discussion of spatial configurations.

The current version was defined as a visual-interactive prototype. It does not yet incorporate formal accessibility standards as automatic constraints, and the virtual scenarios were not built from real residential measurements. Therefore, the prototype should be understood as a platform for testing the interaction workflow and the feasibility of environmental simulation, not as a validated accessibility measurement tool.

B. Development Process and System Architecture

The development process followed an iterative approach. First, the project focused on studying wheelchair prescription, rehabilitation environments, and accessibility requirements. In parallel, Unreal Engine resources were studied, including interaction systems, view control, collision behavior, and possibilities for future VR integration.

The prototype is organized into four main modules: the virtual environment module, the wheelchair simulation module, the environment editing module, and the inventory module. The virtual environment represents the residential layout. The wheelchair module controls navigation and basic collision with objects. The editing module allows objects and structural elements to be modified during execution. The inventory module stores and instantiates furniture and other elements used to build the simulated home.

The system was planned to work in two basic modes: navigation and editing. In navigation mode, the user controls the wheelchair and observes its interaction with the environment. In editing mode, the user changes the scene by inserting, moving, rotating, or resizing objects. The same

environment can be adjusted and tested repeatedly. Fig. 1 summarizes the main modules and the interaction flow.

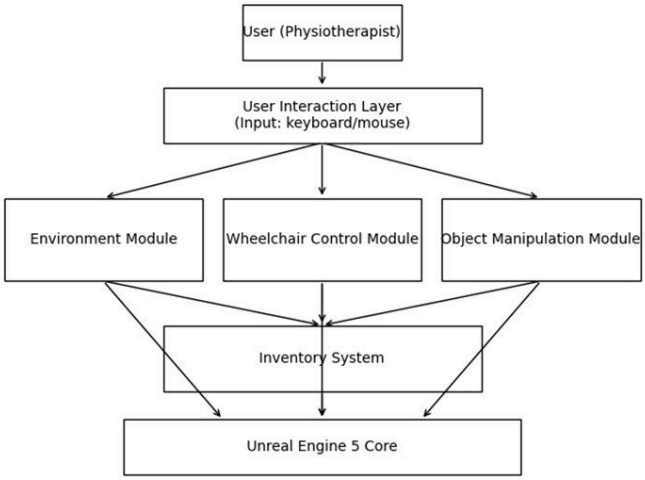

Fig. 1. Overall architecture of the system and interaction between implemented modules .

C. Wheelchair Control and Interaction Model

The wheelchair model is currently controlled by keyboard commands. The W key moves the wheelchair forward, the S key moves it backward, the A key rotates it to the left, and the D key rotates it to the right. This control strategy was adopted to provide a simple and reproducible way to test navigation through the virtual layouts during the prototype stage.

Basic collision detection was implemented for interactions with walls and objects inserted in the scene, including chairs, tables, cabinets, and other elements available through the inventory. This allows the user to observe whether the wheelchair can pass through simplified circulation areas or whether an object blocks the route. However, the current movement model is simplified and does not reproduce the full behavior of a real wheelchair.

At this stage, the system does not include a biomechanical model of the user, a detailed kinematic model of the wheelchair, propulsion effort estimation, automatic turning radius calculation, trajectory analysis, task completion time, or minimum passage width measurement. These functions are planned as future improvements and are necessary before the prototype can be used as an objective accessibility evaluation tool.

D. Virtual Environment and Editing Tools

A virtual indoor environment was created to represent rooms, circulation areas, walls, and furniture placement zones. The environment was intentionally simplified in this version because the main objective was to test the interaction workflow and not to produce a final architectural rendering. The prototype also includes doors, windows, furniture elements, and configurable blocks that can be used to approximate obstacles or structural components of a residence.

After an object is inserted into the scene, the user can reposition it using manipulation controls. As shown in Fig. 2, the object can be translated in different directions and rotated without recreating it. This is useful for testing small layout changes, such as repositioning furniture or changing object orientation to improve wheelchair circulation in the simulated scene.

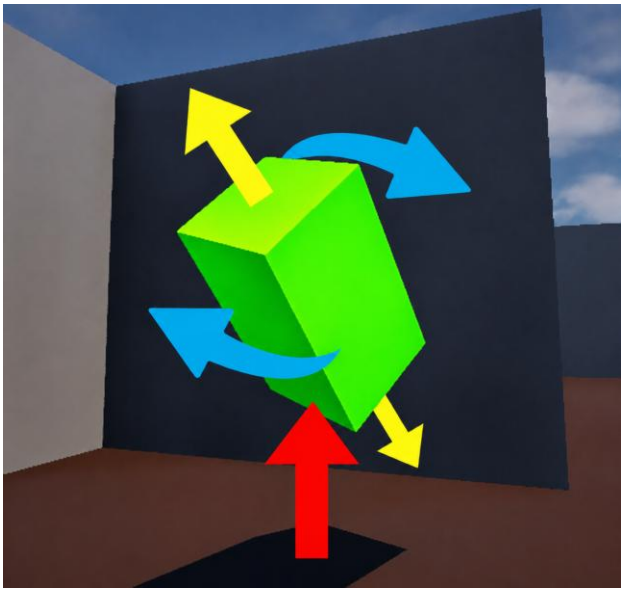

Fig. 2. Object translation and rotation controls used during environment editing.

A modular object generation mechanism was also implemented, allowing the user to create configurable blocks and structural elements at runtime. The purpose is to enable simplified construction of patient-specific layouts without requiring the entire scene to be modeled in advance. Fig. 3 illustrates the object generation and positioning tools available in the system.

Fig. 3. Object generation and positioning tools available within the system.

E. Inventory System and User-Type Views

The inventory system was developed to simplify the insertion of objects into the virtual environment. It contains furniture elements such as tables, chairs, and cabinets, and it can be expanded with new elements in future versions. The user can select an object, instantiate it in the scene, and then adjust its position through the editing tools.

The inventory and editing systems were designed to work together so that the user can insert an object, test wheelchair circulation, change the object position, and test the route again without leaving the simulation. In addition, the user-type view switching mechanism provides both a patient-

centered view and a caregiver/conductor view. These views support inspection of the scene from different perspectives and were included based on feedback from the physiotherapy collaborators

IV. RESULTS

The prototype integrated environment creation, object manipulation, inventory management, user-type view switching, and wheelchair navigation in the same environment. Fig. 4 shows the simplified residential layout used to test the prototype. This scene was not modeled from a real patient's house and does not represent validated residential dimensions. Its purpose is to demonstrate the interaction flow and the main functions implemented in the system.

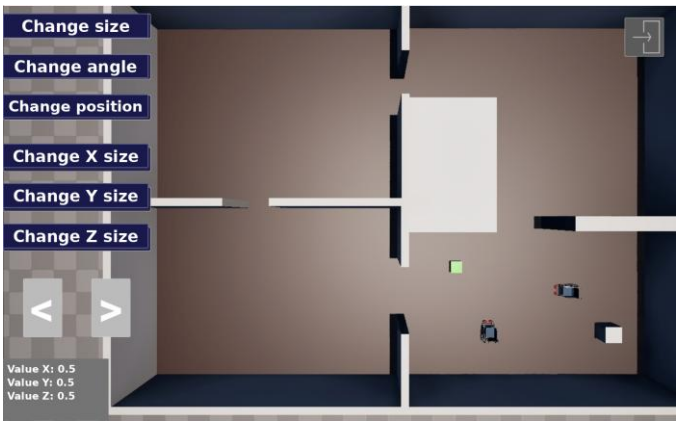

Fig. 4. Virtual environment representing an overview of walls and floor plan of a house developed for the simulation platform.

The view switching mechanism allowed transition between the view of the person conducting or assisting the wheelchair user and the patient-centered view, as shown in Fig. 5. This function was implemented to support both navigation and scene inspection. It does not represent a clinical outcome measure, but it helps the user observe the layout from different perspectives during planning.

Fig. 6 shows the inventory interface and examples of available objects. The implemented inventory allows furniture to be inserted into the scene and adjusted through the editing tools. The current inventory is limited, but it is sufficient for testing the basic workflow of object insertion, repositioning, and repeated navigation.

As a whole, the prototype allows users to create simplified residential layouts, insert furniture from an inventory, move and rotate objects, switch user-type views, and navigate the environment using a wheelchair model. Basic structures such as rooms, walls, corridors, and circulation areas can be modified during execution, enabling rapid layout changes without rebuilding the scene.

The current version does not reproduce all physical aspects of a real wheelchair or generate clinical metrics automatically. Table I summarizes what was functionally verified and what remains outside the current scope.

Fig. 5. Camera switching between patient-centered and companion views.

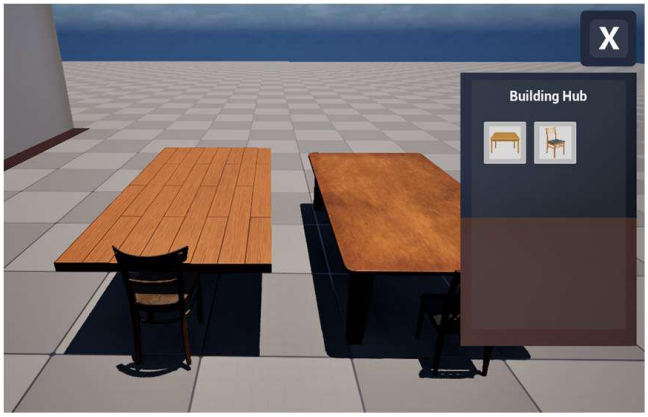

Fig. 6. Inventory interface and examples of available objects

TABLE I. FUNCTIONAL VERIFICATION AND CURRENT SCOPE

Function	*Current implementation*	*Current limitation*
Residential layout	Simplified rooms, walls, doors, windows, corridors, and circulation areas.	No geometric validation with real homes yet.
Object manipulation	Translation, rotation, resizing, and repositioning during execution.	No automatic measurement of distances or clearances yet.
Inventory	Insertion of tables, chairs, cabinets, and structural elements.	Limited object categories.
Wheelchair navigation	Keyboard control (W/A/S/D) with basic collision.	Simplified dynamics; no biomechanical model.
User-type views	Switching between patient-centered and caregiver/conductor views.	Not yet immersive VR.
Accessibility metrics	Not implemented in the current version.	Turning radius, trajectory, time, effort, and passage width remain future work.

V. DISCUSSION

The prototype demonstrates preliminary technical feasibility for a visual-interactive environment aimed at wheelchair prescription planning. Its main purpose is to allow the professional to modify a simplified residential layout and immediately observe how a wheelchair model behaves in that updated space. This is different from claiming clinical validation or objective accessibility assessment, which were not performed in this stage.

Compared with wheelchair simulators focused on user training and driving performance [6], [7], [9], the proposed system gives more emphasis to environmental modification by the clinician. Monteiro et al. [11] presented an accessibility evaluation tool that captures trajectory and time metrics, whereas the current prototype prioritizes scene editing, object inventory, and view switching. Therefore, the differential is not the use of Unreal Engine 5 alone, but the combination of these functions in the same planning workflow.

The participation of physiotherapy collaborators in the project helped define initial requirements, such as the need to represent household elements, model obstacles, and switch between patient-centered and caregiver/conductor views. This involvement supported the design of the prototype, but it should not be confused with formal clinical validation. The system still needs usability testing with physiotherapists, comparison with conventional assessment procedures, and testing based on real residential measurements.

Several limitations remain. The virtual environment is simplified and was not geometrically validated against real homes. The current wheelchair model uses simplified movement and basic collision only. It does not calculate turning radius, minimum passage width, trajectory, time, maneuvering effort, or collision metrics. It also does not include anthropometric models of patients, biomechanical simulation, different commercial wheelchair models, or complex architectural adaptations frequently found in real residences.

Table II compares the main characteristics of the proposed system with those of related wheelchair simulation studies. In this comparison, “VR” refers to immersive virtual reality as described in the corresponding studies. The proposed prototype, in contrast, currently operates as a non-immersive interactive 3D environment. The term “Prescription Planning Support” in the table refers only to visual support for environmental simulation and planning and does not indicate clinically validated decision-making support. Although the current prototype cannot yet determine whether a specific wheelchair model should be prescribed, it supports the identification of potential spatial constraints through visualization.

TABLE II. COMPARISON BETWEEN RELATED WORKS AND THE PROPOSED SYSTEM

Work	*VR Environment*	*Environment Customization*	*Wheelchair Simulation*	*Clinical Prescription Support*
Yang et al. [6]	Yes	No	Yes	No
Bigras et al. [7]	Yes	No	Yes	No
Riera et al. [8]	Yes	No	Yes	No
Chaar and Archambault [9]	Yes	Limited	Yes	No
Monteiro et al. [11]	Yes	Limited	Yes	Partial
Proposed System	Not yet	Yes	Yes	Visual planning only

VI. CONCLUSION

This paper presented a virtual simulation prototype developed in Unreal Engine 5 for environmental analysis during wheelchair prescription planning. The current version allows the user to edit simplified home layouts, manipulate objects, insert elements from an inventory, switch between patient-centered and caregiver/conductor views, and navigate with a simulated wheelchair.

The study demonstrates preliminary technical feasibility of integrating these functions in the same interactive environment. The system is not intended to replace clinical assessment and should not yet be interpreted as a validated prescription tool. Its current contribution is to provide a visual

environment in which spatial configurations can be created, modified, and inspected during planning.

The main lessons from development are that real-time editing, reusable object inventories, and user-type view switching are relevant functions for this type of application. At the same time, the work shows important research gaps: the need for quantitative accessibility metrics, geometric validation with real homes, more realistic wheelchair dynamics, and formal usability studies with physiotherapists.

Future work will focus on enhancing wheelchair movement, adding measures such as turning radius, trajectory, time, collisions, and minimum passage width, expanding the inventory, and testing the system with real residential scenarios. Further studies could also examine how each system module contributes to the overall functionality of the platform, including through controlled ablation experiments. Other possibilities include integration with spatial scanning, mobile devices, immersive virtual reality, augmented reality, and automatic accessibility analysis methods. These steps are necessary before evaluating the clinical utility of the platform in actual prescription workflows.

***Abstract*—We retrospectively assessed the technology readiness and laboratory-scale reproduction cost of a 128-channel heterogeneous wearable edge-computing platform that integrates high-density surface electromyography (HD sEMG) acquisition, flexible embedded processing, and autonomous on-device myoelectric control. The Technology Readiness Level (TRL) assessment covered hardware, software, and functional integration. Offline integrity checks found no missing or empty samples in the analyzed recordings. The platform exhibited acquisition-to-command latencies ranging from 63.3 ± 1.0 to 219.1 ± 4.5 ms. Across three full-load discharge tests, the mean runtime was 11 h 45 min. The accumulated evidence included an estimated 321 h of end-to-end myoelectric control exposure with physical and virtual terminal devices, including pilot demonstrations involving two participants with transradial amputations. Collectively, the evidence supported a TRL 6 classification. With reusable specialized infrastructure amortized across 25 units, the estimated laboratory-scale reproduction cost was USD 5,754.41 per unit, 20.2–94.7 % lower than the 2026 reference acquisition prices of selected commercial and modular systems offering at least 128 channels. Together, the technology readiness assessment and quantified reproduction cost provide a technical and economic basis for further validation in assistive technology and motor rehabilitation.**

***Index Terms*—high-density surface electromyography, motor rehabilitation, myoelectric control, edge-computing, technology readiness level, reproduction cost, assistive technology.**

The Brazilian Public Ministry of Labor (MPT) supported the work and funded postdoctoral fellowships for Ricardo G. Molinari under Contract No. 002118.2019 and for Natanael P. Batista under Contract No. 39433-26. The Coordination for the Improvement of Higher Education Personnel (CAPES) supported Valeria Avilés-Carrillo through the Academic Excellence Program (PROEX), Process No. 88887.842775/2023-00. The São Paulo Research Foundation (FAPESP) funded Cristian D. Guerrero-Mendez through PhD Scholarship No. 2025/03022-2. The Brazilian Innovation Agency (FINEP) supported Mário S. M. Santana under Agreement No. 01.24.0110.00 (Ref. 2140/22). The National Council for Scientific and Technological Development (CNPq) supported Leonardo A. Elias through Research Productivity Grant No. 316320/2023-4.

I. Introduction

Upper-limb functional loss resulting from amputation, neurological injury, or musculoskeletal disease compromises autonomy, activities of daily living, and social interaction. Studies of individuals with spinal cord injury report restrictions in autonomy in 72–80 % of evaluated participants [1]. Unequal access to assistive technologies across Latin America further underscores the need for adaptable, economically accessible rehabilitation systems [2].

Myoelectric interfaces can capture residual motor intention and translate it into commands to assistive and rehabilitation systems [3], [4], including prostheses [5], exoskeletons [6], visuomotor feedback [7], and virtual environments for motor training [8]. High-density surface electromyography (HD sEMG) further expands the capabilities of myoelectric interfaces by increasing the spatial resolution of acquisition and facilitating the decoding of hand motor intention [9].

Despite the potential of HD sEMG-based interfaces, their progression from laboratory prototypes to assistive and rehabilitation applications requires architectures that combine high-channel-count acquisition, computational flexibility, and autonomous wearable operation. Existing platforms often trade one requirement for another: microcontroller-centered systems face throughput and processing constraints, field-programmable gate array (FPGA)-centered systems increase development complexity, and distributed architectures depend on external computing resources and connectivity [10]. These limitations, together with high acquisition costs, proprietary architectures, and limited reporting on technology readiness and reproduction costs, hinder broader research and translational use [2].

The platform evaluated here addresses this gap through

a heterogeneous edge-computing architecture in which programmable logic performs time-critical 128-channel acquisition, while Arm Cortex-A53 cores running Linux/PYNQ execute myoelectric decoding, system control, and user interaction. Acquisition, processing, and command generation, therefore, remain on-device [10]. Building on the platform's previous technical characterization, this study evaluates its Technology Readiness Level (TRL) across hardware, software, and functional integration and quantifies the resources required to reproduce one functional unit at laboratory scale. The main contribution is the joint technical-economic characterization of the platform, linking accumulated system-level evidence to explicit readiness criteria and a transparent cost model encompassing components, labor, services, consumables, and reusable infrastructure. The combined perspective provides a structured basis for planning subsequent validation, laboratory replication, technology transfer, and translation to assistive and rehabilitation applications [11].

II. Methods

A. Technology Readiness Assessment

We assessed the platform's technology readiness using Mankins's TRL framework [12], [13]. The system under assessment comprised the entire wearable embedded chain, from 128-channel HD sEMG acquisition to on-device myoelectric command generation. The assessment covered three dimensions: hardware, including a ZU3EG embedded processing module, two analog front ends for HD sEMG acquisition, wireless communication, and battery power; software, encompassing the functions responsible for real-time myoelectric control; and functional integration, defined as the coordinated operation of the hardware and software with physical or virtual terminal devices. Prostheses and other external interfaces served only as terminal devices for functional demonstration, remained outside the platform scope, and received no separate TRL classification. In this study, Technology Readiness Assessment (TRA) refers to the structured process of mapping the available technical and functional evidence to the definitions and criteria of the TRL framework. The authors retrospectively mapped the available evidence to each assessed dimension, assigned the corresponding readiness levels, and resolved disagreements by consensus. For the global classification, we applied a conservative TRA rule: the lowest level across the three dimensions and, in cases of ambiguity, the lower level [13].

The assessment focused on TRL 4–6 because earlier work had documented evidence consistent with the lower levels [10], whereas progression to higher levels requires demonstration in an operational environment and, at later stages, real-world use. We defined supervised clinical use and unsupervised home use as operational environments [13]. We required three system-level criteria for TRL 6: an integrated prototype configuration, end-to-end operation, and demonstration in a relevant environment. Supervised laboratory protocols met the relevant-environment criterion when the battery-powered wearable system operated end-to-end during dynamic tasks involving body movement and interaction with physical or virtual terminal devices. Evaluation segments included movements, object interactions, and task states not contained in the brief calibration sequence. We regarded these conditions as functionally representative laboratory constraints, not as operational or clinical use. The two participants with transradial amputations provided additional target-population evidence but were neither treated as a sufficient sample for clinical inference nor used to claim an operational environment.

The Research Ethics Committee of the University of Campinas (UNICAMP) approved the studies involving human participants under CAAE Nos. 80299124.2.1001.5404 (October 24, 2024) and 59961616.8.0000.5404 (February 26, 2025). The ongoing studies described below were conducted under CAAE No. 90477225.9.0000.5404 (August 5, 2025). All procedures involving human participants were conducted in accordance with the Declaration of Helsinki, and written informed consent was obtained from all participants.

The ongoing evidence comprised visuomotor-tracking, physical and virtual manual-dexterity, and multimodal acquisition studies. The first two used the same core platform and one-degree-of-freedom proportional decoder, with approximately 100-ms command updates and per-session calibration based on 20 s of dynamic data, to control physical or virtual terminal devices during tracking, manipulation, the Box and Block Test (BBT), and tasks inspired by the Southampton Hand Assessment Procedure (SHAP); the manual-dexterity study included two participants with transradial amputations. The multimodal study synchronized myoelectric, kinematic, and visual signals without command generation and therefore provided subsystem-level evidence. Only sessions completed by June 17, 2026, were included; further protocol details are provided in the Supplementary Material [14].

For the reported counts, one "study enrollment" was defined as the inclusion of one individual in one study; therefore, enrollment counts did not necessarily represent unique participants. End-to-end exposure included acquisition, processing, command generation, and interaction with a physical or virtual terminal device. Because continuous device logs were not available for every session, cumulative exposure was estimated from the number of recorded sessions and the nominal duration of each protocol; the reported hours therefore represent approximate experimental exposure rather than precisely logged operating time.

B. Reproduction Cost Estimation

We estimated the cost of reproducing one functional platform unit at laboratory scale. We defined total cost as the sum of unit-specific materials and components (C_{mat}); reproduction-related services, labor, and consumables (C_{serv}); and an allocated share of reusable specialized infrastructure (C_{infra}/N), as shown in (1). The term C_{infra} includes bench equipment for soldering, printed circuit board rework, inspection, electrical validation, and 3D printing. The term N denotes the number of platform units across which we amortized infrastructure costs. The deterministic sensitivity analysis

varied C_{mat} by ± 30 % to examine favorable and adverse scenarios involving prices, exchange rates, freight, taxes, and material losses; varied C_{serv} by ± 20 %; and evaluated $N = 5$, 25, and 125.

$$C_{\mathrm{total}}(N) = C_{\mathrm{mat}} + C_{\mathrm{serv}} + \frac{C_{\mathrm{infra}}}{N} \tag{1}$$

We decomposed materials and components according to (2). The term C_{PCB} denotes printed circuit boards; C_{comp}, front-end electronic components; C_{mod}, commercial modules; C_{conn}, connectors, cables, and interfaces; and C_{power}, the power and charging system. Documented unit prices were used as the base inputs. Freight, taxes, and import charges were retained when included in the source price but were not added separately when unavailable; the potential effect of these procurement conditions was examined within the ± 30 % material-cost scenarios.

$$C_{\mathrm{mat}} = C_{\mathrm{PCB}} + C_{\mathrm{comp}} + C_{\mathrm{mod}} + C_{\mathrm{conn}} + C_{\mathrm{power}} \tag{2}$$

We descriptively compared the platform with commercial and modular systems offering 128 channels or more. We expressed acquisition costs in 2026 US dollars (USD) and adopted June 17, 2026, as the economic base date. We updated historical US-dollar-denominated prices using the US Consumer Price Index for All Urban Consumers (CPI-U) [15] and historical euro-denominated prices using the Harmonised Index of Consumer Prices (HICP) for the euro area [16]. We converted Brazilian-real-denominated (BRL) values using an exchange rate of BRL 5.05/USD and euro-denominated (EUR) values using the cross-rate implied by BRL 5.88/EUR and BRL 5.05/USD. We did not assess functional or regulatory equivalence among systems. When applicable, we reported quantitative results as mean $\pm$ standard deviation. The Supplementary Material [14] provides the input data, economic assumptions, and calculation records supporting the cost analysis.

III. Results

A. Technical and Functional Evidence of the Platform

The technical evidence supported three defining system-level capabilities of the platform: reliable high-density acquisition, embedded real-time processing, and autonomous wearable operation. As previously reported [10], the acquisition subsystem continuously acquired signals from 128 channels at 2052.52 Hz per channel. Offline integrity checks found that the analyzed recordings contained the number of samples expected from their duration and sampling rate, with no empty sample values. The signal-to-noise ratio (SNR) was 13.93 ± 7.51 dB. The processing module achieved 8.5 billion floating-point operations per second in the LINPACK benchmark. Previously published characterization reported mean acquisition-to-command latencies ranging from 63.30 ± 1.01 ms for a 30-ms acquisition window to 219.11 ± 4.47 ms for a 150-ms window, with the reported standard deviations representing timing jitter. This metric includes acquisition-window duration, embedded processing, and controller area network (CAN) command transmission [10].

TABLE I
Retrospective evidence-to-criterion mapping supporting the TRL 6 classification.

Dimension: Hardware	**TRL 6**
Integrated prototype: Wearable integration of 128-channel acquisition, processing, communication, and battery power.	
End-to-end operation: Continuous hardware operation supporting acquisition, embedded processing, command generation, and communication with physical or virtual terminal devices during task execution.	
Relevant environment: Dynamic tasks involving user movement and interaction with physical or virtual terminal devices.	
Dimension: Software	**TRL 6**
Integrated prototype: Concurrent acquisition, processing, and myoelectric command generation on the embedded platform.	
End-to-end operation: Continuous data flow from acquisition to control of the terminal device through a common software core.	
Relevant environment: Real-time decoding of motor intention during dynamic tasks and interaction with a terminal device.	
Dimension: Functional integration	**TRL 6**
Integrated prototype: Functional coupling of the platform to multiple physical and virtual terminal devices while preserving the core architecture.	
End-to-end operation: Continuous myoelectric control of physical and virtual terminal devices for approximately 321 h of estimated cumulative exposure.	
Relevant environment: Demonstrations with physical and virtual terminal devices, including approximately 10.8 h with two participants with transradial amputations.	
Global TRL: 6 (lowest level across dimensions)	

Note: Because multimodal acquisition included only signal acquisition and synchronization, we treated it solely as subsystem evidence.

Autonomous operation was characterized across three independent battery units, with a mean power consumption of 6.02 ± 0.11 W and a mean runtime of 11 h 45 min under continuous full-load operation until cutoff by the battery management system (BMS) [10]. The power-subsystem architecture, monitoring conditions, and charge–discharge characterization are detailed elsewhere [17]. In the visuomotor feedback tasks, the estimated motor intention reached a peak normalized cross-correlation of 0.80 ± 0.16 with the reference trajectory [10]. Across all end-to-end scenarios, the acquisition-to-command chain remained on-device; only the experimental task and the physical or virtual terminal device varied.

Our joint assessment of hardware, software, and functional integration classified the platform as TRL 6 (Table I). The evidence base combined the previously published initial validation with the ongoing studies described in Methods. The visuomotor-tracking and manual-dexterity studies contributed end-to-end evidence, whereas the multimodal study contributed subsystem-level evidence. The manual-dexterity study included pilot demonstrations with two participants with transradial amputations (Fig. 1).

Across the studies, we counted 67 study enrollments and 136 sessions, corresponding to an estimated 359 h of cumulative use (Table II). End-to-end myoelectric control exposure was calculated as 84 h of initial validation plus 180 h of

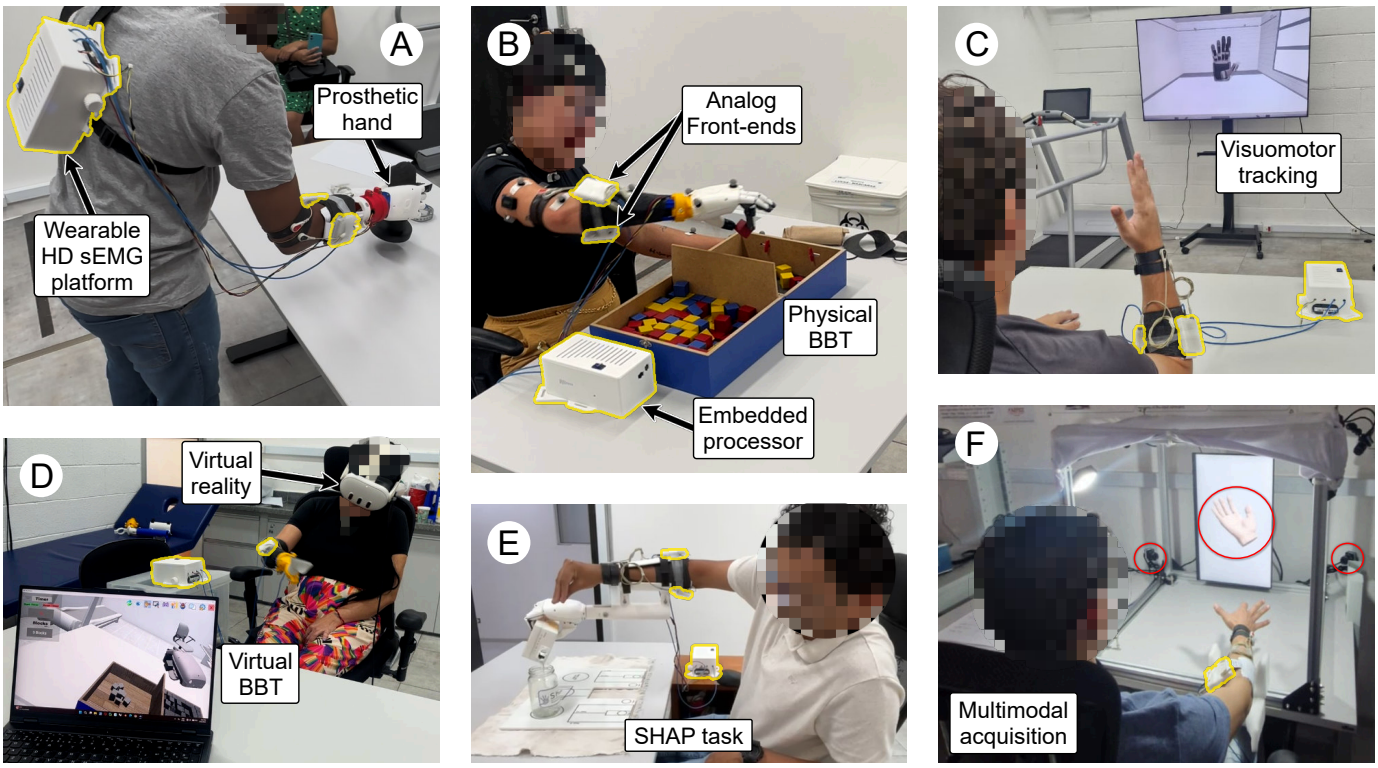

Fig. 1. Functional evidence of the platform in representative scenarios. Panels A, B, D, and E depict tasks included in pilot demonstrations with two participants with transradial amputations. **(A)** Wearable use with a myoelectric prosthesis during a manipulation task. **(B)** Physical Box and Block Test (BBT) using a prosthetic hand with simultaneous kinematic recording. **(C)** Real-time virtual-hand control during visuomotor tracking. **(D)** Virtual BBT with arm tracking and myoelectric hand control. **(E)** Prosthetic-hand control during a Southampton Hand Assessment Procedure (SHAP)-inspired task. **(F)** Synchronized acquisition of myoelectric signals, markerless kinematic data, and a visual reference.

TABLE II
ESTIMATED CUMULATIVE EXPERIMENTAL EXPOSURE OF THE PLATFORM ACROSS USAGE SCENARIOS.

Scenario	Enrollments	Sessions	Exposure
Initial validation†	21	21	84 h
Visuomotor tracking‡	15	60	180 h
Physical/virtual BBT and SHAP‡	8*	32	57 h
Multimodal acquisition‡	23	23	38 h
Total	**67**	**136**	**359 h**

† Published data [10]; ‡ ongoing studies described in the Supplementary Material [14]; * includes two participants with transradial amputations. BBT = *Box and Block Test*; SHAP = *Southampton Hand Assessment Procedure*.

visuomotor tracking and 57 h of physical/virtual BBT and SHAP-inspired tasks, totaling approximately 321 h. A further 38 h of multimodal acquisition was counted only as subsystem evidence. The visuomotor-tracking and manual-dexterity cohorts did not overlap. However, we could not determine whether participants in either cohort also took part in the initial validation or multimodal acquisition studies. As a result, we could not calculate the total number of unique participants.

Descriptive and exploratory pilot demonstrations involving two participants with right transradial amputations of the dominant upper limb accounted for approximately 10.8 h of use. Neither participant had previous experience using a prosthesis. During the physical and virtual BBT and the task inspired by the Southampton Hand Assessment Procedure (SHAP) [18], both used a 3D-printed socket coupled to the open-source Brunel Hand 2.0 prosthetic hand. From the first to the fourth session, participant 1 improved from 5 to 12 blocks in the physical BBT (+140.0 %), from 8.6 ± 1.1 to 13.8 ± 1.1 blocks in the virtual BBT (+60.5 %), and from 14.56 to 35.78 points in the SHAP-inspired task (+145.7 %). For participant 2, the corresponding values increased from 8 to 9 blocks (+12.5 %), from 9.6 ± 1.7 to 12.6 ± 1.1 blocks (+31.3 %), and from 39.22 to 43.98 points (+12.1 %). These demonstrations provided evidence of integrated platform operation with participants from the target population and contributed to the technology readiness assessment.

B. Laboratory Reproduction Cost Estimate

In the reference scenario ($N = 25$), we estimated the laboratory-scale reproduction cost of one platform unit at $C_{\text{total}}(25) =$ USD 5,754.41 (Table III); materials and components accounted for 62.49 % of the total. In the sensitivity analysis, varying C_{mat} by ± 30 % changed total cost by ± 18.75 %, whereas varying C_{serv} by ± 20 % changed total

TABLE III
LABORATORY-SCALE REPRODUCTION COST OF ONE PLATFORM UNIT IN THE REFERENCE SCENARIO ($N = 25$).

Category	Estimated cost (2026 USD)
Printed circuit boards (C_{PCB})	110.50
Front-end electronic components (C_{comp})	1,281.60
Commercial modules (C_{mod})	691.93
Connectors, cables, and interfaces (C_{conn})	820.02
Power and charging system (C_{power})	691.65
Materials and components (C_{mat})	**3,595.70**
Electronic assembly and electrical validation	1,542.57
3D-printed enclosure and associated labor	386.14
Services, labor, and consumables (C_{serv})	**1,928.71**
Specialized infrastructure amortized over 25 units ($C_{\mathrm{infra}}/25$)	230.00
Total reproduction cost (C_{total})	**5,754.41**

TABLE IV
DETERMINISTIC SENSITIVITY ANALYSIS OF THE REPRODUCTION COST.

Scenario	Total cost (USD)	Variation
Reference: $N = 25$	5,754.41	Reference
C_{mat}: -30 %	4,675.70	-18.75 %
C_{mat}: $+30$ %	6,833.12	$+18.75$ %
C_{serv}: -20 %	5,368.67	-6.70 %
C_{serv}: $+20$ %	6,140.15	$+6.70$ %
$N = 5$	6,674.41	$+15.99$ %
$N = 125$	5,570.41	-3.20 %
Combined adverse*	8,138.86	$+41.44$ %

* A 30 % increase in C_{mat}, a 20 % increase in C_{serv}, and $N = 5$. For the individual analyses, we changed only the indicated parameter.

cost by ± 6.70 %. Changing the amortization scale to $N = 5$ or $N = 125$ changed total cost by $+15.99$ % and -3.20 %, respectively. The combined adverse scenario increased the cost to USD 8,138.86, 41.44 % above the reference scenario (Table IV). After expressing all values in 2026 US dollars, the $N = 25$ estimate was 20.2–94.7 % lower than the acquisition costs of commercial and modular systems offering 128 channels or more (Table V).

TABLE V
COST COMPARISON OF COMMERCIAL OR MODULAR MULTICHANNEL MYOELECTRIC/BIOPOTENTIAL ACQUISITION SYSTEMS AND THE PROPOSED PLATFORM.

System	Cost (2026 USD)
Proposed platform ($N = 25$)	**5,754.41**
Open Ephys Acquisition Board, 128 channels (two 64-channel modules) [19]	7,213.19
Intan RHD Recording System, 128 channels [20]	13,160.00
g.HIamp 256 [21]	45,471.65
Quattrocento 128+256 [22]	44,524.25
BioSemi ActiveTwo/ActiveThree 128+8 [23]	52,396.04
actiCHamp 128/160 [24]	108,162.20

Note: We adjusted historical prices using indices compatible with the source currency (CPI-U for USD and the euro-area HICP for EUR) and converted current prices using the adopted exchange rates. The platform value represents laboratory-scale reproduction at $N = 25$; differences in purpose and regulatory status preclude direct equivalence with the listed systems.

IV. DISCUSSION

A. Technology Readiness and System-Level Significance

Applying the retrospective criteria, we classified the platform as TRL 6 because it progressed beyond validation of isolated subsystems and operated as an integrated system in a relevant experimental environment [12], [13]. Although laboratory supervision distinguished these protocols from operational use, the platform operated under functionally representative constraints for the intended application: continuous battery-powered wearable operation, body movement, interaction with objects and physical or virtual terminal devices, and, in some demonstrations, involvement of participants from the target population. In the end-to-end demonstrations, signal acquisition, processing, and command generation remained embedded and did not depend on bench equipment or external computing resources; external systems were used only to implement the experimental task or to serve as the terminal device. The TRL 6 classification, therefore, reflects the maturity of the integrated system demonstrated under these laboratory conditions.

The previously reported processing and command-transmission time of 33.3–69.1 ms remained within the range associated with favorable myoelectric control performance [10], [25]. The previously characterized mean runtime of 11 h 45 min across three full-load discharge tests supported prolonged experimental protocols without external power [10], [17]. Pilot demonstrations with two participants with transradial amputations provided additional evidence of integrated use in the target population. However, the small exploratory sample does not support inferences regarding robustness across users and use contexts or clinical effectiveness. The lack of demonstration in an operational environment, particularly in supervised clinical or unsupervised home use, precludes classification as TRL 7. The available evidence also does not support claims of regulatory qualification or commercial availability.

B. Reproduction Cost and Translational Potential

The commercial-system comparison was secondary and descriptive: systems were selected according to channel count and the availability of price evidence, without requiring equivalence in intended use, electrodes, amplifiers, software, support, or certification. After adjustment to 2026 US dollars, the platform's estimated laboratory-scale reproduction cost was lower than the acquisition costs of all selected commercial and modular systems offering at least 128 channels. Because the estimate covers an integrated wearable edge-computing platform, including 128-channel acquisition, embedded processing, battery-powered operation, and control of terminal devices, rather than acquisition hardware alone, it may indicate lower barriers to laboratory replication and multicenter validation [10]. The estimate may support planning

for laboratory replication and subsequent economic evaluation, including future assessments of comparative cost-effectiveness and budget impact.

C. Lessons Learned

The assessment highlighted two methodological considerations relevant to the development of modular wearable myoelectric systems. First, explicit definition of the system boundary ensured that readiness evidence and the resulting classification referred consistently to the wearable acquisition, processing, and control platform, while physical and virtual terminal devices remained external use-case interfaces. Second, establishing TRL milestones prospectively can make readiness assessment an integral part of the development process rather than solely a retrospective classification exercise, providing a structured basis for design decisions, verification planning, configuration control, and evidence generation across successive stages of maturity.

D. Limitations

Our cost estimate covers the laboratory-scale reproduction of one unit, not industrial production or a commercial product with regulatory qualification. We excluded certification, testing for compliance with applicable standards, regulatory documentation, support, warranty, logistics, commercial margins, and post-deployment activities. The reference estimate assumes successful reproduction of one functional unit and does not model manufacturing yield, failed boards beyond the inspection and correction labor already included, repeated calibration, software maintenance, replacement parts, field servicing, or lifecycle support. These omissions distinguish the reported laboratory reproduction cost from industrial production and commercial lifecycle cost. The estimate also depends on commercially available components and reflects the prices, sourcing conditions, exchange rates, freight, and taxes adopted for the reference scenario; costs may therefore vary across countries and procurement contexts.

The economic comparison provides only an order-of-magnitude reference. Differences in intended purpose, certification, support, product finish, functional integration, and cost composition, along with inconsistent inclusion of taxes, freight, import charges, maintenance, and training, prevent direct inferences of functional equivalence or economic superiority.

The TRA was conducted retrospectively by consensus among the platform developers, using evidence from studies that were not originally designed around prospectively specified readiness criteria. Consequently, the classification depends on the retrospective interpretation of the available evidence and applies to the evaluated platform configuration under supervised laboratory conditions. As an ordinal framework, TRL summarizes readiness at a given stage but does not fully capture iterative or nonlinear development trajectories. Readiness should therefore be reassessed as the platform configuration and intended-use context evolve.

Cumulative exposure was estimated from session counts and nominal protocol durations because continuous device logs were not available for every experiment. In addition, some participants may have enrolled in more than one study, and the number of unique individuals could not be reconstructed. The exposure totals therefore characterize the accumulated use of the platform, not the duration of a controlled reliability test or the number of unique users.

E. Next Steps

Future work should first expand evaluation in participants with transradial amputations and subsequently extend it to populations with spinal cord injury, stroke, and neuromuscular diseases under conditions progressively closer to real-world use [1], [26], [4]. The ongoing extension from one to four degrees of freedom should be evaluated for decoding performance, end-to-end latency, robustness, and usability. Progression from TRL 6 to TRL 7 will require a stable, reproducible prototype configuration and demonstration in an operational environment, such as supervised clinical use or unsupervised home use.

Further translation will require a clearly defined intended use and corresponding regulatory pathway, supported by application-specific evidence of performance and usability. Progression toward scalable manufacturing will also depend on qualified suppliers, controlled production processes, product traceability, and maintenance planning. Adoption within public healthcare systems would further require evidence of clinical effectiveness, comparative cost-effectiveness, and budget impact, together with assessment of implementation requirements, workforce training, and long-term service sustainability.

V. Conclusion

The retrospective assessment supported a TRL 6 classification for the 128-channel wearable edge-computing HD sEMG platform, and its laboratory-scale reproduction cost was estimated at USD 5,754.41 per unit. Evidence accumulated across physical and virtual tasks demonstrated the coordinated operation of high-density acquisition, embedded myoelectric processing, battery power, and terminal-device control under representative laboratory conditions. By combining technology readiness assessment with a transparent reproduction cost model, this study establishes a system-level reference for platform replication and continued development toward deployment in assistive and rehabilitation applications.

***Abstract*—Anterior Cruciate Ligament (ACL) reconstruction requires rigorous rehabilitation to restore knee functionality. Clinical monitoring relies on assessing joint range of motion and movement symmetry, yet practitioners often lack affordable, continuous tracking tools outside biomechanical laboratories. This paper presents ACL-Digital Assist, a low-cost, centralized e-health ecosystem designed for the longitudinal monitoring of lower limb rehabilitation. Built on a cross-platform framework, the architecture integrates a patient-facing mobile application and a web-based clinical dashboard, synchronized through a secure cloud backend utilizing strict row-level security. By leveraging the embedded inertial sensors of a standard smartphone secured to the patient distal tibia, the platform captures kinematic telemetry at 20 Hz. The system introduces distinct protocols to evaluate active mobility, passive joint limits, and isometric endurance, while computing a normalized acceleration variation score to detect physiological hesitations. To validate the technical feasibility and data pipeline integrity, a preliminary evaluation was conducted on healthy volunteers within a laboratory setting. The results indicate the system's capability to capture repeatable kinematic data, manage high-frequency telemetry via JSON storage arrays, and automatically generate standardized clinical reports, highlighting its promising potential to optimize physiotherapy workflows.**

***Index Terms*—Anterior cruciate ligament, biomechanical stability, cloud computing, mobile health, range of motion, row-level security, sensor telemetry.**

I. Introduction

Rupture of the Anterior Cruciate Ligament (ACL) is one of the most prevalent musculoskeletal injuries, frequently requiring surgical reconstruction to restore joint function and prevent long-term complications such as osteoarthritis [1], [2]. The rehabilitation process often spans several months, with the goal of restoring full joint functionality and preventing reinjury. Recovery relies heavily on achieving symmetrical knee mechanics, quantified in clinical settings using the Limb Symmetry Index (LSI). To ensure a safe return to sports, continuous tracking of the knee Range of Motion (ROM), movement stability, and static endurance is very important. Recent studies have demonstrated that mobile health-based interventions and smartphone self-rehabilitation applications can effectively complement standard care, significantly improving early functional outcomes, reducing pain, and increasing adherence in post-operative patients [3]–[5].

In current practice, longitudinal monitoring suffers from a technological divide. Precise biomechanical assessments rely on computerized isokinetic dynamometers or optical motion-capture systems. While highly accurate, they are exceedingly expensive and restricted to specialized facilities. Conversely, everyday clinical monitoring often depends on manual goniometers, which can exhibit clinically relevant measurement error and inter-operator variability [6], [7]. Traditional manual methods still lack automated historical logging, and only capture static angular boundaries rather than dynamic movement quality. In contrast, self-measurement of knee ROM using smartphone applications has proven to be a feasible and highly reliable alternative [8].

To help address this gap, this paper introduces ACL-Digital Assist, a low-cost e-health Proof-of-Concept designed to assist in monitoring post-ACL reconstruction rehabilitation. The architecture comprises two software applications sharing a unified, centralized cloud backend: a mobile application for telemetry acquisition and a web dashboard for healthcare professionals. By leveraging the embedded inertial sensors of a standard smartphone securely strapped to the distal tibia, the system extracts kinematic data to evaluate three clinical modalities: active movement, passive guided ROM, and isometric endurance. To address the need for qualitative movement analysis, the platform computes a normalized

stability score based on angular acceleration variations. To validate the technical feasibility and data pipeline integrity, a proof-of-concept (PoC) evaluation was conducted on healthy volunteers.

The remainder of this paper is organized as follows. Section II details the dual-application system architecture, kinematic processing, and clinical protocols. Section III presents the preliminary technical validation alongside the automated clinical reporting features. Finally, Section IV concludes the paper and discusses future work, including the integration of computer vision pipelines.

II. SYSTEM ARCHITECTURE AND BIOMECHANICAL METHODOLOGY

The system architecture is illustrated in a block diagram (Fig. 1), which details the interaction between the front-end data acquisition tools and the backend cloud infrastructure.

A. Mobile Application and Sensor Data Acquisition

Fig. 2. Experimental setup ensuring geometric accuracy.

The patient-facing application was developed using the React Native framework[1], a cross-platform mobile development environment, combined with Expo tools[2] to access native hardware capabilities. Real-time kinematic data is acquired via the Expo DeviceMotion API. Instead of extracting raw uncalibrated gyroscope data, the system leverages the native sensor fusion engine of the mobile operating system (OS) to obtain pre-filtered Euler angles, specifically the rotation around the X-axis (*DeviceMotionMeasurement.rotation.beta*). This design choice significantly reduces the computational load on the mobile CPU while providing stable kinematic readings.

Inertial Measurement Units (IMUs) have shown good accuracy in sagittal-plane knee motion, offering a reliable and accessible alternative to complex motion-capture systems for longitudinal tracking [9], [10]. The mobile device is firmly secured to the distal tibia using an elastic armband (as illustrated in Fig. 2, displaying the leg setup). To guarantee accuracy, strict starting postures are enforced: seated with thighs perpendicular to the torso for extension exercises, and standing straight for flexion exercises.

Data sampling operates at a sampling frequency f_s of 20 Hz utilizing the smartphone's embedded Inertial Measurement Unit (IMU). This rate of 20 Hz was selected as a practical compromise between mobile-device constraints and the need to capture low-frequency rehabilitation motions, as biomechanical studies indicate that the knee joint primarily exhibits low-frequency dynamic responses during movement [19]. To maintain acquisition stability, the telemetry strictly operates in the application foreground, preventing OS background sleep modes. Furthermore, the architecture mandates an active Wi-Fi connection, as data is directly streamed to the cloud without local offline caching. To enhance clinical usability, a "Monitor Mode" was implemented, allowing the physiotherapist to control the exercise flow and view real-time feedback on a secondary synchronized device (tablet or smartphone, as depicted in Fig. 3).

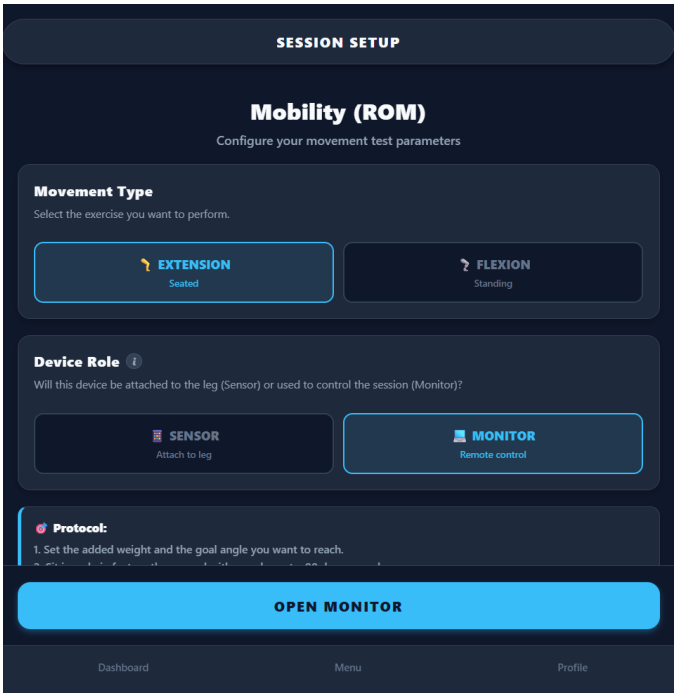

Fig. 3. The Monitor Mode interface displayed on a secondary synchronized device, allowing the physiotherapist to control the exercise state machine and monitor real-time kinematic feedback.

B. Kinematic Processing and Repetition State Machine

Let θ_{rest} define the resting baseline angle, θ_{th1} the initial trigger threshold angle, and θ_{th2} the validation threshold angle, with Δt representing the movement duration.

The angular data is first converted from radians to degrees. To map the telemetry to a clinically relevant plane, the algorithm references an θ_{rest} absolute vertical baseline. For instance, a patient standing with the leg straight registers at an

[1]https://reactnative.dev/, accessed July 2026.
[2]https://docs.expo.dev/, accessed July 2026.

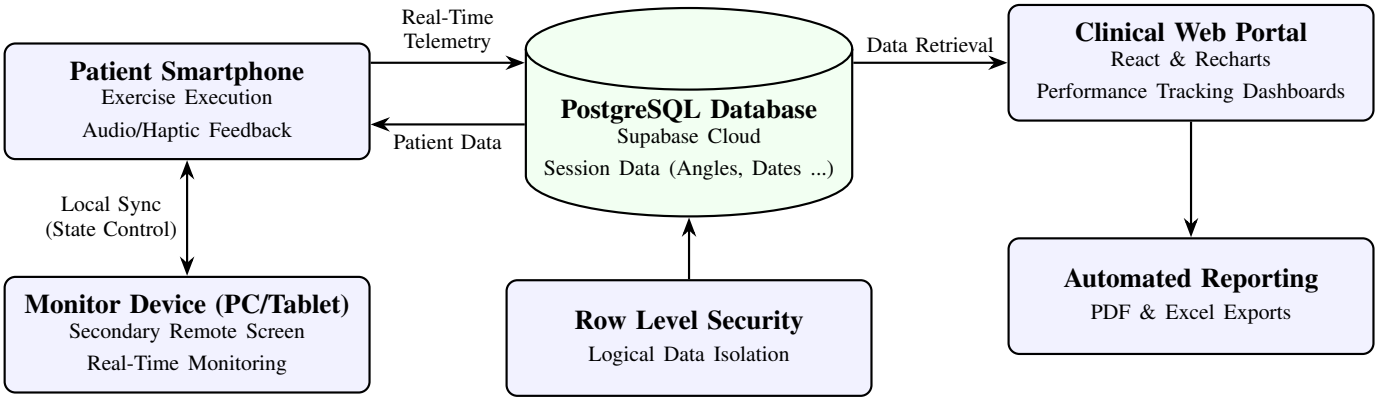

Fig. 1. System architecture of ACL-Digital Assist. The patient smartphone acts both as an exercise execution device and a personal dashboard retrieving data from the Supabase cloud. The physiotherapist controls the flow locally via a secondary monitor device (PC or tablet). The web portal accesses the cloud for clinical analytics and performance tracking.

θ_{rest} typically equal to $90°$; flexing the knee backwards until the lower leg is parallel to the floor approaches $0°$, and further flexion yields negative values. This mathematical continuity natively supports measuring a Range of Motion exceeding $90°$.

A dynamic state machine governs repetition counting. A repetition is initialized when the knee angle drops below an θ_{th1} threshold (e.g., $65°$) and concludes when returning past an θ_{th2} threshold (e.g., $70°$). Based on empirical tests conducted on healthy subjects, an invalidation criterion is applied: repetitions are only logged if the total movement duration Δt is superior or equal to 500 ms, effectively filtering out transient noise.

C. Multi-Modal Exercise Protocols

The platform supports three distinct clinical protocols:

- Extension Exercises (Fig. 4): This module evaluates knee extension. In the Active Dynamic mode, the subject performs five voluntary repetitions per limb, with the system logging the peak Range of Motion (ROM) for each repetition. The protocol mandates testing the healthy leg first to ensure a natural rest period during the arm-band transfer, preventing central nervous system fatigue crossover. In the Passive ROM mode, the patient remains relaxed while the practitioner manually guides the limb to its maximum extension, with data acquisition controlled via the monitor device's state machine to prevent parasitic noise during setup.
- Flexion Exercises (Fig. 5): This module evaluates knee flexion. Similar to the extension protocol, it supports two modalities: Active Dynamic repetitions, where the subject performs five voluntary movements to evaluate the peak flexion ROM, and Passive ROM, where the practitioner guides the limb to its maximum amplitude. Both modes maintain the same rigorous safety protocols, including initial testing of the healthy limb and the use of the remote state machine for passive sessions to ensure accurate, artifact-free data logging.
- Isometric Hold and Endurance (Fig. 6): The patient maintains the limb at a target angle. An endurance timer runs as long as the angle remains within a $\pm 10°$ tolerance window, which absorbs natural anatomical variances such as the posterior tibial slope. Real-time haptic, audio, and visual feedback guide the patient. A 2-second grace period accommodates minor postural adjustments and is currently included in the final endurance tally.

At the conclusion of any session, the application prompts the patient to input a self-reported pain score and optional clinical comments.

(a) (b)

Fig. 6. Isometric hold and endurance protocol. The patient maintains the limb at a specific target angle, guided by real-time haptic, audio, and visual feedback within a defined tolerance window.

D. Biomechanical Assessment Metrics

Limb Symmetry Index (LSI): For dynamic exercises, the system computes the ROM as $90° - \theta_{\text{maxAngle}}$. The LSI is then derived from the average ROM of both legs:

$$\text{LSI}_{\text{dynamic}} = \left(\frac{x}{y}\right) \times 100\,, \tag{1}$$

where x denotes the average ROM of the rehabilitated limb, and y denotes the average ROM of the healthy limb, yielding a result expressed as a percentage. Longitudinal tracking models indicate that the uninvolved limb's function also fluctuates during rehabilitation, underscoring the necessity of continuously monitoring both limbs to derive an accurate LSI rather than relying on a static baseline [11]. Furthermore, while LSI is a standard metric, relying solely on it for return-to-sport clearance has shown poor discriminatory ability for preventing secondary injuries, highlighting the need for the multi-modal assessments provided by this platform [12]. To prevent mathematical instability or division by zero in cases of failed extension, the algorithm enforces a safety constraint: if healthyAvgROM $\leq 5°$, the dynamic LSI is defaulted to 0.

Biomechanical Stability Score: To quantify hesitations, an acceleration-based stability score is computed. The angular velocity v_i is defined by $\frac{\theta_i - \theta_{i-1}}{\Delta t}$, where Δt is the sampling interval. Variations in acceleration are accumulated $(\sum |v_i - v_{i-1}|)$ and divided by the absolute angular distance $(\sum |\theta_i - \theta_{i-1}|)$. The result is normalized into a 0 to 100 scale. While small interval variations may occur due to OS processing, the normalization over the total movement minimizes their impact.

E. Cloud Infrastructure

The ecosystem utilizes a centralized Supabase[3] cloud backend powered by an open-source PostgreSQL[4] database. To prevent high-frequency telemetry from causing database bloat, the 20 Hz raw data points are compressed and stored as JSON[5] (JavaScript Object Notation, a lightweight, text-based data interchange format) arrays, within single session records. Privacy is enforced natively via logical Row Level Security (RLS) policies, restricting data access based on authenticated user identities.

F. Clinical Analytics and Dashboard Reporting

To transform raw telemetry into actionable insights, a dedicated web-based dashboard processes the backend data. The system executes temporal aggregations, grouping post-surgical data by elapsed weeks (e.g., "W+2", "W+4") to allow for cohort-independent comparisons regardless of the actual surgery date. The dashboard calculates weekly averages for the LSI, ROM, hold durations, and stability scores while automatically filtering null values. To monitor patient safety, a clinical alert engine flags sessions where the self-reported pain score exceeds 7/10. The analytics engine also splits exercises into "mobility" and "strength" categories using case-insensitive filtering, normalizing movement angles to overlay curves coherently for visual comparison between the healthy and rehabilitated leg.

G. Hybrid Approach

A primary limitation encountered with the current single-sensor IMU solution is its inability to detect potential postural compensations made by the patient during exercises. Literature shows that ACL patients may show compensatory trunk/proximal strategies, such as forward trunk leaning, ipsilateral trunk lean, and altered hip kinematics to compensate for knee deficits [13]–[15]. Moreover, reduced degrees-of-freedom IMU setups are particularly susceptible to measurement errors induced by frontal plane misalignments [16]. These compensations can artificially alter the recorded angles, thereby potentially impacting the accuracy of the clinical results. While various tracks are possible to address this issue, the chosen solution, which will form the core of future work, is the combination of our current system with an image-based approach. The objective will be to film the performed exercises to extract information regarding the correct or incorrect execution of the movement. The subsequent section will discuss how this visual computation-based approach translates into our future developments.

III. PRELIMINARY RESULTS AND DISCUSSION

A. Technical Feasibility and Pipeline Validation

To validate the data pipeline, state machine responsiveness, and cloud synchronization, a preliminary Proof-of-Concept (PoC) evaluation was conducted on a limited number of healthy volunteers. The objective was strictly to validate the technical integration, rather than providing clinical diagnostic validation.

Due to the lack of access to standard calibrated goniometers or optical motion-capture systems, an exploratory concurrent assessment of the sensor logic was performed using the MoveNet Thunder deep learning model. This model was selected as a comparative baseline due to its established performance in remote knee Range of Motion (ROM) tracking. [17]. However, it must be strongly emphasized that this vision-based tool does not constitute a sufficient clinical reference standard, as both the smartphone IMU and the 2D camera model are inherently affected by placement variations and two-dimensional geometric assumptions. The smartphone was tested alongside a synchronized webcam setup under controlled lighting conditions during 10 dynamic repetitions of both knee extension and knee flexion.

To quantify the system's precision, the Mean Absolute Error (MAE) and the Standard Deviation (SD) of the error were calculated in degrees. The MAE serves as an indicator of the system's trueness, while the SD evaluates its repeatability across multiple trials. The results are summarized in Table I.

TABLE I
KINEMATIC VALIDATION: SMARTPHONE IMU (GOOGLE PIXEL 8) VS. COMPUTER VISION

Movement	Reps	MAE	SD
Knee Extension	10	1.52°	$\pm 0.66^\circ$
Knee Flexion	10	2.67°	$\pm 1.34^\circ$

The exploratory data provided an MAE of 1.52° (SD $\pm 0.66^\circ$) for extension and 2.67° (SD $\pm 1.34^\circ$) for flexion. While these figures demonstrate measurement repeatability, supporting the system's potential for longitudinal patient tracking, they must be interpreted with caution. Given the nature of this PoC, claims regarding absolute angle agreement, clinical validity, or the complete removal of inter-operator variability cannot be established. The proposed system primarily serves as a technological foundation designed to inspire future scalable e-health solutions, rather than acting as a definitive clinical assessment tool at this stage.

B. Clinical Analytics and Dashboard Reporting

The web-based dashboard seamlessly retrieves metrics from the Supabase backend, utilizing the Recharts library[6] to render responsive time-series graphs of the ROM, LSI, and Stability Scores (as seen in the dashboard interface example in Fig. 7). The platform successfully aggregates metrics into standardized PDF and Excel exports. These reports combine the objective telemetry with the patient-reported pain scores collected at the end of each session. Furthermore, external applied weights are successfully registered, providing critical context to the physiotherapist regarding the kinetic load associated with the recorded kinematic performance.

[6]https://recharts.org/, accessed July 2026.

C. Limitations and Future Work

As a PoC, the current system exhibits several limitations to be addressed in the near future. First, the evaluation was conducted exclusively on healthy volunteers. As a result, the system assumes a baseline capacity to perform movements with a minimum range of motion. Its performance remains to be evaluated in patients recovering from ACL reconstruction, who often present different movement patterns, pain levels, and compensatory strategies. Second, by relying on a single IMU attached to the tibia, the kinematic model assumes strict movement within the 2D sagittal plane. This design inherently ignores complex 3D joint mechanics, such as the screw-home mechanism, and limits the ability to detect proximal postural compensations, such as pelvic tilting. Third, the system assumes optimal patient compliance to reach true muscular failure during isometric tests. Finally, before deploying the platform in real healthcare settings, the security framework needs to be expanded. While Row-Level Security (RLS) is a good starting point for data isolation, future versions will build on this foundation. Next steps include adding robust authentication, end-to-end encryption, and clear governance rules for data anonymization to meet LGPD and GDPR data retention standards.

To address unconscious postural compensations (e.g., pelvic tilting or trunk leaning) that single-sensor setups cannot inherently detect, future work will focus on integrating a supplementary Computer Vision Pipeline. An image-based approach allows for more precise insights on the patient's posture. With the use of a webcam and pose-detection deep learning models, such as MoveNet Thunder, valuable information on the subject's positioning, such as shoulder and hip alignment, knee height variation and hip-knee-heel angle, can be utilized to verify the execution's correctness. The model receives an image (a frame captured by the webcam) as input and outputs 17 body keypoints (y-coordinate, x-coordinate and confidence score). By processing such points provided by the model, the algorithm can go through a checklist of conditions in order to determine whether the subject is in an appropriate posture:

- The subject must be seated. This may be checked by a geometric heuristic to verify a quasi-horizontal orientation of the femur: the vertical distance between the hip and knee is less than half of their horizontal distance (The thigh segment is lying horizontally). Similarly, the same result may be reached by monitoring the thigh's angle with the x-axis.
- In order to properly assess the subject's posture, the subject must be positioned in a side-view (sagittal) orientation relative to the camera, such that the leg executing the exercise is facing the camera.

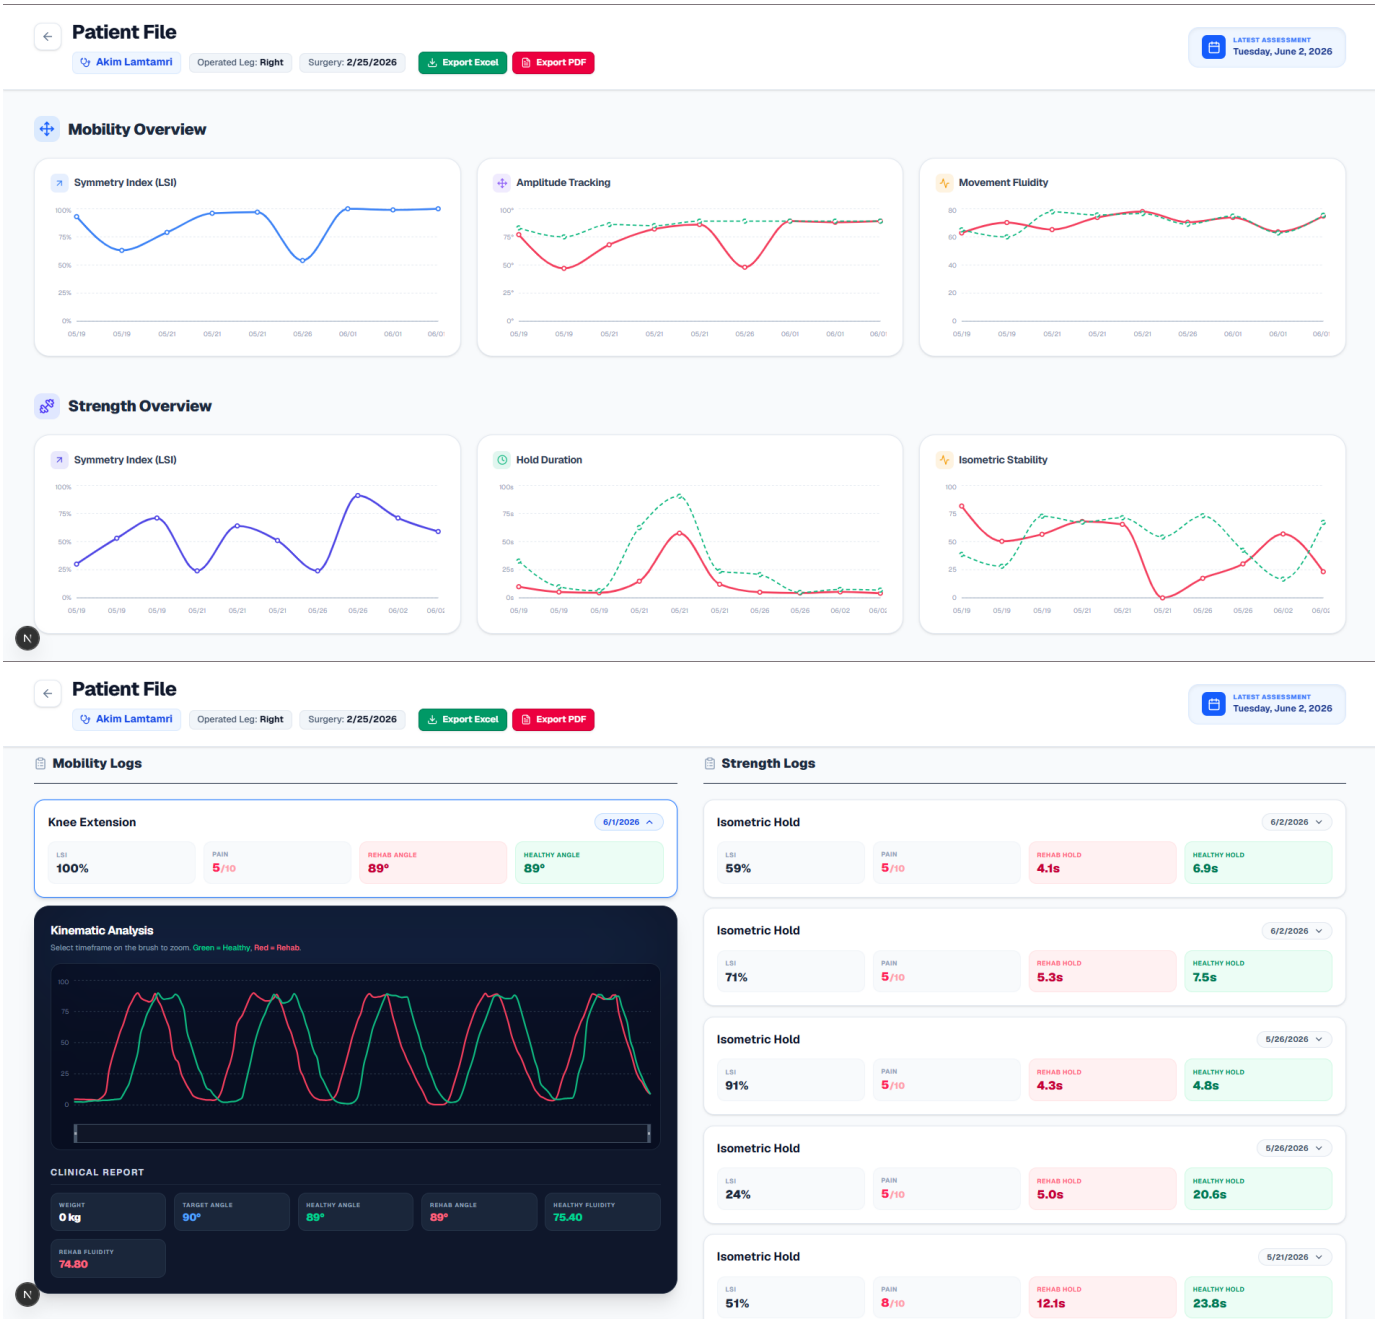

Fig. 7. The clinical web dashboard interface utilizing the Recharts library to render responsive, time-series graphs of the ROM, Limb Symmetry Index (LSI), and Stability Scores for longitudinal patient tracking.

- The subject's leg which is doing the exercise must be facing the camera. Given that the subject is expected to be seated, for a right-facing subject, this condition may be verified by checking if the x-coordinate of the knee is greater than the hip. Similarly, for a left-facing subjects, the x-coordinate of the hip must be greater than the knee.
- In order to account for trunk leaning, the subject must remain with their shoulders and hips aligned. This may be ensured by monitoring the angle between the y-axis and the segment created by the hip and shoulder.
- In order to account for pelvic tilting, the subject's hip's position must not vary greatly during the exercise. This may be ensured by monitoring the distance between the hip's initial position at the beginning of a repetition and the hip's current position.

Finally, the image-based approach must take into consideration frames in which the model was unable to correctly assess the subject's pose. Such errors in the model's predictions may be intensified in low-light or low-resolution images [18]. To enhance reliability against noisy data, frames with

low-confidence keypoints may be filtered out. Moreover, the software must ignore sharp changes in the subject's position. For instance, a variation of 60° in the subject's hip-knee-heel angle in a single frame is unreasonable and should, therefore, not be taken into consideration.

IV. CONCLUSION

This paper presented ACL-Digital Assist, an e-health platform designed to offer a more accessible alternative between expensive biomechanical laboratories and simple manual measurements. By using a centralized database, the system combines a patient mobile application, a dual-device monitor mode, and a web dashboard for clinicians. Laboratory tests on healthy subjects showed that the system can successfully record movements at 20 Hz, handle data using JSON arrays, and calculate recovery metrics like the Limb Symmetry Index and a Stability Score. While relying on a single smartphone sensor for 2D tracking naturally limits the system's precision, the automatic data collection and clinical reports show promising potential for improving physiotherapy workflows. To prepare the system for real clinical use, future work must focus on usability tests with both clinicians and patients. These first tests will help prepare for larger studies to evaluate patient engagement, how reliable the platform is at home, and its actual impact on recovery. Ultimately, by showing that standard smartphone IMUs can be used for this task, this work aims to encourage more accessible research on low-cost patient tracking solutions.

ACKNOWLEDGMENT

The authors thank the research laboratory facilities at the Federal Technological University of Paraná (UTFPR) in Curitiba, Brazil, for providing the software engineering environment necessary for the development of this project.

Resumo—Este trabalho apresenta o desenvolvimento e a avaliação experimental de um fluxo de fabricação digital para prótese facial auricular utilizando escaneamento tridimensional, modelagem CAD, manufatura aditiva e moldagem em silicone. O estudo teve caráter exploratório e laboratorial, com cinco ensaios consecutivos, cada condição executada uma única vez (n=1), destinados a investigar a influência do material do molde e da formulação do silicone sobre a obtenção do protótipo. Os resultados indicaram incompatibilidade entre o molde produzido em resina fotopolimerizável e o silicone empregado, enquanto o molde em ABS, após acabamento superficial, apresentou comportamento mais favorável à cura. A exploração preliminar de ferramentas baseadas em inteligência artificial indicou limitações na reconstrução da geometria auricular e não foi utilizada como fonte de dados para a fabricação final. Os achados demonstram viabilidade técnica nas condições laboratoriais avaliadas, mas não constituem avaliação experimental clínica.

Palavras-Chave—Manufatura Avançada. Próteses Faciais. Impressão 3D. Silicone. Tecnologia Assistiva.

I. INTRODUÇÃO

Atualmente pacientes com câncer que passaram por mutilações faciais, devido a abscisão cirúrgica de tumores, acidentes ou malformações congênitas que necessitam de próteses faciais como dispositivo de reabilitação funcional e psicossocial, buscam seu tratamento fora da região Goiana se locomovendo para o Sul e Sudeste devido a escassez de mão de obra qualificada em Goiás, onde não se tem documentado locais especializados, públicos ou privados com tal serviço.

Enquanto isso, o Paraná se consolida como referência na área, por meio do ambulatório de Prótese Facial Reconstrutiva do Hospital de Reabilitação, idealizado pela Dra. Roberta Zanicotti. Projeto esse que passou por implementação no SUS (Sistema Único de Saúde) em 2020, operando em Curitiba. Desde sua criação já foram efetuados 1.500 atendimentos de pacientes multilados faciais (nem todos eletivos ao uso do dispositivo), sendo entregues 200 próteses. Dentro do projeto mencionado, cerca de 70% dos pacientes tiveram suas mutilações causadas pelo câncer e 30% por traumas em acidentes.[2]

Esses dados, apresentados em matéria ao ANDIFES (Associação Nacional dos Dirigentes das Instituições Federais de Ensino Superior) em janeiro de 2026, demonstram a demanda crescente por esse dispositivo e sua eficácia ao tratamento de reabilitação dos usuários, o que levanta a problemática dessa polarização de mão de obra no Brasil nos dias de hoje. Ademais consultórios particulares cobram cerca de 5.000 a 10.000 reais pelas próteses, o que desde 2020 está sendo entregue de forma gratuita via SUS pelo projeto supracitado, porém com aplicação somente no Sul do país.

Segundo dados da secretaria de estado da saúde de Goiás, estima-se que em 2025 houve cerca de 13.281 novos casos de câncer e em 2026 cerca de 553, desses 553 sendo 105 de pele, uma das tipologias de câncer causadora das mutilações faciais, isto reforça a necessidade de profissionais especializados e qualificados na área de confecção de próteses faciais no estado de Goiás. [9]

As próteses faciais configuram-se como importantes Tecnologias Assistivas (TA) destinadas à reabilitação de pacientes multilados faciais. Essas TAs desempenham um papel funcional e fisiológico quanto à oclusão de cavidades expostas (Figura 1). Para além da reabilitação funcional do paciente, esses dispositivos são ferramentas psicossociais, as quais ajudam na reintegração social do usuário, devolvendo sua autoestima e minimizando o sentimento de rejeição.

Possuindo assim, uma carga emocional e identitária no papel da reinserção em suas atividades diárias comunitárias, como o trabalho. Dentro desse contexto, nota-se a importância da reintegração social do paciente por meio das próteses faciais atuando ativamente em seu estado psicológico e em sua qualidade de vida.[12]

Fig. 1—Exemplos de próteses faciais utilizadas na reabilitação de pacientes com mutilações faciais.
Fonte: adaptado de [4], [10].

Contudo a reabilitação do paciente não se dá somente pelo dispositivo e seu uso cotidiano, para a recapacitação mais eficaz do paciente é necessário uma equipe transdisciplinar que cuide dos aspectos psicológicos e dos processos de desenvolvimento da prótese, podendo incluir profissionais de diversas áreas a depender do caso [8]. Os profissionais de design entram nessa cadeia interdisciplinar no que tange o desenvolvimento das próteses visando um modelo de produção com maior efetividade e menor gasto de energia.

O processo convencional de fabricação envolve moldagem física da região afetada, obtenção de modelos em gesso, escultura manual, confecção do molde, processamento do silicone, acabamento e adaptação. Essas etapas dependem de habilidade técnica e podem demandar sucessivas intervenções manuais [7], [12].

Entre as limitações do método convencional estão o desconforto durante a moldagem, a dependência da habilidade do profissional, o desperdício de materiais e a dificuldade de reproduzir digitalmente modificações realizadas durante o processo. Por isso, fluxos baseados em escaneamento e manufatura aditiva vêm sendo investigados como alternativas para etapas da fabricação [3], [5], [7].

A manufatura avançada permite integrar aquisição tridimensional, modelagem computacional e impressão 3D, criando possibilidades de armazenamento digital, ajuste do modelo antes da fabricação e produção de moldes personalizados. Neste contexto, este trabalho investigou experimentalmente um fluxo digital para fabricação de prótese facial auricular, com foco na aquisição da geometria, modelagem do molde, manufatura aditiva e compatibilidade entre o material do molde e o silicone utilizado. O estudo também explora, de forma preliminar, ferramentas de inteligência artificial para reconstrução tridimensional, sem utilizá-las como evidência clínica.

O objetivo é desenvolver e avaliar experimentalmente um fluxo de fabricação digital, identificar limitações técnicas e validar sua eficácia. O estudo não pretende validar o uso clínico da prótese nem avaliar conforto, retenção, durabilidade ou satisfação de usuários.

II. METODOLOGIA

Este estudo consiste em um desenvolvimento tecnológico com avaliação experimental de um fluxo digital para prótese facial auricular. O trabalho foi conduzido em ambiente laboratorial e não incluiu instalação de prótese em pacientes e avaliação clínica.

O desenvolvimento foi orientado por princípios do Design Centrado no Usuário (UCD), especialmente quanto à redução da invasividade da moldagem e à consideração de requisitos de personalização. Entretanto, não houve avaliação formal com usuários finais; portanto, o estudo não deve ser interpretado como avaliação experimental de UCD.

Fig. 2—Fluxo comparativo entre o método convencional e o fluxo digital investigado.
Fonte: imagem gerada por IA, utilizada apenas como representação esquemática do fluxo; não constitui evidência clínica.

O fluxo compreendeu: (1) aquisição da geometria por escaneamento 3D; (2) tratamento e reconstrução da malha; (3) modelagem CAD do molde negativo; (4) fabricação do molde por manufatura aditiva; (5) preparação do silicone; e (6) moldagem e avaliação experimental.

A. Aquisição de dados (escaneamento 3D)

A primeira etapa consistirá no escaneamento tridimensional da orelha de uma paciente hipotética, empregando o Revopoint Scanner 3D Range 2, com o propósito de avaliar a produção de uma prótese auricular. Por integrar a classificação das próteses faciais, esse dispositivo foi selecionado por apresentar menor complexidade de confecção, permitindo a validação inicial do método e dos materiais empregados em sua fabricação.

Cabe ressaltar que a paciente hipotética selecionada não apresentará mutilações faciais. Além da justificativa anteriormente apresentada para a escolha da prótese auricular, a seleção desse modelo fundamenta-se no fato de que pacientes oncológicos frequentemente apresentam perda unilateral da orelha. Dessa maneira, em uma aplicação futura com um caso real, seria possível realizar a digitalização da orelha saudável e utilizar seu modelo tridimensional como referência para o espelhamento no lado afetado, dando prosseguimento às etapas subsequentes.

B. Modelagem Computacional (CAD)

Após a aquisição dos dados tridimensionais, a malha resultante será processada no Blender 5.1, visando à eliminação de ruídos e à correção de eventuais falhas geométricas. Fotografias serão empregadas exclusivamente como referências visuais para a reconstrução de detalhes anatômicos.

Com a superfície digital devidamente tratada, o arquivo será exportado no formato STL e posteriormente encaminhado ao Fusion 360, no qual será convertido em corpo sólido. Nessa etapa, serão executadas operações booleanas, estabelecida a linha de partição e desenvolvida a geometria do molde negativo. O Meshmixer poderá ser empregado, quando necessário, para intervenções complementares na superfície digital.

C. Manufatura Aditiva (Impressão 3D)

Para a preparação do arquivo correspondente ao molde negativo destinado à impressão tridimensional, será selecionado um dos softwares de fatiamento disponíveis, LycheeSlicer ou o software de fatiamento da Creality, de acordo com a tecnologia de fabricação empregada.

A versão inicial será confeccionada em resina utilizando a impressora Creality LD-002R, com o material KEDAGBR/F1 Branco. Para a fabricação dos moldes pela tecnologia FDM, será empregado filamento ABS. O pós-processamento desse material exigirá acabamento superficial com acetona. Considerando que esse procedimento pode modificar a textura da superfície, o componente será submetido à inspeção visual antes da etapa de moldagem.

D. Pigmentação e aplicação do silicone ao molde

A moldagem será conduzida sob diferentes condições experimentais envolvendo o silicone, contemplando combinações com e sem catalisador e com ou sem pigmentação intrínseca, conforme cada ensaio. A incorporação do pigmento ocorrerá previamente à introdução do silicone no molde.

Inicialmente, o material pigmentado será distribuído sobre a superfície interna do molde, que em seguida, será fechado e o restante de silicone será introduzido por meio de uma seringa, possibilitando a formação da peça.

Cada uma das cinco condições experimentais será executada uma única vez (n=1). O propósito dessa etapa é identificar possíveis incompatibilidades entre os materiais e orientar o refinamento iterativo do fluxo de fabricação, não sendo objetivo realizar inferência estatística. Serão avaliados os seguintes aspectos: ocorrência de cura completa ou incompleta, presença de vazamentos, facilidade de desmoldagem, preservação da integridade geométrica, qualidade da superfície e necessidade de ajustes no modelo CAD.

III.RESULTADOS

O desenvolvimento ocorreu de maneira iterativa, de modo que os resultados obtidos em cada ensaio serviram como referência para a definição da condição subsequente. Considerando que cada condição experimental foi realizada uma única vez (n=1), os achados apresentados possuem caráter exclusivamente descritivo.

Durante a aquisição tridimensional com o Revopoint Range 2, foram identificadas falhas nas regiões posteriores e nas áreas de maior reentrância da orelha. A digitalização demandou múltiplas tentativas, seguida de tratamento e correção da malha obtida. Também foram testados marcadores fotorrefletores como recurso auxiliar à captura; entretanto, essa estratégia não proporcionou melhoria suficiente na qualidade dos dados para justificar sua incorporação ao fluxo metodológico definitivo. Figura 3

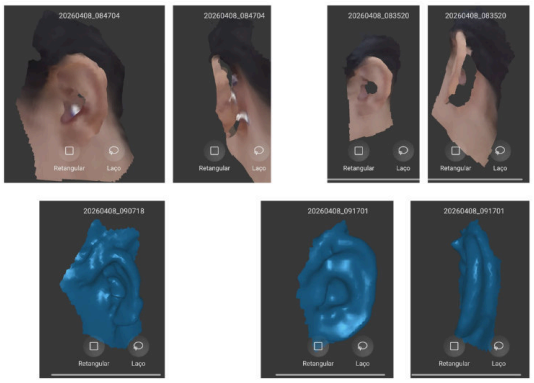

Fig. 3—Modelos 3D obtidos durante a aquisição da anatomia auricular.
Fonte: Acervo dos autores.

Como uma tentativa de mitigar tais problemas enfrentados na obtenção da malha gerada por escaneamento 3D, ferramentas baseadas em inteligência artificial foram avaliadas apenas de forma exploratória. Algumas produziram distorções da geometria auricular; outras geraram modelos visualmente plausíveis, mas apresentaram restrições de exportação. Por essas limitações, os modelos de IA não foram utilizados para a fabricação final nem considerados evidência de precisão anatômica.

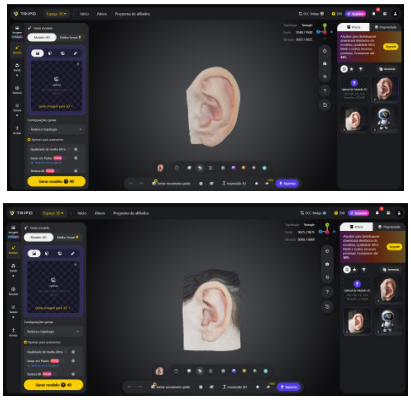

Fig. 4—Exemplo de modelo tridimensional gerado por ferramenta de IA.
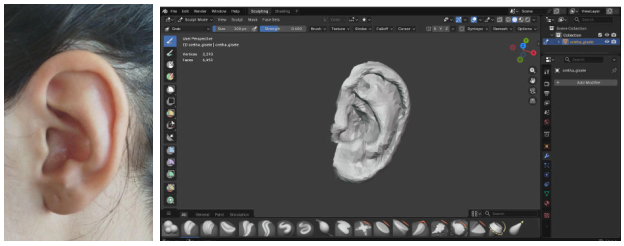
Fonte: Acervo dos autores; ferramenta de IA utilizada apenas para exploração metodológica.

Devido às limitações encontradas no uso da inteligência artificial quanto à exportação de um modelo com qualidade adequada, optou-se pela utilização do arquivo obtido por escaneamento. Como complemento aos dados tridimensionais, foi registrada uma fotografia da orelha da paciente hipotética com um smartphone Redmi Note 13, a qual foi empregada como referência visual durante a etapa de modelagem. A partir desse referencial, iniciou-se o tratamento, a modelagem e o refinamento do arquivo STL selecionado no Blender 5.1. Figura 5



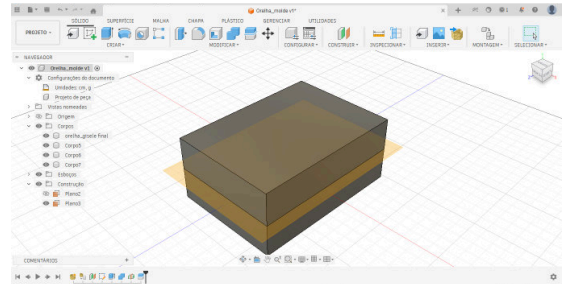


Fig. 5—Referência fotográfica e modelo digital utilizado na reconstrução anatômica.
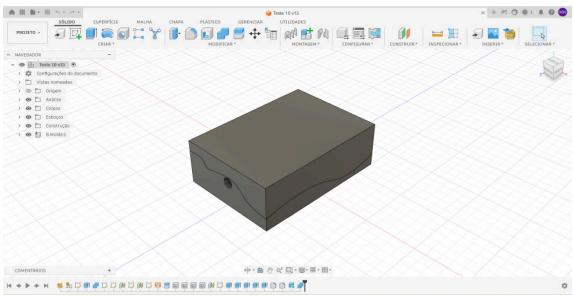
Fonte: Acervo dos autores.



A malha foi exportada do Blender 5.1 no formato STL e, posteriormente, importada para um novo projeto no Fusion 360. Inicialmente, empregou-se a ferramenta de edição direta de malha para realizar os ajustes necessários e transformar a estrutura, inicialmente caracterizada apenas como uma "casca", em um volume preenchido. Na sequência, o modelo digital foi convertido em um corpo sólido.

Para a elaboração do molde, foi criado um esboço retangular, posteriormente submetido à extrusão de modo a envolver completamente a geometria da orelha. Nessa operação, a extrusão foi configurada como "Novo Corpo", evitando sua união indesejada à peça original. Em seguida, utilizou-se o comando Combinar, estabelecendo o retângulo como corpo de destino e a orelha como ferramenta. A operação selecionada foi Corte, mantendo-se habilitada a opção "Manter Ferramentas".

Na etapa seguinte, foi criado um plano de construção destinado à delimitação da linha de partição do molde. A partir desse plano, aplicou-se o comando Divisão de Corpo, obtendo-se duas metades distintas do conjunto (Figura 6-A). Por fim, foram incorporados os elementos necessários ao funcionamento do molde, incluindo os canais para injeção do silicone e os sistemas de encaixe e travamento entre as partes (Figura 6-B).

.A

.B

Fig. 6- Print tirado da área de trabalho do software Fusion 360 da modelagem final VF com acabamento do molde em negativo
Fonte: Acervo do autor

Após o tratamento da malha, o modelo foi refinado no Blender 5.1 e convertido em sólido no Fusion 360. Foram identificadas dificuldades na operação booleana quando havia descontinuidades na malha, exigindo correções adicionais. A linha de partição do molde foi modificada de um corte plano (Figura 6-A) para uma geometria acompanhando a anatomia, melhorando o encaixe entre as partes. Figura 6-B

Em seguida, para o primeiro teste de impressão do molde foi selecionada a impressão em Resina devido ao seu acabamento, porém cabe ressaltar que o molde de resina interfere diretamente na cura do silicone que precisa de catalisador, acredita-se que seja devido às propriedades da resina, impedindo a saída da umidade de dentro do molde, impedindo assim a cura completa do silicone. Figura 7

Para a impressão em Resina será usado a impressora Creality LD-002R, usando os seguintes parâmetros para resina no software de fatiamento:

- marca 3DLAB;
- nome Standard White;
- espessura 50um (oficial).

Porém a resina utilizada para o molde será a da marca KED, a KEDAGBR/F1 BRANCO.

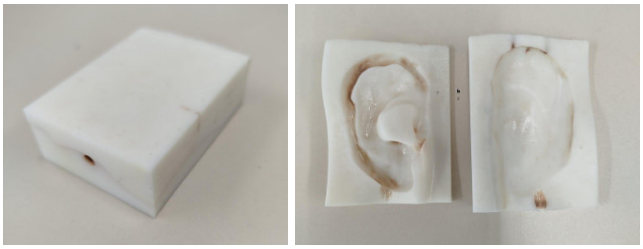


Fig. 7—Molde negativo produzido em resina fotopolimerizável.
Fonte: Acervo dos autores.

No primeiro ensaio, o molde foi impresso em resina fotopolimerizável. Observou-se cura incompleta do silicone, com superfície viscosa e úmida em regiões de contato com o molde. O resultado inviabilizou a obtenção da peça e motivou a substituição do material do molde. Figura 8

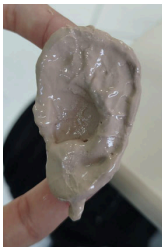

Fig. 8—Resultado do ensaio 1.
Fonte: Acervo dos autores.

Conforme mencionado anteriormente, a resina interfere no processo de catalização do silicone, comprometendo o resultado. Diante da inviabilidade técnica observada com o molde de resina, confeccionou-se um novo componente utilizando o filamento ABS (Acrilonitrila Butadieno Estireno), com o propósito de viabilizar a cura adequada do silicone. Figura 9

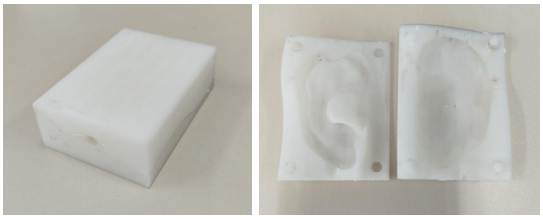

Fig. 9—Molde negativo produzido em ABS.
Fonte: Acervo dos autores.

No segundo ensaio, foi utilizado molde em ABS. O comportamento do silicone foi melhor, mas a peça apresentou cura apenas parcial e textura pegajosa. Esse resultado indicou que a condição química do silicone e/ou do sistema de catalisação também influenciava a polimerização. Figura 10

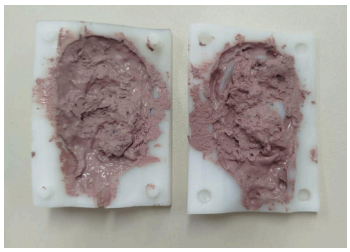

Fig. 10—Resultado do ensaio 2.
Fonte: Acervo dos autores.

Após as intercorrências registradas nos dois ensaios anteriores, conduziu-se um terceiro teste utilizando o mesmo molde em filamento ABS, porém alterando as variáveis do processo: o silicone foi aplicado sem a adição de pigmentos e utilizou-se uma marca distinta, cuja formulação não necessita de catalisador. Este procedimento obteve êxito no que diz respeito à cura do material (Figura 11). Todavia, identificou-se a necessidade de retornar à etapa de modelagem digital para reajustar os furos de injeção do silicone. Essa revisão foi necessária uma vez que ocorreu o escoamento indesejado do material por essa abertura logo após o preenchimento do molde.

Fig. 11—Resultado do ensaio 3.
Fonte: Acervo dos autores.

Após a implementação dos ajustes e a avaliação experimental do terceiro ensaio, realizou-se um novo teste incorporando a pigmentação ao silicone sob a condição da que havia apresentado melhor cura. Foi obtida a peça com o resultado mais satisfatório dentre os experimentos conduzidos anteriormente apresentando cura homogênea e reprodução geral da geometria do molde, porém ainda possui necessidade de ajustes no que tange a mitigação de bolhas que geram falhas na prótese. Figura 12

Fig. 12—Resultado do ensaio 4.
Fonte: Acervo dos autores.

Por fim, realizou-se um ensaio adicional (o quinto ensaio) no presente trabalho, visando ao ajuste cromático e à eliminação de bolhas de ar (Figura 13). Contudo, alguns ajustes serão necessários, como: controle bolhas de ar para evitar vazios estruturais e garantir a integridade da peça; aprimoramento da mistura para a reprodução fidedigna do tom de pele do usuário; intensificação do acabamento com acetona no molde impresso, visando reduzir a rugosidade superficial e, consequentemente, minimizar a transferência das linhas de impressão para a textura da peça final; e inclusão de uma camada envoltória à estrutura auricular projetada, com o intuito de proporcionar uma interface de encaixe e fixação mais precisa à face do paciente.

Fig. 13—Resultado do ensaio 5.
Fonte: Acervo dos autores.

Os cinco ensaios são sintetizados na Tabela 1. A comparação evidencia que a substituição do molde de resina por ABS e a alteração da formulação do silicone foram as principais modificações associadas à melhora do resultado experimental.

Ensaio	**Material do molde**	**Condição do silicone**	**Resultado observado**	**Réplica / conduta**
Teste 1	Resina fotopolimerizável (SLA)	Silicone + catalisador + pigmento	Cura incompleta; superfície viscosa	n=1; substituir molde
Teste 2	ABS (FDM)	Silicone + catalisador + pigmento	Cura parcial; textura pegajosa	n=1; alterar condição química

Teste 3	ABS (FDM)	Silicone sem catalisador e sem pigmento	Cura satisfatória; vazamentos	n=1; ajustar CAD/vedação
Teste 4	ABS (FDM)	Silicone pigmentado	Melhor resultado; cura homogênea	n=1; refinar acabamento
Teste 5	ABS (FDM)	Silicone pigmentado; ajuste cromático	Persistência de bolhas e limitações de cor/textura	n=1; requer novos testes

TABELA 1—Síntese dos ensaios experimentais.
Fonte: Dados do estudo.

Em conjunto, os resultados indicam viabilidade técnica preliminar do fluxo em ambiente laboratorial, especialmente quanto à utilização do ABS como material de molde nas condições avaliadas.

IV. DISCUSSÃO

Os resultados indicam que a principal contribuição do estudo é a identificação experimental da influência do material do molde sobre a cura do silicone. A incompatibilidade observada no molde de resina fotopolimerizável evidencia que a escolha do material do molde deve considerar não apenas acabamento e resolução de impressão, mas também sua compatibilidade química com o elastômero.

A cura incompleta observada no primeiro ensaio pode estar relacionada à presença de resíduos de fotoiniciadores ou monômeros não reagidos na superfície de peças produzidas por fotopolimerização, especialmente quando o pós-processamento não elimina completamente esses componentes. O resultado, contudo, não permite determinar o mecanismo químico específico, pois não foram realizados ensaios laboratoriais de caracterização de resíduos.

Os moldes em ABS apresentaram comportamento mais favorável nas condições avaliadas. O acabamento com acetona reduziu irregularidades superficiais, mas esse procedimento também altera a superfície do polímero e exige controle para evitar deformações.

As dificuldades de escaneamento demonstram que a qualidade da malha depende da geometria anatômica, da aquisição e do processamento posterior. A exploração de IA não permitiu substituir o escaneamento, pois as reconstruções não foram submetidas a análise quantitativa de desvio. Assim, os resultados de IA devem ser interpretados somente como observação preliminar.

Sob a perspectiva da Engenharia Biomédica, o estudo oferece uma contribuição prática ao documentar um problema de compatibilidade entre materiais e uma alternativa de molde que apresentou melhor comportamento nas condições testadas. Estudos futuros devem quantificar desvios geométricos entre o modelo original e a peça, realizar avaliação profissional cega, comparar custos e tempos de fabricação e investigar biocompatibilidade, estabilidade de cor, retenção, resistência e durabilidade antes de qualquer uso clínico.

Embora o fluxo proposto integre as etapas de escaneamento tridimensional, modelagem CAD e manufatura aditiva, este estudo não teve como objetivo estabelecer uma comparação quantitativa com o método convencional. A proposta concentrou-se na validação da viabilidade do método desenvolvido como alternativa para a produção de próteses faciais, buscando verificar sua aplicabilidade e identificar aspectos que possam ser aprimorados em etapas futuras.

Outra limitação é o número de réplicas. Cada condição foi executada uma única vez (n=1), o que impede conclusões sobre variabilidade do processo. Os resultados devem, portanto, ser considerados exploratórios e úteis para direcionar experimentos subsequentes.

Este estudo desenvolveu e avaliou experimentalmente, em ambiente laboratorial, um fluxo digital para a fabricação de uma prótese facial auricular. Os resultados permitiram identificar limitações no escaneamento e na modelagem e, principalmente, uma diferença de comportamento entre moldes em resina fotopolimerizável e ABS durante a moldagem em silicone.

Nas condições investigadas, o molde em resina apresentou cura incompleta do silicone, enquanto o ABS apresentou comportamento mais favorável após acabamento superficial. A melhor condição experimental foi obtida após ajustes na formulação do silicone e incorporação de pigmentação, embora tenham permanecido limitações de bolhas, cor e acabamento superficial.

Os resultados não permitem afirmar que o fluxo esteja validado ou pronto para aplicação clínica, pois cada condição foi testada uma única vez (n=1) e não foram realizadas avaliações quantitativas de precisão, repetibilidade, custo, tempo, propriedades mecânicas, biocompatibilidade, retenção, durabilidade ou satisfação do usuário.

Somente após essas etapas deverá ser considerada a validação clínica do fluxo.

AGRADECIMENTOS

Os autores agradecem pelo apoio no desenvolvimento deste trabalho à Universidade Federal de Goiás (UFG)— Faculdade de Artes Visuais (FAV) e ao Laboratório de Estudos Inventivos em Tecnologia Assistiva (Lab. E.I.T.A.).

***Abstract*—The relationship between manual performance in myoelectrically controlled virtual reality (VR) environments and equivalent real-world tasks is currently poorly understood. The present study investigated the correlation between scores on a conventional physical Box and Blocks Test (BBT) and on the same test performed using a VR setup. In the VR setup, the BBT was implemented as a virtual reality environment, in which virtual hand opening and closing were controlled through a proportional control strategy based on high-density surface electromyography (HD sEMG), while hand position was tracked using the Meta Quest controller. Ten healthy participants completed the BBT under conventional physical and VR setups. Spearman's rank correlation revealed a significant positive association between performance under the two experimental conditions ($\rho_{spearman} = 0.80$; 95% confidence interval (CI): $[0.27, 0.97]$; $p - value = 0.003$). The mean BBT scores under the conventional physical and VR setups were 52.7 (standard deviation (SD) = 5.17) and 9.8 (SD = 3.49) blocks, respectively. The difference between the mean scores of the two conditions was 42.9 blocks (SD = 3.67; 95% CI: [40.8, 45.1]; $p - value = 0.001$). These results indicate that the proposed VR setup may be able to differentiate between varying levels of manual dexterity. Nonetheless, larger sample sizes are necessary to establish a more precise estimate of the association and to further validate the proposed VR setup as a viable alternative for hand dexterity assessment.**

***Index Terms*—Virtual Reality, Box and Blocks Test, High-Density Surface Electromyography, Myoelectric Control, Manual Dexterity.**

I. Introduction

It remains unclear to what extent virtual reality (VR) environments controlled by myoelectric signals can be used as an alternative to physical hand dexterity tests. Differences between physical and virtual environments, such as discrepancies between simulated and real-world physics [1], potential discomfort associated with VR headset use [2], and difficulties with initial contact with myoelectric control [3], [4], may directly influence the execution and performance of the proposed tasks.

The Box and Blocks Test (BBT) is widely used to assess gross manual dexterity in upper-limb motor rehabilitation [5], [6]. More recently, virtual implementations of the BBT have been explored due to their potential to support remote and home-based assessment, provide automatically computed quantitative performance measures, and be incorporated into virtual rehabilitation systems [7]. Everard et al. [7] investigated the relationship between the physical BBT and a VR version without myoelectric control, in which participants manipulated virtual blocks using VR controllers through button presses. The authors reported strong positive correlations between the two environments in both healthy participants and individuals with stroke. Furthermore, Hashim et al. [8] investigated the relationship between performance in a virtual myoelectrically controlled version of the BBT and its physical counterpart in healthy participants, reporting a weak positive correlation between the two conditions. However, the methodology of the latter study does not clearly describe how the correlation analysis was performed. Since each participant completed multiple repetitions of the task, it remains unclear whether the reported correlation was computed from independent observations or from repeated measurements within the same individuals. In addition, Hashim et al. employed a conventional dual-site proportional myoelectric control strategy based on antagonistic forearm muscle activation, rather than an HD sEMG-based proportional motor-intention estimation approach.

Investigating the relationship between performance on the conventional physical Box and Blocks Test (BBT) and on a virtual reality implementation using proportional myoelectric control based on high-density surface electromyography (HD sEMG) still represents a gap in the literature. If a strong

Mário Santana was supported by FINEP under Agreement No. 01.24.0110.00 (Ref. 2140/22). Natanael Batista was supported by the Brazilian Public Ministry of Labor under Contract No. 39433-26.

correlation is observed between scores across the respective environments, such an association would suggest that the proposed VR interface can consistently reflect differences in manual dexterity, even if its scores do not directly reproduce those obtained in the conventional physical BBT. Such a relationship could support the use of the proposed interface as an alternative approach for assessing hand dexterity in clinical populations.

Therefore, the present study aimed to investigate the correlation between the performance of healthy participants on the conventional physical BBT and on a VR implementation of the BBT using proportional myoelectric control based on HD sEMG [9].

II. Methodology

The experimental protocol adopted in the present study is part of a broader research project involving experiments with myoelectric prostheses. However, the prosthesis-related data are outside the scope of the present study and will be analyzed in future work.

The two experimental conditions analyzed in the present study are referred to as the *conventional physical setup*, corresponding to the standard administration of the BBT, and the *VR setup*, in which participants performed a VR implementation of the BBT using a virtual hand whose opening and closing were controlled by proportional myoelectric control based on HD sEMG, while hand position was tracked using the Meta Quest controller. In addition to these two setups, the experimental protocol included a third setup, referred to as the *myoelectric prosthetic setup*, in which the conventional physical BBT was performed using the myoelectric prosthetic system. As stated above, data obtained under the myoelectric prosthetic setup are outside the scope of the present study and will not be included in the analyses.

A. Participants

Ten healthy right-handed participants (age: 31.2 ± 10.2 years) were recruited for the experiment. Inclusion criteria were as follows: absence of upper-limb musculoskeletal injuries and no history of neurological, musculoskeletal, autoimmune, or metabolic diseases. All participants signed an informed consent form prior to participating in the study. The experimental protocol was approved by the Research Ethics Committee of the University of Campinas (UNICAMP), Brazil (CAAE: 90477225.9.0000.5404).

B. Hardware Setup

The developed interface was executed on a Lenovo Legion Pro 5i (Lenovo, Beijing, China) computer equipped with an Intel Core i9-14900HX processor, 32 GB of RAM, and an NVIDIA RTX 4070 GPU with 8 GB of dedicated memory, together with a Meta Quest 3 (Meta, CA, USA) mixed reality headset. HD sEMG signals were acquired at a sampling rate of 2052.52 Hz using a wearable system developed in our laboratory [9].

C. HD sEMG Electrode Placement

Before experiments, the participant's forearm skin was prepared with a light abrasion and alcohol cleaning to reduce skin-electrode impedance. Two 8×8 electrode grids with a 10-mm inter-electrode distance (GR10MM0808, Bioelettronica, Torino, Italy) were positioned in the proximal forearm over the finger flexor and extensor muscles according to the recommendations of Zipp [10]. Specifically, the proximal border of the electrode array placed over the flexor muscles was positioned approximately at 25% of the distance from the medial epicondyle to the anterior wrist crease, measured from the medial epicondyle, and adjusted by palpation to align with the muscle belly. Likewise, the proximal border of the electrode array placed over the extensor muscles was positioned approximately at 25% of the distance between the lateral epicondyle and the ulnar styloid process, measured from the lateral epicondyle, and similarly adjusted by palpation to align with the extensor muscle belly.

D. Myoelectric Control Strategy

To enable proportional myoelectric control, the HD sEMG signals acquired in real time were processed to continuously estimate the participant's movement intention. The control algorithm is fully described in [9], following a synergy-based method [11]. Briefly, root mean square (RMS) features extracted from the HD sEMG recordings were decomposed using non-negative matrix factorization (NMF) into components associated with opposite finger movement directions (flexion and extension). A proportional movement-intention signal was then obtained from these components. The resulting estimate was used to generate proportional control commands to VR hand or a prosthetic device.

Before performing the experimental tasks, the model was calibrated individually for each participant. For the purposes of the present study, participants interacted with the blocks using a three-finger pinch. Therefore, only this gesture was used during model calibration and subsequent task execution. The calibration procedure consisted of the following steps:

1) Initially, the participant performed successive opening and closing movements of a three-finger pinch in synchrony with the movements of a prosthetic or VR hand for 25s while recording HD sEMG signals.
2) Next, the acquired signals were used to estimate the parameters of the myoelectric control model. The model was evaluated based on two criteria: the maximum cross-correlation between the estimated movement-intention signal and the corresponding reference signal, and a brief practical control test performed by the participant. In general, maximum cross-correlation values above 0.5 were considered indicative of satisfactory control performance.
3) If both the correlation metric and the practical control test yielded satisfactory results, the experimental protocol continued. Otherwise, the previous steps were repeated until a suitable model was obtained. If satisfactory performance could not be achieved after multiple

attempts, the experiment was conducted using the best-performing model obtained up to that point.

In the present study, the calibration procedure required a mean of 3.9 attempts per participant ($SD = 2.42$).

E. Box and Blocks Test

The BBT is a functional test to assess the gross manual dexterity [6]. The test consists of a box divided into two compartments by a central barrier, containing wooden blocks on only one side. The participant must transfer, one block at a time, as many blocks as possible from one compartment to the other within 60 seconds. Performance was quantified by the total number of blocks correctly transferred during this time interval. Throughout this paper, the terms *performance*, *score*, and *number of blocks transferred* are used interchangeably to refer to the participant's result on the BBT.

In the present study, the BBT test was performed under three experimental conditions (see Figure 1): the conventional physical setup, the myoelectric prosthetic setup, and the VR setup. In all conditions, the participant remained seated in front of the box positioned on a table.

In the conventional physical and myoeletric prosthetic setups,the BBT box measured approximately 53 cm $\times$ 25.5 cm $\times$ 8.5 cm and was divided into two compartments by a 15.3-cm-high partition. The blocks were cubic, measuring 2.5 cm $\times$ 2.5 cm $\times$ 2.5 cm. These dimensions are close to those reported by Mathiowetz et al. [6]. In the VR setup, the entire BBT environment, including the box, partition, and virtual blocks, was proportionally scaled according to the corresponding real-world dimensions.

F. Virtual Reality Environment

The VR environment developed consists of a replica of the laboratory room where the experiments were conducted. The interface was developed in Unity (Unity Technologies, San Francisco, CA, USA) and designed to support two users simultaneously: the participant immersed in the VR environment using the Meta Quest 3 headset, and the experimenter responsible for monitoring and configuring the test via an external computer. Figure 2 illustrates the developed VR version of the BBT.

During the experiment, the experimenter was able to view the environment as seen by the participant in real time, as well as to make necessary adjustments to the interface and experimental parameters. These adjustments included positioning the participant within the virtual scene and adjusting their height.

G. Experimental Protocol

The experiment was conducted in a single session. Before the experiment, the participant was screened for eligibility and demographics were collected. After these initial steps, the HD sEMG electrode grids were positioned on the participant as described in Subsection II-C. Once the grids were secured and connected to the HD sEMG acquisition system, the experiment started.

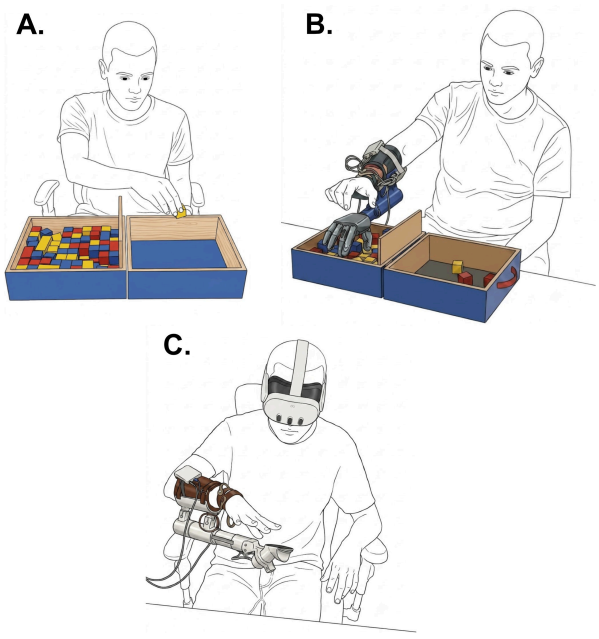

Fig. 1. Experimental conditions of the Box and Blocks Test: (A) conventional physical setup, (B) myoelectric prosthetic setup, used for model calibration and not included in the analyses presented in this study, and (C) VR setup, consisting of a virtual reality implementation of the BBT, in which virtual hand opening and closing were driven by proportional myoelectric control based on high-density surface electromyography (HD sEMG), while hand position was tracked using the Meta Quest controller.

First, the participant performed the BBT under the conventional physical setup. Before the test, the participant received instructions regarding the test procedure and completed a brief familiarization task by transferring five blocks from one compartment of the box to the other. After the familiarization phase, the full test was administered once, and the participant's score was recorded.

After completing the conventional physical BBT, the participant performed the BBT under the myoelectric prosthetic setup. As previously noted, the data obtained under the prosthetic condition are not included in the analyses presented in the present work and will be reported in future studies. For this stage, a socket that attaches the prosthesis to the participant's arm was used. In addition, as described in Section II-D, the myoelectric control model was calibrated using the prosthetic hand as the reference hand. Once again, the participant received instructions regarding the test procedure and completed a shortened version of the task, transferring five blocks between the box compartments to become familiar with both the prosthetic system and the task dynamics. After this adaptation phase, the complete test was performed once, and the score was recorded.

Finally, the participant performed the BBT under the VR setup. For this purpose, the same myoelectric control model previously calibrated for the prosthetic condition was used, along with a socket similar to that used in that condition, which secured the Meta Quest 3 controller to the participant's arm. Once again, the participant received instructions regarding

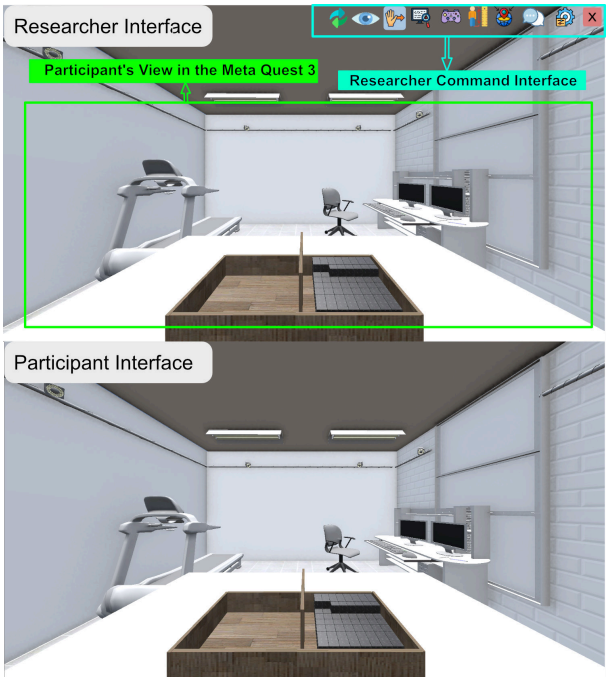

Fig. 2. Interfaces of the VR setup developed in Unity. The upper portion displays the researcher interface, containing controls for scene configuration, while the lower portion displays the participant interface used to interact with the virtual environment.

the test procedure and completed an adaptation phase by transferring five blocks between the box compartments in the VR environment. Subsequently, the complete VR BBT was performed once, and their performance was recorded.

In cases where the model calibrated for the prosthetic condition did not provide satisfactory control performance in the VR setup, an additional calibration procedure was performed following the protocol described in Section II-D, using the virtual hand as the reference. The latter condition occurred only for one participant, who was unable to successfully perform the task using the prosthetic system. After recalibration, satisfactory control performance was achieved in the VR environment.

It is worth noting that no BBT trials performed under the conventional physical and VR setups were excluded from the analyses.

H. Data Analysis

1) Correlation Analysis: The performance of each participant was represented by an ordered pair corresponding to the results obtained under the VR and physical setups, respectively. The relationship between VR and physical performance was evaluated using Spearman's correlation coefficient ($\rho_{spearman}$). For this analysis, the correlation coefficient, the p-value associated with Spearman's test, and the corresponding 95% confidence interval were estimated, with the latter obtained using the percentile bootstrap method [12] with $20,000$ paired resamples. The number of resamples was selected after preliminary analyses indicated that further increases produced only negligible changes in the estimated confidence intervals. Since the study hypothesis assumed that participants with better performance in VR would tend to exhibit better performance with their physical hand, a one-tailed test was used to evaluate the presence of a positive correlation between the conditions ($H_0 : \rho_{spearman} \leq 0$ and $H_1 : \rho_{spearman} > 0$). A statistical significance level of 5% was adopted.

2) Difference Between Mean Scores of the Environments: The difference between the mean scores obtained under the conventional physical and VR setups was evaluated. The p-value of this difference was obtained using an exact paired permutation test based on all possible sign permutations of the paired differences [13], whereas the 95% confidence interval was estimated using the percentile bootstrap method [12] with 20,000 resamples. Similarly to the correlation analysis, preliminary analyses indicated that increasing the number of resamples beyond 20,000 did not change the estimated confidence intervals. Since the study hypothesis assumed that performance in the conventional physical setup is superior to that observed in VR, a one-tailed test was adopted for the comparison between means ($H_0 : \mu_{Physical} - \mu_{VR} \leq 0$ and $H_1 : \mu_{Physical} - \mu_{VR} > 0$). A significance level of 5% was adopted.

III. Results

A positive Spearman's correlation was observed between the performance under the VR and conventional physical setups ($\rho_{spearman} = 0.80$; 95% confidence interval (CI): $[0.27,\ 0.97]$; $p - value = 0.003$). The relationship between the scores obtained under the two conditions is presented in Figure 3.

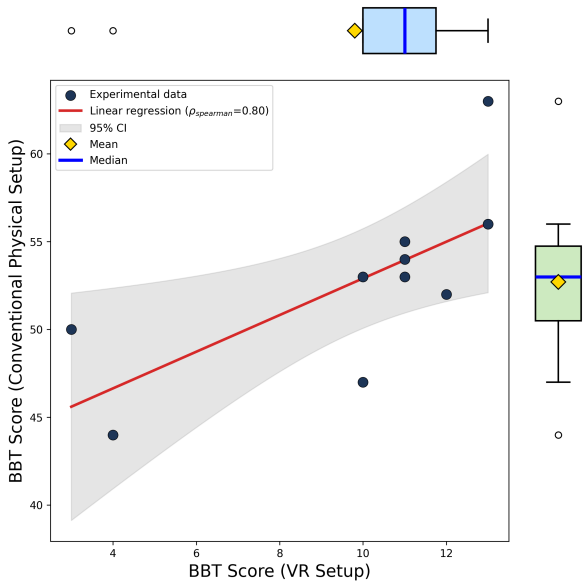

Fig. 3. Relationship between the BBT scores obtained under the VR and conventional physical setups. The solid line represents the linear fit to the data, and the shaded region corresponds to the 95% confidence interval of the fitted line.

In addition to analyzing the relationship between performances obtained under the two experimental conditions, the difference between the mean BBT scores obtained under the conventional physical and VR setups was also evaluated. The mean scores obtained under the conventional physical and VR setups were 52.7 (standard deviation (SD) = 5.17) and 9.8 (SD = 3.49) blocks, respectively. The difference between the mean scores of the two conditions was 42.9 blocks (SD = 3.67; 95% CI: [40.8, 45.1]), and this difference was statistically significant ($p-value = 0.001$). The distribution of the scores under each condition is shown in Figure 4.

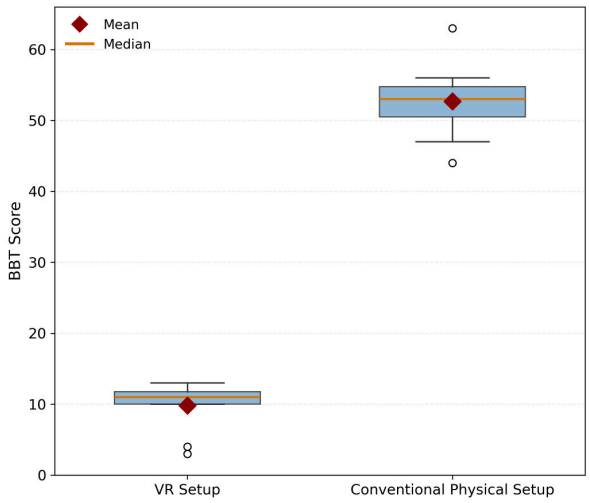

Fig. 4. Distribution of BBT scores under the conventional physical and VR setups. Diamonds represent the sample means, and horizontal lines represent the median values.

IV. Discussion

The results of the present study showed a positive correlation between BBT performance under the conventional physical and VR setups, suggesting that participants who perform better under one condition tend to perform better under the other. However, the wide confidence interval for the correlation coefficient suggests that the magnitude of this association should still be interpreted with caution, given the small sample size ($N = 10$). The observed positive association between performance under the conventional physical and VR setups is consistent with previous findings in the literature. Everard et al. [7] also reported positive correlations between performance on the conventional BBT and its VR counterpart, even in the absence of myoelectric control. Similarly, Hashim et al. [8] observed a positive association between performance on the original test and its VR version with myoelectric control. However, the latter study did not employ an HD sEMG-based motor-intention estimation approach. Also, in [8], the description of the procedure used to calculate the correlation coefficient was not sufficiently detailed to allow a clear interpretation of the independence of the data points included in the analysis. Therefore, evidence regarding the association between performance under conventional physical conditions and VR tasks controlled through myoelectric interfaces remains limited in the literature, and the present study provides additional evidence to address this gap.

Regarding the BBT scores, participants transferred significantly fewer blocks under the VR setup than under the conventional physical setup. One possible explanation for this difference is that, unlike the conventional physical setup, the VR setup required participants to control the virtual hand through an HD sEMG-based myoelectric interface, simultaneously performing the functional task and managing a control strategy with which they had little familiarity. This interpretation is supported by Tabor et al. [3], who demonstrated that myoelectric control learning is a gradual and complex process, with consistent improvements occurring across successive training sessions and no evidence of an early performance plateau. Their findings suggest that performance measured during the initial stages of myoelectric training may underestimate an individual's true capability after sufficient practice. Therefore, the participants' limited experience with myoelectric control likely contributed to the lower scores observed under the VR setup compared with the conventional physical setup.

Additionally, it should be considered that participants have extensive experience using their hands in activities of daily living, making superior performance under the conventional physical setup expected when compared with performance achieved using a newly learned myoelectric control strategy. In agreement with this perspective, Daud et al. [14] state that activities of daily living, such as writing, tying shoelaces, and buttoning a shirt, contribute to the development of fine motor skills and manual dexterity. Therefore, the participants' extensive prior experience performing these tasks with their physical hands may have contributed to the superior performance observed under the conventional physical setup.

Factors inherent to VR environments may also have contributed to the observed reduction in performance. Such factors include the absence of natural tactile feedback [7], differences in spatial perception [15], and discomfort associated with VR headset use [2]. Evidence supporting this interpretation is provided by Everard et al. [7], who also observed lower performance in a virtual version of the BBT that did not employ myoelectric control. Therefore, because reduced performance was observed in two interfaces using different control strategies, the present results suggest that this phenomenon is not solely due to the limitations of HD sEMG-based myoelectric control but also reflects, at least in part, challenges inherent to interaction within VR environments.

Taken together, the results suggest that the proposed VR setup has the potential to effectively differentiate between levels of manual dexterity, despite not perfectly mimicking performance under the conventional physical setup. Although a significant difference in mean scores was observed between the conventional physical and VR setups, performance across both modalities was positively correlated. This indicates that, despite the systematic difference in absolute scores between the two setups, participants who performed better under the conventional physical setup also tended to perform better

under the VR setup. Therefore, the utility of the VR setup for assessing manual dexterity does not necessarily depend on reproducing the absolute scores obtained under the conventional physical setup, but rather on its ability to distinguish different levels of manual dexterity.

However, the findings of the present study should be interpreted in light of some additional limitations. First, the different experimental setups were performed in a fixed order (conventional, prosthetic, and VR setups, respectively), which may have introduced learning and fatigue effects during the tests in subsequent setups. In addition, as previously discussed, the relatively small sample size ($N = 10$) limits the precision of the estimates obtained, as evidenced by the wide 95% confidence intervals. The present study also did not investigate the intra-subject repeatability or test-retest reliability of the proposed VR setup, nor did it assess potential learning and adaptation to its HD-sEMG-based myoelectric control strategy.

Future studies should address these limitations by using larger sample sizes and randomized or counterbalanced experimental orders to minimize potential effects associated with learning and fatigue and to obtain more precise estimates with narrower confidence intervals. Furthermore, protocols involving multiple sessions and repeated assessments should be adopted to investigate the intra-subject repeatability and test-retest reliability of the proposed VR setup, as well as potential learning and adaptation effects associated with repeated use of the HD-sEMG-based myoelectric control strategy. Beyond these considerations, future work could explore alternative control strategies that increase the number of degrees of freedom of the virtual hand, enabling more complex and versatile hand movements.

V. Conclusion

The present study examined the correlation between performance on the BBT under the conventional physical and VR setups. The results showed a positive correlation between performance under the two experimental conditions, suggesting that participants who performed better under the conventional physical setup also tended to perform better under the VR setup, despite differences in absolute scores between the two setups. These findings contribute to the understanding of manual dexterity assessment in virtual reality using proportional HD sEMG-based control and suggest that the proposed VR setup may have potential for future use in assessment and rehabilitation training applications. Future studies with larger sample sizes are necessary to confirm the observed association and to further validate the proposed VR setup.

Acknowledgment

The authors would like to thank Mr. Flavio Renato Santos and Mr. Nelio Hilton Gava from the Main Design Lab, Center for Biomedical Engineering (CEB), UNICAMP, for their technical support in manufacturing the sockets used in this study and in fabricating and maintaining the prosthetic system.

***Abstract*—Noninvasive peripheral electrical stimulation has been investigated as an alternative approach for managing tremor in Parkinson's disease, particularly due to the limitations of prolonged pharmacological treatment and the invasiveness of surgical treatments. The aim of this work was to develop and implement an integrated platform for alternating peripheral electrical nerve stimulation with real-time tremor monitoring, enabling the evaluation of different waveforms and individualized stimulation parameters. The system consisted of a dual-channel electrical stimulator, a hand-worn wireless triaxial accelerometry module, and graphical user interfaces for stimulation control, signal acquisition, visualization, and analysis. A protocol was implemented in the user interface to apply patterned bursts of either biphasic pulse or sinusoidal electrical stimulation. The median and radial nerves were stimulated alternately at the patient's tremor frequency. A pilot study was conducted with ten patients with Parkinson's disease (PD), assigned to either the biphasic pulse stimulation group (n = 5) or the sinusoidal stimulation group (n = 5). The stimulator interface allowed configuration of waveform type, amplitude, frequency, and burst frequency. The monitoring interface enabled real-time acquisition and analysis of acceleration signals. In the pilot study, both biphasic pulse and sinusoidal stimuli produced a median tremor reduction of -29.66% and -17.25%, respectively. The integrated platform was shown to be flexible and functional for alternating peripheral electrical nerve stimulation and real-time tremor monitoring. The system supports the investigation of different protocols and waveforms, although it currently operates in an open-loop configuration; future work should integrate stimulation control with the accelerometry system to implement closed-loop strategies.**

***Index Terms*—Electrical stimulation, neurostimulation, Parkinson's Disease, TAPS.**

I. Introduction

Noninvasive electrical stimulation represents a well-established therapeutic modality in clinical settings, encompasses diverse techniques and anatomical targets, including transcranial, neuromuscular, and peripheral nerve stimulation (PNS) [1]. In particular, PNS is utilized across a wide spectrum of disorders, including: neurological and movement disorders (attenuation of pathological tremors in Parkinson's Disease and Essential Tremor, spasticity management, and facilitation of neural plasticity following stroke) [2], [3]; acute and chronic pain conditions (modulation of nociceptive and neuropathic pain through spinal gate mechanisms and endocrine opioid release) [4], [5]; autonomic and circulatory dysfunctions (modulation of peripheral blood flow, acceleration of tissue healing, and regulation of sympathovagal tone via transcutaneous vagus nerve stimulation) [6], [7].

Parkinson's disease (PD) is a progressive neurodegenerative disorder and one of the most prevalent worldwide, affecting approximately 6.1 million people [8]. PD is characterized by the loss of dopaminergic neurons in the substantia nigra [9], [10], causing motor symptoms such as tremor [11], bradykinesia [12], and gait disturbances [13]. Tremor is one of the most prevalent manifestations in patients with PD, significantly impacting daily activities and quality of life. Pharmacological treatment with levodopa and other dopaminergic agents is a common approach for managing motor symptoms in DP. However, the prolonged use of these medications can lead to relevant side effects, such as motor fluctuations, dyskinesias, and other complications that may limit their long-term effectiveness [14], [15].

Non-pharmacological alternatives based on electrical stimulation, such as Deep Brain Stimulation (DBS), have been explored as complementary methods for tremor management. DBS applies electrical pulses to specific subcortical nuclei for tremor reduction. Despite its clinical efficacy, DBS is an invasive intervention associated with surgical risks [16]. Consequently, non-invasive neuromodulation techniques have

emerged as promising alternatives for tremor management.

Among the non-invasive alternatives, peripheral electrical stimulation such as Functional Electrical Stimulation (FES) and Transcutaneous Electrical Nerve Stimulation (TENS) has been investigated. FES applies electrical pulses to evoke muscle contractions, generating compensatory forces that counteract tremor-related oscillations [17]. In contrast, TENS delivers sub-motor-threshold stimulation (electrical pulses) to peripheral afferent nerves, primarily activating thick sensory fibers [18], and is typically applied over the radial and/or median nerves at the wrist [19]. Although the underlying mechanism through which TENS attenuates tremor remains elusive, it is widely hypothesized that the stimulation of peripheral sensory fibers modulates pathological oscillations within the central nervous system [20]. In patients with PD, these oscillations may be associated with abnormally synchronized neural activity. Abnormally synchronized neuronal firing in structures such as the basal ganglia and thalamus may occur at a frequency close to that of the clinically observed tremor [21]. Computational studies of coordinated reset (CR) neuromodulation [21], [22] showed that sequential phase-resetting stimuli, delivered with coordinated delays corresponding to fractions of the characteristic oscillation period (e.g., a fraction of the Parkinsonian tremor period), can separate a pathologically synchronized neuronal population into phase-shifted subgroups. This phase-shifted can be implemented through direct electrical stimulation of neurons' somata or indirectly through synaptically mediated stimulation, such as non-invasive sensory stimulation [22].

Studies have evaluated the wrist-worn Cala ONE stimulator device (Cala Health, Inc., San Mateo, CA, EUA) in patients with Essential Tremor (ET) [23] and more recently in DP [24], reporting promising reductions of tremor. The device uses Transcutaneous Afferent Patterned Stimulation (TAPS), a neuromodulation technique that delivers patterned bursts of electrical biphasic pulse stimulation alternately to the median and radial nerves at the patient's tremor frequency (e.g., 5 Hz). Stimulation parameters for tremor reduction, including intensity, frequency, duration, and waveform, remain insufficiently defined in the literature [17].

Pulsatile electrical stimulation is widely utilized to artificially elicit tactile responses, recruit intermediate nerve fibers ($A\beta$) [25], [26]. However, elevating the stimulation intensity subsequently recruits small-diameter fibers ($A\delta$ and C) [27]. These limitations suggest that more selective engagement of somatosensory pathways could potentially yield superior therapeutic effects on motor symptoms. Among the alternative stimulation waveforms, sinusoidal electrical stimulation has been shown to provide more selective activation of sensory nerve fibers [28], [29]. Within this context, we proposed to develop an integrated platform to investigate Transcutaneous Somatosensory Sine-Wave Electrical Stimulation (tSSES) —a modality employing continuous sinusoidal waveforms to target specific afferent fiber populations [28]–[30] -recently emerged as a promising alternative for tremor management in Parkinson's disease [31].

II. Materials and Methods

The proposed system is composed of three main components: A) a dual-channel electrical stimulator; B) a hand-worn wireless accelerometry module; and C) a user interface for control and signal monitoring. The general structure is shown in Fig. 1, and each subsystem is described in this section.

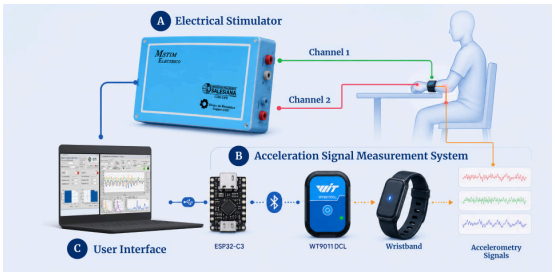

Fig. 1. General system structure. A) Dual-channel electrical stimulator to arbitrary waveform; B) Wireless accelerometry module; and C) User interface for stimulation control and signal monitoring.

A. Electrical Stimulation

The stimulation module is based on the MESTIM-ELECT stimulator [32], powered by a 12-V battery supply. Each channel includes a constant-current source capable of delivering up to 10 mA. The stimulator provides two fully independent channels, each capable of generating arbitrary waveforms (sinusoidal, square, or custom).

Stimulation parameters -including waveform, amplitude, and channel activation- are sent through a LabVIEW interface and transmitted to the stimulator via Ethernet communication. This architecture enables the configuration of diverse protocols for the user.

B. Accelerometer System

The tremor monitoring subsystem is based on the BWT901CL-BT50 module (WitMotion Shenzhen Co., Ltd.), which integrates a 9-axis IMU (accelerometer, gyroscope, and magnetometer) with onboard Kalman filtering for real-time motion estimation. The module supports Bluetooth Low Energy (BLE) communication and sampling rates up to 200 Hz; for this study, the sampling frequency was set to 50 Hz.

A XIAO-ESP32-C3 microcontroller (Seeed Studio) was used as the BLE receiver. It establishes a wireless link with the IMU and forwards the decoded motion data to the computer via serial communication. This setup enables continuous, low-latency acquisition of tremor signals during stimulation.

C. User Interface

The user interface originally developed for the MESTIM-ELECT stimulator [32] was expanded to support novel stimulation paradigms. Currently, a stimulation protocol based on TAPS, designed for tremor suppression in Parkinson's disease, was incorporated. In this protocol, each channel alternately delivers electrical stimulus to two different peripheral nerves. The alternation rate is determined by a user-configurable burst frequency (F_{b}) parameter, allowing the system to be

adapted to different experimental protocols as well as to the individual needs of each patient. Actually, two stimulation options are available: a charge-balanced biphasic square wave and a sinusoidal waveform.

The biphasic square waveform consisted of a 150 Hz waveform with a positive phase (300 μs), an interphase interval of 50 μs, and a negative phase (300 μs), following stimulation parameters commonly reported in studies involving peripheral nerve stimulation for ET and PD [23], [33]. The novel protocol utilizing a sinusoidal signal was proposed. For both waveform types, the stimulation amplitude and the frequency parameters can be configured by the user through the user interface. The user can also define a burst frequency (F_{b}) that controls the temporal alternation between the two independent output channels of the stimulator. Each channel remains active for a period equal to $1/(2 \times F_{\mathrm{b}})$, while the other channel remains inactive.

D. Graphical User Interface Customized for monitoring tremors in Parkinson's disease

A custom Graphical User Interface (GUI) was developed to monitor, record, and analyze real-time acceleration signals from Parkinson's disease patients in both time and frequency domains. The interface establishes a serial communication protocol with the microcontroller ESP32-C3 to receive multi-axis kinematic data, which is simultaneously logged into structured text (.txt) files for offline analysis.

The GUI processes the incoming data utilizing a sliding-window architecture, where both the window length and the sampling frequency are fully configurable. To isolate pathological tremors from voluntary movements and constant gravitational acceleration components, the raw signals are filtered using a 4th-order Butterworth filter. This filtering stage allows the user to select between low-pass, high-pass, band-pass, or band-stop topologies, with a predefined default band-pass range from 3 to 12 Hz. The GIU performs concurrent spectral and temporal analyses on the segmented data blocks.

Power Spectral Density (PSD) Estimation: Spectral analysis (PSD) is conducted by applying a Hanning window to each signal segment. To ensure statistical stability and smooth transient noise, a running exponential average of five consecutive PSD windows was implemented. This averaging method gives greater weight to recent PSD estimates than to older ones, enabling rapid adaptation to recent tremor variations. To provide an omnidirectional representation of tremor power independently of sensor orientation, the individual PSDs from the orthogonal axes (X, Y, and Z) are combined to construct a joint Random Vector PSD [34]. Within the computed PSDs, two primary metrics are extracted: first, a peak-detection algorithm identifies the dominant frequency; second, the ratio between the power of the dominant spectral peak and the total power within the filtered frequency band (3–12 Hz) is calculated. This ratio provides a quantitative criterion for detecting the presence of tremor [35], [36].

Envelope Extraction: Temporal amplitude variations are tracked via the analytical signal obtained through the Hilbert Transform, computed over the same operational sliding windows. The signal envelope is defined as the magnitude of this analytical signal, which is subsequently averaged to a single representative value per window. These windowed values are utilized to compute a cumulative acceleration magnitude vector, which is plotted in real-time against the time domain to monitor changes in movement amplitude.

E. Pilot Experimental Protocol

A pilot study was conducted with ten male patients diagnosed with Parkinson's disease and presenting clinically evident tremor. The patients were between 58 and 75 years of age (66 $\pm$ 5.8 years) and were classified as stages 1 to 3 according to the Hoehn and Yahr scale. Patients with Parkinson's disease-related dementia, diabetes, a history of upper-limb injuries or implanted biomedical devices, such as cardiac pacemakers or Deep Brain Stimulation (DBS) systems, were excluded. The protocol was approved by the Research Ethics Committee (CAAE 58744222.2.1001.5257), and all patients provided written informed consent.

The study was performed in a temperature-controlled room (24 $\pm$ 1 °C) at the Neurology Service of the Hospital Universitário Clementino Fraga Filho (HUCFF), Federal University of Rio de Janeiro (UFRJ). Patients remained seated with their forearms supported on a table, and the upper limb most affected by tremor was selected. After the skin was cleaned, bipolar gel electrodes were positioned over the median and radial nerves, and a triaxial accelerometer was also attached to the dorsum of the same hand.

Subsequently, a postural tremor task based on the Movement Disorders Society–Unified Parkinson's Disease Rating Scale (MDS-UPDRS Part III) was performed. During the task, participants maintained the upper limb in the required posture for 20 s while acceleration signals were recorded. The dominant tremor frequency was identified as the frequency component with the highest spectral amplitude during the postural task.

Patients were randomly assigned to either the biphasic stimulation group (n = 5) or the sinusoidal stimulation group (n = 5). The stimulation waveform frequency was set to 150 Hz for biphasic stimulation and 3 kHz for sinusoidal stimulation. Before the intervention, the sensory threshold (ST) was determined separately for the median and radial nerves according to the procedure described in [29]. For each nerve, the stimulation amplitude was gradually increased from the respective ST until the highest comfortable and well-tolerated amplitude was reached, and lower sub-motor threshold.

Electrical stimulation was applied for 40 min, with stimulation alternating (burst frequency = initial postural frequency) between the median and radial nerves according to the previously determined dominant tremor frequency. Immediately after the stimulation, the postural task was performed again following the same procedure used in the pre-stimulation assessment.

F. Processing

Accelerometer signals were saved for offline analysis and processed in MATLAB (MathWorks, Inc., Natick, USA). A 4th-order Butterworth high-pass filter at 0.5 Hz was first applied to remove low-frequency drift. Subsequently, the Power Spectral Density (PSD) was estimated using Welch's method.

The relative percentage reduction was calculated with respect to the pre-stimulation period, and results are presented as medians with the quartile range [Q1–Q3], corresponding to the 25th (Q1) and 75th (Q3) percentiles. For full experimental pilot study and analysis details, see the companion manuscript entitled "Effects of Peripheral Electrical Stimulation Waveforms on Tremor in Parkinson's Disease: A Pilot Study" submitted to the XXX Brazilian Congress of Biomedical Engineering (CBEB 2026) [37].

III. Results

A. Electrical Stimulator User Interface

Fig. 2 presents the user interface implemented for setting the stimulation protocol. The interface includes the protocol stimulation (section 1), the configuration of the burst frequency (F_b) to control the alternation between the two channels (section 2), and the independent adjustment of waveform type, frequency, and amplitude for each channel. It also displays the waveforms generated by both channels (section 3). Channel 1 is active during the first half of the burst period, whereas Channel 2 is activated during the second half, producing an alternating stimulation pattern. Fig. 2.A shows the charge-balanced biphasic waveform configured at 150 Hz, while Fig. 2.B shows the sinusoidal waveform configured at 3 kHz. The enlarged waveform segments illustrate the morphology of each stimulation signal.

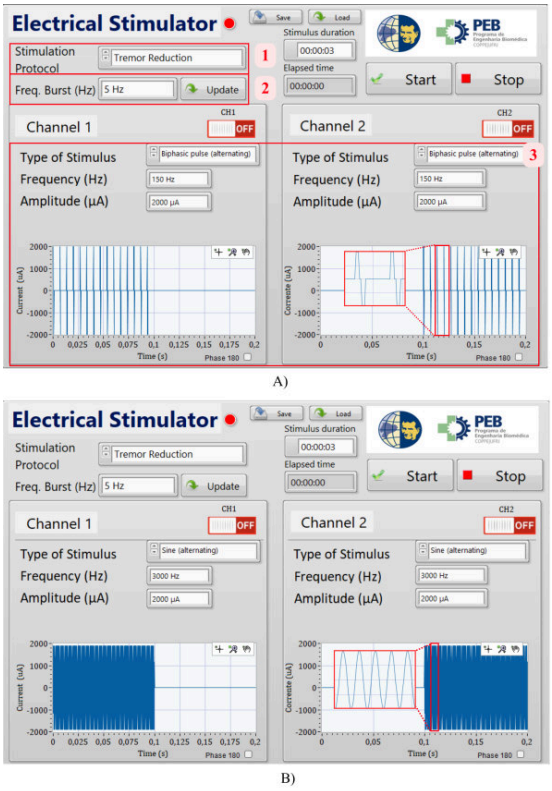

Fig. 2. User interface of the MESTIM-ELECT electrical stimulator. A) Interface configured with a charge-balanced biphasic square waveform (150 Hz); B) Interface configured with a sinusoidal waveform (3 kHz). Both configurations use the protocol designed for tremor suppression in Parkinson's disease (section 1) and include burst frequency (F_b) adjustment (section 2) to control the alternation between stimulation channels.

B. Application for monitoring tremor in Parkinson's disease

The custom graphical user interface (GUI) was successfully implemented for the real-time acquisition, visualization, and processing of triaxial acceleration signals. As shown in Fig. 3, the interface is divided into functional modules that support experimental control and simultaneous time- and frequency-domain analysis.

- *Section A* contains the main acquisition settings. It allows the operator to select and connect the acquisition device through the designated serial COM port, stop data acquisition, and configure the parameters used for spectral analysis, including the number of samples per window, window overlap, and sampling frequency.
- *Section B* integrates the controls required to monitor the experimental protocol. The tool enables operators to select a specific MDS-UPDRS movement, insert a tracking marker, and record execution time.
- *Section C* contains signal-processing controls. It allows operators to enable or disable the digital filter, select the filter type, and define the lower and upper cutoff frequencies. Users can also select the window function for power spectral density (PSD) estimation. In addition, the PSD reset control clears the accumulated spectral estimate at the start of a new task or recording stage.
- *Section D* includes a configurable PSD threshold for tremor validation and visual indicators (LEDs) that show whether the criterion is met for acceleration axis or the three-dimensional Random Vector [34].

Sections E, F, and H display the acquired and processed signals.

- *Section E* presents the acceleration signals in the time domain.
- *Section F* displays the PSD estimates and dominant frequencies for the X, Y, and Z axes. Visual indicators identify the axis with the maximum spectral peak.
- *Section G* displays the PSD of the three-dimensional Random Vector, together with its peak PSD value.
- Finally, *Section H* displays the time-domain envelope of the triaxial acceleration signals, with event markers as dashed vertical lines.

C. Pilot Study

This section presents an example of the results obtained with the Integrated Platform for Alternating Peripheral Electrical Nerve Stimulation. The complete findings of the pilot study are reported in [37].

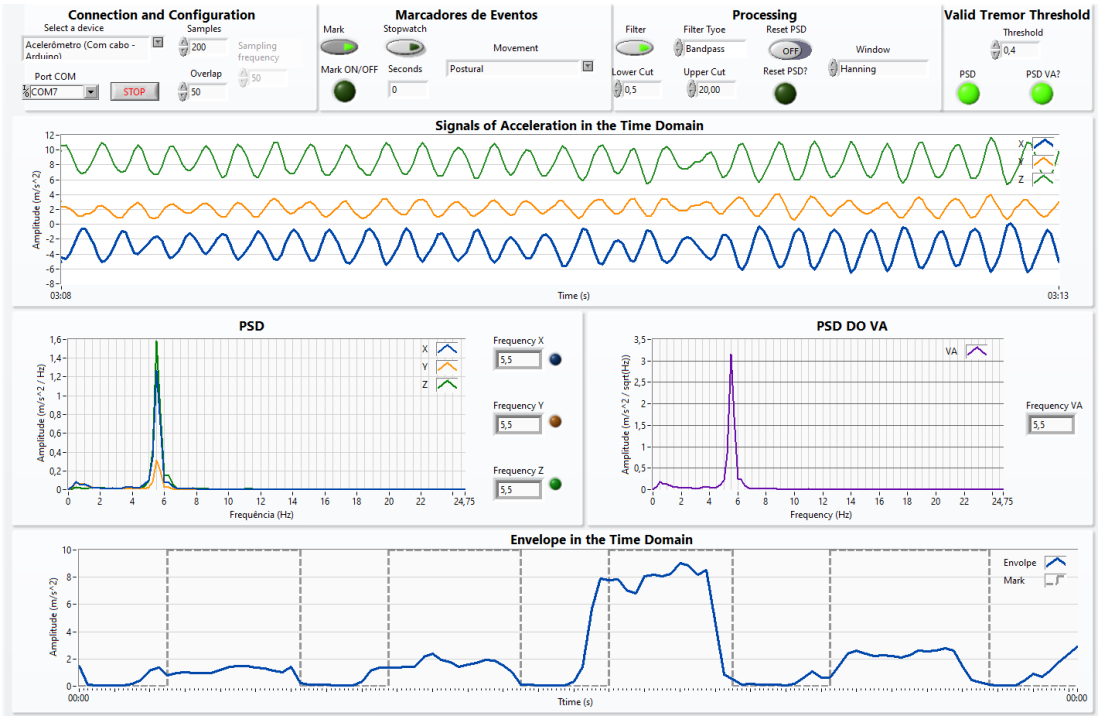

Fig. 3. Graphical user interface developed for real-time acquisition, monitoring, and analysis of tremor-related acceleration signals. A) Device connection and acquisition settings; B) MDS-UPDRS movement selection, event-marker controls, and task timing; C) Digital filtering and PSD configuration; D) Tremor validation threshold setting; E) Time-domain acceleration signals for the X, Y, and Z axes; F) PSD estimates of the three acceleration axes and their dominant frequencies G) PSD of the three-dimensional Random Vector and its dominant frequency; H) Time-domain signal envelope with MDS-UPDRS movement markers.

Fig. 4 shows the PSD of the postural tremor recorded pre- and post-stimulation for both the biphasic pulse and sinusoidal protocols. In both protocols, the dominant tremor peak power decreased post-stimulation: biphasic pulse stimulation produced a 60% reduction in peak tremor power, while sinusoidal stimulation produced a 57% reduction. In addition to changes in amplitude, the biphasic pulse protocol did not produce a change in the dominant tremor frequency, which remained at 2.5 Hz during both the pre to post stimulation; similarly, in the sinusoidal protocol, the dominant frequency also remained unchanged.

Post-stimulation, the median relative reduction across participants was -29.66% $[-71.58; -13.34]$ for the biphasic-pulse protocol and -17.25% $[-20.92; 10.86]$ for the sinusoidal protocol.

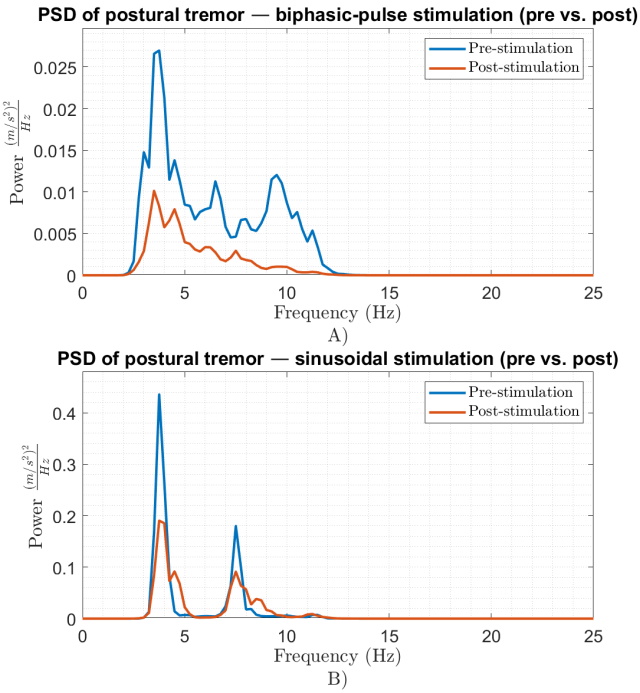

Fig. 4. Power spectral density (PSD) of postural tremor recorded pre- and post-stimulation. A) Patient A — PSD pre and post biphasic square stimulation, and B) Patient B — PSD pre and post sinusoidal stimulation.

IV. Discussions and Conclusions

In the present work, an Integrated Platform for Alternating Peripheral Nerve Stimulation was developed and implemented, combining a programmable dual-channel electrical stimulator, wireless triaxial accelerometry, and dedicated graphical interfaces for stimulation control, signal monitoring, and analysis. Its contribution is the implementation of a flexible experimental framework that accommodates alternative stimulation paradigms while providing a platform for the exploration of new waveforms. This is relevant because key aspects of peripheral electrical stimulation for Parkinson's disease, including

the site of stimulation, stimulation protocols, amplitude, and waveform design, have yet to be comprehensively evaluated, warranting further investigation [17]. Compared with commercial wrist-worn devices for specific clinical applications, such as gammaCore and Cala One, the present platform allows user-defined adjustment of waveform type, amplitude, stimulation frequency, burst frequency, channel alternation, and session duration. This configurability enabled the implementation of a charge-balanced biphasic pulse stimulus based on Transcutaneous Afferent Patterned Stimulation (TAPS) like stimulation reported in Essential Tremor and Parkinson's disease studies [23], [24]. In addition, the platform demonstrated the feasibility of implementing sinusoidal stimulation as an alternative paradigm for investigating somatosensory afferent neuromodulation. Sinusoidal stimuli are particularly relevant because current perception threshold (CPT) studies indicate that stimulation frequency can influence the activation of specific sensory fiber populations. For example, high-frequency stimuli (2-3 kHz) preferentially activate large-diameter, $A\beta$ fibers.

Another aspect of the system is the use of tremor information to individualize the stimulation protocol before the intervention. As indicated by computational simulations in [21] and [22], phase coordinated stimulation can promote desynchronization by dividing a synchronized neuronal population into multiple subpopulations (M), each receiving sequential stimuli with delays equal to a fraction of the pathological tremor oscillation. In these computational studies, M = 3 and 4 were more efficiently than M = 2 to disrupt pathological synchrony by creating several out of phase subgroups. In our practical implementation, stimulation was applied through two peripheral nerves, producing M = 2 subpopulations, similar to the configuration used in the Cala ONE [33]. Even with two stimulation subpopulations, the system still suggests tremor reduction.

This theoretical concept is also supported by studies in patients showing that knowledge of individual tremor characteristics can be relevant for defining stimulation parameters. Pascual-Valdunciel et al. [38] reported that transcutaneous spinal cord stimulation delivered at the individual tremor frequency reduced tremor amplitude by approximately 25% during the latter half of stimulation and produced a greater reduction than stimulation delivered at 21 Hz. Similarly, in patients with Parkinson's disease, Arruda et al. [39] showed that median nerve stimulation phase-locked to limb acceleration could either attenuate or amplify tremor depending on the phase at which stimulation was delivered. Together, these findings indicate that the motor response to electrical stimulation depends not only on the stimulation parameters themselves, but also on their temporal relationship with the ongoing tremor oscillation.

The burst frequency was defined based on the dominant initial postural tremor frequency estimated using the accelerometry module, allowing the stimulation parameters to be adapted to each participant. These features highlight the platform's flexibility and its potential to be adapted for a wide range of applications in research, diagnosis, and treatment.

For example, Sigurdsson et al. proposed transcutaneous cervical vagus nerve stimulation (tcVNS) as a potential therapeutic approach for gait rehabilitation and for non-motor symptoms, including cognitive impairment, depression, anxiety, gastrointestinal dysfunction, and autonomic disturbances [40]. Mondal et al. (2024) [41] subsequently evaluated tcVNS using the commercial gammaCore device, which delivers 1 ms of 5 kHz sinusoidal waveform repeated every 40 ms (25 Hz). After one month of treatment, the authors reported an increase in gait velocity of 16% (p = 0.003) and step length of 11% (p = 0.007), as well as a reduction in step time of 16% (p = 0.003), compared with pre-treatment values [41].

Beyond Parkinson's disease, one emerging application is bimodal neuromodulation combining peripheral electrical stimulation with auditory stimulation for tinnitus rehabilitation [42]. This type of paradigm could potentially be investigated by integrating our platform with devices of auditory stimulation.

Despite its flexibility, the proposed platform currently operates as an open-loop system, in which the stimulation parameters are individualized before treatment but remain fixed throughout the stimulation session. In contrast, recently developed closed-loop systems, such as the Felix NeuroAI Wristband for Essential Tremor [43], continuously monitor tremor characteristics through triaxial accelerometry and an artificial intelligence-based algorithm to continuously characterize the tremor pattern and automatically adjust the stimulation current, allowing the intervention to respond to fluctuations in tremor over time. Future work should therefore focus on integrating the MESTIM-ELECT user interface with the accelerometry system to implement a closed-loop control strategy.

Although the pilot study included five participants in each group, its results provide an initial functional validation of the complete platform during a real experimental protocol involving peripheral nerve stimulation and tremor monitoring. In the illustrative cases, both biphasic and sinusoidal stimulation were followed by reductions of -29.66% and -17.25%, respectively. These preliminary findings are consistent with the broader literature suggesting that peripheral stimulation may attenuate pathological tremor in some patients with Parkinson's disease. For example, similar results were reported by Brillman et al., who evaluated four weeks of home-based biphasic TAPS therapy in patients with Parkinson's disease and found a median 64% reduction in postural tremor power ($p < 0.001$); 79% of participants achieved at least a 50% reduction, and 78% reported that relief persisted after stimulation for a median of 60 minutes. However, the present study was limited to the assessment of pre and immediate post-stimulation responses following a single stimulation session and to the analysis of postural tremor alone. The absence of a control or sham condition prevents the observed changes from being specifically attributed to the stimulation. In addition, the small sample size limited the statistical power to detect differences between stimulation conditions. Given the marked inter- and intra-individual variability characteristic of Parkinsonian tremor, future studies should preferably adopt a crossover

design in which the same participants receive the different stimulation conditions in separate sessions, thereby allowing within-subject comparisons and reducing the influence of inter-individual variability. Future studies should therefore evaluate tremor changes over longer post-stimulation periods and include different motor tasks to determine whether the response to peripheral nerve stimulation is task-dependent and to provide a broader characterization of its effects on motor performance.

In conclusion, this work presented an integrated and flexible platform for alternating peripheral electrical nerve stimulation with real-time tremor monitoring. The platform provides a configurable experimental tool for evaluating different stimulation waveforms, individualized alternation frequencies with an interface for the visualization and analysis of accelerometer signals. Furthermore, its modular architecture enables future expansion to other experimental paradigms requiring peripheral electrical stimulation.
