The objective of this work is to develop and evaluate a binary classifier for breast lesions in ultrasound images using deep learning and transfer learning techniques to distinguish between benign and malignant lesions. In addition to model development, the study investigates different strategies for performance improvement, including data augmentation, fine-tuning, and decision-threshold calibration. As the first contribution, we analyze the impact of threshold selection on classifier performance, showing how the calibration of this parameter can modify the trade-off between sensitivity and specificity, as well as the occurrence of false positives and false negatives. Secondly, we adapt the InceptionV3 architecture using transfer learning and investigate whether a single model can be adapted to different classification objectives, such as maximizing the detection of malignant lesions or increasing confidence in benign classifications, without requiring modifications to its architecture or additional training.

II. Background and Related Work

In 2016, Google Research introduced the InceptionV3 architecture [10], an evolution of the Inception/GoogLeNet networks [11]. The architecture was designed to enhance visual feature extraction while maintaining computational efficiency. To this end, it incorporates optimized Inception modules, factorized convolutions, and regularization techniques that enable the analysis of visual patterns at multiple scales with a reduced number of parameters. This combination of high performance and computational efficiency has made InceptionV3 a widely adopted architecture for computer vision applications, particularly as a foundation for transfer learning.

Transfer learning is recognized as a powerful deep learning technique [12]. Its primary objective is to improve the predictive performance of a target domain by leveraging knowledge acquired from a source domain and task [13]. This approach exploits features learned in the deeper layers of neural networks, such as edges, shapes, textures, and other visual patterns, and transfers this knowledge to new classification tasks.

Given the success of convolutional neural networks (CNNs) and transfer learning across multiple domains, their application to medical imaging emerged naturally. The study reported in [14], which focused on the diagnosis of retinal OCT images, demonstrated that deep CNNs pre-trained with InceptionV3 can achieve performance comparable to that of specialists in a real clinical setting.

A systematic review of studies published between 2020 and 2024 on deep learning applications for breast cancer diagnosis [5] examined classification approaches across multiple imaging modalities, including mammography and ultrasound. The review found that a substantial proportion of studies relied on pre-trained deep convolutional architectures, underscoring the widespread adoption of transfer learning in breast cancer diagnosis.

The model proposed in [6] for breast cancer classification in mammograms employed a hybrid CNN-LSTM architecture and achieved high performance in lesion detection. Similarly, the study presented in [7] introduced an ensemble learning model for breast ultrasound imaging and reported strong classification results. However, both studies focused primarily on global performance metrics and did not investigate alternative operating points tailored to different clinical objectives. This limitation is particularly important in medical applications, where the consequences of false-positive and false-negative predictions may vary according to the intended clinical use.

To address this gap, the study presented in [8] employed a CNN-based mammography classifier operating at high-sensitivity operating points. Rather than relying on a fixed decision threshold, the authors selected thresholds that achieved target sensitivities of 99% and 97%, enabling the identification of examinations with a low likelihood of cancer. The present study builds upon the threshold calibration strategy proposed in [8]. Accordingly, a transfer learning-based classifier using the InceptionV3 architecture was adopted because of its strong performance and computational efficiency. The objective is to demonstrate how decision-threshold calibration can modify classifier behavior across different operating points, thereby enabling adaptation to distinct clinical scenarios.

III. Methods

A. Dataset

The images used in this study were obtained from the Breast-Lesions-USG dataset, curated by Pawłowska et al. [15] and made available through The Cancer Imaging Archive. The dataset comprises breast ultrasound examinations acquired from 256 adult female patients and includes imaging data together with associated clinical information, such as BI-RADS classification and histopathological diagnosis when available. The dataset used in this study is publicly available and contains anonymized images; therefore, no additional institutional ethics approval or informed consent was required. Each retained primary ultrasound image corresponded to a distinct patient. Because only one image per patient was included in the classification dataset, the stratified image-level split was also patient-independent, with no patient overlap among the training, validation, and test subsets. The original dataset contains 98 malignant lesions, 154 benign lesions, and 4 normal tissue images. For the present study, the normal tissue images were excluded, and only the primary ultrasound images were retained for binary classification, resulting in a final dataset of 252 images. Additionally, the dataset was divided into training, validation, and test subsets using an approximate ratio of 70%, 15%, and 15%, respectively, following the data partitioning strategy adopted by [4]. A stratified splitting strategy was adopted to preserve the original class distribution within each subset (see Table I).

B. Artificial Neural Network Architecture

To implement the transfer learning strategy, the InceptionV3 architecture was adopted as the backbone network. The convolutional base was kept frozen, and a dense layer with a Softmax activation function was added to perform the binary classification of breast lesions into benign and

malignant classes. Figure 1 presents the architecture employed for lesion classification. The transfer learning approach allows the model to leverage knowledge previously acquired from large-scale computer vision tasks, including the detection of low-level visual features such as edges, textures, and shapes [16], [17]. By keeping the convolutional layers frozen and introducing a new Softmax classification layer, the network can adapt its learned representations to the specific domain of breast ultrasound imaging [18], [19].

TABLE I. DISTRIBUTION OF THE DATASET AFTER STRATIFIED SPLITTING INTO TRAINING, VALIDATION, AND TEST SUBSETS

Subset	***Benign***	***Malignant***	***Total***
Training	107	68	175

Test	24	16	40
Total	154	98	252

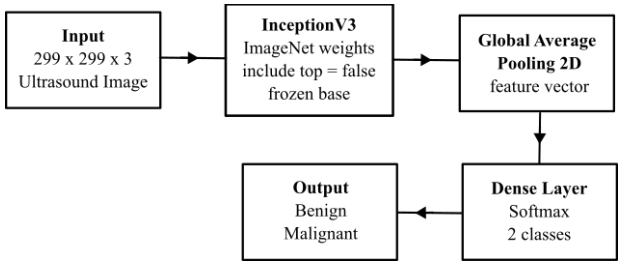

Fig. 1. Architecture used for the binary classification of breast lesions.

The InceptionV3 architecture was selected for two main reasons. First, it has demonstrated the ability to achieve satisfactory performance even when trained on relatively small datasets, which is a common limitation in medical imaging applications [20] - [22]. Second, the objective of this study was not only to develop a classification model but also to evaluate multiple decision-threshold calibration strategies and clinical operating points [23], [24]. Therefore, it was necessary to adopt an architecture with moderate computational requirements, allowing multiple iterative experiments to be conducted within acceptable training time and processing constraints. InceptionV3 meets these requirements while maintaining competitive classification performance.

C. Training Strategies

To evaluate the effects of different training strategies on model performance, the experimental procedure was conducted in multiple stages. In the first stage, the model was trained using only the original training set. The convolutional base of InceptionV3 remained frozen, while the newly added classification layer was trained to distinguish between benign and malignant breast lesions.

In the second stage, data augmentation was applied exclusively to the training set to increase image variability. The transformations included random rotations, horizontal and vertical shifts, and horizontal flipping. The validation and test sets were not subjected to any augmentation procedure (see Figure 2).

Unlike strategies that impose strict numerical balancing, the target sizes were defined independently for each class. This approach is consistent with class-dependent augmentation strategies in medical imaging, in which greater augmentation intensity is applied to underrepresented classes to reduce class imbalance [25].

TABLE II. DATASET DISTRIBUTION AFTER THE DATA AUGMENTATION STAGE

Subset	***Benign***	***Malignant***	***Total***
Training (augmentation)	200	300	500
Validation	23	14	37
Test	24	16	40
Total	247	330	577

The target sizes were predefined as part of the experimental design. A larger augmentation factor was assigned to the malignant class, which was originally underrepresented. At the same time, the expansion was limited to 200 benign images and 300 malignant images to avoid excessive growth of the training set based on multiple transformations of the same original images, thereby reducing the risk of redundancy among synthetic samples. These values were not derived from a numerical balancing formula but were adopted as class-specific experimental parameters.

$$N_{aug},c \;=\; N_{target},c \;-\; N_{orig},c \qquad (1)$$

where N_{orig},c denotes the original number of training images in class c, N_{target},c represents the predefined target size for that class, and N_{aug},c is the number of synthetic images generated through data augmentation. For the benign class, N_{orig},c was 107 and N_{target},c was defined as 200, resulting in the generation of 93 synthetic images. For the malignant class, N_{orig},c was 68 and N_{target},c was defined as 300, resulting in the generation of 232 synthetic images. Therefore, the adopted class-dependent augmentation strategy intentionally assigned a higher augmentation intensity to the malignant class instead of enforcing strict numerical balancing between the classes.

In the subsequent stage, fine-tuning was investigated by unfreezing subsets of the final layers of the InceptionV3 architecture, allowing part of the pretrained convolutional base to adapt to the breast ultrasound domain [14]. Two configurations were evaluated: aggressive fine-tuning, with 62 unfrozen layers, and conservative fine-tuning, with 21 unfrozen layers. Both fine-tuning configurations used a learning rate of 1×10^{-6}, differing only in the number of unfrozen layers.

As the final experimental stage, a systematic decision-threshold calibration procedure was performed. In binary classification, a default threshold of 0.50 is commonly used to convert predicted probabilities into class labels. However, this threshold may not provide the most appropriate trade-off between sensitivity and specificity when the consequences of false-positive and false-negative predictions are asymmetric. The calibration procedure was inspired by the high-sensitivity operating-point strategy described in [8] for computer-aided mammographic screening. In the present study, thresholds ranging from 0.000 to 1.000 were evaluated in increments of 0.001 using the predicted class probabilities.

All decision thresholds were selected exclusively using the validation set. The test set was not used during threshold selection and was reserved solely for the final evaluation of the predefined operating points. For the sensitivity-oriented strategy, the predicted probabilities for the malignant class were analyzed. For each predefined target sensitivity, the

algorithm selected the highest threshold capable of achieving at least the required sensitivity on the validation set, thereby avoiding unnecessary reductions in the decision threshold. Target sensitivity levels of 85%, 90%, 92%, 95%, 97%, and 99% were evaluated.

A second independent strategy, referred to as Safe Benign, was also implemented. In this strategy, threshold selection was based on the predicted probability of the benign class, with the objective of identifying operating points associated with predefined benign-class precision levels. Target precision levels of 90%, 95%, 97%, 99%, and 100% were evaluated using only the validation set. Once selected, the thresholds were fixed and applied to the independent test set without further adjustment. The two calibration strategies were designed to evaluate different operating conditions using the same trained model. The sensitivity-oriented strategy prioritized malignant lesion detection, whereas the Safe Benign strategy prioritized the precision of benign classifications. No architectural modification or additional model training was performed after threshold selection. To quantify the uncertainty associated with the limited test-set size, 95% confidence intervals for proportion-based metrics were calculated using the Wilson score method.

D. Implementation and Reproducibility Details

All experiments used InceptionV3 pretrained on ImageNet with the original classification head removed, input images resized to 299 × 299 pixels and processed using the standard InceptionV3 preprocessing function. The convolutional backbone was initially frozen, and the classifier comprised global average pooling followed by a two-unit Softmax layer. Training used the Adam optimizer with a learning rate of 0.001, categorical cross-entropy loss, a batch size of 32, and a maximum of 100 epochs. Early stopping monitored validation loss with a patience of 15 epochs and restored the best weights, while model checkpointing retained the model with the lowest validation loss. Class weights were applied during training, test inference was performed with a batch size of 1, and a random seed of 42 was used to improve the reproducibility of the experiments.

IV. RESULTS

The baseline model exhibited substantial limitations in the detection of malignant lesions, primarily due to the high number of false-negative cases observed in the test set. Table IV presents the baseline performance obtained with the InceptionV3 architecture, establishing a reference benchmark for comparison with the threshold-based operating modes proposed in this study.

TABLE III. BASELINE MODEL PERFORMANCE USING THE INCEPTIONV3 ARCHITECTURE

Class	***Precision***	***Recall***	***F1-Score***	***Support***
Benign	0.77	0.96	0.85	24
Malignant	0.90	0.56	0.69	16
Accuracy	-	-	0.80	40

The results highlight important limitations of the baseline model for clinical applications focused on malignant lesion detection. The low recall achieved for the malignant class, indicating a substantial number of false-negative cases, resulted in reduced diagnostic sensitivity for identifying cancerous lesions. This behavior becomes more evident when the confusion matrix (Fig. 2) is examined. The model correctly classified 23 benign cases and 9 malignant cases, while seven malignant lesions were misclassified as benign. Considering malignant lesions as the positive class, this performance corresponds to a true positive rate (TPR) of 56.25%, a false positive rate (FPR) of 4.17%, and a specificity of 95.83%. Collectively, these results indicate high specificity but insufficient sensitivity for malignant lesion detection.

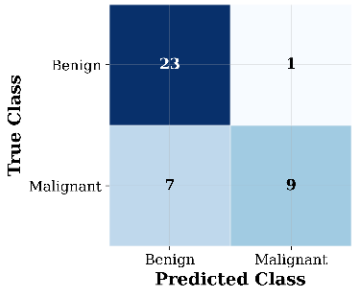

Fig. 2. Confusion matrix of the baseline model.

To address this limitation, a data augmentation strategy was applied. Compared with the baseline model, malignant-class recall increased and the number of false-negative classifications decreased. Table V also shows higher F1-scores for both classes, indicating improved performance on the evaluated test set and a more balanced relationship between precision and recall.

TABLE IV. TEST-SET PERFORMANCE OF THE MODEL TRAINED WITH DATA AUGMENTATION

Class	***Precision***	***Recall***	***F1-Score***	***Support***
Benign	0.82	0.96	0.88	24
Malignant	0.92	0.69	0.79	16
Accuracy	-	-	0.85	40

The confusion matrix (Fig. 3) shows a reduction in the number of malignant lesions incorrectly classified as benign, decreasing from seven to five cases compared with the baseline model. At the same time, the model maintained a high ability to identify benign lesions, producing only one false-positive classification. Despite the observed improvement, a considerable number of malignant cases were still misclassified, indicating that the use of data augmentation alone was insufficient to achieve a satisfactory reduction in false negatives.

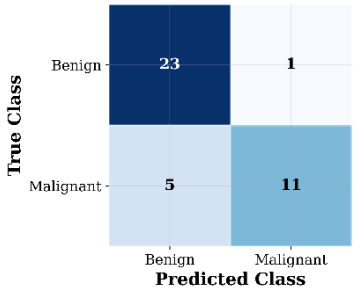

Fig. 3. Confusion matrix corresponding to the model trained with data augmentation.

Subsequently, a fine-tuning strategy was explored by unfreezing additional layers of the InceptionV3 architecture. Two approaches were evaluated: an aggressive strategy, in which 62 layers were unfrozen (approximately 11 million trainable parameters), and a more conservative strategy, in which only 21 layers were unfrozen (approximately 2.38

million trainable parameters). The aggressive approach led to severe overfitting, as evidenced by deteriorating validation metrics despite improved training performance. Although the conservative strategy partially mitigated overfitting, it still failed to achieve consistent performance gains compared with the model trained using data augmentation alone.

With 21 layers of the InceptionV3 architecture unfrozen, the default operating point (threshold = 0.500) achieved a TPR of 75.0% and an FPR of 20.8%, as illustrated by the confusion matrix (Fig. 4). The model correctly classified 19 benign cases and 12 malignant cases while producing five false positives and four false negatives, demonstrating inferior performance compared with the model trained using data augmentation alone. These results indicate that increasing the number of trainable layers did not improve performance on the evaluated test set and was associated with a less favorable balance between sensitivity and specificity.

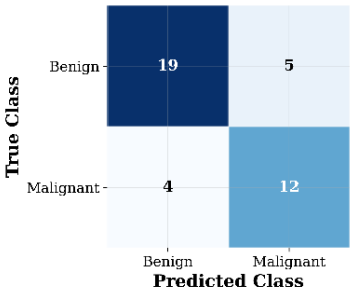

Fig. 4. Confusion matrix of the model trained using the conservative fine-tuning strategy with 21 unfrozen layers of the InceptionV3 architecture.

Therefore, to develop a classifier adaptable to different clinical requirements, the model trained with data augmentation was selected for the decision-threshold calibration stage. This approach had a substantial impact on classifier behavior, particularly regarding the trade-off between sensitivity for malignant lesion detection and specificity for benign lesion identification. By adjusting the operating point, different operating regimes could be achieved, ranging from balanced configurations to highly sensitive settings specifically designed to minimize false-negative cases.

A. Sensitivity-oriented operating points

As shown in Fig. 5, progressively lowering the decision threshold consistently improved the model's ability to detect malignant lesions. However, this improvement was accompanied by reduced specificity for benign lesions and an increase in false-positive predictions.

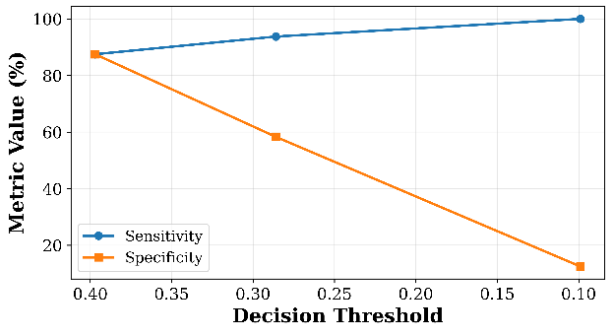

Fig. 5. Relationship between sensitivity and specificity as a function of the decision threshold.

The results highlight the trade-off between malignant lesion detection and the preservation of diagnostic specificity. As higher target sensitivities were adopted, an additional reduction in the false-negative rate was observed. For operating points corresponding to target sensitivities of 90% and 92%, the selected threshold was 0.286, yielding a malignant recall of 93.75% while reducing the number of false negatives to a single case. However, this increase in sensitivity was accompanied by a decrease in specificity and an increase in false positives to ten cases.

The balanced operating point selected by the algorithm (threshold = 0.397) achieved 87.5% sensitivity and 87.5% specificity. As shown by the confusion matrix (Fig. 6), the classifier correctly identified 14 malignant lesions while producing only three false positives and two false negatives. This operating point provided a balanced trade-off between sensitivity and specificity in the evaluated test set.

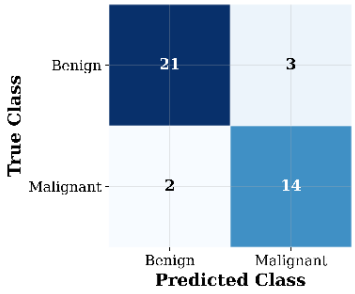

Fig. 6. Confusion matrix of the balanced operating point selected for malignant lesion classification (threshold = 0.397).

B. Safe Benign Strategy

Different operating points were identified according to the target precision established for the benign class, allowing the trade-off between benign-class precision and the coverage of cases classified as benign to be analyzed. Increasing the threshold improved benign-class precision but reduced the number of cases assigned to this class. For a target precision of 90%, the algorithm selected a threshold of 0.603, yielding a benign-class precision of 91.3%, equivalent to the negative predictive value when malignancy is considered the positive class, a benign recall of 87.5%, and an overall accuracy of 87.5%. At this operating point, 23 cases were classified as benign, of which 21 were correctly classified and two malignant lesions were misclassified as benign.

When higher confidence levels were adopted, a substantial reduction in safe-benign coverage was observed. For operating points corresponding to target confidence levels of 95%, 97%, 99%, and 100%, the selected threshold was 0.901, yielding a benign precision of 100%, but reducing benign recall to 12.5% and classifying only three cases as safe benign.

As shown in Figs. 7 and 8, increasing the decision threshold produced an inverse relationship between benign-class precision and the number of cases classified as benign. Thus, the evaluated operating points ranged from broader benign-case coverage with lower precision to restricted coverage with higher precision.

Among the operating points evaluated for the Safe Benign strategy, the threshold of 0.603 provided the highest coverage of cases classified as benign. Under this configuration, the model achieved a benign-class precision of 91.3%, a benign recall of 87.5%, and an overall accuracy of 87.5%.

The operating point with the highest safe-benign coverage (threshold = 0.603) is illustrated by the confusion matrix (Fig.

9). Under this configuration, the model classified 23 examinations as safe benign, correctly identifying 21 while producing only two false-benign classifications and successfully detecting 14 of the 16 malignant lesions. Collectively, these results indicate the potential of the selected operating point for identifying a subset of cases classified as benign, although further validation is required before considering its use in clinical rule-out applications.

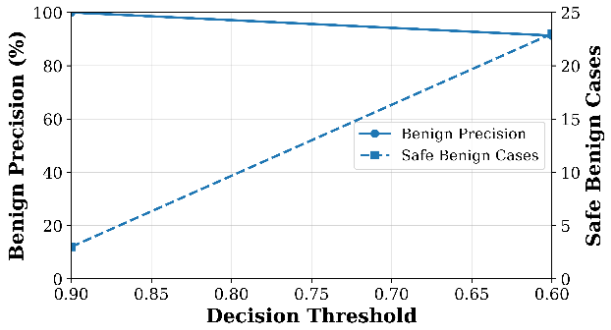

Fig. 7. Relationship between benign-class precision and safe-benign coverage as a function of the decision threshold.

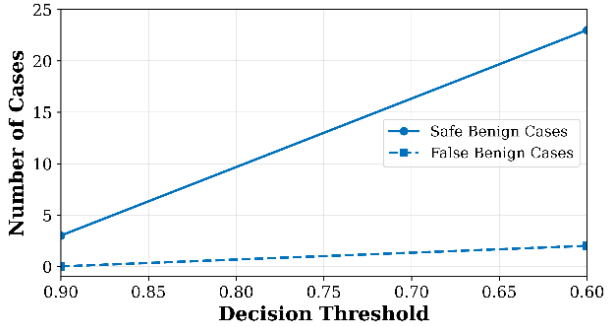

Fig. 8. Relationship between the number of safe benign cases and the occurrence of false-benign classifications.

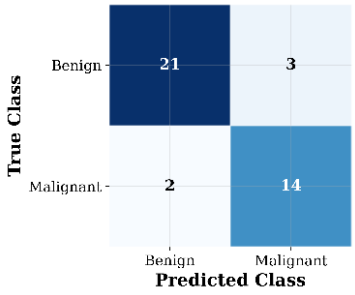

Fig. 9. Confusion matrix corresponding to the operating point with the highest safe-benign coverage (threshold = 0.603).

C. Global Comparison of Strategies

To consolidate the findings across the experimental stages, the evaluated strategies were compared in Figs. 10, 11 and 12. Data augmentation increased malignant-class recall relative to the baseline model, whereas fine-tuning did not provide consistent performance gains and showed signs of overfitting. The Balanced threshold of 0.397 for the malignant class and the Safe Benign threshold of 0.603 for the benign class produced the same test-set classifications because the two class probabilities are complementary. Thus, these operating points represent the same decision boundary expressed according to different target-class objectives.

D. Confidence Interval Analysis

Given the limited size of the independent test set, 95% confidence intervals were calculated using the Wilson score method for the main proportion-based performance metrics. The analysis included overall accuracy, malignant-class sensitivity, specificity, malignant-class precision, and benign-class precision. Malignant lesions were considered the positive class throughout this analysis. Benign-class precision is therefore equivalent to the negative predictive value. The confidence intervals were relatively wide, particularly for malignant-class sensitivity and precision, because these estimates were based on only 16 malignant cases. For example, although the balanced operating point achieved a malignant-class sensitivity of 87.5%, its 95% confidence interval ranged from 64.0% to 96.5%. Similarly, the benign-class precision of 91.3% obtained at the Safe Benign operating point was associated with a 95% confidence interval of 73.2% to 97.6%. These intervals indicate substantial uncertainty around the point estimates and reinforce the need for cautious interpretation of the observed differences among the evaluated configurations.

V. Discussion

The results obtained in this study indicate that conventional training strategies, such as the direct use of a pre-trained model and the isolated application of data augmentation, although beneficial for improving overall performance, still present important limitations when applied to the classification of breast lesions in ultrasound images derived from relatively small datasets. In particular, the baseline model exhibited a high number of false-negative cases, a clinically undesirable outcome in applications focused on malignancy detection. Data augmentation improved the performance observed on the test set and increased malignant-class recall, indicating a greater ability to identify cancerous lesions. However, the findings also showed that strategies based solely on data augmentation are insufficient. The fine-tuning experiments did not produce consistent performance gains, suggesting that the limited dataset size may restrict the effective adaptation of deep architectures and increase susceptibility to overfitting. In contrast, decision-threshold calibration emerged as the main practical contribution of this work.

The operating-point analysis showed that classifier behavior can be adapted to different performance objectives, ranging from balanced configurations to high-sensitivity operating points specifically designed to minimize false-negative cases. This finding reinforces the importance of defining application-specific operating points in artificial intelligence systems for medical diagnosis, particularly in scenarios where the costs associated with classification errors are asymmetric. Despite the promising results, this study has important limitations. The dataset is relatively small and was obtained from a single public source, with no external validation performed on independent clinical datasets. Therefore, future work will include external validation using independent clinical datasets and repeated stratified cross-validation, for example, 5-fold cross-validation repeated ten times, to evaluate the robustness and generalizability of the proposed approach across different clinical settings.

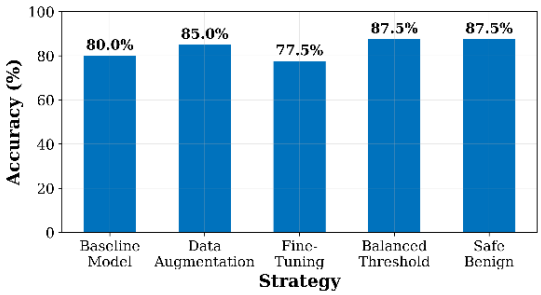

Fig. 10. Comparison of accuracy across the evaluated models.

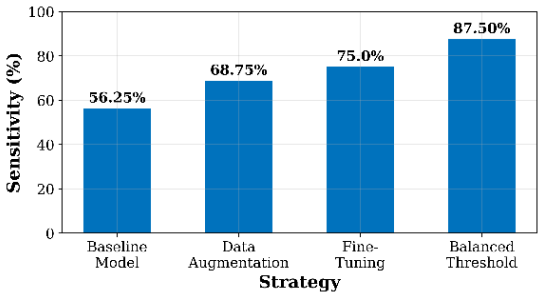

Fig. 11. Comparison of sensitivity for malignant lesion detection across the evaluated models.

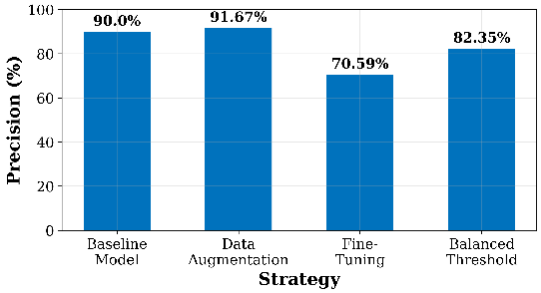

Fig. 12. Comparison of malignant lesion classification precision across the evaluated models.

A previous mammography study reported a 17% reduction in workload while missing 1% of cancer-containing examinations [26]. Because the studies in [26], [27] evaluated mammography rather than breast ultrasound, their results provide methodological context for threshold-based triage but are not directly comparable with those of the present study. In the present study, the most conservative operating point classified 7.5% of examinations as benign, with no false-benign cases observed in this test set. Although both studies indicate that threshold calibration can control the trade-off between coverage and classification errors, the operating points evaluated in [26] were predefined, whereas those in the present study were established based on explicit confidence targets for the target class. This strategy may allow adaptation to scenarios focused either on the identification of benign lesions or on maximizing sensitivity for malignant lesion detection.

In [27], the model classified 71.5% of examinations as normal using a predefined threshold (AI Score ≤ 7), achieving a negative predictive value of 99.98% while excluding only 2 of the 76 cancer cases in the dataset. At the operating point corresponding to 90% confidence for the benign class, the proposed model classified 57.5% of examinations as benign, with two false-benign cases. At more conservative operating points, no false-benign cases were observed, although coverage decreased to 7.5% of examinations. These findings highlight the importance of evaluating multiple thresholds, an aspect not explored in [27], which reported results based on a single decision threshold.

In addition to the identification of lesions classified as benign, threshold calibration enabled adjustment of classifier behavior for high-sensitivity scenarios targeting malignant lesion detection. For the model trained with data augmentation, lowering the malignant-class decision threshold increased sensitivity from 68.75% (11/16) at the default threshold to 87.5% (14/16) at the balanced operating point. At the threshold of 0.10, sensitivity reached 100% (16/16), but specificity decreased to 12.5% (3/24), resulting in 21 false-positive classifications. These findings show, in this test set, that a single model can be configured for different classification objectives solely through threshold calibration. This interpretation is consistent with the observations reported by [28], who demonstrated substantial variations in sensitivity and specificity as a function of the selected operating point.

More recently, a study evaluating five transfer-learning CNNs, including InceptionV3, used a public dataset of 526 breast ultrasound images and an institutional dataset of 392 images. At a 2% malignancy threshold, three models achieved 98.3% sensitivity, with specificity ranging from 15.3% to 18.6% [29]. These findings support the relevance of threshold adjustment in breast ultrasound, although direct comparison with the present study is limited by differences in dataset composition and experimental design.

Taken together, these results reinforce that the choice of decision threshold directly influences the predictive behavior of a classifier and may be as important as the choice of model architecture itself.

From the perspective of possible future integration into the clinical workflow, decision-threshold adjustment could allow the same classifier to serve multiple complementary purposes. The Safe Benign configuration showed potential for identifying a subset of lesions classified as benign, whereas sensitivity-oriented operating points increased malignant lesion detection in the evaluated dataset. Thus, threshold selection may influence not only statistical performance but also, after additional validation, patient prioritization, resource allocation, and clinical risk management. However, the current results are not sufficient to establish reductions in biopsies, changes in clinical management, or diagnostic safety in independent populations.

Although the proposed threshold-adjustment strategy yielded promising results, further validation using larger and independent datasets is required to confirm its robustness and clinical applicability. Future work will investigate statistically optimized threshold-selection strategies aimed at increasing malignant-class sensitivity while simultaneously limiting the increase in false positives, without assuming in advance that this balance will result in greater clinical safety or a lower diagnostic burden.

VI. Conclusion

This study presented a deep learning-based approach for classifying breast lesions in ultrasound images using the InceptionV3 architecture with transfer learning. Data augmentation improved the performance observed on the independent test set and increased sensitivity for malignant lesion detection, whereas fine-tuning failed to provide consistent performance gains because of overfitting and the

limited dataset size. In contrast, decision-threshold calibration enabled a single trained model to be adapted to different classification objectives, representing the main practical contribution of this work.

The operating-point analysis showed that the balanced threshold provided an effective trade-off between sensitivity and specificity, whereas the Safe Benign strategy achieved 91.3% benign-class precision and correctly identified 21 of the 23 cases classified as benign in the test set. These findings indicate that threshold calibration is a computationally efficient strategy for adjusting classifier behavior according to different operating requirements. However, the results should be interpreted as preliminary because of the limited test-set size and the absence of external validation. Larger and independent clinical datasets are required before conclusions regarding clinical applicability can be established.

To facilitate reproducibility and future research, the implementation developed in this study will be made publicly available through a GitHub repository upon publication.

***Abstract*—Environmental noise and reverberation are major challenges in voice communication systems, degrading both speech quality and intelligibility. Deep learning-based speech enhancement methods have emerged as the state of the art by learning complex mappings between noisy and clean speech directly from large paired datasets. This work investigates and compares two time-frequency domain architectures for monaural speech enhancement on the VoiceBank-DEMAND dataset: a baseline 2D Convolutional U-Net and a Convolutional Recurrent Network (CRN) integrating a bottleneck Bidirectional Long Short-Term Memory (LSTM). Both models estimate an Ideal Ratio Mask from the Short-Time Fourier Transform magnitude spectrum and are evaluated using Perceptual Evaluation of Speech Quality (PESQ), Short-Time Objective Intelligibility (STOI) and Scale-Invariant Signal-to-Distortion Ratio (SI-SDR). Across ten independently trained models per architecture, the CRN attains a higher mean PESQ (2.89 against 2.81) and STOI (0.95 against 0.94) than the U-Net, both statistically significant, at the cost of 7.5 times more parameters (14.5M against 1.94M), with no significant difference in SI-SDR. To interpret this gain, a magnitude oracle experiment is introduced, decomposing the overall performance ceiling into a recoverable magnitude-estimation margin and a structural phase-preservation cost. This decomposition shows that the recurrent bottleneck closes only a small fraction of the recoverable margin, indicating that long-range temporal modeling is not the main missing component, and that the dominant remaining limitation stems from noisy-phase preservation under real-valued masking, particularly under low signal-to-noise ratio and highly non-stationary noise conditions.**

***Index Terms*—Speech enhancement, Convolutional Neural Network, Recurrent Neural Network, Time-Frequency Analysis, Ideal Ratio Mask, Speech Intelligibility.**

I. Introduction

Voice communication underpins an increasing number of everyday applications, such as video calls, virtual assistants, automatic speech recognition (ASR) systems and real-time transcription services. Among these, hearing assistive devices represent a particularly demanding application from a biomedical engineering standpoint: for users with hearing loss, environmental noise and reverberation do not merely reduce comfort, but can severely compromise speech intelligibility and, consequently, social communication and quality of life. This impact is amplified for listeners with sensorineural hearing loss, who already exhibit reduced frequency and temporal resolution compared to normal-hearing listeners [1]–[4]. Speech signals captured by hearing aid and other biomedical audio device microphones are frequently corrupted by noise sources such as traffic, competing speakers, ventilation systems and background music, as well as reverberation, impairing both perceptual quality and the performance of downstream automated systems such as ASR-based communication aids [5]. As a result, robust speech enhancement techniques have become a key enabling technology not only for general voice communication but specifically for assistive hearing technology and other embedded biomedical audio processing systems.

In this context, classical speech enhancement techniques offer limited performance under real-world conditions [6]. Consequently, deep learning-based approaches have emerged as the state of the art, as they are capable of learning complex mappings between noisy and clean speech directly from large paired datasets, without relying on restrictive statistical assumptions about the noise [6]. A wide range of neural network architectures has been explored for this task, including Convolutional Neural Networks (CNNs) [7], Recurrent Neural Networks (RNNs) and Long Short-Term Memory (LSTM) networks [8]–[10], Generative Adversarial Networks (GANs) [11], [12], hybrid architectures [13], [14] and waveform domain models operating directly on raw audio signals [15], [16].

More recently, two additional model families have emerged as competitive alternatives to purpose-built discriminative networks. Diffusion-based generative models formulate speech enhancement as a stochastic denoising process, learning to reverse a gradual corruption of clean speech into a noisy or Gaussian-perturbed state, and have demonstrated strong out-of-domain generalization compared to discriminative baselines [17], [18]. In parallel, foundation-model-based approaches repurpose large self-supervised or weakly supervised speech representations — such as WavLM, HuBERT, and Whisper — as frozen or fine-tuned backbones for mask estimation, with recent work showing that careful architectural adaptation and perceptual pre-processing allow these models to close much of the historical performance gap with specialized speech enhancement architectures while requiring substantially less labeled training data [19].

This work investigates a deep learning-based approach for monaural speech enhancement using the publicly available VoiceBank-DEMAND dataset [8], a single-microphone benchmark whose monaural setting reflects a common hardware constraint in hearing aids and other compact biomedical listening devices. The objective is to design, train and critically evaluate a model capable of suppressing environmental noise while preserving speech quality and speaker

naturalness. Performance is evaluated using objective metrics widely adopted in the speech enhancement literature, namely Perceptual Evaluation of Speech Quality (PESQ), Short-Time Objective Intelligibility (STOI), and Scale-Invariant Signal-to-Distortion Ratio (SI-SDR), enabling direct comparison with related work [6]–[8], [11], [13], [16].

The main contributions of this study are as follows:

- A controlled, head-to-head comparison between a 2D convolutional U-Net and a Convolutional Recurrent Network (CRN) with a bottleneck BiLSTM for Ideal Ratio Mask-based monaural speech enhancement, trained and evaluated under an identical data pipeline, preprocessing, and training protocol on VoiceBank-DEMAND;
- A magnitude oracle analysis that decomposes the overall PESQ performance ceiling of the real-valued masking formulation into a recoverable magnitude-estimation margin and a structural, phase-preservation cost, providing an interpretable upper bound against which architectural gains can be measured;
- An empirical finding, enabled by this decomposition, that the recurrent bottleneck closes only a small fraction of the recoverable margin, indicating that long-range temporal modeling is unlikely to be the dominant missing component in this magnitude-masking setting, despite the hypothesis motivated by the recurrent design adopted in DCCRN [13].

The remainder of this paper is organized as follows. Section II presents the methodology, including the dataset and exploratory data analysis, the preprocessing pipeline, the U-Net and CRN model architectures, the training setup, the objective evaluation metrics, and the magnitude oracle analysis used to decompose the performance ceiling of the masking formulation. Section III reports the experimental results, comparing the proposed architectures against each other and against reference values from the literature, and discusses these results in light of the oracle decomposition. Finally, Section IV concludes the paper by summarizing the main findings, discussing the structural limitations identified, and outlining directions for future work.

II. Methodology

A. Dataset

This work used the VoiceBank-DEMAND dataset, a widely used benchmark for supervised monaural speech enhancement introduced by Valentini-Botinhao *et al.* (2016) [8]. The dataset combines clean speech recordings from the Voice Bank Corpus [20] with environmental noises from the DEMAND database [21]. Each sample consists of a pair of recordings, one noisy and one clean, enabling supervised training and objective evaluation. The original recordings are provided in WAV format with a sampling rate of 48 kHz.

The dataset contains 12,396 paired utterances, divided into 11,572 training samples from 28 speakers (14 male and 14 female) and 824 test samples from two previously unseen speakers (one male and one female). Noisy speech signals were generated by mixing clean recordings with environmental noises at nominal signal-to-noise ratios (SNRs) of $\{0, 5, 10, 15\}$ dB for training and $\{2.5, 7.5, 12.5, 17.5\}$ dB for testing [8]. It is publicly available at https://datashare.ed.ac.uk/handle/10283/2791.

An exploratory data analysis (EDA) was performed prior to model development. The analysis confirmed that all noisy-clean pairs were complete and correctly aligned, with no missing or corrupted files. Fig. 1 presents the distribution of measured SNR values for randomly sampled utterances from the training and test sets. The observed distributions closely match the nominal SNR levels defined during dataset construction, confirming the expected separation between training and testing conditions. An offset of approximately 1.5 dB was observed between the nominal and measured values. This discrepancy is expected, since the nominal SNRs were defined based on the speech-active portions of each utterance, while the SNR measurements performed in this work consider the entire audio signal, including silent segments. Nevertheless, the measured distributions remain consistent with the intended training and testing SNR levels.

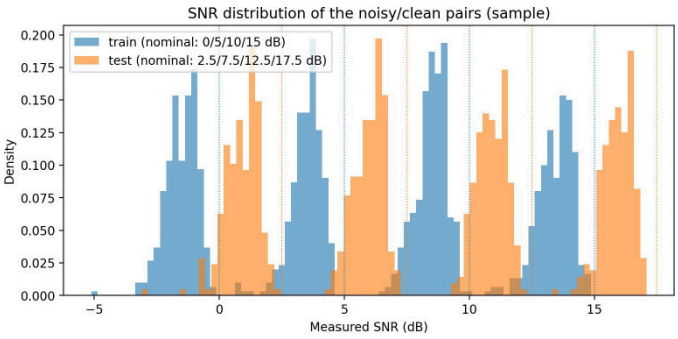

Fig. 1. Distribution of measured SNR values for randomly sampled utterances from the training and test sets.

B. Preprocessing

The original utterances were downsampled to 16 kHz for literature compatibility [11], [13], [16], allowing direct metrics comparison (PESQ wideband is defined at 16 kHz) and reducing computational cost without discarding perceptually relevant information, since the majority of human speech frequency content lies below 8 kHz. The last two speakers in alphabetical order among the 28 available training speakers (p286 and p287) were separated from the training set to compose the validation set, yielding 872 samples for validation and 26 speakers for the actual training subset, resulting in 10,700 training samples. This deterministic criterion, rather than a random draw, ensures full reproducibility of the speaker-independent split. As in the official test partition, validation speakers remain entirely unseen during training, preventing voice identity leakage and ensuring that the validation loss measures the same generalization property as the official test evaluation.

The audio signals were then segmented into fixed, non-overlapping windows of 32,640 samples (2.04 s). This specific

length was chosen to yield exactly 256 temporal frames after the Short-Time Fourier Transform (STFT) with hop size 128 (8 ms) and window length of 512 (32 ms), ensuring exact divisibility by 16, which is mandatory for the symmetric downsampling and upsampling operations of the U-Net architecture, which will be discussed further. Signals shorter than this window length were zero-padded to maintain the fixed input size. Besides, amplitude normalization was applied in each segment, dividing it by the standard deviation of its corresponding noisy audio. The identical scaling factor was applied to the clean speech target, strictly preserving the fundamental additive noise formulation ($x = y + n$, where x stands for the noisy audio, y, for the clean audio and n, for the noise).

C. Model Architecture

This work evaluates two time-frequency domain architectures for monaural speech enhancement: a 2D Convolutional U-Net baseline and a CRN. Both networks process the STFT magnitude spectrum to estimate an Ideal Ratio Mask $M \in [0, 1]^{256\times256}$. Given a 16 kHz sampling rate and 32,640-sample windows, the STFT is computed using a 512-point Hann window and a 128-sample hop size. Truncating the Nyquist component yields a square input matrix $|X| \in \mathbb{R}^{256\times256}$. The input of the models consists of $\log(1 + |X|)$ to compress the dynamic range and to be gradient-friendly. The enhanced complex spectrum is reconstructed via $\hat{Y} = M \odot X$, preserving the noisy phase before applying the inverse STFT (iSTFT). This magnitude-masking approach avoids the training instability and high computational overhead of generative adversarial alternatives like SEGAN [11].

The baseline U-Net consists of a symmetric encoder-decoder structure with channel concatenation via skip connections, as shown in Fig. 2. Symmetrical skip connections are preferred over the standard R-CED [7] topology to prevent the severe loss of fine-grained spectral lines during upsampling. The encoder comprises four 2D convolutional layers with channels scaling as $1 \to 16 \to 32 \to 64 \to 128 \to 256$, utilizing a 3×3 kernel and a padding of 1. Each layer is coupled with Batch Normalization and a LeakyReLU activation ($\alpha = 0.2$), compressing the feature map to a $256 \times 16 \times 16$ bottleneck due to 2×2 max pooling layer at the end. The decoder mirrors this topology using four 2D transposed convolutional layers. The final layer applies a 1×1 convolution followed by a Sigmoid activation to bound the mask values. This architecture results in 1.94M trainable parameters.

The proposed CRN directly modifies this topology by replacing the static 2D convolutional bottleneck with a recurrent sequential block to capture long-term temporal dependencies across distant STFT frames (Fig. 3). While the baseline treats the $256 \times 16 \times 16$ feature map purely through localized spatial convolutions, the CRN flattens the channel and frequency dimensions into a sequence of shape 16×4096, where 16 represents the compressed temporal frame axis. This sequence is processed by a multi-layer Bidirectional LSTM (BiLSTM) with 256 hidden units per direction, capturing forward and backward phonetic context across the entire 2.04-second utterance, totaling 32 temporal frames. The bidirectional outputs are concatenated, linearly projected back to 4096, and reshaped to $256 \times 16 \times 16$ before entering the decoder stage. This modification increases the number of trainable parameters to 14.5M. This architectural upgrade serves as a lightweight mechanism to optimize magnitude estimation before expanding into complex-valued operations (DCCRN [13]) or raw waveform models (Demucs [16]).

D. Training Setup

The models were implemented in PyTorch and trained using the AdamW optimizer with a learning rate of 3×10^{-4} and a batch size of 32. The networks were optimized using the Mean Absolute Error (L1 loss) calculated between the enhanced magnitude spectrum ($|\hat{Y}| = M \odot |X|$) and the clean magnitude spectrum ($|Y|$). Training was capped at 30 epochs, with an early stopping mechanism (patience of 5 epochs based on validation loss) used to mitigate overfitting, and the checkpoint achieving the best validation performance was retained for evaluation. All simulations were conducted using an NVIDIA RTX 5070 TI.

In total, ten models were trained per architecture across different random seeds, mitigating training-run variance in the metric estimates and enabling a statistical comparison between the two proposed architectures, discussed further in the Results section.

E. Evaluation Metrics

The performance of the models is evaluated using three objective metrics widely adopted in the speech enhancement literature, all computed on the reconstructed utterances (obtained after applying the inverse STFT to $\hat{Y}$):

- PESQ (Perceptual Evaluation of Speech Quality): Evaluated under the wideband configuration (ITU-T P.862.2), it estimates the perceptual quality of enhanced speech by modeling human auditory processing (from –0.5 to 4.5).
- STOI (Short-Time Objective Intelligibility): It measures the structural correlation of short-time temporal envelopes between the clean reference and the enhanced signal, yielding a bounded score between 0 and 1 that correlates with human speech intelligibility.
- SI-SDR (Scale-Invariant Signal-to-Distortion Ratio): A time-domain metric that quantifies overall waveform alignment, noise suppression, and artifact insertion while remaining invariant to global gain or scale modifications, expressed in decibels (dB).

F. Magnitude Oracle Analysis

To quantify the performance ceiling imposed by the masking formulation itself, an oracle experiment was conducted using the available noisy-clean pairs. The estimated mask M was replaced with an oracle reconstruction in which the noisy magnitude is substituted by the ground-truth clean magnitude

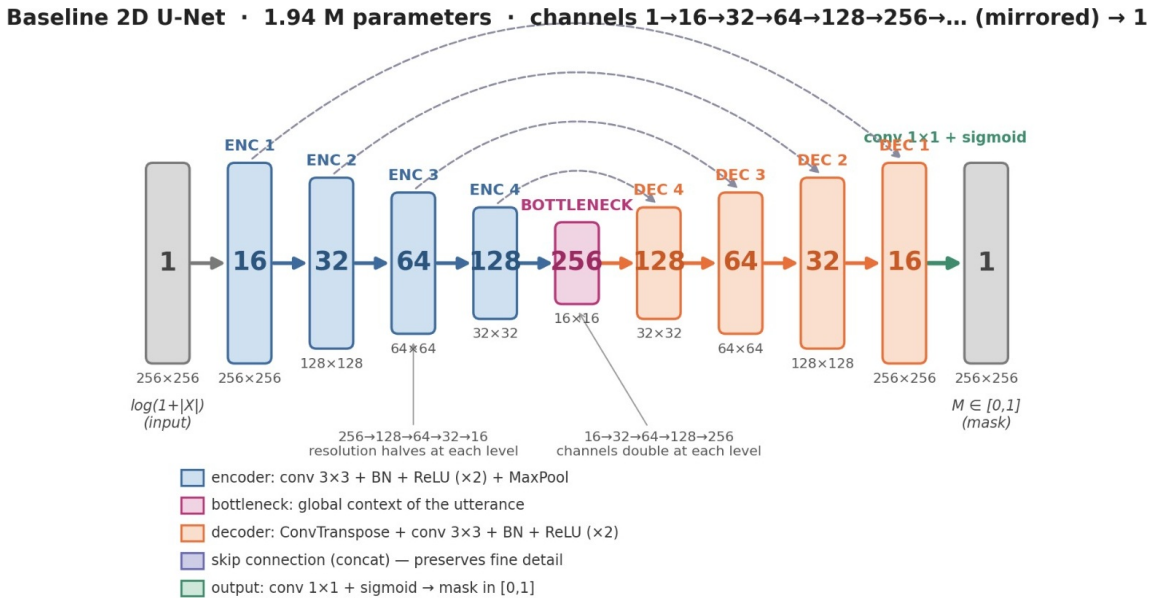

Fig. 2. Block diagram of the baseline 2D Convolutional U-Net architecture showing feature map dimensions across the encoder, bottleneck, and decoder stages.

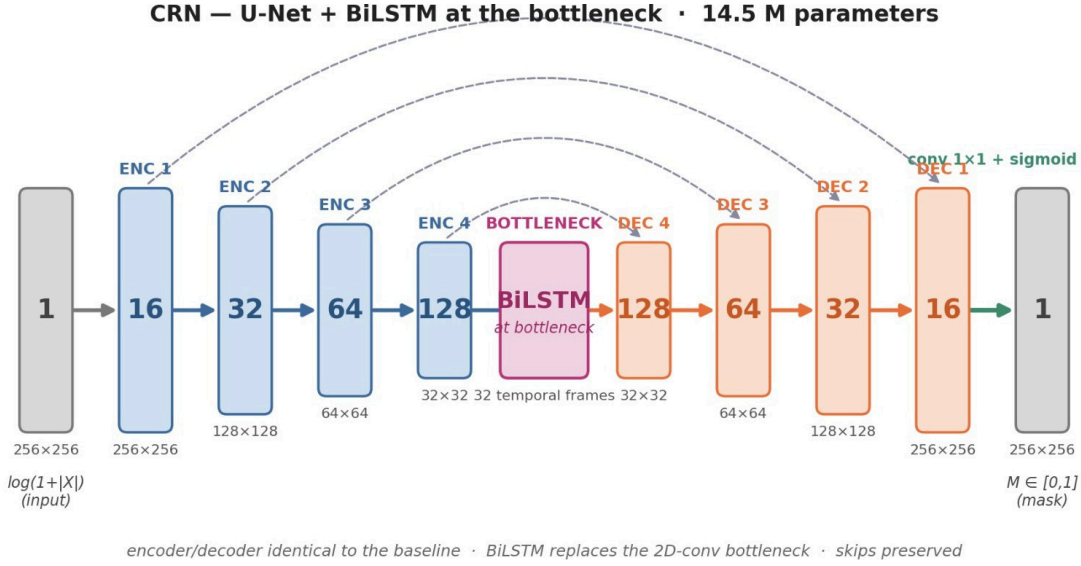

Fig. 3. Block diagram of the proposed CRN, featuring a BiLSTM at the low-dimensional bottleneck for temporal sequence modeling.

$|Y|$, while the noisy phase $\angle X$ is preserved exactly as in the trained models:

$$\hat{Y}_{\text{oracle}} = |Y| \odot e^{j\angle X}. \tag{1}$$

The inverse STFT of $\hat{Y}_{\text{oracle}}$ yields the best possible reconstruction achievable under perfect magnitude estimation, isolating the residual degradation caused exclusively by the noisy phase. Comparing this oracle PESQ score against (i) the trained models and (ii) the theoretical metric ceiling (4.5) decomposes the overall performance gap into two independent components: a magnitude-estimation component, which can, in principle, be reduced by improving the network, and a phase-preservation component, which is structurally bounded by the real-valued masking formulation and can only be addressed by complex-valued or phase-aware approaches.

III. Results

Fig. 4 shows the mean values and their standard deviations of the three evaluated metrics on the reconstructed utterances for the ten trained models of each of the two proposed architectures (U-Net baseline and CRN). The mean gain of the CRN over the baseline was +0.080 for PESQ, +0.003 for STOI and +0.059 for SI-SDR. To assess whether the difference between architectures is significant, for each metric a paired Wilcoxon signed-rank test and a paired bootstrap test were performed across the ten per-model mean values, each computed over the

824 test samples. Both tests indicate, at the 5% significance level, that the CRN significantly improves PESQ and STOI scores relative to the baseline (Wilcoxon $p = 0.002$ for both metrics), but the SI-SDR improvement is not statistically significant. This indicates that the gain introduced by the recurrent bottleneck is concentrated in perceptual quality and intelligibility (PESQ and STOI) rather than waveform-level alignment (SI-SDR), suggesting that the additional 12.5M parameters mainly refine fine-grained magnitude estimation rather than producing structurally different reconstructions.

The objective performance of the developed models on the VoiceBank-DEMAND test set is summarized in Table I, alongside reference values reported in the literature for R-CED [7], SEGAN [11], Demucs [16], DCCRN [13], WavLM-Large with PCS preprocessing [19] and SGM-EMA [18]. These reference values were obtained directly from the original publications under their own experimental protocols and are reported here as an approximate point of reference rather than a strictly controlled comparison. Both proposed architectures outperform the unprocessed noisy baseline, R-CED and the generative SEGAN model on every metric for which reference values are available, despite using substantially fewer parameters than SEGAN (43M) and Demucs (60M).

Furthermore, more recent approaches based on foundation models (e.g., WavLM-Large with PCS preprocessing) achieve higher PESQ (3.54) [19], but at parameter cost orders of magnitude larger (roughly 22–163$\times$ more parameters than our CRN and U-Net), reinforcing the practical trade-off between perceptual quality and deployability in embedded, real-time biomedical applications. Also, SGM-EMA, a recent and complex score-based diffusion model with multi-resolution U-Net structure and attention mechanism, reaches a PESQ of 2.89 [18] essentially tied with our CRN (2.89) and a higher SI-SDR (19.6 dB vs. 18.39 dB), at the cost of greater computational demand and longer inference times due to high-quality reconstruction and better modeling of global dependencies despite the lack of a reported parameter count for direct efficiency comparison. Its ESTOI of 0.91, while not numerically identical to the STOI metric we report, suggests comparable intelligibility.

TABLE I
OBJECTIVE EVALUATION ON THE VOICEBANK-DEMAND TEST SET.

Method	PESQ	STOI	SI-SDR	Params.
Noisy (unprocessed)	1.97	0.91	8.44	–
R-CED [7]	2.07	0.93	–	33k
SEGAN [11]	2.16	–	–	43M
2D U-Net (ours)[a]	2.81	0.94	18.34	1.94M

SGM-EMA [18]	2.89	0.91[c]	19.6	–

[a]Mean values across ten independently trained models per architecture.
[b]Number of parameters of WavLM-Large backbone only.
[c]ESTOI value reported instead of STOI for this reference.

To better interpret the modest but statistically significant PESQ and STOI improvements, the magnitude oracle described in Section II-F was evaluated on the same test set, yielding a PESQ of approximately 3.95. This result decomposes the overall performance gap into two components: a gap of +1.14 PESQ points between the U-Net baseline and the oracle, representing the margin that could, in principle, still be recovered through improved magnitude estimation, and a gap of +0.55 PESQ points between the oracle and the theoretical ceiling of 4.5, representing the irreducible cost of preserving the noisy phase under the real-valued masking formulation.

The architectural motivation for introducing the BiLSTM bottleneck in the CRN was the hypothesis, inspired by the recurrent design adopted in DCCRN [13], that part of the gap toward the oracle ceiling stemmed from long-range temporal dependencies between distant STFT frames that the finite receptive field of two-dimensional convolutions cannot capture. However, the PESQ improvement obtained closes only 7% of the available margin (+0.08 of 1.14 points), indicating that this hypothesis is not well supported for the present configuration: while the recurrent bottleneck yields a small gain, most of the residual gap does not appear to originate from a lack of long-term temporal context, but rather from a combination of finer local magnitude-estimation errors and the irreducible phase-related ceiling identified by the oracle analysis. This interpretation is consistent with the remaining gap between our models and DCCRN itself (PESQ 3.07), which, unlike the CRN evaluated here, additionally models the complex spectrum rather than relying purely on magnitude masking with noisy-phase reconstruction. Besides, the nearly identical performance of the multi-resolution U-Net-based architecture SGM-EMA (PESQ 2.89) compared to our models, despite its additional complexity, further corroborates the structural phase-related ceiling.

Qualitative improvements are visually evaluated through the spectrograms of a complete reconstructed utterance from an example test sample, produced by one paired trained model from each architecture, as depicted in Fig. 5. Comparing the target representations, the unprocessed noisy spectrogram displays severe broadband and localized environmental distortions that mask weak speech harmonics. The baseline 2D U-Net successfully filters out background noise but introduces noticeable over-smoothing, attenuating high-frequency components and fine formant structures. Conversely, the proposed CRN provides superior definition in the high-frequency spectra, preserving sharp harmonic transitions and phonetic details. This visual difference reflects a localized improvement in high-frequency spectral definition for the CRN output, preventing the over-suppression of valid speech energy in these regions.

IV. CONCLUSION

This work proposed and compared two time-frequency domain architectures: a baseline 2D U-Net and a CRN incorporating a bottleneck BiLSTM, for monaural speech enhancement on the VoiceBank-DEMAND benchmark. Both architectures achieved competitive results relative to the reference literature despite their reduced parameter count, with the U-Net

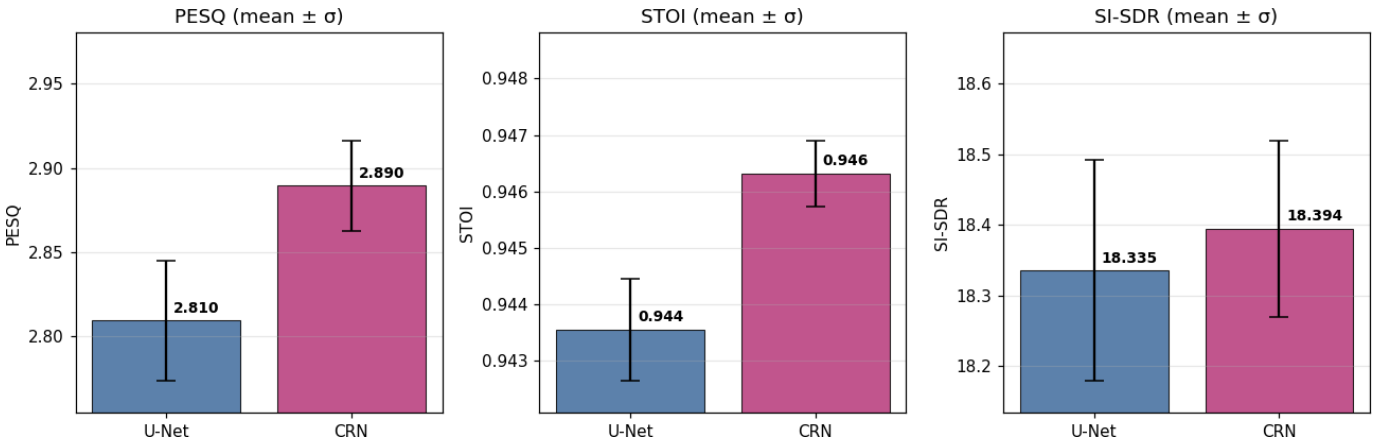

Fig. 4. Mean and standard deviation values for the PESQ, STOI and SI-SDR scores attained by the proposed architectures.

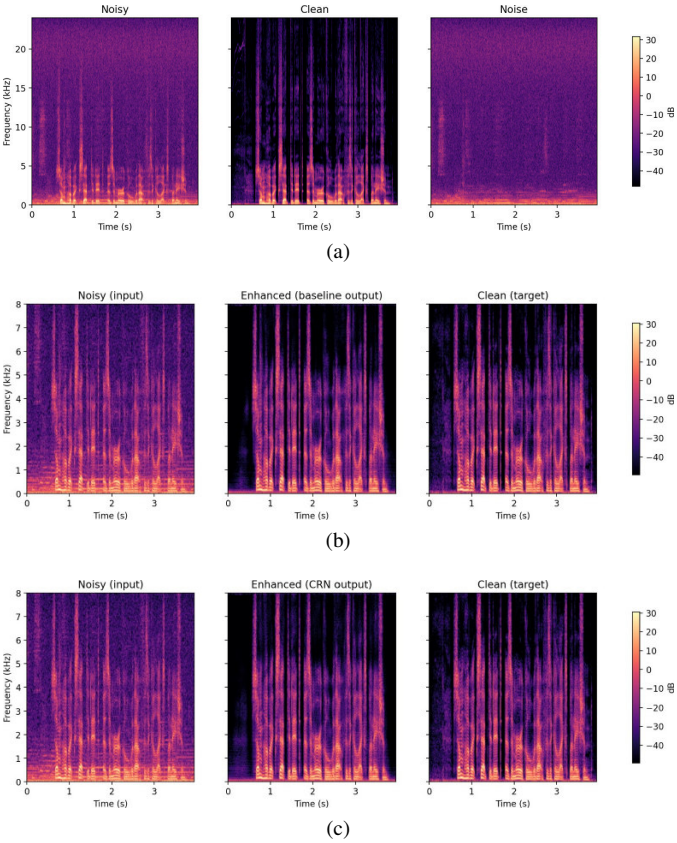

Fig. 5. Spectrograms comparison between the original example sample (a), 2D U-Net reconstruction (b) and the proposed CRN reconstruction (c).

baseline (1.94M parameters) approaching the performance of substantially larger models such as SEGAN (43M parameters) and Demucs (60M parameters).

A contribution of this work is the magnitude oracle analysis, which decomposes the performance ceiling of the masking formulation into a recoverable magnitude-estimation margin (+1.14 PESQ from the U-Net baseline) and a structural phase-preservation cost (+0.55 PESQ). This decomposition shows that the CRN's modest improvement over the baseline (+0.080 PESQ, +0.003 STOI and no statistically significant SI-SDR gain) fails to close the recoverable margin. This indicates that the initial hypothesis – motivated by the recurrent design adopted in DCCRN [13] – that long-range temporal modeling via a recurrent bottleneck was the main missing component is not supported for this configuration. This structural ceiling is further corroborated by the sharper performance degradation observed under severe non-stationary distortions (e.g., babble noise) and low-SNR regimes, conditions in which the noisy phase departs most strongly from the clean phase.

Future research should therefore prioritize approaches that directly address the phase-preservation ceiling rather than further enlarging magnitude-domain networks, namely complex-valued masking architectures to explicitly reconstruct the phase spectrum, multi-resolution STFT perceptual losses to better capture fine-grained magnitude detail, and a causal unidirectional LSTM variant to enable real-time operation, following the design principles adopted in DCCRN. These directions are relevant for embedded biomedical applications such as hearing aids, where real-time, low-latency and low-power operation requires a causal, parameter-efficient processing pipeline; in this sense, the present results reinforce the practical value of parameter-efficient, magnitude-masking architectures such as the 1.94M-parameter U-Net baseline over substantially larger, phase-agnostic alternatives.

***Abstract*—Early identification of oral ulcers and mucosal inflammation remains challenging using conventional visual examination, which provides limited information about tissue composition. Hyperspectral imaging combined with machine learning offers a promising alternative by revealing spectral patterns unavailable in conventional RGB images. However, no previous studies have been identified that apply machine learning to the classification of oral ulcers and inflammatory lesions in hyperspectral images. To address this gap, this study presents a deep learning framework for pixel-wise detection and segmentation using images from the Oral and Dental Spectral Image Database (ODSI-DB). The proposed Multilayer Perceptron (MLP) receives the reflectance spectrum of each pixel and estimates a probability map for the combined ulcerative and inflammatory region. The selected valid pixels from the ten eligible images, originating from three subjects, were pooled without separating the data by subject. The images were decomposed into pixel-level samples, and 5-fold stratified cross-validation was performed at the pixel level. The model achieved an Accuracy of 98.70% ($\pm$0.27 p.p.), Precision of 97.73% ($\pm$0.41 p.p.), Recall of 99.71% ($\pm$0.18 p.p.), ROC-AUC of 0.9979 ($\pm$0.0007), and PR-AUC of 0.9974 ($\pm$0.0009). These preliminary findings demonstrate the feasibility of the proposed approach within the available image pool and support further investigation of hyperspectral imaging and deep learning for computer-assisted analysis of oral mucosal lesions.**

***Index Terms*—Oral ulcers, mucosal inflammation, hyperspectral imaging, deep learning, multilayer perceptron, image segmentation.**

I. Introduction

Oral mucosal ulcers are frequently encountered in dental practice due to their high clinical occurrence, etiological diversity, and possible association with more severe conditions. They may result from local trauma, inflammation, infections, systemic disorders, or processes with malignant potential. In many cases, they present a benign and self-limiting course. Nevertheless, the morphological similarity among lesions of different natures requires caution during the initial evaluation. Visual inspection of the mucosal surface does not always allow a reliable distinction between healthy tissue, the ulcerated center, and the surrounding inflammatory halo. This limitation may delay clinical management, increase the dependence on complementary examinations, and reduce the accuracy in selecting the most appropriate site for incisional biopsy [1].

Subtle alterations related to vascularization, inflammation, and tissue structural composition may remain poorly evident, particularly when lesions exhibit a similar appearance during clinical examination. The early identification of ulcers and inflammatory lesions in the oral cavity is relevant for clinical practice, as these lesions may represent manifestations of systemic conditions or, in some cases, alterations requiring closer investigation. Chronic oral lesions, particularly leukoplakia and erythroplakia, present a significant risk of progression to squamous cell carcinoma, the most common form of oral cancer [1]. In routine clinical practice, the initial assessment of these lesions is typically performed by visual inspection under white light and interpreted according to the examiner's clinical experience. Although indispensable, this approach has well-recognized limitations. Visual perception is affected by ambient illumination, the presence of saliva, shadows, reflections, and individual anatomical variations within the oral cavity. In addition, conventional images, especially RGB images, condense optical information into only three color channels [2].

Hyperspectral Imaging (HSI) has emerged in this context as a non-invasive optical approach capable of expanding the assessment of the oral mucosa. Instead of limiting the image to the traditional color representation, HSI captures the interaction between light and tissue across dozens or hundreds of narrow, contiguous bands of the electromagnetic spectrum [3].

Each pixel contains its own spectral signature, organized into a hyperspectral data cube that integrates both spatial and spectral information. This structure facilitates the analysis of optical patterns associated with vascularization, edema, inflammation, tissue architecture, and alterations caused by the ulcerative process [4].

The translation of HSI into clinical settings, however, depends on analytical strategies compatible with the complexity of the generated data. The high dimensionality, spectral redundancy, and large volume of information make purely manual interpretation impractical for real-world applications [5]. Artificial Intelligence methods, particularly Deep Learning models, provide a promising approach for recognizing complex patterns present in medical images. In the hyperspectral domain, these models can be employed in tissue detection, segmentation, and classification tasks, provided that they are adapted to the specific characteristics of spectral data and to the limited sample availability commonly found in biomedical applications [6].

The automated analysis of oral lesions offers significant benefits for both public health and clinical practice. First, it may enable rapid and standardized patient screening, reducing the dependence on subjective clinical interpretation while facilitating the identification of cases that require specialized evaluation. The digitalization of diagnostic support systems can integrate complex spectral data into clinical workflows, making the analysis more accessible and reproducible. In public health settings, this approach may contribute to large-scale screening programs, allowing patients to be prioritized for specialized care while supporting the early identification of oral mucosal alterations. Furthermore, it may reduce operational costs and increase diagnostic efficiency, democratizing access to detection tools in regions with limited availability of specialized dental care [7].

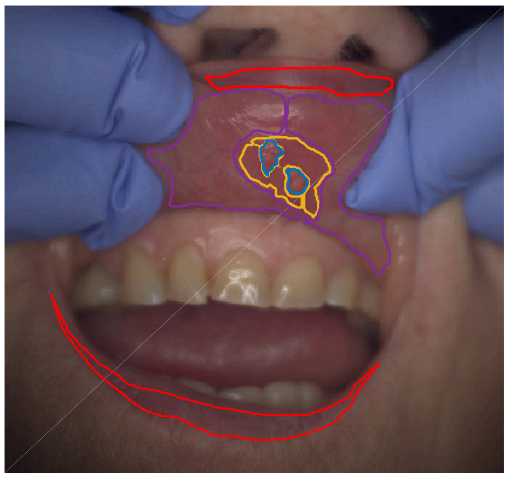
Recently, hyperspectral imaging has been increasingly explored in dentistry and oral sciences, often in combination with machine learning and, in several studies, deep neural networks. Previous studies using artificial intelligence have primarily focused on oral cancer detection, tongue melanosis, oral tissue classification, and pathological staging [4], [8], [9], [11], [12]. Other investigations have addressed applications more directly related to dentistry, including the development of the Oral and Dental Spectral Image Database (ODSI-DB) and dental hyperspectral image analysis [13], [14], the identification of dental caries and calculus [15], [16], gingival region detection [17], and periodontal assessment [18]. In addition, hyperspectral microscopy, histopathological slides, and multimodal imaging have been employed for classification and segmentation tasks [10], [19], [20]. Despite these advances, a considerable proportion of the literature is based on hyperspectral microscopy, histological specimens, or images acquired under controlled experimental conditions rather than hyperspectral images captured directly from in vivo oral tissues using hyperspectral cameras. Furthermore, to the best of our knowledge, none of the published studies has specifically investigated the detection and segmentation of oral ulcers and mucosal inflammation, highlighting an important gap that the present work aims to address.

This work presents a structured computational pipeline based on a deep neural network for the automated detection and segmentation of oral ulcerative and inflammatory regions in hyperspectral images from the ODSI-DB.

II. Materials and Methods

A. Dataset

This study uses the ODSI-DB [13], a publicly available hyperspectral image database. In the present study, only images acquired with the Specim IQ hyperspectral camera and containing annotations for oral ulcers or mucosal inflammation were considered. Among the available images, ten images from three patients met these criteria and were included in the analysis. The Specim IQ acquisitions provide reflectance information over 204 narrow and contiguous spectral bands.



The preprocessing stage consisted of loading the hyperspectral images together with their corresponding annotation masks in `.tif` format. Pixel intensities were normalized to the interval $[0, 1]$ by dividing the original 16-bit grayscale values by 65,535.[1]

Pixels corresponding to technical artifacts previously annotated in the database, including specular reflections, shadow/noise regions, and out-of-focus areas, were excluded from the training and validation datasets. The remaining valid pixels were subsequently extracted individually and randomly shuffled to reduce the influence of sample ordering during model training.

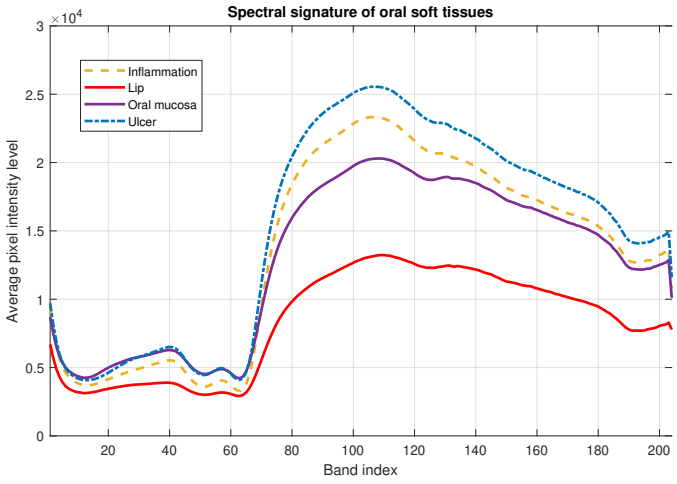


Fig. 1 illustrates one representative hyperspectral image used in this study, with the manual annotations (1.a) and the corresponding mean spectral signatures of the annotated regions (1.b). The example highlights that different oral tissues and pathological regions exhibit distinct spectral patterns across multiple bands, providing information beyond the three channels available in conventional RGB images. Each curve was obtained by averaging the pixel values within a given annotated region across the hyperspectral bands. It is important to note that the original manual annotations of the ODSI-DB dataset do not necessarily cover the entire extent of each tissue or lesion, but rather selected representative regions.

In this study, ulcer and inflammatory regions were grouped into a single positive class during model training. This strategy was adopted because the reference masks provided by the ODSI-DB are based on polygonal annotations manually delineated by specialists, and the transition between the fibrin-covered ulcer region and the surrounding inflammatory border may be gradual in several images. Therefore, both annotations were considered part of the same target class throughout the training process. The negative class was composed of the remaining valid non-lesion pixels after the exclusion of technical artifacts.

[1] According to the official ODSI-DB documentation, the hyperspectral images are stored as multi-page TIFF files containing 16-bit grayscale spectral bands. Available at: https://sites.uef.fi/spectral/databases-software/odsi-db/. Accessed: Jun. 2026.

(a) Ground-truth annotations overlaid on the RGB image. Annotation colors indicate the lips (red), inflammation (yellow), ulcer (blue), and oral mucosa (purple).

(b) Average spectral signatures of the annotated classes.

Figure 1: Ground-truth annotations and their corresponding spectral signatures. (a) Colored borders overlaid on the RGB image define the annotated classes used in this study. (b) Average spectral signatures extracted from each annotated class.

The extraction of negative pixels was balanced with respect to the positive class. For each of the ten eligible images, an equal number of positive and negative pixels was extracted, yielding a dataset of 24,328 pixels, evenly divided into 12,164 positive pixels, corresponding to ulcer or inflammation, and 12,164 negative pixels. To reduce the model bias toward the majority class caused by class imbalance, random undersampling was applied to the negative class until the number of negative pixels matched that of the positive pixels [22].

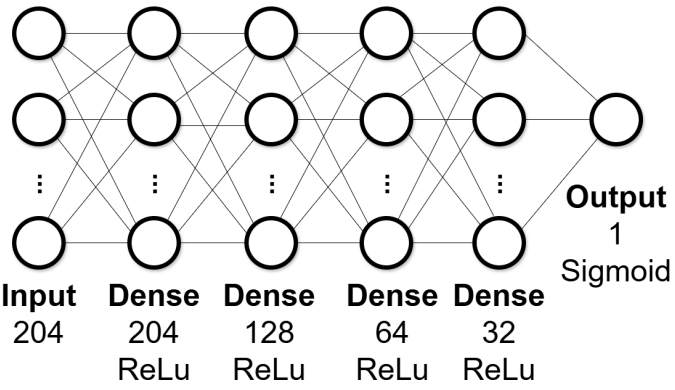

Figure 2: Schematic representation of the proposed MLP-based pixel-wise spectral classification model.

All valid pixels from the ten eligible images were then pooled into a single dataset. A 5-fold stratified cross-validation with random shuffling was performed at the pixel level. In each iteration, approximately 80% of the pixels were used for training and 20% for validation, while preserving the balance between the two classes. Accordingly, each training partition contained 19,462 or 19,463 pixels, and each validation partition contained 4,865 or 4,866 pixels. The model was trained on four folds and evaluated on the remaining fold, and the validation metrics were averaged across the five folds.

B. Neural Network Architecture

A Multilayer Perceptron (MLP) architecture was designed for pixel-wise spectral segmentation. Each input sample corresponds to the reflectance spectrum of a single pixel, represented by the values of the 204 spectral bands acquired by the hyperspectral camera. Consequently, the input layer contains 204 neurons, followed by four fully connected hidden layers comprising 204, 128, 64, and 32 neurons, respectively. All hidden layers employ the Rectified Linear Unit (ReLU) activation function. To mitigate overfitting, a Dropout layer with a rate of 0.1 was applied after each hidden layer during training. The architecture was empirically defined after preliminary experiments to provide a compromise between model capacity and overfitting.

The output layer consists of a single neuron with a sigmoid activation function, which estimates the probability that the input pixel belongs to the positive class. The proposed architecture is illustrated in Fig. 2.

C. Training Protocol

The training adopted a batch size of 256 samples and the Adam optimizer with a learning rate of 1×10^{-5}. Each fold was trained for up to 2000 epochs, with an early-stopping criterion monitoring the validation PR-AUC, a patience of 100 epochs, and restoration of the model weights from the epoch with the best validation PR-AUC once training stopped. For each fold, both the metrics obtained at the last training epoch and the metrics obtained at the restored (best) epoch were recorded, together with the number of epochs actually

Table I: Epochs run, restored epoch, and best validation PR-AUC per fold.

Fold	Epochs run	Restored epoch	Best val. PR-AUC
1	1,302	1,202	0.9964
2	2,000	1,987	0.9983
3	1,360	1,260	0.9970
4	1,564	1,464	0.9984
5	1,304	1,204	0.9969

run before training was stopped, either by the early-stopping criterion or by reaching the maximum epoch limit.

The Binary Cross-Entropy loss function was used, defined as

$$\mathcal{L}_{BCE} = -\left[y \log(p) + (1-y)\log(1-p)\right], \tag{1}$$

where $y \in \{0,1\}$ is the ground-truth label and $p \in [0,1]$ is the probability predicted by the network for the positive class, corresponding to inflammation or ulcer.

For the computation of Accuracy, Precision, and Recall, the predicted probability p was converted into a binary prediction $\hat{y}$ using

$$\hat{y} = \begin{cases} 1, & p \geq \tau, \\ 0, & p < \tau, \end{cases} \tag{2}$$

with a decision threshold of $\tau = 0.5$. ROC-AUC and PR-AUC were computed directly from the predicted probabilities, without applying a fixed decision threshold, using the default TensorFlow/Keras AUC metric implementation [21].

Mean training and validation curves were computed by averaging the per-epoch values across the five cross-validation folds. Since the folds converged at different epoch counts, the curves were aligned by their epoch index and the mean was calculated element-wise over the available values.

For the qualitative evaluation, the trained model was applied to each pixel of the hyperspectral images, and the resulting probability scores were mapped back to their spatial positions to generate a probability map for each image. Binary segmentation masks were then obtained by thresholding the probability maps, with pixels of probability $p \geq \tau$ classified as positive, corresponding to ulcer or inflammation, and the remaining pixels classified as negative.

III. Results

Table I summarizes the number of epochs run, the restored epoch, and the best validation PR-AUC obtained for each fold. Four folds were stopped by the early-stopping criterion, whereas Fold 2 reached the maximum limit of 2000 epochs.

The mean training and validation curves across the five folds are shown in Fig. 3. The curves present the evolution of the loss, accuracy, and PR-AUC over the training epochs. The training and validation curves remained closely aligned throughout the training process, indicating stable convergence with no evidence of overfitting under the adopted training protocol.

Under the 5-fold stratified cross-validation protocol, performance at the restored epoch of each fold is reported as the mean and standard deviation, calculated with Bessel's

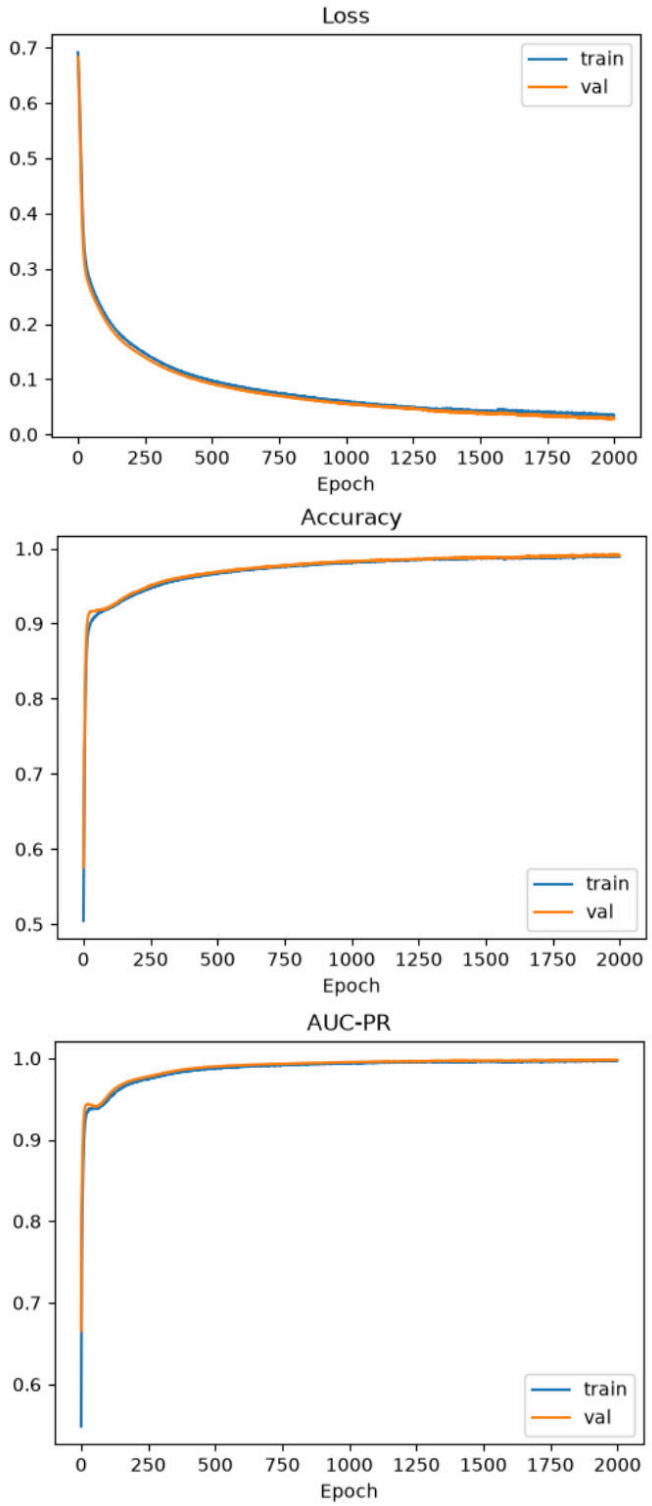

Figure 3: Mean training and validation curves across the five folds, showing loss, accuracy, and PR-AUC over epochs.

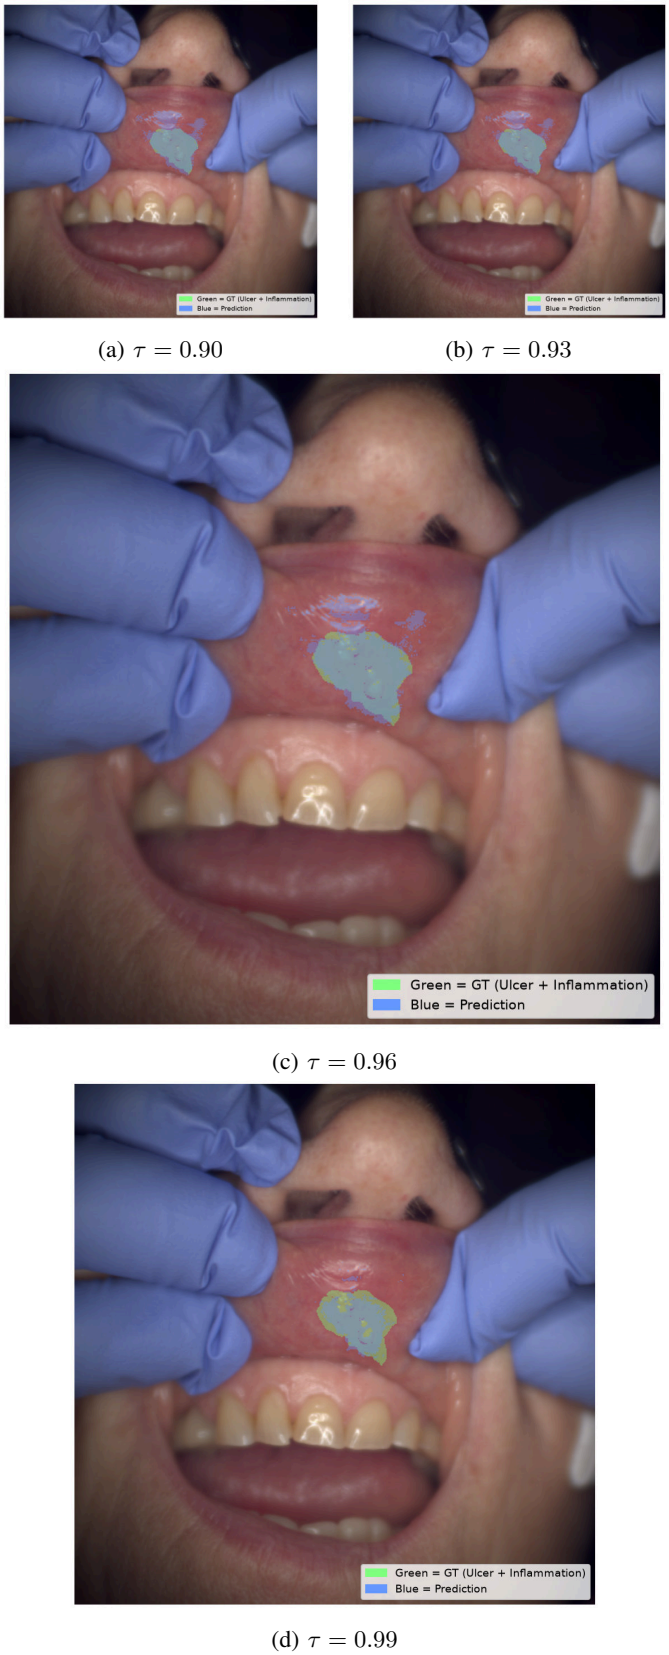
Table II: Per-fold performance metrics (mean ± std), restored best-epoch weights.

Fold	Acc.	Prec.	Rec.	Dice	ROC-AUC	PR-AUC	Loss
1	98.36%	97.27%	99.51%	98.38%	0.997	0.996	0.051
2	99.03%	98.30%	99.79%	99.04%	0.999	0.998	0.030
3	98.62%	97.74%	99.55%	98.64%	0.998	0.997	0.044
4	98.89%	97.91%	99.92%	98.90%	0.999	0.998	0.036
5	98.58%	97.43%	99.79%	98.60%	0.997	0.997	0.047
Mean	98.70%	97.73%	99.71%	98.71%	0.998	0.997	0.042
Std.	0.27%	0.41%	0.18%	0.26%	0.001	0.001	0.008

correction ($n-1$): Accuracy of 98.70% (±0.27 p.p.), Precision of 97.73% (±0.41 p.p.), Recall of 99.71% (±0.18 p.p.), Dice of 98.71% (±0.26 p.p.), ROC-AUC of 0.9979 (±0.0007), PR-AUC of 0.9974 (±0.0009), and loss of 0.0417 (±0.0083), with the Dice coefficient derived from the Precision and Recall values above. Table II details the individual fold results together with the overall mean and standard deviation. These metrics were computed at the standard threshold $\tau = 0.5$, while the higher thresholds in Figs. 4 and 5 ($\tau = 0.90$ to 0.99) were used only for qualitative visualization of the segmentation boundary. Notably, increasing τ tends to reduce false positives, increasing Precision, while increasing false negatives and reducing Recall. This trade-off does not affect ROC-AUC and PR-AUC, which are threshold-independent metrics. In clinical applications, where failing to detect an existing lesion may be more critical than a false alarm, Recall could be favored by selecting a lower decision threshold. For the quantitative results reported above, however, the standard threshold $\tau = 0.5$ was retained.



For the qualitative analysis, segmentation masks were generated using decision thresholds ranging from $\tau = 0.90$ to $\tau = 0.99$. This analysis illustrates how increasing the decision threshold affects the extent of the detected regions, with higher values of τ producing progressively more conservative segmentations by retaining only pixels associated with higher predicted probabilities.

Fig. 4 presents the segmentation results for image `f533af9b_lip_3.tif`, which contains both ulcer and inflammation annotations. As the decision threshold increases from 0.90 to 0.99, the segmented region progressively decreases, and only pixels associated with higher predicted probabilities are retained.

Fig. 5 presents a second example for image `4ad8fb28_lip_3.tif`, which contains annotations only for the ulcer region. As in the previous case, increasing the decision threshold produces progressively more conservative segmentations.

IV. Discussion

The proposed model achieved strong overall classification performance across all evaluated metrics, with particularly high Recall, which is especially relevant for the intended clinical application, where false negatives are more critical than false positives. Although neural network training is inherently stochastic, the proposed network achieved consistent segmentation results under the adopted experimental configuration.

(a) $\tau = 0.90$ (b) $\tau = 0.93$

(c) $\tau = 0.96$

(d) $\tau = 0.99$

Figure 4: Segmentation results for image `f533af9b_lip_3.tif` obtained using different decision thresholds. Both ulcer and inflammation are present. Green indicates the ground-truth annotations, and blue indicates the regions detected by the model.

(a) $\tau = 0.90$

(b) $\tau = 0.93$

(c) $\tau = 0.96$

(d) $\tau = 0.99$

Figure 5: Segmentation results for image `4ad8fb28_lip_3.tif` obtained using different decision thresholds. Only ulcer is present. Green indicates the ground-truth annotation, and blue indicates the regions detected by the model.

A relevant limitation of this study is related to the dataset itself. To the best of our knowledge, ODSI-DB is the only publicly available database containing hyperspectral images with annotations of oral ulcers and mucosal inflammation. Despite the limited number of annotated hyperspectral images available, each image provides rich spectral information through 204 bands, yielding a high-dimensional representation for every pixel. This spectral richness was sufficient to train the neural network and demonstrate the feasibility of the approach.

Nevertheless, the lack of additional comparable datasets limits broader external validation. Moreover, given the limited number of patients and annotated images, the cross-validation splits were not constrained at the patient level. Therefore, the reported metrics reflect discrimination within the current image pool rather than generalization to unseen patients. Even so, the generated segmentation maps showed visual agreement with the annotated ulcerative and inflammatory regions, as illustrated in Figs. 4 and 5. Future studies should include larger datasets and additional annotated hyperspectral images to further evaluate the robustness and generalization capability of the proposed framework.

Another limitation arises from the exclusion of pixels corresponding to technical artifacts, such as specular reflections, shadow/noise regions, and out-of-focus areas, during model training. Although this preprocessing strategy prevents the network from learning non-informative patterns, it may reduce its generalization capability in real clinical scenarios, where such artifacts are naturally present. Consequently, the performance observed under the controlled experimental conditions may overestimate the accuracy achievable in future datasets.

The characteristics of the ODSI-DB annotations should also be considered when interpreting the results. The ground-truth masks correspond exclusively to regions manually delineated by specialists and do not necessarily encompass the complete spatial extent of the anatomical structures of interest, as shown in Fig. 1a. As a consequence, some pixels visually similar to annotated lesions may be treated as negatives during evaluation, which may increase the apparent false-positive rate. This behavior may reflect either the presence of unannotated inflamed tissue or the inherent uncertainty associated with manual annotation.

An additional limitation concerns the discrimination between the fibrin-covered ulcer surface and the surrounding inflammatory border. As illustrated in Fig. 4, increasing the decision threshold progressively reduces the response over the central fibrin-covered region, while the inflammatory border remains detected with higher confidence, resulting in discontinuities within the lesion. This behavior is consistent with the spectral analysis shown in Fig. 1b, where both regions exhibit highly similar spectral signatures, especially in spatially adjacent transition areas. These subtle spectral differences reflect the gradual anatomical transition between ulcerated and inflamed tissues, which is also difficult to distinguish during routine clinical examination because of the morphological continuity between these structures [1]. The same characteristic is reflected in the ODSI-DB annotations, where the ulcer

border and independently annotated inflammatory regions do not always present a clearly defined boundary. Therefore, the observed segmentation behavior may be explained by both the intrinsic spectral similarity between ulcerated and inflamed tissues and the uncertainty associated with manual reference annotations, supporting the strategy adopted in this work of merging ulcer and inflammation into a single positive class during model training.

Overall, the proposed methodology demonstrates the potential of hyperspectral imaging combined with deep learning for the automatic identification of oral ulcerative and inflammatory regions. The approach is not intended to replace the assessment performed by dental professionals or to provide standalone diagnosis. Rather, it provides a methodological framework for digital image processing and spectral analysis that may support future computer-assisted tools for oral mucosal assessment. Future work should prioritize the development of larger annotated hyperspectral databases for oral mucosal lesions. In addition, morphological processing may be incorporated to refine the segmentation masks, and spatial-spectral deep learning architectures may be explored to jointly exploit spectral and spatial information.

V. Conclusion

This study presented a computational framework for the automatic segmentation of oral ulcerative and inflammatory regions in hyperspectral images using an MLP network. The proposed methodology combines pixel-wise spectral analysis and supervised deep learning. The pixel-level cross-validation protocol, performed by decomposing the images into pixel-level samples without separating the data by subject, achieved high and consistent performance across the five folds, with a mean Accuracy of 98.70%, Recall of 99.71%, and PR-AUC of 0.9974.

The findings indicate that hyperspectral imaging combined with deep learning may support the automatic identification of oral ulcerative and inflammatory regions. Nevertheless, the interpretation of the results should consider the limited availability of annotated hyperspectral datasets for oral mucosal lesions, the characteristics of manual annotations, and the exclusion of technical artifacts during training.

Future work should prioritize the development of larger annotated hyperspectral databases for oral mucosal lesions. In addition, morphological processing may be incorporated to refine segmentation masks, and spatial-spectral deep learning models may be explored to jointly exploit spectral and spatial information.

***Abstract*—Melanoma is one of the most aggressive types of skin cancer, carrying a high mortality rate when not diagnosed early. The automatic detection of melanocytic lesions using artificial intelligence has emerged as a promising alternative to assist specialists in identifying the disease. In this work, an approach for the binary classification of dermoscopic images is proposed using the ResNet50 architecture combined with transfer learning, data augmentation, and fine-tuning techniques. The training process incorporated data augmentation operations and the adjustment of the network's deeper layers to enhance generalization and adaptation to the medical imaging domain. Experiments were conducted using dermoscopic images of melanoma and non-melanoma lesions under various training configurations. The results demonstrated that combining transfer learning, data augmentation, and fine-tuning significantly improved model performance, achieving 88.7 percent accuracy, 74.7 percent recall, and 66.1 percent precision in lesion classification. These findings highlight the potential of the proposed approach as a supportive tool for the early diagnosis of melanoma.**

***Index Terms*—Melanoma Detection, Dermoscopic Images, Deep Learning, Transfer Learning, ResNet50.**

I. Introduction

Artificial Intelligence (AI) is rapidly being integrated into daily life. In the medical field, significant efforts have been devoted to developing intelligent systems capable of supporting real-time diagnosis and clinical decision-making.

Melanoma is one of the most aggressive and lethal forms of skin cancer, with global incidence steadily rising. According to recent cancer statistics, the estimated number of new melanoma cases reached 57,180 in men and 42,600 in women within the analyzed period [1]. Furthermore, the World Health Organization (WHO) has reported approximately 132,000 melanoma cases worldwide [2]. Late detection of this malignancy drastically increases the risk of metastasis, contributing to poor patient prognosis. Consequently, early detection plays a crucial role in improving survival rates, prompting considerable research into accurate and efficient methods for melanoma screening.

Machine Learning (ML) techniques have been widely applied to advance automated melanoma diagnosis. These techniques enable computational models to learn complex patterns from labeled data and generalize predictions to unseen samples. This computational shift is critical, as conventional biopsy-based diagnostic procedures remain labor-intensive, time-consuming, and costly [3].

1) Dermoscopic Images: Dermoscopic images are acquired using a specialized optical device known as a dermatoscope. This instrument enables the visualization of subsurface skin structures that are invisible to the naked eye, assisting in the detection and assessment of melanocytic lesions. Dermoscopic examination can reveal characteristic pigmented structures, such as pigment networks, blotches, globules, and streaks. These images are typically captured and stored using digital imaging systems, allowing sequential recording and longitudinal monitoring of lesions to identify morphological changes over time [4].

2) Melanoma: Melanoma develops in specialized skin cells known as melanocytes, which become malignant when they begin to proliferate uncontrollably. It frequently occurs in areas regularly exposed to sunlight, including the arms, lips, nose, face, and hands [5]. Clinically, melanoma is classified into four major subtypes: nodular melanoma, superficial spreading melanoma, lentigo maligna melanoma, and acral lentiginous melanoma [6].

3) Non-Melanoma Skin Cancer: Non-melanoma skin cancer is generally less aggressive than melanoma; however, it remains a significant public health concern. Its development is strongly associated with exposure to ultraviolet (UV) radiation from sunlight. UV radiation is categorized into three types: UVA, UVB, and UVC, where prolonged exposure to UVB radiation constitutes one of the primary risk factors for skin

malignancy. Additional risk factors include fair skin, advanced age, the presence of freckles, and exposure to certain chemical agents [6]. Non-melanoma skin cancer encompasses several variants, including basal cell carcinoma, squamous cell carcinoma, Merkel cell carcinoma, and Kaposi's sarcoma [6]. Moreover, recurrence may occur even after successful clinical intervention.

To address these challenges, several studies have explored machine learning and deep learning architectures for skin lesion classification.

Sabir and Mehmood [7] proposed a melanoma classification framework based on convolutional neural networks, comparing CNN, ResNet-18, and EfficientNet-B0 architectures. Their objective was to improve the early diagnosis of melanoma by evaluating the effectiveness of different deep learning models. Using the ISIC skin lesion dataset, the framework incorporated image preprocessing, data augmentation, segmentation, feature extraction, and classification. The EfficientNet-B0 model achieved the best performance, reaching an accuracy of approximately 97% recall of 99%. However, the proposed pipeline involves multiple processing stages, increasing computational complexity.

Thwin and Park [8] introduced a deep ensemble model combining VGG16, Inception-V3, and ResNet-50 for skin lesion classification. The study aimed to improve classification robustness by integrating complementary CNN architectures through transfer learning and fine-tuning. Evaluated on the balanced ISIC 2018 dataset, the ensemble model achieved an accuracy of 97% and a melanoma recall of 91%, outperforming the individual networks. Nevertheless, the use of multiple deep models significantly increases computational cost and memory requirements during inference.

Selvaraj et al. [9] proposed an ensemble framework integrating ResNeXt101, SE-ResNeXt101, ResNet152V2, DenseNet201, GoogLeNet, and Xception for automated skin lesion classification. The objective was to improve diagnostic performance while addressing challenges such as class imbalance, image noise, and limited data availability. The method was evaluated on the HAM10000 and ISIC datasets, where the weighted ensemble model achieved an accuracy of approximately 89% and a recall of 95.24%. However, the large number of deep models considerably increases training time and computational requirements.

Padhy et al. [10] proposed the R-LSTM50 architecture, combining ResNet50 for feature extraction with Long Short-Term Memory (LSTM) networks. The objective was to enhance skin lesion classification by exploiting spatial and sequential feature representations simultaneously. Evaluated on the ISIC2020, the proposed model achieved accuracies of 95.72% and a recall of 95.24%, outperforming several conventional transfer learning approaches. Nevertheless, integrating LSTM layers increases model complexity and training time compared with standard CNN-based methods.

Islam and Panta [11] proposed a transfer learning framework for automated skin cancer classification by comparing five pre-trained convolutional neural networks, including ResNet50. The objective of the study was to improve the early detection of malignant skin lesions through transfer learning, fine-tuning, and data augmentation. The framework was evaluated on a subset of the ISIC dataset containing 3,297 dermoscopic images, where the ResNet50 model achieved an accuracy of 93.5% and a recall of 77%. However, the proposed framework was evaluated only for binary classification, which may limit its applicability to more complex multi-class skin lesion classification tasks.

Therefore, the objective of this work is to investigate the effectiveness of a ResNet50-based transfer learning framework for automated melanoma detection in dermoscopic images. The proposed method combines transfer learning, data augmentation, and fine-tuning strategies to achieve competitive classification performance using a single ResNet50 architecture. The model is evaluated on the ISIC 2019 dataset through standard classification metrics.

II. Methodology

The experimental workflow was structured into three sequential phases to systematically evaluate different optimization strategies. First, a baseline configuration was established by employing the ResNet50 architecture strictly as a fixed feature extractor, where the convolutional backbone remained frozen and only the fully connected (FC) classification layer was trained without data augmentation. In the second phase, a data augmentation strategy was introduced into the training pipeline to evaluate its impact on model generalization. Finally, the third configuration combined the same data augmentation pipeline with partial fine-tuning of the deeper layers of the network, targeting a localized adaptation to the domain-specific features of the dataset.

A. Dataset

This study utilizes the ISIC Challenge 2019 dataset, which contains 25,331 images in its official training set across nine diagnostic categories of skin lesions. In this work, the melanoma class was defined as the positive class (4,522 images), while the remaining eight categories (20,809 images) were aggregated into a single non-melanoma class, establishing a binary classification task.

Due to computational constraints, the official ISIC test set labels were unavailable; thus, the 25,331 images were partitioned using a stratified 80/20 train-validation split with a fixed random seed of 42. This stratified strategy ensured that the original class proportions were preserved across both subsets, yielding 20,264 images for model training (3,617 melanoma and 16,647 non-melanoma) and 5,067 images for internal validation (905 melanoma and 4,162 non-melanoma). Given metadata availability constraints, this partition was conducted directly at the image level based on class labels rather than using patient or lesion identifiers; consequently, the potential for cross-set lesion overlap remains a limitation of the current validation split.

It should be noted that the 20% validation subset serves strictly for model optimization and internal performance com-

parison rather than as an independent test set. Prior to model input, all dermoscopic images were resized to 224×224 pixels to match the standard input resolution of the ResNet50 architecture.

B. Data Augmentation

Data augmentation techniques contribute to mitigating overfitting by increasing the diversity of training samples and promoting more robust feature learning [12]. In medical imaging, these transformations enable the network to recognize patterns across different orientations and illumination conditions, which is essential since structures of interest may appear in various positions [13], [14].

In this work, the training images were subjected to a pipeline of geometric transformations, including vertical and horizontal flipping. These transformations were considered appropriate for dermoscopic images because skin lesions do not have a fixed anatomical orientation relative to the camera during image acquisition. Therefore, changes in the spatial orientation of the lesions do not necessarily alter their relevant morphological characteristics. Both the vertical and horizontal flipping transformations were applied with a probability of 0.5, increasing the variability of the training samples while preserving relevant visual characteristics of the lesions.

C. Transfer Learning and Fine-Tuning

This work proposes an end-to-end approach for effective melanoma classification. Publicly available dermoscopic images from the ISIC dataset were utilized, and a binary classification task (melanoma vs. non-melanoma) was performed using the ResNet50 architecture combined with deep learning optimization strategies. An overview of the network architecture is illustrated in Fig. 1.

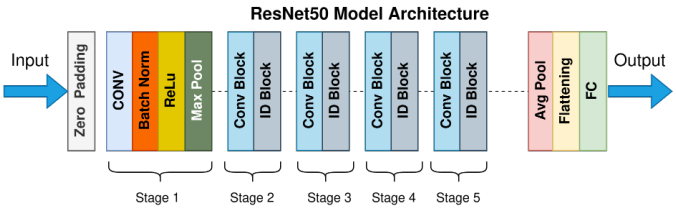

Fig. 1. Overview of the ResNet50 architecture. Source: [15]

Given the limited size of medical imaging datasets, training a deep network from scratch often leads to sub-optimal results or premature convergence. To mitigate this, transfer learning was incorporated by leveraging weights pretrained on the ImageNet dataset, significantly reducing convergence time and improving feature adaptation [16].

Subsequently, fine-tuning was employed to adapt the pretrained network to the target medical domain. This process consisted of unfreezing the deeper layers of the ResNet50 model and retraining them using the ISIC dataset with a reduced learning rate. Consequently, the previously learned generic weights were slightly adjusted to capture domain-specific features of melanocytic lesions while preserving the structural visual hierarchy acquired during the initial training phase [16].

The classifier was optimized using AdamW with a learning rate of 5e-4. Subsequently, during the fine-tuning stage, the layer3 and layer4 of the ResNet50 backbone were unfrozen and jointly trained with the classification layer using a learning rate of 1e-6 and 1e-5, respectively. The training was performed with a batch size of 64 for a maximum of 85 epochs. Early stopping was employed based on the validation loss, using a patience of 15 epochs, and the model checkpoint corresponding to the lowest validation loss was retained for evaluation. To address the class imbalance between melanoma and non-melanoma samples, Weighted Random Sampler was employed during training. The final classification was performed using a decision threshold of 0.5, whereby samples with a predicted melanoma probability equal to or greater than this value were classified as melanoma.

D. Evaluation Strategy

For the proposed application, clinical recall is prioritized over precision. Recall measures the model's ability to correctly identify positive cases, which is critical in melanoma detection, where a false negative (misclassifying a melanoma as benign) can have fatal clinical consequences. Conversely, a false positive can be subsequently reviewed and discarded by a specialist. Thus, maximizing recall stands as the primary optimization objective.

III. Results

The evaluation of the baseline configuration where ResNet50 acts strictly as a frozen feature extractor reveals moderate classification capabilities, as presented in Table I. The model achieved an initial validation accuracy of 83.90%; however, the precision remained constrained at 54.10%, indicating a substantial rate of false positives, resulting in an F1-Score of 59.60%. This baseline diagnostic behavior is further detailed in the confusion matrix in Fig. 2, which maps the absolute sample counts alongside class-wise recall and precision rates, establishing the numerical benchmark from which optimization strategies were evaluated. Specifically, out of 905 melanoma validation samples, the baseline correctly identified 600 true positives, while generating 305 false negatives, 3,653 true negatives, and 509 false positives.

TABLE I
Results without Data Augmentation.

Accuracy	Recall	Precision	F1-Score
83.90%	66.30%	54.10%	59.60%

To improve upon the baseline, a data augmentation strategy consisting of horizontal and vertical flipping operations was incorporated into the training pipeline. The introduction of these transformations improved the validation accuracy from 83.90% to 87.70% and increased precision from 54.10% to 65.80%, as summarized in Table II, corresponding to an F1-Score of 65.60%.

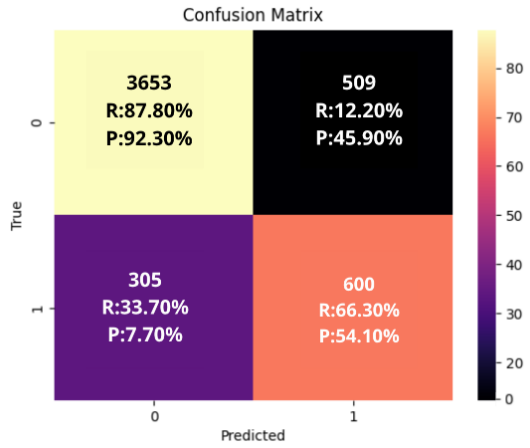

Fig. 2. Confusion matrix obtained without Data Augmentation. Source: Authors' own work.

However, a noticeable decrease in recall was observed, dropping from 66.30% to 65.30%. This behavior suggests that the model adopted a more conservative classification strategy, reducing false positives at the expense of a higher rate of false negatives within the melanoma class. The confusion matrix shown in Fig. 3 highlights this reduction in true positive predictions for the melanoma class, which directly correlates with the decreased recall, while concurrently demonstrating the reduction in false positives that drove the precision improvement. Under data augmentation, true positives dropped to 591 (increasing false negatives to 314), while true negatives improved to 3,855 and false positives decreased to 307.

TABLE II
RESULTS WITH DATA AUGMENTATION.

Accuracy	Recall	Precision	F1-Score
87.70%	65.30%	65.80%	65.60%

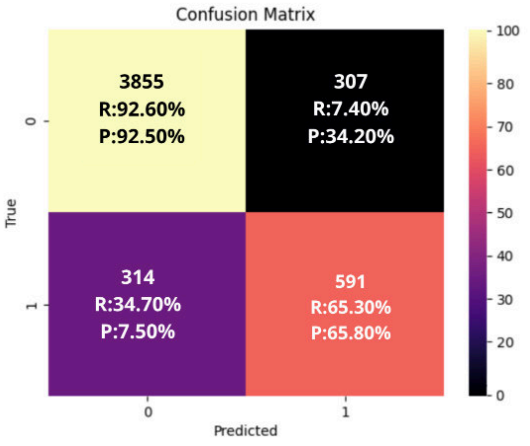

Fig. 3. Confusion matrix obtained with Data Augmentation. Source: Authors' own work.

Subsequently, fine-tuning was applied to the deeper layers of ResNet50 (`layer3` and `layer4`), while the initial layers responsible for extracting generic visual features remained frozen. Preliminary empirical evaluations indicated that unfreezing early layers did not yield significant performance gains; thus, this partial unfreezing configuration was adopted for the final experimental stage. The metrics achieved with this configuration are reported in Table III.

TABLE III
RESULTS WITH FINE-TUNING.

Accuracy	Recall	Precision	F1-Score
88.70%	74.70%	66.10%	70.20%

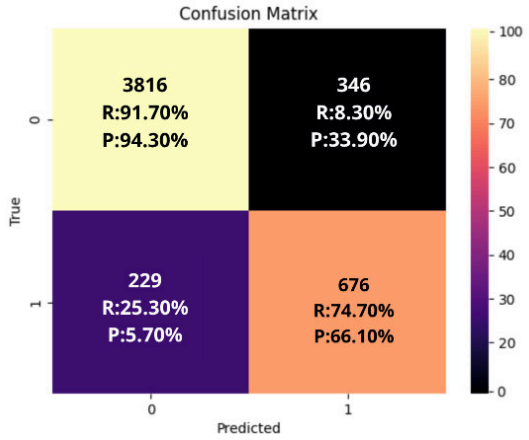

Fig. 4. Confusion matrix obtained with Fine-Tuning. Source: Authors' own work.

A comparative analysis across the three experimental setups indicates that fine-tuning the deeper layers of ResNet50 provides the most effective strategy among the evaluated configurations. While the introduction of data augmentation alone increased model precision (from 54.10% to 65.80%), it inadvertently degraded melanoma recall from 66.30% to 65.30%, causing the network to adopt an overly conservative decision boundary. However, incorporating partial fine-tuning successfully recovered and substantially boosted the recall to 74.70%, while maintaining a competitive precision of 66.10%, yielding an F1-Score of 70.20%, the highest among the three configurations.

Specifically, in terms of absolute sample counts, the fine-tuning configuration correctly identified 676 out of 905 melanoma cases (True Positives) and reduced false negatives to 229, while achieving 3,816 True Negatives and 346 False Positives for the non-melanoma class (Fig. 4).

From a clinical screening perspective, recall represents the primary optimization target. In automated melanoma detection, a false negative misclassifying a malignant lesion as non-melanoma carries severe, potentially fatal consequences by delaying life-saving medical intervention. Conversely, false positives can be subsequently re-evaluated and ruled out by a specialist through follow-up dermoscopic examinations

or biopsies. Although overall accuracy reached 88.70%, the 9.40 percentage-point improvement in recall is particularly noteworthy, as it directly translates to a significant reduction in false negative melanoma classifications. Among the evaluated configurations, the proposed approach achieved the best overall performance, particularly in terms of recall, indicating its potential for supporting early-stage screening

Finally, Table IV provides a benchmarking overview comparing the proposed approach against literature benchmarks. Although some existing frameworks report higher overall accuracy, these results should be interpreted with caution, as several studies were developed using smaller and more balanced datasets. For instance, some approaches were trained on datasets containing approximately 3,300 dermoscopic images that were already nearly balanced between benign and malignant lesions, considerably simplifying the classification task. In contrast, the proposed method was evaluated on the ISIC 2019 Training dataset, which contains 25,331 dermoscopic images and presents a substantial class imbalance, making melanoma detection significantly more challenging. Despite these more demanding conditions, the proposed method establishes a competitive trade-off, achieving 88.70% accuracy while specifically optimizing clinical recall, which is a vital parameter for early screening systems where reducing false negatives is critical.

TABLE IV
PERFORMANCE COMPARISON WITH STATE-OF-THE-ART METHODS.

Reference	Year	Datasets	Accuracy	Recall
[7]	2024	ISIC	97.00%	99.00%
[8]	2024	ISIC 2018	97.00%	91.00%
[9]	2024	HAM10000	89.00%	91.00%
[10]	2025	ISIC 2020	95.00%	95.24%
[11]	2024	ISIC	93.50%	77.00%
Proposed Method	**2026**	**ISIC 2019**	**88.70%**	**74.70%**

IV. CONCLUSION

Melanoma remains one of the most aggressive forms of skin cancer, highlighting the critical importance of developing computational tools to support early diagnosis. In this work, a ResNet50-based approach was proposed for the binary classification of dermoscopic images, integrating transfer learning, data augmentation, and fine-tuning techniques.

The experimental results demonstrated that transfer learning enables satisfactory performance even when dealing with imbalanced datasets. The application of data augmentation supported feature variability, while fine-tuning the deeper layers of the network yielded the highest classification performance among the evaluated configurations, with improvements in recall and precision.

Overall, the empirical findings indicate that combining transfer learning, data augmentation, and fine-tuning constitutes a promising strategy for automated melanoma detection in dermoscopic images. The proposed framework has the potential to serve as a supportive preliminary tool for clinical decision-making and early screening.

Future research will focus on evaluating the model using external datasets and cross-validation protocols, investigating alternative deep architectures, exploring advanced class-balancing strategies, and incorporating explainable artificial intelligence (XAI) techniques to enhance interpretability for clinical practice.

***Abstract*—ST-segment and T-wave (ST/T) abnormalities are important electrocardiographic markers of myocardial ischemia and ventricular repolarization disorders. Existing methods rely mainly on conventional morphological descriptors and do not distinguish persistent ST/T episodes from transient beat abnormalities, limiting interpretability. This work proposes a framework combining conventional ECG descriptors, Recurrence Quantification Analysis (RQA), and multiscale physiological labeling to characterize ST/T alterations. ECG recordings from the European ST-T Database were segmented into beat-based windows and evaluated at two distinct temporal scales to characterize persistent ST/T episodes and local beat abnormalities. Logistic regression evaluated the contribution of RQA features, while a mixed-effects multinomial model quantified associations across four physiological states. In Group 1, RQA increased episode classification accuracy from 50.0% (chance level) to 63.0% (+26.0% relative), with recall and F1-score increasing by 24.0% and 20.4%, respectively. In Group 2, AUC increased from 75.0% to 80.0% (+6.7% relative). Beat abnormality classification achieved 80.0% accuracy and 76.0% AUC in Group 1, and 83.0% accuracy and 84.0% AUC in Group 2. Mixed-effects analysis showed distinct dynamical signatures across physiological states, with average diagonal line length (L) showing the strongest positive association across altered classes and determinism (DET) exhibiting distinct associations with episodes and beat abnormalities. These findings demonstrate that RQA provides complementary information beyond conventional ECG descriptors and supports multiscale labeling for distinguishing persistent ST/T alterations from transient beat perturbations. Rather than maximizing predictive performance, classification was used as a comparative tool to demonstrate the value of recurrence descriptors and the interpretability gains of multiscale labeling.**

***Index Terms*—Electrocardiogram, Recurrence Quantification Analysis, Multiscale physiological labeling, Myocardial ischemia, Nonlinear dynamics.**

I. Introduction

Coronary artery disease remains one of the leading causes of mortality worldwide, and myocardial ischemia is among its most common manifestations [1]. Ischemic events alter the electrical properties of cardiac tissue, affecting the electrocardiogram (ECG), particularly the ST segment and T wave [1]. Consequently, the automatic detection and characterization of ST/T abnormalities have been extensively investigated to support early diagnosis and clinical decision-making [2]. However, these abnormalities are often subtle, patient-dependent, and susceptible to noise and baseline variations, making their robust characterization a challenging problem [1], [3]. Conventional approaches typically rely on morphological measurements extracted from predefined ECG landmarks, which may not fully capture the complexity of the underlying cardiac dynamics.

The European ST-T Database (EDB) provides a unique framework for studying this problem because it combines two complementary annotation levels [4]. In addition to expert annotations defining the onset, peak, and end of ST/T alteration episodes, the database provides beat-by-beat annotations describing local cardiac events. These annotations naturally represent different temporal scales of cardiac physiology: ST/T episodes describe persistent changes in the underlying myocardial state, whereas beat annotations characterize transient electrical perturbations occurring within that state. This distinction suggests that ECG windows should be interpreted simultaneously from both perspectives rather than using a single label.

Recurrence analysis provides an alternative framework for

characterizing ECG signals from the perspective of nonlinear dynamics. Recurrence Plots (RPs) represent the recurrence of cardiac states in phase space as a two-dimensional fingerprint of the underlying dynamics [5], [6], while Recurrence Quantification Analysis (RQA) summarizes these patterns through descriptors such as recurrence rate, determinism, entropy, and laminarity [7], [9]. Unlike conventional morphological descriptors, RQA quantifies the temporal organization and geometric structure of cardiac trajectories [10], potentially revealing subtle dynamical changes associated with ventricular repolarization abnormalities. Although recurrence analysis has demonstrated promising results in physiological signal analysis, its application to ST/T alteration episodes remains relatively unexplored.

During the exploratory analysis, we observed that beat abnormalities frequently occur both inside and outside annotated ST/T episodes. Consequently, models trained solely using episode annotations may inadvertently learn beat-related characteristics, reducing the interpretability of the resulting classifiers. Rather than treating these alterations as independent classes, we propose a multiscale hierarchical physiological labeling framework in which each ECG window is simultaneously described according to (i) the persistent ST/T episode state and (ii) local beat-level perturbations. The resulting four analysis groups arise naturally from the Cartesian product of these complementary physiological descriptors, allowing the influence of persistent and transient alterations to be analyzed separately. Accordingly, the objective of this work was twofold. First, we investigated whether recurrence-based descriptors provide complementary information to conventional ECG features for the characterization of ST/T alteration episodes. Second, we evaluated how beat-level abnormalities influence this characterization through the proposed physiological labeling framework. The classification models were adopted as a comparative framework rather than with the aim of maximizing predictive performance or competing with state-of-the-art methods. Instead, the primary contribution lies in assessing the added value of recurrence-based descriptors and in demonstrating how the proposed disentangling strategy and multiscale physiological labeling improve the physiological interpretability of ECG dynamics by separating persistent ST/T alterations from transient beat perturbations.

II. Methods

A. Dataset

The experiments were conducted using ECG recordings from the European ST-T Database (EDB), accessed via the PhysioNet platform. The database provides multi-lead ECG signals sampled at a fixed frequency of 250 Hz and annotated beat-by-beat by expert cardiologists using the WFDB annotation system. The ECG signals and annotations were loaded using the WFDB library, which enables synchronized access to waveform data (rdrecord/rdsamp) and reference annotations (rdann). Each record consists of continuous ECG signals along with temporal markers indicating cardiac events, which were used as ground truth for segmentation and labeling.

The original dataset consists of 90 annotated excerpts of ambulatory ECG recordings from 79 subjects. The subjects were 70 men aged 30 to 84, and 8 women aged 55 to 71. The subjects were 70 men aged 30 to 84, and 8 women aged 55 to 71. From the 90 records, 30 records were selected for this study, corresponding to the largest subset of recordings acquired using the same pair of leads, namely V4 and MLIII. A second subset of 14 records, corresponding to the second-largest group acquired using the same pair of leads, namely V5 and MLI, was also included in the study and analyzed separately due to the different lead configuration. The group with 30 records present exclusively male subjects, with a mean age of 52 ± 8 years. The group with 14 records comprised 13 men and 1 woman, with a mean age of 55 ± 10 years. Each ECG recording was sampled at 250 Hz and contains a total of 1,800,000 samples, corresponding to 120 minutes of continuous monitoring. Although this selection ensured lead consistency across all recordings, it limits the generalizability of the findings to populations with different lead configurations and to female subjects.

B. Exploratory Data Analysis (EDA)

An EDA was performed on the ECG dataset to characterize its structure, annotation scheme, and demographic composition before the experimental pipeline. The dataset includes two annotation types: beat-by-beat labels, which mark individual cardiac cycles, and episode-level annotations, indicating the onset, peak, and offset of clinically relevant ST/T deviations. These complementary annotations enable both local (beat-level) and global (episode-level) analyses of ECG dynamics and are summarized in Table I.

A grouping strategy based on ECG lead configuration was then applied to ensure methodological consistency. Records were grouped by available leads, and the largest homogeneous subgroup comprised 30 individuals with the same configuration (V4 and MLIII). This subgroups were selected for all subsequent analyses to ensure signal comparability and minimize variability arising from different lead configurations.

C. Signal Preprocessing

The raw ECG signals were subjected to the preprocessing pipeline illustrated in Fig. 1A (preprocessing) and Fig. 1B (R-Peaks).

- Power Spectral Analysis: Power Spectral Density (PSD) analysis was performed to characterize the frequency content of the signals, verify preprocessing effectiveness, and identify dominant frequency bands associated with cardiac activity.
- Baseline wander and high-frequency noise were reduced using digital filtering while preserving the morphology of the P, QRS, and T waves. A high-pass filter (0.5 Hz) and a low-pass filter (50 Hz), defined from the power spectrum analysis, were applied [11].
- Normalization: Signal amplitudes were standardized across recordings and leads using z-score normalization, ensuring zero mean and unit variance per channel. In

TABLE I
ANNOTATIONS DICTIONARY

Annotation	Description
Episode-level annotations	
N	Normal rhythm
ST0+	ST-segment elevation episode on lead 0
ST0–	ST-segment depression episode on lead 0
ST1+	ST-segment elevation episode on lead 1
ST1–	ST-segment depression episode on lead 1

T0–	T-wave depression episode on lead 0
VT	Ventricular tachycardia
Beat-level annotations	
N	Normal beat
V	Premature ventricular contraction
S	Supraventricular premature or ectopic beat
+	Rhythm change
F	Fusion of ventricular and normal beat

multi-lead recordings, normalization preserved relative amplitude relationships between leads, avoiding distortion of morphological differences [12].

- R-Peak Detection: R-peaks were detected using the GQRS algorithm implemented in the WFDB processing library. Widely used in PhysioNet-based studies, GQRS identifies QRS complexes from signal morphology and amplitude variations to determine R-peak locations [13]. Detection was performed sequentially across available leads until a valid set of R-peaks was found, ensuring robust performance even when some leads presented lower signal quality or higher noise levels.

D. Signal windowing

After R-peak detection, ECG recordings were segmented using a heartbeat-based sliding-window approach. Each window contained 5 consecutive heartbeats, defined by the interval between the first and tenth detected R-peak, with an overlap of 2 heartbeats between adjacent windows. This overlap increased the number of samples while preserving temporal continuity, as illustrated Fig. 1C. This strategy ensured that each window contained a comparable amount of cardiac activity regardless of heart rate variations. Although window durations varied over time, all segments preserved the same number of cardiac cycles and their morphological information.

E. Features

- **Morphology-based features:** Morphology-based features were extracted from each ECG window to characterize cardiac rhythm and waveform morphology. Temporal dynamics were represented by the mean R-peaks interval (R-peaks-mean), reflecting the average cardiac cycle duration, and the standard deviation (R-peaks-std), measuring beat-to-beat variability. Signal energy was quantified using the Root Mean Square (RMS), a widely adopted measure of signal amplitude and energy. Because the selected records include two ECG leads (V4 and MLIII), RMS was calculated separately for each lead to preserve lead-specific amplitude information. Together, R-peaks-mean, R-peaks-std, and lead-specific RMS values formed the set of signal-derived features used in the subsequent analyses.
- **Recurrence-based Features:**
Recurrence-based features were extracted from each windowed segment using RQA, which characterizes temporal patterns in the joint evolution of the two ECG leads. RP provides a two-dimensional representation of trajectory recurrences in phase space by identifying states that revisit neighboring regions over time, acting as a dynamical fingerprint of the system. In this sense, the RP acts as a dynamical fingerprint of the system, revealing characteristic patterns associated with the way the trajectory revisits previously explored regions and evolves through phase space over time. Let $\mathbf{x}_i \in \mathbb{R}^m$ denote the state of the system at time i, represented either by a directly observed multivariate state vector or by a reconstructed phase-space vector. The recurrence matrix is defined as

$$R_{i,j} = \Theta\left(\varepsilon - \|\mathbf{x}_i - \mathbf{x}_j\|\right), \qquad i,j = 1,\ldots,N, \quad (1)$$

where $\|\mathbf{x}_i - \mathbf{x}_j\|$ represents the distance between the states of the system at times i and j, ε is a predefined recurrence threshold, and $\Theta(\cdot)$ is the Heaviside function. Thus, $R_{i,j} = 1$ when two states are sufficiently close in phase space, according to the selected distance criterion and threshold, and $R_{i,j} = 0$ otherwise. The resulting RP encodes the temporal organization of the trajectory as a binary pattern whose isolated points and diagonal and vertical line structures form the basis for RQA [9].
For each window, the two ECG leads were combined into a multivariate embedding. The neighborhood radius was empirically set to $\varepsilon = 0.1$, based on qualitative inspection of the resulting RPs and the corresponding recurrence rate (RR). Specifically, the threshold was selected to provide visually meaningful recurrence structures. The resulting RRs were also evaluated in relation to the 5–15% range commonly suggested for recurrence-based analyses [8]. A Theiler correction of 1 sample excluded temporally adjacent points, reducing autocorrelation bias.
Based on the resulting RPs, six RQA descriptors were extracted to characterize the temporal organization and complexity of the reconstructed phase-space trajectories, following Marwan et al. [9]. Recurrence rate (RR) quantifies the density of recurrent states, with higher values indicating more frequent revisits to previously occupied regions of phase space. Determinism (DET) measures the proportion of recurrent points forming diagonal lines, where higher values indicate more predictable and temporally ordered dynamics. The average diagonal line length (L) reflects the mean duration of similar trajectory evolution, while the longest diagonal line (Lmax) represents the longest predictable episode; unlike RR and DET, both are expressed in samples or time units and have no fixed

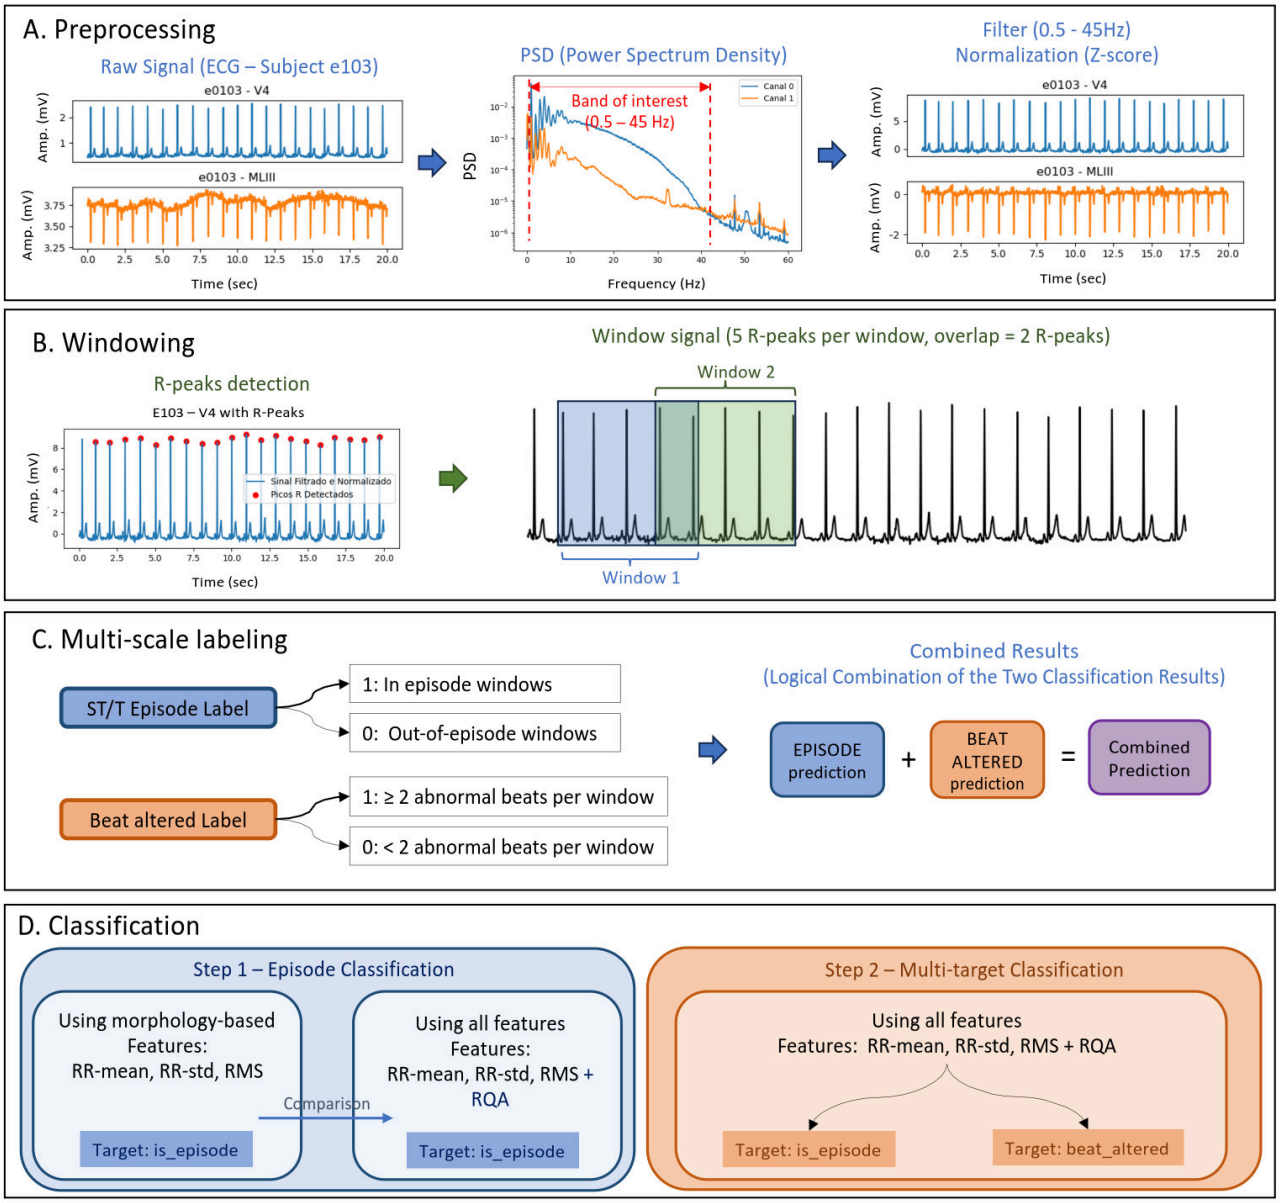

Fig. 1. Overview of the proposed pipeline for ischemic episode classification from ECG recordings. (A) Preprocessing stage. (B) Segmentation of the preprocessed ECG into overlapping windows. (C) Hierarchical labeling strategy combining episode annotations and beat-level alterations to generate four analysis classes. (D) Classification framework.

upper bound. The entropy of diagonal line lengths (Lentr) quantifies the diversity of diagonal-line durations, with higher values indicating greater heterogeneity of recurrent temporal patterns. Finally, laminarity (LAM) measures the proportion of recurrent points forming vertical lines, reflecting the persistence of laminar states, with higher values indicating more sustained dynamics within restricted regions of phase space.

F. Multi-scale physiological labeling

The EDB Database provides two complementary annotation levels describing cardiac activity at different temporal scales. ST/T episode annotations identify persistent ventricular repolarization alterations over relatively long intervals, whereas beat annotations capture transient electrical events on a beat-by-beat basis.

Each ECG window was simultaneously characterized by these two physiological descriptors, reflecting that local beat perturbations occur within an underlying myocardial state. Their combination naturally defines four physiological groups: (i) normal beat outside an ST/T episode, (ii) altered beat outside an ST/T episode, (iii) normal beat during an ST/T episode, and (iv) altered beat during an ST/T episode.

The `is_episode` label was generated from the episode-level annotations in Table I. A window was labeled positive

(is_episode = 1) if it overlapped any annotated ST/T episode; otherwise, it was labeled negative (is_episode = 0).

The beat_altered label was derived from the beat-level annotations in Table I. A window was labeled as altered (beat_altered = 1) if at least two beats contained abnormal symbols; otherwise, it was labeled normal (beat_altered = 0).

The multiscale labeling is illustrated in Fig. 1C and enables persistent episode-related alterations and transient beat abnormalities to be analyzed separately, providing a more interpretable representation of cardiac dynamics.

G. Classification and Evaluation

Two independent binary classification models were trained to investigate complementary aspects of cardiac dynamics. The first distinguished ECG windows belonging to ST/T alteration episodes from normal segments, characterizing persistent myocardial changes. The second classified windows according to the presence or absence of beat abnormalities, representing transient electrical perturbations.

Both classifiers used the same feature extraction pipeline and evaluation protocol, enabling recurrence-based descriptors to be assessed independently for each physiological phenomenon. Their outputs were then combined through the proposed multiscale labeling framework to define the four physiological analysis groups, rather than by training a dedicated four-class classifier.

The classification was organized into two steps to evaluate the impact of feature representation and label type, as illustrated in Fig. 1D. All models were implemented using logistic regression with L2 regularization and evaluated under a stratified 5-fold cross-validation scheme. The data were split into 75% training and 25% testing sets using a group-wise split by record, ensuring that all windows from the same record were assigned exclusively to one set to prevent data leakage.

*a) **Step 1—Episode-based classification**:* In the first step, a binary classifier was trained using the is_episode label, representing the presence or absence of ST/T episodes. Two feature sets were evaluated independently:

- Morphological features only, including mean and standard deviation of R-peaks intervals and RMS values per lead;
- Combined feature set, integrating morphological features with RQA descriptors.

This comparison isolated the contribution of nonlinear dynamical information provided by RQA features. Model performance was evaluated using accuracy, precision, recall, and ROC curves.

*b) **Step 2—Multi-scale classification** (is_episode and beat_altered):* In the second step, the role feature set (morphological + RQA) was used to train two separate classification models with distinct targets:

- is_episode, representing clinically annotated ST/T segment alteration episodes;
- beat_altered, representing beat abnormalities.

This stage investigated how different physiological scales are represented within the same feature space.

The joint analysis of both steps provides a comprehensive interpretation of ECG behavior by identifying four complementary signal regimes:

- Normal: Out-of-episode with normal beats;
- Beat: Out-of-episode with altered beats;
- Episode: In-episode with normal beats;
- EpisodeBeat: In-episode with altered beats.

H. Mixed-effects analysis of disentangled ECG dynamics

To further investigate whether recurrence-based descriptors discriminate sustained ischemic episodes from local beat abnormalities, a mixed-effects multinomial logistic regression was fitted considering the four combined classes (Normal, Episode, Beat, and EpisodeBeat). The Normal class was adopted as the reference level, while patient-specific variability was modeled through a random intercept for each record.

This analysis was restricted to the 30-record subset with the V4 and MLIII lead configuration.

The model was implemented in R using the brms package with a categorical likelihood and logit link. Parameters were estimated using Hamiltonian Monte Carlo (No-U-Turn Sampler) with two Markov chains, 1,000 iterations per chain (500 warm-up iterations). Posterior means and 95% credible intervals were computed, with convergence assessed using $\hat{R}$ and the effective sample size (ESS). Regression coefficients were exponentiated to obtain odds ratios (OR) for interpretation. The model can be written as in

$$\log\left(\frac{P(Y_i = k)}{P(Y_i = \text{Normal})}\right) = \beta_{0k} + \sum_{j=1}^{p} \beta_{jk} x_{ij} + b_{r(i)}, \quad (2)$$

where Y_i denotes the class of the i-th ECG window, $k \in \{\text{Episode}, \text{Beat}, \text{EpisodeBeat}\}$, x_{ij} represents the j-th predictor, β_{jk} are the fixed-effect coefficients, and $b_{r(i)} \sim \mathcal{N}(0, \sigma^2)$ is the random intercept associated with the record containing observation i.

III. Results

A. Features

Table II summarizes the extracted features by type of each group of records, with their mean and standard deviation across the four hierarchical label combinations. This organization facilitates comparison of feature distributions across physiological conditions and highlights how signal-derived and recurrence-based descriptors vary with episode presence and beat alterations.

B. Classification and Evaluation

Table III summarizes the classification results of the proposed multiscale framework. The first scale identifies ST/T alteration episodes (is_episode), while the second classifies local beat abnormalities (beat_altered).

Figure 2 illustrates the multiscale framework by combining the outputs of the two binary classifiers into the four

C. Mixed Effects Analysis

The model was fitted to the complete dataset to characterize the contribution of each descriptor to the proposed disentangling strategy. Convergence and sampling diagnostics were assessed using the potential scale reduction factor ($\hat{R}$) and the effective sample size (ESS). Across all model parameters, $\hat{R}$ values ranged from 1.00 to 1.03, while Bulk ESS and Tail ESS ranged from 172 to 1549 and from 272 to 924, respectively. These diagnostics indicated generally adequate chain mixing, although the slightly elevated $\hat{R}$ observed for the Episode intercept ($\hat{R} = 1.03$) was noted.

For illustration, the linear predictor for the Episode class of patient `e0119` is given by

$$\begin{aligned}\eta_{\text{Episode}}^{(\text{e0119})} = & -1.84 - 0.01\,R - peak_{\text{mean}} - 0.09\,R - peak_{\text{std}} \\ & - 0.77\,RR + 1.73\,DET + 2.07\,L \\ & - 0.62\,L_{\max} - 1.97\,L_{\text{entr}} - 1.00\,LAM \\ & + 0.57\,RMS_{V4} - 0.03\,RMS_{MLIII} + b_{\text{e0119}}.\end{aligned} \tag{3}$$

where b_{e0119} represents the patient-specific random intercept. Similar equations are estimated for the Beat and EpisodeBeat classes, allowing each feature to have a distinct contribution depending on the underlying physiological condition.

Overall, the mixed-effects multinomial analysis revealed distinct associations between recurrence-based descriptors and the Episode, Beat, and EpisodeBeat classes. The corresponding odds ratios and 95% credible intervals are shown in the forest plots (Fig. 3). Among the evaluated descriptors, L showed the strongest positive association across altered classes, while

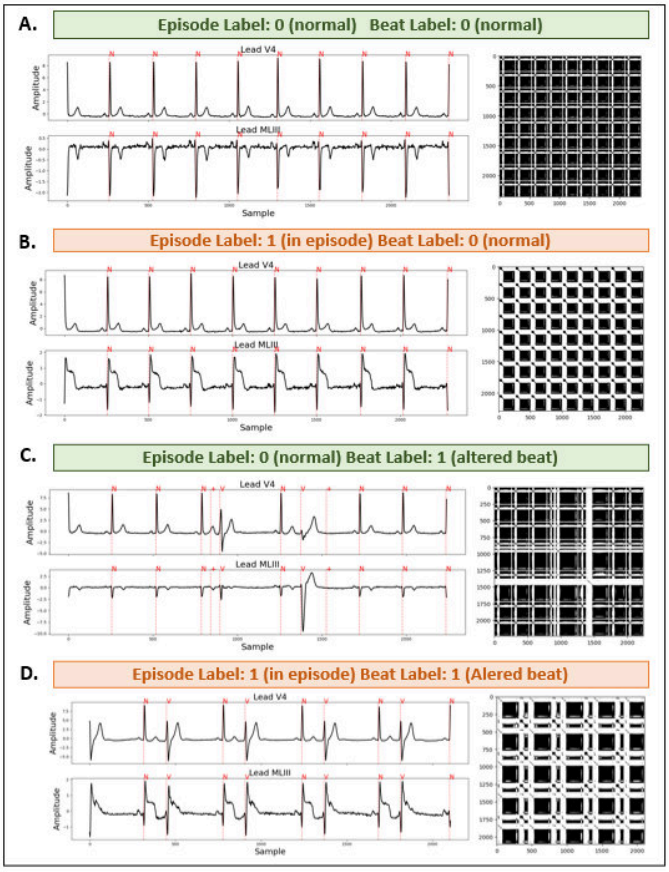

Fig. 2. Examples of ECG signals and recurrence plots for each label combination.

DET exhibited opposite effects for the Episode and Beat classes.

IV. Discussion

The results demonstrate that combining conventional ECG descriptors with recurrence-based features provides a richer characterization of ECG signals than using morphological features alone.

In Step 1, the inclusion of RQA metrics improved all classification measures, increasing accuracy from 0,5 to 0,63 (+26% relative) in group 1 where the initial 50.0% accuracy corresponds to chance-level classification. In Group 2, AUC increased from 75.0% to 80.0% (+6.7% relative). In Group 1, precision remained unchanged, whereas recall and F1-score increased by 24.0% and 20.4%, respectively. These results suggest that RQA descriptors capture temporal organization and dynamical complexity not fully represented by conventional ECG descriptors, supporting their potential for characterizing alterations across different temporal scales. These findings are consistent with previous studies [10], [14], [15].

The mixed-effects multinomial model further demonstrated that RQA descriptors capture distinct dynamical patterns associated with the four physiological states while accounting for repeated observations from the same subject. The average diagonal line length (L) showed the strongest positive association with all altered classes, particularly classes Episode and EpisodeBeat, indicating that prolonged recurrent trajectories are a relevant marker of abnormal ECG dynamics. Since L represents the persistence of similar state evolution in the reconstructed phase space, its association suggests that sustained ST/T episodes and combined alterations are characterized by increased temporal persistence rather than isolated waveform changes.

The remaining RQA metrics showed class-dependent behavior, supporting the proposed disentangling strategy. DET was positively associated with Episode but negatively associated with Beat class, suggesting that sustained ST/T abnormalities are related to more deterministic temporal organization, whereas isolated beat alterations exhibit more irregular dynamics. Conversely, LAM showed the opposite pattern, being strongly associated with class Beat and negatively related to Episode class. These findings indicate that beat-related abnormalities do not represent weaker manifestations of ischemic episodes, but rather a distinct dynamical regime. The EpisodeBeat class presented intermediate behavior, suggesting that the coexistence of both phenomena modifies the recurrence structure observed when each alteration occurs independently.

Conventional ECG descriptors also remained relevant in the analysis. The positive association of RMS-V4 across altered classes confirms that morphological information continues to contribute to ECG characterization, while the opposite effects of R-peak-std between Episode and Beat classes agree with the physiological interpretation of the labels. Sustained ST/T episodes tend to occur without pronounced beat-to-beat variability, whereas beat alterations are associated with increased rhythm fluctuations. Thus, RQA descriptors complement rather than replace conventional ECG features, providing a broader representation of cardiac dynamics.

An important contribution of this study is the multi-scale labeling strategy that separates persistent ST/T alterations from local beat perturbations, combined with RQA to characterize their distinct temporal behaviors. Traditional approaches often rely exclusively on episode annotations, assuming that relevant ECG variations are restricted to clinically defined events. However, EDA revealed substantial variations both inside and outside episode boundaries. By separating episode-related and beat-related alterations, the proposed framework avoids combining different physiological processes into a single classification task and enables a more detailed interpretation of ECG dynamics.

The analysis of the four label combinations further supports this interpretation. Windows classified as neither episode nor altered beat represent baseline cardiac behavior, whereas altered beats outside episodes indicate electrophysiological changes not captured by ST/T annotations alone. Conversely, episodes without beat alterations show that clinically relevant ST/T abnormalities may occur independently of rhythm disturbances. Finally, windows containing both alterations represent the most complex physiological condition, combining persistent and local abnormalities. This decomposition provides

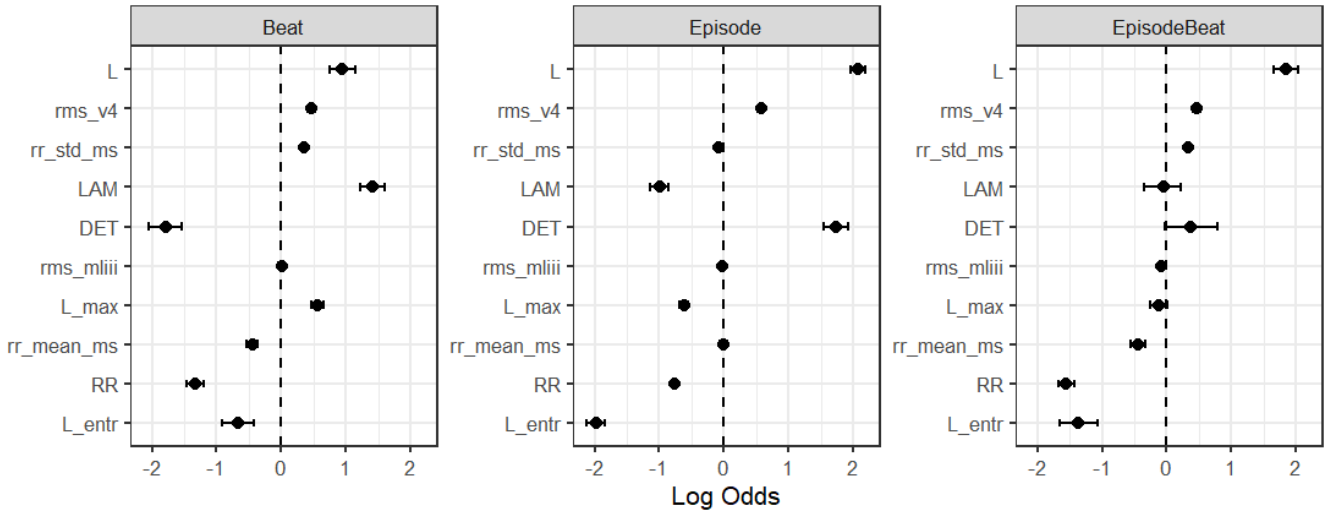

Fig. 3. Forest plots of the mixed-effects multinomial logistic regression for the Beat, Episode, and EpisodeBeat classes relative to the Normal class. Points denote the estimated log-odds coefficients and horizontal bars represent the 95% credible intervals. The dashed vertical line indicates the null effect (log-odds = 0).

a more comprehensive framework for interpreting classifier decisions and understanding the underlying ECG dynamics.

V. Conclusion

Overall, the findings suggest that combining morphological metrics, RQA, and hierarchical multi-scale labeling provides a comprehensive methodology for studying ECG abnormalities. The proposed approach not only improves the characterization of ST/T alteration episodes but also highlights the ability of recurrence analysis to characterize ECG morphology across different temporal scales. This capability enables the differentiation of transient beat-level abnormalities from more persistent ST/T episodes, providing a more interpretable representation of ECG dynamics and contributing to the development of more explainable ECG analysis systems. Given the limited number of individuals within each lead configuration, future work will extend the analysis to a larger number of individuals and additional ECG datasets to further assess the generalizability of the proposed framework.

***Abstract*—Advances in quantitative, sensitive, and objective biomarkers of neuromotor control are essential for early diagnosis and optimized rehabilitation following neurological and motor impairments. In this context, corticomuscular coherence (CMC) and intermuscular coherence (IMC) have been investigated as measures of brain–muscle communication and muscular coordination, respectively, yet their differential sensitivity to the physical properties of manipulated objects has not been systematically explored within a single paradigm. This study examined the modulation of CMC and IMC during a precision grip-and-hold task as a function of object weight and surface friction, using the WAY-EEG-GAL dataset (12 healthy subjects, 4 EEG channels, 5 forearm and hand muscles, 6 experimental conditions). Behaviorally, grip force and safety margin scaled with decreasing friction without concurrent changes in load force, confirming selective adjustment of the tangential force component. Neurophysiologically, the CMC peak proved to be the most sensitive variable, with surface friction accounting for 51.31% of total variance in the Beta band ($p < 0.0001$), uniformly across all 20 channel–muscle pairs evaluated. Conversely, IMC was predominantly modulated by object weight, with the heaviest condition (660g) significantly increasing coherence between forearm synergist muscles in the Gamma band. This dissociation — cortical descending coupling driven by precision demands, intermuscular coordination driven by force demands — is reported here for the first time. These findings support the complementary use of CMC and IMC as functionally distinct biomarkers, with potential implications for neurorehabilitation and prosthetic control strategies.**

***Index Terms*—CMC, IMC, muscle synergy, grasp**

I. Introduction

In 2024, a survey by the World Health Organization (WHO) highlighted the persistent impacts of neurological injuries on public health and the quality of life of those who suffer from them, whether due to persistent deficits impacting the individual's functionality or their need for rehabilitation and prolonged care [1]. Given this scenario, the improvement of tools that allow for the individualization of therapeutic planning and diagnostic anticipation, in a quantitative and parameterizable way, becomes fundamental, since traditional methods such as DASH [2] and the Rosén Score [3] demonstrate subjectivity and low sensitivity in detecting subtle changes during the process of neural degeneration and regeneration, in addition to a considerable impact stemming from their subjective nature. Based on this need, an understanding of the mechanisms of action of neurorehabilitation techniques [4], [5], and of the anatomical-functional remodeling of ascending and descending pathways of primordial phase is crucial. Among the various tools available, in the field of electrophysiology, Corticomuscular Coherence (CMC) and Intermuscular Coherence (IMC) stand out. Obtained through the mathematical combination of cerebral electrophysiological signals, captured through electroencephalography (EEG), and muscle activity, recorded by electromyography (EMG), CMC reflects the functional connectivity in a synchronous, although not causal, way between the motor cortex and the target muscle [6], [7]. In healthy individuals, CMC is predominantly observed in the mu (8–13 Hz) and beta (15–30 Hz) frequency bands, indicating both downward motor modulation and upward sensory feedback during motor tasks [8]. Studies suggest that alterations found in this synchronization may be consequences of remodeling of spinal pathways, cortical structure, and/or neuromuscular junctions (NMUs), potentially characterizing various pathological conditions such as neuropathies and lesions of the central nervous system [9]–[11]. The IMC, in turn, analyzes the functional connectivity between muscles and the shared common drive between pools of motor neurons through EMG data. It is based on the principle of synergistic muscle control, in which a shared oscillatory control signal (common drive) is sent from the motor cortex (M1) to different spinal motor neuron nuclei, "simplifying" the complexity in the activation of the musculoskeletal system [12]. The IMC can exhibit coherence in different frequency bands, reflecting different levels of control: the alpha/mu band is associated with physiological microtremors, cerebellar modulation, and continuous sensory feedback; the beta band is the classic signature of corticospinal

This work was supported in part by CNPq, CAPES, FAPEMIG, and FINEP.

tract modulation during isometric contractions and postural holds; the gamma band, finally, is associated with rapid adjustments, linked to dynamic coordination that demands speed and a high level of sensorimotor integration [13]. In general, the potential for mapping central and peripheral pathways revealed by the joint implementation of both tools is evident, expanding the possibilities for understanding the mechanisms responsible for movement. However, despite this potential, the integrated behavior of CMC and IMC and their combined interpretation in different task contexts remain insufficiently explored.

Beyond being a neuromotor biomarker, both CMC and IMC stand out as fundamental components for the bio-inspired functioning of human-machine interfaces and the development of more efficient assistive technologies, as indicated by works such as [14], [7], [15], and [16]. In these studies, the ability of CMC to act not only as a marker of evolution during rehabilitation, but also of corticomotor remodeling itself, was demonstrated; as was the correlation between CMC and IMC in the exposure of pathological compensations of the motor system; and IMC as a potential tool in reducing energy expenditure and assisting in kinematic calculations in prosthetic robotics, these being just some demonstrations of the potential of this research field. In particular, it remains unknown whether these two measures are differentially sensitive to distinct mechanical constraints, such as friction and load, within a single experimental paradigm, or whether they reflect a common underlying modulation.

In this context, this study proposes to explore the correlations between CMC and IMC in healthy individuals performing a grasping task. However, it remains unclear whether these measures exhibit distinct sensitivities to different task demands, such as variations in friction and load. The dataset used (WAY-EEG-GAL, [17]) allows the exploration of these correlations through controlled changes in texture and weight of the handled object, in addition to tracking the force applied by the volunteer. In this context, this study aims to investigate how corticomuscular coupling and intermuscular coordination are differentially modulated during object manipulation. By doing so, we seek to clarify their complementary roles as neuromotor biomarkers under varying mechanical constraints. To our knowledge, this is the first study to demonstrate a functional dissociation between CMC and IMC modulation within a unified grip control paradigm, with friction selectively driving cortical coupling and load selectively driving intermuscular coordination.

II. Methodology

A. Dataset

The dataset is the WAY-EEG-GAL, obtained from Luciw et al. [17], and consists of synchronized EEG, surface EMG (sEMG), force, and biomechanical data acquired during a standardized reach-to-grasp task with semi-random variations in object weight and surface texture. For the present analysis, only electrophysiological data were considered. EEG signals were recorded using 32 electrodes (10–20 system) at 5 kHz, while sEMG signals were acquired from five muscles of the right arm and hand at 4 kHz.

Although the dataset provides trial-based segmentation, all signals are available in their raw continuous form, allowing flexible definition of analysis windows.

B. Task & Acquisition Protocol

Participants were seated comfortably with arm support and performed a reach-to-grasp task. In each trial, the subject reached, grasped (thumb and index finger), lifted, briefly held, and returned an object to its initial position. Task timing was standardized using visual cues (LEDs).

The protocol consisted of multiple experimental series with controlled variations in object weight (165 g, 330 g, 660 g) and surface texture (sandpaper, suede, or silk), organized into Weight, Surface, and Mixed conditions. These variations were structured to be unpredictable to the participant while remaining controlled within the experimental design.

C. Signal Processing & Analysis

1. Acquisition & pre-processing

EEG signals (6 channels: FC6, T7, C3, Cz, C4, T8) and sEMG (5 muscles: Anterior Deltoid - AD, Brachioradialis - BR, Common Extensor Digitorum - EDC, Flexor Digitorum Superficialis - FD, and First Dorsal Interosseus - FDI) were acquired simultaneously at 500 Hz and 4000 Hz, respectively. Grip force and load force were recorded by the device's transducer at 500 Hz. The EEG was filtered with high-pass at 5 Hz and low-pass at 80 Hz (4th and 6th order Butterworth, zero phase via filtfilt). Artifacts were identified by amplitude threshold (100 μV) and gradient (50 μV/sample). Contaminated samples were linearly interpolated when the fraction of bad samples did not exceed 20% of the segment, otherwise, the channel was excluded from that trial. Electrodes were selected for coverage of the primary motor (C3, C4) and premotor (FC6) areas, with T7 and T8 as temporal references.

sEMG was bandpass filtered between 5–400 Hz (4th order Butterworth, phase zero). Trials with sEMG amplitude above 100 units were rejected. Muscles with a task/baseline RMS ratio lower than 1.5 were excluded from that pair, condition, and subject.

The segments of interest were anchored at the LiftOff instant (object release), defined as t = 0 s. The Hold phase comprised the interval [LiftOff - 0.1 s; LiftOff + minimum Hold duration], where the minimum duration was determined per subject as the shortest observed LiftOff→LEDOff interval, ensuring identical length for all trials. Super-padding of 0.8 s (before) and 0.5 s (after) was added to protect the region of interest from the wavelet's influence cone, and was discarded after coherence calculation.

2. Corticomuscular Coherence (CMC)

The EEG signal was resampled from 500 Hz to 4000 Hz to match the native sEMG rate. Time-frequency coherence between each EEG–EMG pair was estimated by continuous wavelet coherence (wcoherence, MATLAB), limited to 5–50

Hz. For each trial, the two-dimensional coherence map (frequency × time) was clipped to the clean window (without padding) and interpolated onto a fixed temporal grid at 4000 Hz. The coherence mean was calculated per frequency band: Mu (8–12 Hz), Beta (15–30 Hz), and Gamma (30–50 Hz) [18], [19]. For each band, the time mean and peak values were extracted as dependent variables. According to Friston [20], functional connectivity is defined by the "statistical dependence between remote neurophysiological events". Given this, we decided to explore corticomuscular coherence (CMC) data in search of a functional marker of neural activity and its synchronicity with muscle activation, mathematically defined as:

$$\mathrm{CMC}_{\mathrm{EEG,EMG}}(f) = \frac{|S_{\mathrm{EEG,EMG}}(f)|^2}{S_{\mathrm{EEG,EEG}}(f) \cdot S_{\mathrm{EMG,EMG}}(f)}, \quad (1)$$

where $S_{\mathrm{EEG,EMG}}(f)$ represents the cross-spectrum between EEG and EMG signals at frequency f, and $S_{\mathrm{EEG,EEG}}(f)$ and $S_{\mathrm{EMG,EMG}}(f)$ correspond to their respective auto-spectra.

3. Intermuscular Coherence (IMC)

The sEMG signals from the active muscle pairs were band pass filtered between 10–400 Hz (pipeline A: phase coherence) and 5–400 Hz (pipeline B: envelope). Both were decimated to 500 Hz after anti-aliasing filtering (6th order Butterworth, cutoff at 200 Hz). Continuous wavelet coherence was calcu lated between sEMG pairs decimated to 500 Hz (wcoherence), using the same clipping and interpolation protocol described for CMC. The bands analyzed were: Mu/Alpha (8–12 Hz), Low Beta (12–20 Hz), Beta (15–30 Hz), High Beta (20–30 Hz), and Gamma (30–50 Hz).

For pipeline B (common drive), the sEMG signal was full wave rectified (module after 5–400 Hz filtering), decimated to 500 Hz, mean-centered, and low-pass filtered at 10 Hz (4th order Butterworth, phase zero). Pearson's correlation between the envelopes of the two muscles was calculated in 200 ms sliding windows with a 20 ms step, generating a temporal correlation profile throughout the Hold. The extracted variables were the mean and peak of the correlation coefficient.

By definition, the IMC quantifies the spectral coherence between two sEMG signals, reflecting the degree of synchronization between motoneuron pools and, consequently, the shared common drive between the evaluated muscles. IMC was defined as:

$$\mathrm{IMC}_{i,j}(f) = \frac{\left|S_{\mathrm{EMG}_i,\mathrm{EMG}_j}(f)\right|^2}{S_{\mathrm{EMG}_i,\mathrm{EMG}_i}(f) \cdot S_{\mathrm{EMG}_j,\mathrm{EMG}_j}(f)}, \quad (2)$$

where $S_{\mathrm{EMG}_i,\mathrm{EMG}_j}(f)$ is the cross-spectrum between EMG signals from muscles i and j, and $S_{\mathrm{EMG}_i,\mathrm{EMG}_i}(f)$ and $S_{\mathrm{EMG}_j,\mathrm{EMG}_j}(f)$ are the corresponding auto-spectra.

4. Force variables

Grip force was extracted as an absolute value to correct for the negative sign convention of the transducer (compression). The safety margin was calculated as the ratio between grip force and load force (SM = |GF| / |LF|), representing the safety factor beyond the minimum required to prevent slippage (SM = 1 would correspond to the slippage threshold). Time averages during the hold window were used as dependent variables.

D. Statistics

The effects of experimental conditions (6 surface × weight combinations) and electrode-muscle pairs (CMC: 20 pairs; IMC: 10 pairs) were evaluated by two-way repeated measures ANOVAs, with Geisser-Greenhouse correction when sphericity was violated ($\epsilon < 0.75$). Post-hoc tests were performed using Tukey's multiple comparisons ($\alpha = 0.05$). The identification of the predominant modulating factor (weight or surface) was based on inspection of the clustering pattern of significant conditions: conditions clustered by surface type, regardless of weight, indicate a friction effect; conditions clustered by weight, regardless of surface, indicate a load effect.

To directly quantify the independent contributions of weight and surface, separate one-way RM ANOVAs were conducted for each factor at fixed levels of the other. A 2×2 interaction analysis (Sandpaper/Suede × 165g/330g) was performed using subject-level contrast scores tested via one-sample t-test. Partial eta squared (η^2p) was reported as effect size. Force variables (grip force, load force, and safety margin) were analyzed by separate one-way ANOVAs for weight (3 levels, fixed surface on sandpaper) and surface (3 levels, fixed weight at 330g), with Tukey's post-hoc test. Finally, to assess the within-subject association between CMC peak and safety margin, Pearson correlations were computed per subject across conditions and Fisher-z transformed before group-level testing via one-sample t-test. All the statistical analyses were conducted using MATLAB R2024a and GraphPad Prism.

III. Results

A. Strength Behavioral Modulation

Grip force increased with weight on the control surface (sandpaper), from 2.61 ± 0.38 N (165 g) to 7.00 ± 0.66 N (660 g; $p < 0.001$), and load force linearly increased with mass ($p < 0.001$). The safety margin decreased progressively with increasing load (1.63 ± 0.10 to 1.03 ± 0.06; $p < 0.001$), indicating a more economical strategy under heavier weights. With a fixed weight of 330g, the reduction in friction increased the grip force (Sandpaper: 4.28 N; Suede: 9.31 N; $p < 0.001$) and the safety margin (Sandpaper: ∼1.3; Silk: ∼2.0; Suede: ∼2.7; $p < 0.001$), without altering the load force between surfaces, confirming selective adjustment of the tangential component (Fig. 1).

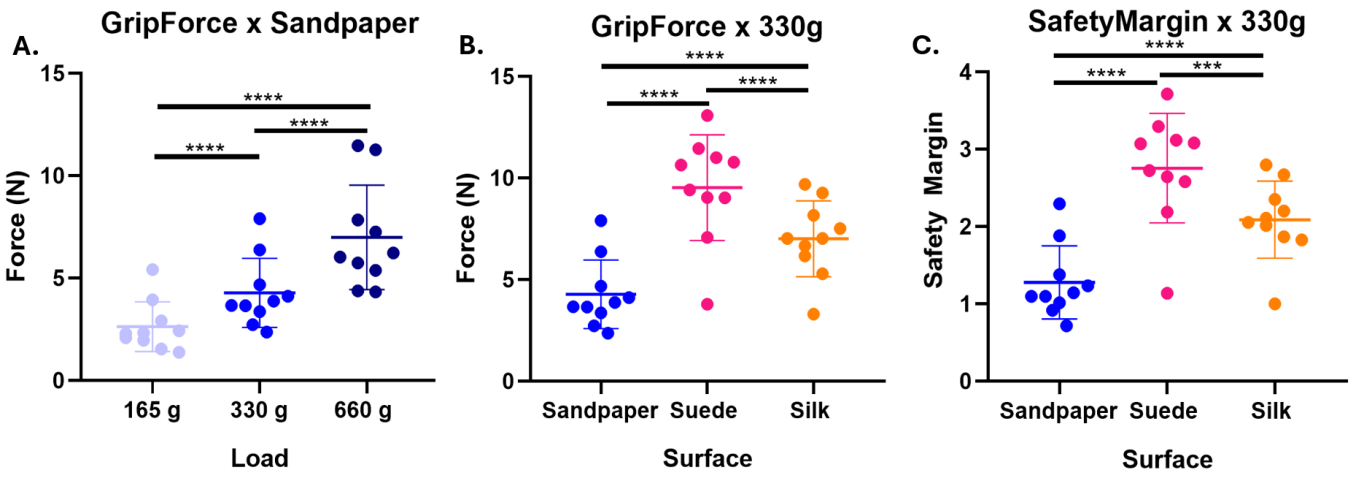

Fig. 1. Grip force and safety margin across experimental conditions. (a) Grip force as a function of object weight on Sandpaper surface (165g, 330g, 660g). (b) Grip force as a function of surface type at constant weight (330g). (c) Safety margin as a function of surface type at constant weight (330g). Load force (not shown) scaled linearly with object mass and did not vary across surfaces. Each dot represents a single subject (n = 10). Lines indicate mean ± SEM. Significance brackets: Tukey post-hoc, **** $p < 0.0001$.

B. Corticomuscular Coupling- CMC

Average CMC was not modulated by experimental conditions in any band (Beta: $p = 0.264$; Gamma: $p = 0.696$; ns interaction). In contrast, peak CMC was the most sensitive variable in the study. In the Beta band, the Column Factor (condition) explained 51.31% of the total variance ($F(2,39; 21,51) = 190.2$; $p < 0.0001$), with a uniform effect across all 20 channel-muscle pairs (interaction: $p = 0.63$). The pattern of post-hoc tests revealed the surface as the predominant modulating factor. In the Gamma band, Suede-165g vs. Sandpaper-330g was significant across all 20 pairs analyzed, being the most consistent effect in the dataset. Sandpaper-165g vs. Suede-165g and Sandpaper-330g vs. Silk-330g was significant in 15 out of 20 pairs; Suede-165g vs. Sandpaper-660g in 13 out of 20. In the Beta band, the same pattern was reproduced with smaller magnitudes (14 and 12 out of 20 pairs, respectively). The ordering of conditions (Suede-165g > Silk-330g ≈ Suede-330g > Sandpaper-165g ≈ Sandpaper-660g > Sandpaper-330g) shows grouping by surface type, not by weight. To further quantify the findings regarding the dominance factor, separate one-way RM ANOVAs were performed and they confirmed surface as the dominant modulator of CMC peak (Beta: $\eta^2p = 0.97$, $p < 0.0001$; Gamma: $\eta^2p = 0.97$, $p < 0.0001$), with weight showing a smaller but significant effect (Beta: $\eta^2p = 0.86$; Gamma: $\eta^2p = 0.75$). The Weight × Surface interaction was significant in both bands (Beta: $t(9) = 8.53$, $p < 0.0001$, $\eta^2p = 0.89$; Gamma: $t(9) = 19.84$, $p < 0.0001$, $\eta^2p = 0.98$), indicating that the effect of weight on CMC depends on the friction condition. The First Dorsal Interosseous showed a systematically lower peak CMC than the other muscles in all EEG channels (grand mean: 0.321 vs. ∼0.340). There was no relevant topographic difference between channels (range: 0.009; interaction ns). Additionally, a within-subject correlation analysis between CMC Beta peak and safety margin revealed a strong positive association across the six conditions (mean $r = 0.80$; Fisher-z: $t(9) = 18.53$, $p < 0.0001$, 95% CI [0.96, 1.23]) (Fig. 2).

C. Intermuscular Coordination

The muscle pair was the main source of variance (Beta: 55.733%; Gamma: 59.41%; $p < 0.0001$), with the Brachioradialis × Flexor Digitorum (hereafter BR × FD) and Brachioradialis × Common Extensor Digitorum (hereafter BR × EDC) pairs being significantly superior to all others, in all conditions and both bands. The condition effect, although significant ($p = 0.0001$), explained a small proportion of the variance (∼2–3%), and the Row × Column interaction was significant, indicating a muscle pair-dependent effect. In the Gamma band, the differences were concentrated in the Brachioradialis × Flexor Digitorum pair, where Sandpaper-660g outperformed all other conditions ($p = 0.002$ to 0.034), and the anterior deltoid × brachioradialis pair showed a similar pattern (Sandpaper-660g > Sandpaper-330g, $p = 0.023$; > Suede-330g, $p = 0.016$). For BR×FD, weight was the primary modulator ($\eta^2p = 0.61$, $F(1.13, 10.14) = 14.12$, $p = 0.003$), while surface had a weaker effect ($\eta^2p = 0.41$, $p = 0.024$) with no significant post-hoc comparisons. No Weight × Surface interaction was observed ($t(9) = 0.64$, $p = 0.536$, $\eta^2p = 0.04$). Altogether, the IMC results corroborate the interpretation that, contrary to CMC, conditions clustered by weight, with the heavier condition standing out regardless of the surface. Friction had a limited impact on IMC, modulating only one isolated pair. This functional dissociation between CMC and IMC constitutes the central finding of the study (Fig. 3).

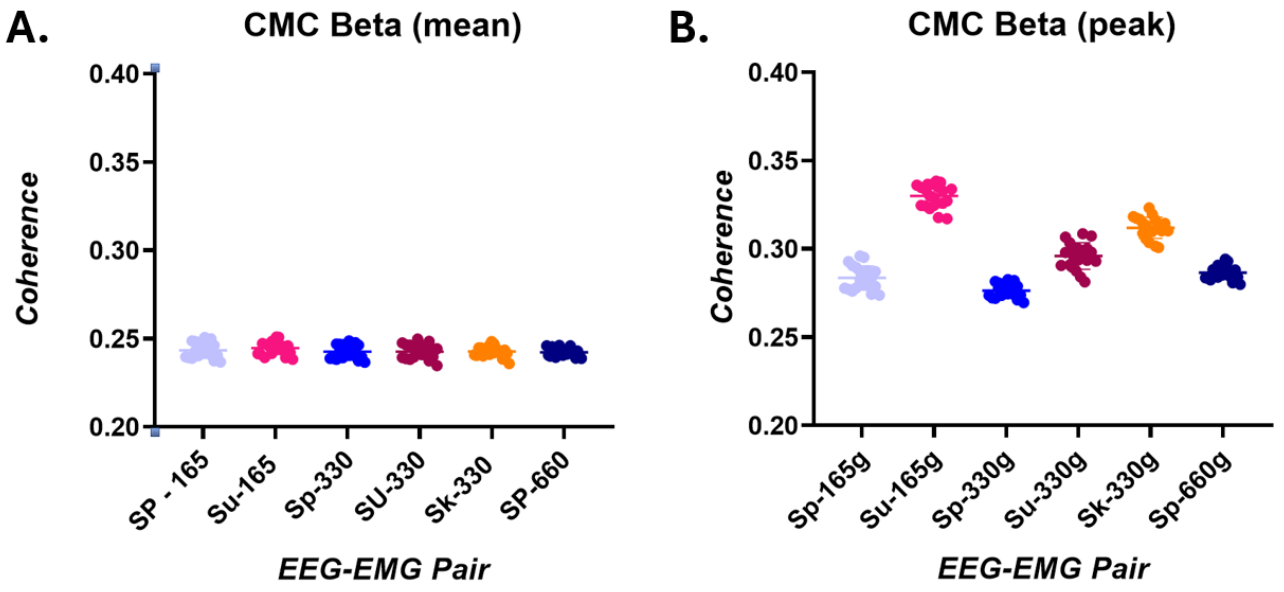

Fig. 2. Corticomuscular coherence (CMC) in the Beta band — mean vs. peak. (a) CMC mean across the 20 EEG–EMG channel pairs and six experimental conditions. (b) CMC peak across the same pairs and conditions. Each dot represents a single subject's value for a given channel–muscle pair. Conditions are color-coded by surface: Sandpaper (blue shades), Suede (pink shades), Silk (orange). No significant effect of condition was observed for CMC mean (Column Factor: 0.64%, $p = 0.264$). CMC peak was strongly modulated by condition (Column Factor: 51.31%, $F(5, 54) = 48.26$, $p < 0.0001$), with no significant interaction with channel–muscle pair ($p = 0.98$). Post-hoc analysis revealed that Suede-165g vs. Sandpaper-330g was significant in 14 of 20 pairs; Sandpaper-165g vs. Suede-165g in 12 of 20. Conditions grouped by surface type, not by weight, identifying friction as the primary modulator. Abbreviations: Sp = Sandpaper, Su = Suede, Sk = Silk.

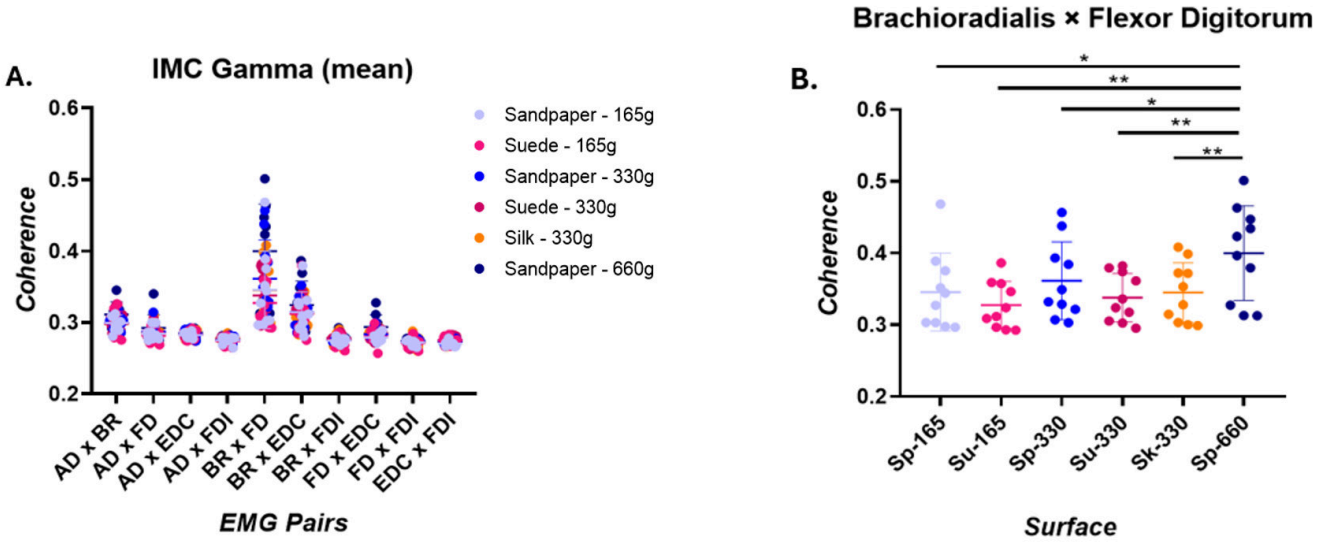

Fig. 3. Intermuscular coherence (IMC) in the Gamma band. (a) IMC across the 10 muscle pairs and six experimental conditions. The pair BR×FD and BR×EDC exhibited significantly higher IMC than all other pairs (Row Factor: 59.41%, $p < 0.0001$). (b) IMC for the BR×FD pair across the six conditions. Sandpaper-660g was significantly higher than all other conditions (Tukey post-hoc: * $p < 0.05$, ** $p < 0.01$), with conditions grouping by weight rather than surface. The Row × Column interaction was significant ($p = 0.0002$), indicating that weight-driven modulation was concentrated in forearm synergist muscle pairs. Each dot represents a single subject ($n = 10$). Lines indicate mean ± SEM. Muscle abbreviations: AD = Anterior Deltoid, BR = Brachioradialis, FD = Flexor Digitorum, EDC = Com. Ext. Digitorum, FDI = First Dorsal Interosseous. Surface abbreviations: Sp = Sandpaper, Su = Suede, Sk = Silk."

IV. Discussion

The impacts of neurological and motor injuries on the quality of life of those who suffer from them, as well as on the burdens generated in Public Health and the available workforce, are undeniable. Thus, the advancement of tools that allow for early diagnosis and optimization of physiotherapy

follow-up after the condition, through quantitative, sensitive, and objective biomarkers, is essential. In line with this need, the present study aimed to investigate the modulation of corticomuscular coupling (CMC) and intermuscular coherence (IMC) as a function of the physical properties of the object, more specifically weight and friction, during a grasping task followed by support, seeking to expand the understanding of its functional role in corticospinal communication and muscle coordination.

Under physiological conditions, corticomuscular coherence is typically observed in the Beta band (12–30 Hz) during static force production and fine control, while the Gamma band (>30 Hz) is associated with dynamic movements and rapid adjustments dependent on sensory feedback [21], [22], [23]. Here, however, more complex modulation patterns were revealed, characterized by spectral dissociation dependent on the type of motor demand imposed.

In the context of the analysis of the force involved in gripping the object, it was possible to observe that it scaled according to the increase in the weight of the object and decreased relative to the decrease in friction with the surface, in addition to a progressive decrease in the safety margin relative to the increase in the load handled. Conversely, surfaces with less friction, such as suede, required greater grip strength and resulted in a larger safety margin, reflecting direct biomechanical compensation for slipperiness, while the support force remained unchanged between surfaces, confirming that perceived weight was not affected by the texture. These findings, when combined, suggest a more economical control strategy, in which the nervous system reduces excess force as the mechanical predictability of the task increases. Additionally, the substantial increases in grip strength and safety margin, without relevant changes in support force, suggest selective adjustment of the tangential component of the force. This pattern is consistent with grip control models based on friction estimation, in which normal and tangential forces are regulated in a partially independent manner [24], [25].

In parallel, friction manipulation produced the most robust neural modulation observed in the study, with significant increases in CMC in the Beta and Gamma bands, observed at their activation peaks, in a large number of electrode-muscle pairs. This result suggests that adaptation to surface properties, particularly under conditions of lower friction, requires greater cortical involvement and greater downward coupling, an adaptive pattern reinforced by the concomitant observation of an increase in the safety margin of the applied grip force. For example, it is observed here that the condition with the highest adaptive demand of the Grip (suede - 165g) is the same one that gave the highest peak of corticomuscular coherence, reinforcing the possible relationship between high corticomuscular coupling and tasks that demand fine adjustments. This association was confirmed quantitatively: a within-subject correlation analysis revealed a strong positive relationship between CMC Beta peak and safety margin across conditions (mean $r = 0.80$, $t(9) = 18.53$, $p < 0.0001$), indicating that conditions eliciting greater grip force adjustment also produced stronger corticomuscular coupling, supporting a direct functional link between cortical engagement and precision grip control. A full trial-level analysis using mixed-effects models remains planned to examine this relationship at the single-trial level.

Still within the scope of corticomuscular correlation analyses, the Beta band is generally associated with the maintenance of isometric force [21], while the Gamma band is related to the dynamic adjustment of motor output [22]. Thus, although the average CMC for both bands does not appear to be modulated by the changes in the presented conditions, the peaks did. The concomitant increase observed as activation peaks for both bands may reflect the integration of tactile information and the need for fine control of grip strength to avoid object slippage, as well as reflecting the transient nature of information transmission between center and periphery. This pattern is consistent with studies that demonstrate CMC modulation in reaching and grasping tasks with different load properties [26]. Additionally, CMC analysis revealed a consistent muscle hierarchy: the First Dorsal Interosseous showed a consistently lower peak corticomuscular coherence than the other muscles evaluated, regardless of the EEG channel and experimental condition. This finding may reflect the more focal cortical representation of this intrinsic hand muscle, in contrast to larger muscles and more proximal muscles, such as the brachioradialis and anterior deltoid, whose more extensive cortical representations would favor greater coherence capture by surface electrodes.

The analysis of intermuscular coherence, in turn, revealed a pattern complementary to that observed in CMC. The increase in weight led to an intensification of IMC between distal muscles (brachioradialis and flexor digitorum and common extensor digitorum) in both bands studied, but more pronouncedly for Gamma. This type of coherence is traditionally interpreted as a reflection of synaptic inputs common to motoneurons [21]. According to [12], IMC is directly related to functional coordination and the formation of muscle synergies. Thus, the increase in coherence with load suggests that the motor system reinforces intersegmental coordination strategies to ensure mechanical stability under greater force demands.

Friction, on the other hand, showed a limited impact on intermuscular coherence. This dissociation between CMC and IMC may suggest that different levels of the motor system are selectively recruited depending on the nature of the demand and is demonstrated for the first time in the present work. The findings indicate that, while friction predominantly modulates corticomuscular coupling, weight mainly affects intermuscular coordination. This functional separation suggests the existence of two complementary levels of motor control: (i) a cortical level, susceptible to sensory feedback and responsible for task-dependent fine adjustments, reflected in CMC; and (ii) a more distributed level, involving common descending and spinal inputs, responsible for the organization of muscle synergies and mechanical stability, reflected in IMC. This interpretation is aligned with studies that demonstrate that CMC and IMC

can reflect distinct, although interrelated, aspects of motor control, especially in clinical contexts [15].

From an applied perspective, in healthy individuals these results support the complementary use of CMC and IMC as functionally distinct neuromotor measures. The strong modulation of CMC in medium and high frequency bands in response to friction suggests sensitivity to fine sensory demands (top-down mechanism), which can be explored in motor rehabilitation contexts and brain-machine interfaces [27]. On the other hand, IMC emerges as a robust indicator of the organization of muscle synergies (lateral coordination) under increased load, with implications for the study of intermuscular coordination in clinical populations, as well as a promising tool for optimizing prosthetic control [28], [29].

Despite these contributions, some limitations should be considered. The relatively non-stationary nature of the task may restrict the generalization of the findings and demands studies with different mathematical tools in a complementary way. Furthermore, the analysis was limited to a specific set of muscles and cortical regions, which may underestimate the extent of the neural networks involved and, in addition, the present findings are limited to healthy individuals and do not assess diagnostic sensitivity in clinical populations. Hence, future investigations should explore tasks with greater functional complexity and incorporate network connectivity approaches for a more comprehensive characterization of motor control and apply them to volunteers with motor impairments. Finally, trial-level studies will be carried out in the next stage of this work, to verify whether the observed association between conditions reflects a direct functional coupling.

In summary, this study demonstrates, for the first time in the same dataset, that corticomuscular coupling and intermuscular coherence are modulated in a dissociated and task-dependent manner, reflecting different levels of organization of the motor system. While increased load promotes greater intermuscular coordination and less cortical dependence at low frequencies, reduced friction intensifies corticomuscular coupling in high-frequency bands, highlighting the critical role of the cortex in adapting to sensory demands. These findings contribute to a more integrated understanding of the neural mechanisms of grip control and reinforce the combined use of CMC and IMC as tools for neurophysiological research and clinical applications.

V. Conclusion

This study demonstrates, in a novel and integrative manner within a single experimental paradigm, that corticomuscular and intermuscular coherence are dissociably modulated during object manipulation, each reflecting a distinct level of motor organization. The robust modulation of CMC peak by surface friction, concomitant with increases in grip force and safety margin, points to a cortical control mechanism that is selectively recruited when fine sensory-dependent force adjustments are required: a top-down process sensitive to the predictability of the mechanical interaction. In a complementary fashion, the modulation of IMC by object weight, concentrated among forearm synergist muscles, reflects the reinforcement of coordinated muscular strategies to ensure mechanical stability under greater force demands, a more distributed process involving common descending and spinal inputs. Taken together, these findings expand the current understanding of the neural mechanisms underlying precision grip, revealing that CMC and IMC capture complementary and non-redundant aspects of motor control. From an applied perspective, these results reinforce the potential of combining both measures as quantitative biomarkers for the assessment of neuromotor function in healthy individuals, with promising avenues for their incorporation into rehabilitation protocols and brain–machine interface design, after clinical cohort validation.

***Abstract*—Electrocardiogram-based screening for Chagas disease is challenging when large-scale datasets provide weak self-reported labels rather than serologically confirmed diagnoses. This study investigates how repeated self-reported Chagas labels in CODE-15% can be operationalized as supervised targets for deep learning. Within-patient label consistency was first assessed using repeated ECG examinations from the same patients, without assuming temporal ordering. Three labeling strategies were then compared: retaining the original examination-level labels; assigning a positive patient-level target when at least one examination contained a positive self-report; and assigning a positive target when at least half of the available examinations were positive. All strategies were evaluated using the same 12-lead one-dimensional convolutional neural network and five-fold patient-level cross-validation. Among examinations from patients who reported Chagas disease at least once, 35.87% were labeled as negative, revealing substantial within-patient discordance. The strategy based on at least one positive self-report achieved the highest F1-score, PR-AUC, and MCC under both fixed and validation-selected decision thresholds, whereas the original labels achieved the highest ROC-AUC. Performance also varied across ECG subgroups, with stronger results generally observed among ECGs with known abnormalities and lower performance among normal ECGs. These findings show that target construction is an important modeling decision when repeated weak labels are available. However, because all targets were derived from repeated self-reported labels, the reported results characterize agreement with alternative operational label definitions rather than clinical diagnostic accuracy against serologically confirmed Chagas disease.**

***Index Terms*—ECG, CODE-15%, Deep Learning, Chagas disease.**

I. Introduction

Chagas disease (CD), caused by the protozoan *Trypanosoma cruzi*, remains a major neglected tropical disease affecting over six million people globally. Although its prevalence is highest in Latin America, migratory patterns have contributed to its spread to non-endemic regions [1]. Early antiparasitic treatment can prevent disease progression when administered in earlier phases [2], [3], but detection remains limited: in many countries, fewer than 10% of cases are diagnosed; in some settings, this figure falls below 1% [2], [4]. This underdiagnosis stems partly from asymptomatic or nonspecific early stages and from reliance on serological methods that are difficult to scale in resource-constrained settings [2], [3], [5]. These limitations motivate accessible and non-invasive ECG-based screening strategies [2], [5], while heterogeneous label sources in ECG datasets raise the question of how disease status and target labels should be defined in data-driven studies [2], [3], [6].

The electrocardiogram (ECG) is a promising tool in this context, as it is widely available, low-cost, non-invasive, and capable of capturing electrical abnormalities associated with the cardiac manifestations of CD [5], [7], [8]. Automated ECG analysis may therefore support large-scale screening, while serial ECG assessment can contribute to the longitudinal monitoring of disease progression, especially in populations with limited access to confirmatory testing [2], [8], [9]. However, CD is clinically heterogeneous: infected individuals may remain in an indeterminate form for long periods, develop chronic Chagas cardiomyopathy (CCC), or present concomitant cardiovascular conditions that affect ECG morphology [8], [9]. This heterogeneity complicates the construction of supervised learning targets since an ECG may capture cardiac involvement more directly than infection status itself [2], [6].

Large-scale ECG datasets have enabled deep learning (DL) models to achieve strong performance in automated ECG interpretation and prognostic modeling. In this context, the Clinical Outcomes in Digital Electrocardiography (CODE) dataset has supported large-scale ECG model development,

while its public subset, CODE-15%, has become an important resource for reproducible ECG-based research [10]–[12]. However, when these datasets are used for CD screening, their usefulness depends on more than signal availability and sample size; it also depends on the clinical reliability and consistency of the target labels [2], [3], [6].

Several Brazilian cohorts have played complementary roles in the development and external evaluation of ECG-based CD models, although they differ substantially in population, clinical profile, label composition, and data accessibility. The ECG tracings from the São Paulo–Minas Gerais Tropical Medicine Research Center (SaMi-Trop) are publicly available. This cohort comprises individuals with serologically confirmed CD and includes substantial representation of patients with CCC [13], [14]. In contrast, the ECG data from the Retrovirus Epidemiology Donor Study-II (REDS-II) and the Brazilian Longitudinal Study of Adult Health (ELSA-Brasil) are not publicly available. REDS-II includes former blood donors with positive and negative CD status established by serological testing, whereas ELSA-Brasil is a broader longitudinal cohort of Brazilian civil servants in which positive and negative CD labels were derived from serological testing [6], [15], [16].

The consequences of this heterogeneity are evident in studies that combine datasets with different label strengths and clinical meanings. In a recent study, a model was developed using the SaMi-Trop and CODE datasets, creating a heterogeneous training setting: SaMi-Trop provides serology-based CD labels and is strongly enriched for seropositive patients and CCC, whereas CODE offers large-scale ECG data with self-reported CD labels, for which CCC status was not available [2]. Although the model achieved an AUC-ROC of 0.80 on an internal validation set combining samples from CODE and SaMi-Trop, its performance decreased under external validation on the REDS-II and ELSA-Brasil cohorts, reaching AUC-ROC values of 0.68 and 0.59, respectively [2]. This gap between internal and external validation illustrates the difficulty of transferring ECG-based CD classifiers across cohorts with different clinical profiles, label definitions, and data distributions [2].

The George B. Moody PhysioNet Challenge 2025 further reinforced this concern by evaluating ECG-based CD detection across heterogeneous data sources and hidden validation/test splits. In this setting, CODE-15% represented a large-scale public dataset with weak self-reported Chagas labels, whereas cohorts such as SaMi-Trop, REDS-II, SaMi-Trop 3, and ELSA-Brasil provided smaller but clinically stronger, serologically based references, although with distinct clinical profiles and evaluation roles [6]. Thus, the Challenge reinforces that ECG-based CD classification should not be interpreted only as a model-performance problem, but also in relation to the source, strength, and clinical meaning of the target labels [6].

Although the scale and public availability of CODE-15% make it valuable for reproducible ECG-based screening studies, its CD labels are derived from patient self-reports rather than from serological confirmation or adjudicated clinical staging [2], [3], [6], [12]. Therefore, CODE-15% should not be treated as a source of clinically confirmed Chagas diagnoses but as a large-scale, weakly labeled dataset whose labels require careful operational definition before supervised training [2], [3], [6]. In supervised DL, this distinction is consequential because such self-reported labels may introduce noise and uncertainty when interpreted as definitive disease status, potentially affecting what the model learns and its ability to generalize beyond the training distribution [17].

A specific source of ambiguity arises when these labels are assigned at the ECG-record level in patients with multiple examinations. The public CODE-15% release contains substantially more ECG records than patients and provides self-reported Chagas labels [6], [12]; therefore, repeated records from the same individual make it possible to assess whether this label source is internally consistent. In this setting, when record-level labels from the same patient are discordant, this inconsistency should be interpreted as an operational source of label uncertainty rather than as confirmed variation in infection status. Such inconsistencies are particularly problematic for supervised learning because they introduce ambiguity into the definition of the positive class and may expose the model to conflicting targets, potentially affecting what the model learns and how it generalizes [17]. This motivates the need to explicitly examine how repeated self-reports should be operationalized as supervised targets for ECG-based CD classification.

To address this challenge, this work frames ECG-based CD classification in CODE-15% as a sensitivity analysis of target definition under self-reported labels. Rather than treating target definition as a fixed component of the classification pipeline or attempting to establish a clinically definitive diagnostic target, our primary scientific contribution is a systematic evaluation of how alternative operational strategies for constructing supervised targets from repeated self-reports affect measured classification performance. In contrast to prior ECG-based CD classification studies, which generally treat the available labels as fixed supervised targets (see Section II), this study makes target definition itself the primary experimental variable.

For this purpose, three labeling strategies are compared. The first retains the original self-reported label of each ECG recording. The second assigns a positive patient-level target to all recordings from an individual who reported CD in at least one available examination. The third assigns a positive patient-level target when at least half of the individual's available records contain a positive self-report. The latter two strategies, therefore, replace potentially discordant record-level targets with a common patient-level target, following inclusive and majority-based interpretations, respectively.

The remainder of this paper is organized as follows. Section II reviews related work on ECG-based CD detection and heterogeneous label sources. Section III describes the analysis of within-patient label consistency, the three operational labeling strategies, ECG preprocessing, model training, and the evaluation protocol. Section IV presents and discusses the experimental results. Finally, Section V summarizes the main conclusions and limitations of the study.

II. Related Work

Reference [2] provides direct evidence that ECG-based CD detection depends on the clinical definition of the positive class. The authors evaluated model performance both for broad CD detection and for an alternative setting in which only patients with CCC were considered positive. For broad CD detection, the model achieved AUC-ROC values of 0.68 on REDS-II and 0.59 on ELSA-Brasil. When only CCC patients were considered positive, performance increased to 0.82 and 0.77 on the same cohorts, respectively [2]. This result suggests that ECG-based models may capture cardiac manifestations of CD more reliably than infection status alone. For the present study, the relevance of this finding is not that CCC should necessarily define the target, but that the clinical meaning of the positive class can change the relationship between ECG patterns and supervised labels.

More broadly, the George B. Moody PhysioNet Challenge 2025 provides a recent benchmark for ECG-based CD detection across heterogeneous data sources. Although the Challenge involved datasets with different label strengths and clinical meanings, published approaches have primarily addressed this setting through model-oriented strategies, such as transfer learning with InceptionTime [5], auxiliary pretraining and fine-tuning across datasets [3], and dilated residual architectures with class-imbalance handling [18]. These examples illustrate the relevance of model design, representation learning, and cross-dataset adaptation in heterogeneous ECG sources.

The presence of self-reported labels within this Challenge also makes the broader literature on learning from uncertain or noisy labels relevant. Methods developed for learning under label noise can reduce the influence of unreliable annotations through robust training strategies [17]. Another approach is to represent label uncertainty explicitly through uncertainty labels or soft label distributions [19], [20]. A complementary strategy is semi-supervised learning, in which highly uncertain cases can be treated as unlabeled, and more consistent cases can be retained as supervised examples [21], [22]. These approaches can provide alternative formulations for learning when the available labels are uncertain, potentially unreliable, or not clinically definitive.

In the specific context of ECG-based CD classification, however, the available disease labels have generally been treated as fixed supervised targets, leaving the target-definition step itself comparatively underexplored. This gap motivates the present focus on the operational definition of supervised targets from repeated self-reported labels.

III. Methodology

The methodology was organized into two stages. First, the within-patient consistency of the exam-level self-reported Chagas labels was assessed using multiple ECG records from the same patients. CODE-15% contains 345,779 exams from 233,770 patients, collected by the Telehealth Network of Minas Gerais between 2010 and 2016 [12]. No missing values were present in the self-reported Chagas labels or in the demographic and ECG covariates considered in the analyses. For patients with multiple exams, the available labels were grouped by patient to characterize patterns of agreement and disagreement across repeated records and to define alternative supervised targets. Because the public CODE-15% metadata does not provide examination dates or timestamps, no temporal ordering of repeated records was assumed. Second, these target definitions were compared under a common experimental pipeline comprising ECG selection and preprocessing, model training, and patient-level cross-validation. Only the labeling strategy was changed across experiments, while the remaining experimental conditions were kept fixed.

A. Within-Patient Consistency of Self-Reported Chagas Labels

Repeated ECG records were analyzed to assess within-patient label consistency across available examinations. Differences between labels recorded for the same patient were interpreted as within-patient discordance in self-report rather than as clinically confirmed changes in infection status.

The analysis was restricted to patients who reported CD in at least one exam. For patients with multiple ECG records, the labels were grouped at the patient level to characterize patterns of agreement and disagreement across available examinations. The characterization included the number and proportion of positive and negative labels, the distribution of the number of available exams per patient, and the most frequent combinations of labels, irrespective of record order.

Fig. 1 presents the distribution of exam-level labels within this subset. Although every included patient had at least one positive self-report, 35.87% of their exams were labeled as negative. Thus, the self-reported label recorded for a given patient was not necessarily consistent across exams.

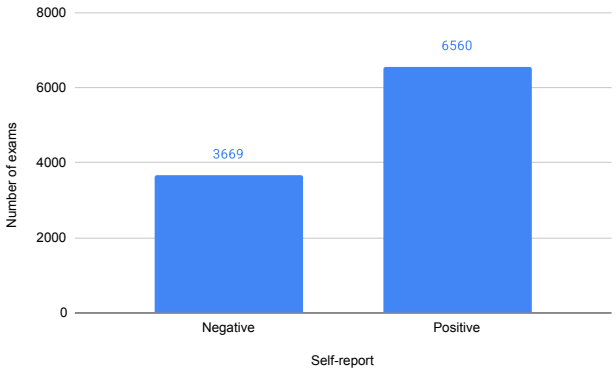

Fig. 1. Distribution of positive and negative exam-level labels among patients who self-reported CD at least once.

The assessment of within-patient label consistency depends on the number of exams available for each patient. Fig. 2 shows the distribution of patients according to their total number of ECG exams. Among 6,560 exams originally labeled as positive, 1,980 belonged to patients represented by a single exam. For these patients, within-patient label consistency could not be assessed because only one exam was available.

For patients with multiple exams, the combinations of available labels were used to characterize patterns of agreement and disagreement irrespective of record order.

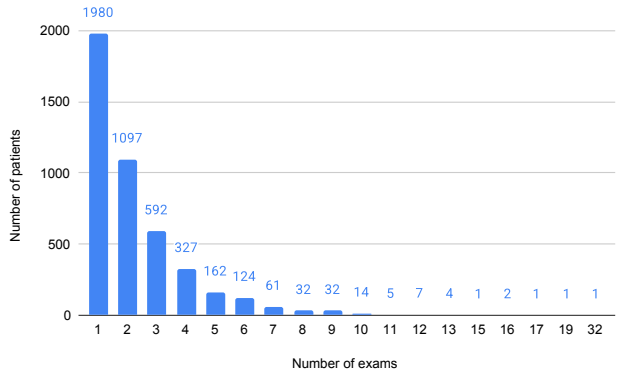

Fig. 2. Distribution of patients according to the total number of available ECG exams

Fig. 3 presents the 15 most frequent self-report configurations among patients with at least one positive self-report. Each configuration is denoted by $E_{\{i,j\}}$, where i is the number of ECG examinations associated with a positive self-report and j is the total number of ECG examinations available for the patient. The configurations satisfying $i = j$ represent consistently positive self-reports, whereas configurations satisfying $0 < i < j$ indicate discordant self-reports across examinations from the same patient.

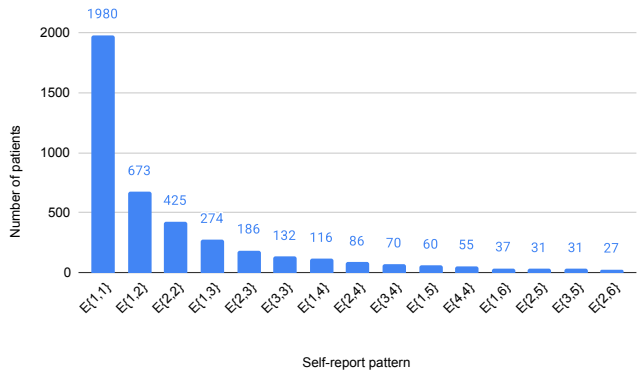

Fig. 3. Fifteen most frequent self-report label patterns among patients who reported CD at least once.

The observed discordance indicates that the original exam-level labels do not always translate into a unique patient-level target. Based on this characterization, three operational labeling strategies were defined to investigate how different uses of self-reported labels across repeated examinations affect supervised ECG classification.

B. Operational Labeling Strategies

Based on the self-reported labels available for each patient, three operational labeling strategies were defined. Let $s_{p,j} \in \{0, 1\}$ denote the original self-reported CD label associated with the j-th ECG recording of patient p, and let n_p denote the total number of ECG recordings available for that patient p. For strategy (i), each ECG recording retained its original self-reported label:

$$y_{p,j}^{(i)} = s_{p,j}. \tag{1}$$

Thus, different ECG recordings from the same patient could retain discordant supervised targets. For strategy (ii), all ECG recordings from a patient were labeled as positive when that patient reported CD in at least one available record:

$$y_{p,j}^{(ii)} = \begin{cases} 1, & \text{if } \sum_{k=1}^{n_p} s_{p,k} \geq 1, \\ 0, & \text{otherwise.} \end{cases} \tag{2}$$

For strategy (iii), all ECG recordings from a patient were labeled as positive if at least 50% of the available records contained a positive self-report:

$$y_{p,j}^{(iii)} = \begin{cases} 1, & \text{if } \frac{1}{n_p} \sum_{k=1}^{n_p} s_{p,k} \geq 0.5, \\ 0, & \text{otherwise.} \end{cases} \tag{3}$$

The strategies (ii) and (iii) therefore converted the original record-level labels into a common patient-level target that was assigned to all recordings from the same individual. The strategy (ii) represented the most inclusive interpretation of a positive self-report history, whereas the strategy (iii) required positive labels in at least half of the available recordings.

C. ECG Selection and Preprocessing

The original 12-lead ECG recordings were sampled at 400 Hz. As an initial preprocessing step, zero-padded regions at the beginning and end of each recording were removed.

Each remaining recording was filtered independently along the lead dimension using a fourth-order Butterworth band-pass filter with cutoff frequencies of 0.3 and 45 Hz. Zero-phase filtering was performed using a forward-backward second-order sections implementation. The filtered signals were subsequently resampled from 400 to 100 Hz using polyphase resampling.

After resampling, each recording was truncated to a whole number of seconds. Therefore, for a resampled recording containing T samples, the retained length was defined as

$$T' = 100 \left\lfloor \frac{T}{100} \right\rfloor. \tag{4}$$

For the classification experiments, a 300-sample window, corresponding to 3 seconds at 100 Hz, was randomly selected from each ECG recording. The same temporal segment was extracted across all 12 leads, resulting in an input shape of 12 leads $\times$ 300 samples.

D. Model Architecture

Reference [23] presents a one-dimensional CNN architecture developed for the George B. Moody PhysioNet Challenge 2025. This architecture served as the basis for the adapted model used in the present study. The adapted model is a one-dimensional convolutional neural network (CNN) composed of three sequential convolutional blocks. Each block consists of a Conv1D layer followed by a ReLU activation function. The first, second, and third blocks contain 32, 64, and 128 filters, respectively, with kernel sizes of 15, 9, and 5 and corresponding padding values of 7, 4, and 2.

The convolutional feature extractor is followed by an adaptive average pooling layer, which reduces the temporal dimension of the learned representation. The resulting feature vector is then processed by a dense classifier composed of three fully connected layers. A dropout layer with a probability of 0.3 precedes the first linear layer, which maps the 128-dimensional feature vector to 64 neurons and is followed by a ReLU activation. A second dropout layer with a probability of 0.2 precedes the linear mapping from 64 to 32 neurons, also followed by ReLU. Finally, a dropout layer with a probability of 0.1 is applied before the output layer, which maps the 32-dimensional representation to a single logit. A sigmoid function is then used to obtain the predicted probability for the positive class. The resulting architecture is illustrated in Fig. 4, where B denotes the batch size and the input tensor has shape $B \times 12 \times 300$, corresponding to 12-lead ECG windows with 300 samples per lead.

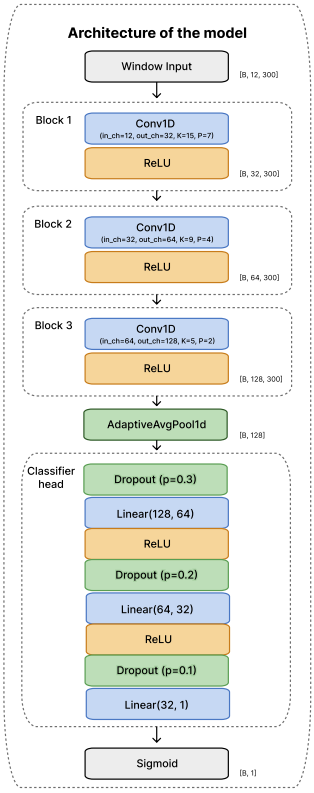

Fig. 4. Architecture of the adapted model.

The overall three-block convolutional structure and dense classification head of the original architecture were retained. However, the convolutional feature extractor was adapted by removing the BatchNorm1d and max-pooling operations from each convolutional block.

E. Loss Function

To account for the strong imbalance between positive and negative labels, the model training used a binary cross-entropy loss with mini-batch-dependent positive-class weighting. For each mini-batch, positive examples, when present, were assigned a weight equal to the ratio between the numbers of negative and positive examples, while negative examples retained unit weight.

Let $y_i \in \{0, 1\}$ denote the supervised target assigned to the i-th training window, and let $\hat{y}_i \in [0, 1]$ denote the probability predicted by the model for the positive class. For a mini-batch containing $N = N_+ + N_-$ examples, where N_+ and N_- denote the numbers of positive and negative examples, respectively, the loss is defined as

$$\mathcal{L} = -\frac{1}{N} \sum_{i=1}^{N} w_i \left[y_i \log(\hat{y}_i) + (1 - y_i) \log(1 - \hat{y}_i) \right], \quad (5)$$

where

$$w_i = \begin{cases} \dfrac{N_-}{N_+}, & \text{if } y_i = 1, \\ 1, & \text{if } y_i = 0. \end{cases} \quad (6)$$

For mini-batches containing no positive examples ($N_+ = 0$), the positive-class weighting factor was set to 1 in the implementation. This fallback had no effect on the loss because no positive samples were present in those mini-batches.

The positive-class weighting factor was recalculated for each mini-batch rather than being fixed according to the overall class distribution of the training partition. When both classes were represented in a mini-batch, the weighting scheme assigned the same total weight to each class. The sum of the weights assigned to the positive examples was $\sum_{i:y_i=1} w_i = N_+ \left(\frac{N_-}{N_+} \right) = N_-$, while the corresponding sum for the negative examples was $\sum_{i:y_i=0} w_i = N_-$. Therefore, the weighting balanced the total class weights within each mini-batch, although the actual loss contributions could still differ according to the predicted probabilities.

F. Model Training

During the training, additive Gaussian noise sampled from $\mathcal{N}(0, 0.005^2)$ was applied to the input windows as a data augmentation procedure. In addition, each window had a 20% probability of having one continuous segment, corresponding to 20% of its duration, replaced with zeros. These augmentations were not applied during validation or testing. No automated or systematic hyperparameter search was performed.

The network parameters were optimized using Adam with a learning rate of 0.001 and a mini-batch size of $B = 2048$

windows. Each fold-specific model was trained for up to 100 epochs. Early stopping was based on the validation PR-AUC, with a patience of 8 epochs, and the checkpoint achieving the highest validation PR-AUC was retained for subsequent evaluation. PR-AUC was used as the model-selection criterion because it summarizes the precision-recall trade-off across decision thresholds and therefore does not require the specification of a fixed classification threshold during model selection. The same architecture, optimizer, learning rate, batch size, number of epochs, data augmentation procedure, and remaining training settings were used for all three labeling strategies, ensuring that their comparison was conducted under the same training configuration.

G. Evaluation Protocol

The model performance was estimated using stratified five-fold cross-validation. The folds were constructed at the patient level, ensuring that all ECG recordings and all windows derived from the same patient were assigned to the same fold. In each cross-validation iteration, three folds were used for training, one fold for validation, and one fold for testing. The training, validation, and test partitions were therefore mutually exclusive at the patient level.

The same patient-level fold assignments were reused for strategies (i), (ii), and (iii), allowing the labeling strategies to be compared under equivalent data partitions. The supervised labels were reconstructed separately for each strategy before model training.

For each ECG recording, three consecutive 3-second windows were extracted, with a 1-second overlap between adjacent windows. Each window was independently processed by the model, and the three resulting predicted probabilities were averaged to obtain a single ECG-level probability. The model performance was therefore evaluated at the ECG level rather than at the individual-window level.

The performance was assessed using F1-score, recall, the area under the receiver operating characteristic curve (ROC-AUC), the area under the precision-recall curve (PR-AUC), and the Matthews correlation coefficient (MCC). ROC-AUC and PR-AUC were computed directly from the predicted probabilities, whereas F1-score, recall, and MCC were computed from binary predictions. Test-set performance was evaluated under two decision-threshold settings. First, a fixed threshold of 0.5 was applied to the test predictions. Second, in each cross-validation iteration, a decision threshold was selected by maximizing MCC on the corresponding validation partition and was subsequently applied to the test partition. For each labeling strategy, the reported results correspond to the mean and standard deviation of each metric across the five cross-validation iterations.

IV. Results and Discussion

The results are presented in two complementary analyses. First, the three operational labeling strategies are compared in terms of overall classification performance, with the objective of assessing how different supervised target definitions affect measured performance under the same experimental configuration. The results are examined using both a fixed decision threshold and thresholds selected from the validation data. Second, performance is examined across different ECG subgroups.

Table I presents the mean performance and standard deviation across the five test folds for the three labeling strategies. For threshold-dependent metrics, binary predictions were obtained using a fixed decision threshold of 0.5, whereas ROC-AUC and PR-AUC were computed directly from the predicted probabilities.

TABLE I
Test performance using a fixed threshold

Metric	Strategy (i)	Strategy (ii)	Strategy (iii)
F1-score	0.094 ± 0.014	$\mathbf{0.148 \pm 0.032}$	0.127 ± 0.020
Recall	$\mathbf{0.717 \pm 0.051}$	0.681 ± 0.100	0.606 ± 0.082
ROC-AUC	$\mathbf{0.803 \pm 0.006}$	0.798 ± 0.004	0.795 ± 0.007
PR-AUC	0.129 ± 0.016	$\mathbf{0.178 \pm 0.015}$	0.138 ± 0.014
MCC	0.137 ± 0.016	$\mathbf{0.176 \pm 0.021}$	0.161 ± 0.016

The strategy (ii) achieved the highest F1-score, PR-AUC and MCC, whereas strategy (i) achieved the highest recall and ROC-AUC. Strategy (iii) produced intermediate F1-score and MCC values but the lowest recall. The ROC-AUC values were similar across the three target definitions, ranging from 0.795 to 0.803, suggesting that the ranking ability of the model changed only modestly across the labeling strategies.

Table II reports the results obtained using validation-selected decision thresholds. For each fold, the decision threshold was selected by maximizing MCC on the corresponding validation set and was subsequently applied to the test set.

TABLE II
Test performance using MCC-optimized thresholds

Metric	Strategy (i)	Strategy (ii)	Strategy (iii)
F1-score	0.216 ± 0.009	$\mathbf{0.253 \pm 0.017}$	0.224 ± 0.013
Recall	0.273 ± 0.060	$\mathbf{0.295 \pm 0.083}$	0.292 ± 0.045
ROC-AUC	$\mathbf{0.803 \pm 0.006}$	0.798 ± 0.004	0.795 ± 0.007
PR-AUC	0.129 ± 0.016	$\mathbf{0.178 \pm 0.015}$	0.138 ± 0.014
MCC	0.204 ± 0.014	$\mathbf{0.235 \pm 0.013}$	0.210 ± 0.015

When the decision threshold was selected on the validation set by maximizing MCC, strategy (ii) achieved the highest F1-score and MCC. It also achieved the highest recall, which had been obtained by strategy (i) under the fixed threshold of 0.5.

The comparison of the two threshold settings shows that the choice of decision threshold affected the threshold-dependent metrics. For all three labeling strategies, validation-based threshold selection increased both F1-score and MCC relative to the fixed threshold of 0.5, while recall decreased markedly. As expected, ROC-AUC and PR-AUC remained unchanged because they are computed from the predicted probabilities and are independent of the decision threshold.

The performance differences observed among the labeling strategies should not be interpreted as evidence of superior clinical diagnostic accuracy for any strategy. Because the three strategies define the positive class differently, the resulting

targets differ in both composition and prevalence, which can affect metrics such as F1-score and PR-AUC. Accordingly, the reported results characterize performance under each operational target definition rather than against a common serologically confirmed reference.

A. Performance across ECG subgroups

To investigate whether model performance varies across different ECG presentations, performance was further evaluated across three mutually exclusive ECG subgroups based on the automatic ECG annotations available in CODE-15%: known abnormality, when at least one of six abnormalities was present, namely first-degree atrioventricular block (1dAVb), right bundle branch block (RBBB), left bundle branch block (LBBB), sinus bradycardia (SB), atrial fibrillation (AF), or sinus tachycardia (ST); unknown abnormality, when the ECG was classified as non-normal by the automatic annotation system but none of these six abnormalities was present; and normal ECG, when the ECG was classified as normal. For each strategy and subgroup, the decision threshold was selected by maximizing MCC on the corresponding validation set and then applied to the test set. The corresponding test results across the three ECG subgroups are reported in Table III.

TABLE III
TEST PERFORMANCE WITHIN ECG SUBGROUPS USING MCC-OPTIMIZED THRESHOLDS

Known abnormality ($N = 37{,}401$)			
Metric	Strategy (i)	Strategy (ii)	Strategy (iii)
Positive labels, n	2,099	3,230	2,289
F1	0.296±0.037	**0.354±0.017**	0.315±0.023
Precision	0.213±0.040	**0.296±0.029**	0.258±0.025
Recall	**0.518±0.117**	0.459±0.097	0.429±0.122
ROC-AUC	**0.802±0.018**	0.792±0.017	0.798±0.022
PR-AUC	0.216±0.029	**0.290±0.031**	0.237±0.022
MCC	0.266±0.034	**0.290±0.024**	0.273±0.033
Unknown abnormality ($N = 170{,}953$)			
Metric	Strategy (i)	Strategy (ii)	Strategy (iii)
Positive labels, n	3,394	5,339	3,702
F1	0.171±0.018	**0.205±0.022**	0.184±0.019
Precision	0.145±0.036	**0.203±0.052**	0.154±0.022
Recall	0.238±0.069	**0.251±0.102**	0.244±0.053
ROC-AUC	**0.769±0.008**	0.766±0.008	0.764±0.007
PR-AUC	0.102±0.018	**0.146±0.018**	0.107±0.019
MCC	0.159±0.016	**0.187±0.014**	0.169±0.017
Normal ECG ($N = 134{,}397$)			
Metric	Strategy (i)	Strategy (ii)	Strategy (iii)
Positive labels, n	1,066	1,658	1,191
F1	0.046±0.005	**0.065±0.006**	0.053±0.012
Precision	0.024±0.003	0.035±0.004	**0.043±0.036**
Recall	**0.448±0.090**	0.428±0.079	0.284±0.165
ROC-AUC	**0.743±0.010**	0.729±0.011	0.718±0.029
PR-AUC	0.029±0.004	**0.038±0.004**	0.030±0.007
MCC	0.075±0.010	**0.086±0.006**	0.067±0.009

As shown in Table III, all reported metrics were numerically higher in the known-abnormality subgroup than in the unknown-abnormality subgroup across the three labeling strategies. Within the known-abnormality subgroup, strategy (ii) achieved the highest F1-score, precision, PR-AUC, and MCC, whereas strategy (i) achieved the highest recall and ROC-AUC, with values of 0.518 and 0.802, respectively.

For ECGs with unknown abnormalities, strategy (ii) achieved the highest F1-score, precision, recall, PR-AUC, and MCC, whereas strategy (i) achieved the highest ROC-AUC. Among normal ECGs, F1-score, precision, ROC-AUC, PR-AUC, and MCC were below the corresponding values observed in both abnormality subgroups. Recall followed a different pattern, with values higher than those observed in the unknown-abnormality subgroup for all three strategies, but lower than those observed in the known-abnormality subgroup. Within the normal ECG subgroup, strategy (ii) achieved the highest F1-score, PR-AUC, and MCC, strategy (i) the highest recall and ROC-AUC, and strategy (iii) the highest precision.

Overall, the results show that classification outcomes differed across ECG subgroups, with the clearest contrast observed between ECGs with known abnormalities and normal ECGs. However, these subgroup differences do not establish that the model relied on any specific ECG abnormality for its predictions.

V. CONCLUSION AND FUTURE WORK

This study investigated how weak self-reported CD labels in CODE-15% can be operationalized for supervised ECG classification when multiple examinations are available for the same patient. The within-patient consistency analysis showed that 35.87% of the examinations belonging to patients who reported CD at least once were labeled as negative. Therefore, examination-level self-reports did not always provide a unique and internally consistent patient-level target.

Three labeling strategies were compared under the same model architecture, preprocessing procedure, training configuration, and patient-level cross-validation folds. Across both decision-threshold settings, the strategy that assigned a positive target to all examinations of a patient who reported CD at least once achieved the highest PR-AUC and provided the highest F1-score and MCC. Its PR-AUC was 0.178, compared with 0.129 for the original examination-level labels and 0.138 for the majority-based strategy. The original labels achieved the highest ROC-AUC, although the differences among the three strategies were small. For threshold-dependent metrics, the results also showed that performance depended on the decision rule: using thresholds selected by maximizing MCC on the validation set increased F1-score and MCC for all three strategies relative to a fixed threshold of 0.5, while reducing recall.

The subgroup analysis further showed that classification performance was not uniform across ECG presentations. ECGs with known abnormalities generally exhibited the strongest performance, whereas normal ECGs showed lower F1-score, precision, ROC-AUC, PR-AUC, and MCC. Strategy (ii) achieved the highest F1-score, PR-AUC, and MCC within all three ECG subgroups. These differences, however, should not be interpreted as evidence that the model relied on any specific ECG abnormality for its predictions.

The main lesson from this study is that target construction should be treated as an explicit modeling decision when repeated weak self-reported labels are available, rather than

as a fixed preprocessing choice. The observed differences across target definitions demonstrate that this decision can affect measured classification performance. At the same time, patient-level aggregation does not resolve the underlying label uncertainty or transform self-reported labels into clinically confirmed diagnoses. In particular, assigning a positive target based on a single positive record may propagate an erroneous self-report to all examinations from the same patient. Consequently, the reported results characterize agreement with alternative operational definitions of the available self-reported labels and should not be interpreted as estimates of clinical diagnostic accuracy for CD.

The study is limited by the use of self-reported labels without serological confirmation, the evaluation of a single model architecture, and the absence of formal statistical tests comparing the labeling strategies. Future work should address these limitations by evaluating the proposed target definitions in serology-based independent cohorts and additional model architectures, quantifying performance differences through appropriate statistical analyses, and investigating uncertainty-aware learning strategies for discordant self-reports.

***Abstract*—This exploratory study examines statistical descriptors of Holo-Hilbert Spectral Analysis (HHSA) maps from six participants with autism spectrum disorder (ASD) and six neurotypical controls. Eleven descriptors were computed per map and averaged across parietal channels P3/P4 and pre-/post-task recordings. Five originally reported group comparisons had nominal $p < 0.05$; none remains below 0.05 after Holm adjustment across the 11 reported tests. The test provenance and individual observations are unavailable for verification. Previously reported leave-one-subject-out classification accuracy reached 83.33% (10/12), but feature selection on the complete sample creates a risk of information leakage, and unbiased predictive performance has not been established. The results provide preliminary descriptive observations, with unresolved issues concerning decomposition settings, matrix normalization, numerical resolution, clinical characterization, overfitting, and restricted channel coverage. They do not establish a diagnostic marker or superiority over alternative approaches.**

***Index Terms*—Autism Spectrum Disorder, Electroencephalography, Holo-Hilbert Spectral Analysis, Machine Learning, Classification.**

I. Introduction

Autism spectrum disorder (ASD) is a heterogeneous neurodevelopmental condition involving differences in social communication and restricted or repetitive behavior [1]. EEG offers high temporal resolution for studying brain activity, and previous reviews have examined EEG abnormalities and classification strategies in ASD [2]–[4]. However, distinguishing clinical groups in a small convenience sample does not establish diagnostic validity.

Holo-Hilbert Spectral Analysis (HHSA) extends empirical mode decomposition and Hilbert spectral analysis by resolving amplitude modulation alongside carrier frequency [5], [6]. Applications to EEG and cognitive assessment illustrate its potential for describing complex signal dynamics [7], [8]. This representation motivates the study of distributional descriptors; its additional dimensions alone do not establish an advantage for ASD classification.

This study explores descriptors of HHSA maps from P3 and P4 before and after a visual task. Its available subject-level results concern averages over the available maps. Accordingly, the present analysis describes aggregate between-group differences and previously reported classification experiments. Both inferential and predictive claims are limited by the small sample and incomplete analytical records.

The contribution is exploratory: it combines an interpretable set of distributional descriptors with conventional group summaries, descriptor correlations, and subject-level classifier results. This organization facilitates hypothesis generation, but it does not by itself establish that the original inferential tests were adequate or that the classifiers generalize beyond this sample.

II. Materials and Methods

A. Participants and Experimental Protocol

The dataset consisted of 12 participants, including six individuals diagnosed with ASD Level 1 according to DSM-5 criteria and six neurotypical controls. Participants were between 20 and 28 years old. Inclusion criteria comprised age between 18 and 30 years, normal or corrected-to-normal vision, and the ability to follow simple visual and auditory instructions. Individuals with a history of epilepsy, brain injury, or other neurological conditions potentially affecting EEG activity were excluded. All participants provided informed consent prior to participation. The study was approved by the Research Ethics Committee of the Federal University of Pará (CAAE 56365722.9.0000.0018).

The overall age range, ASD support level, eligibility criteria, consent, and ethics identifier above are retained as reported in the supplied manuscript; individual records were not provided for independent verification. Group-specific age summaries, sex distribution, cognitive assessments, ASD severity scores and diagnostic instruments, medication use, and relevant comorbidities are unavailable. Consequently, demographic and

Fig. 1. Example of the computerized visual cancellation task adapted from the Cars Test, in which participants identified a target stimulus among multiple distractors.

clinical balance cannot be assessed, and confounding remains unresolved.

The experimental protocol followed the methodology proposed by Silva Filho et al. [9]. EEG signals were recorded before and after the execution of a computerized visual cancellation task adapted from the Cars Test proposed by Cascaes et al. [10]. Participants remained seated approximately 60 cm from a 21.5-inch monitor in a controlled environment with indirect lighting, controlled temperature, and reduced acoustic interference throughout the experiment.

Figure 1 illustrates the computerized visual cancellation task adapted from the Cars Test, in which participants were instructed to identify a target stimulus among multiple distractors using a computer mouse.

Initially, a 3-minute resting-state EEG recording was acquired while participants observed a blank screen and were instructed to remain relaxed, minimizing blinking, swallowing, and voluntary movements. Subsequently, participants conducted the visual cancellation task for 7 min and 30 s. After each correct selection, both the target and distractor positions were automatically updated, maintaining a continuous visual search paradigm throughout the experiment. Immediately after task completion, a second resting-state EEG recording was scheduled for 3 minutes and acquired under the same conditions as the initial recording. These are protocol durations; the effective duration retained for each HHSA map and the amount rejected as artifacts are not documented in the supplied package. Only the pre-task and post-task resting-state EEG segments were considered in the present study, as these recordings were used to generate the HHSA spectral representations analyzed in the subsequent stages.

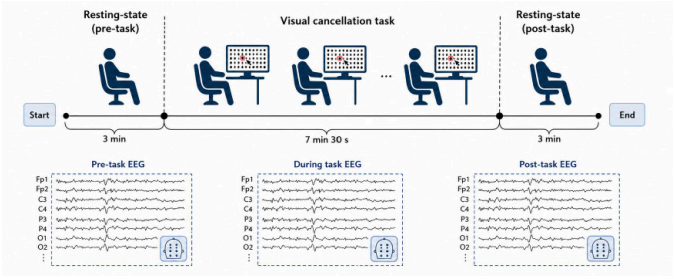

Fig. 2. Experimental protocol consisting of resting-state EEG acquisition before and after the computerized visual cancellation task.

B. HHSA Decomposition and Reproducibility

The original manuscript reports visual inspection, 0.5–40 Hz band-pass filtering, independent component analysis (ICA), channel selection, and temporal segmentation, referring to Silva Filho [9]. Acquisition and preprocessing logs and executable decomposition scripts were not supplied. Therefore, these reported operations cannot be independently verified. Sampling frequency, EEG reference, filter order and phase response, ICA algorithm, channels entered into ICA, component rejection criteria, and numbers of removed components or rejected segments must be recovered from study records.

Conceptually, EMD decomposes a signal into intrinsic mode functions (IMFs). Their analytic representations provide instantaneous amplitude and carrier frequency. A further decomposition of amplitude envelopes resolves modulation frequencies [5], [6]. This conceptual description is not a complete implementation specification. The EMD variant, stopping criterion, maximum sifting iterations, boundary treatment, handling of mode mixing, IMF inclusion/exclusion criteria at both layers, and envelope/frequency estimator are not documented in the supplied package. Neither the numerical frequency grid nor spectral weighting, temporal aggregation, smoothing, and normalization can be confirmed. No specific settings are assumed in this revision.

These omissions prevent an independent reproduction of the HHSA maps. The distinction between signal preprocessing, numerical spectral estimation, and display rendering must be maintained when the original code is recovered.

C. HHSA Map Processing

The HHSA spectral representations provided by Silva Filho et al. [9] were stored as MATLAB figure files (`.fig`), containing the original numerical matrices used to generate the spectral maps. To enable quantitative analysis, a custom MATLAB function, named *getHHSA*, was developed to automatically extract these data.

For each `.fig` file, the function opens the figure in invisible mode, identifies the axis corresponding to the HHSA representation, and retrieves the numerical matrix associated with the HHSA image object. The reported function applies a vertical flip (`flipud`). Correct orientation must be checked against the stored axis coordinates and axis direction, rather than assuming that every MATLAB image requires inversion.

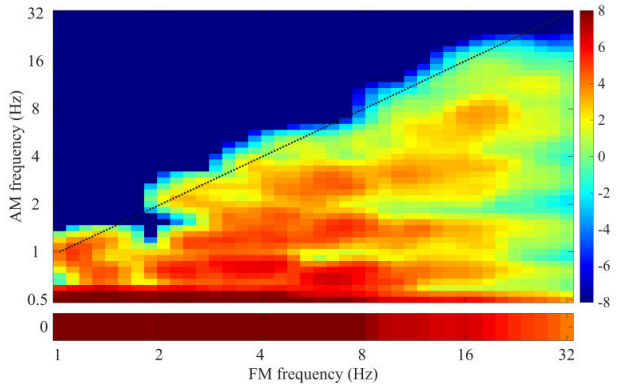

Fig. 3. Representative HHSA spectral map extracted from channel P3 during the first resting-state epoch (Part 1).

A vertical flip permutes entries and therefore leaves the full-matrix distributional descriptors unchanged.

The described extraction is intended to avoid manual reading of plotted colors. However, the supplied archive contains raster illustrations, not the underlying `.fig` files or *getHHSA* source. It is therefore unverified whether the extracted `CData` contains physical spectral values, transformed values, indexed colors, or RGB data. Numerical matrix values must not be equated with physical energy without checking these properties. Figure 3 illustrates an example of an HHSA spectral map extracted from channel P3 during the first resting-state epoch (Part 1). In this representation, frequency modulation (FM) is displayed along the horizontal axis, amplitude modulation (AM) along the vertical axis, and the color scale displays the supplied map values; their units and transformation require verification.

D. Feature Extraction

Eleven statistical descriptors were extracted from each HHSA spectral matrix: mean, standard deviation, variance, energy, entropy, skewness, kurtosis, coefficient of variation, median, interquartile range (IQR), and robust range. These descriptors characterize central tendency, dispersion, asymmetry, and distributional shape of the matrix values.

Four HHSA maps were available for each participant (P3-Part1, P3-Part3, P4-Part1, and P4-Part3). Feature values were computed independently for each map and then averaged to obtain one subject-level descriptor. If D denotes a descriptor and H_{itc} a participant's matrix, the reported quantity is

$$\bar{D}_i = \frac{1}{4} \sum_{t\in\{1,3\}} \sum_{c\in\{P3,P4\}} D(H_{itc}). \tag{1}$$

This is an average of descriptors, not a descriptor of an averaged map.

E. Statistical Analysis and Scope of Inference

The original manuscript reports Student's t and Mann–Whitney U tests and Cohen's d, but supplies only one unidentified p column per feature. The two tests are not interchangeable; the table does not identify which generated each value, whether tests were two-sided, or whether variance assumptions were checked. Raw subject-level features, test statistics, degrees of freedom, and confidence intervals were not supplied. They cannot be recovered reliably by combining rounded summaries with an assumed test. The original d values are retained as unverified standardized effect estimates, with ASD minus control as the reported direction.

For this revision, Holm adjustment was applied to the eleven published, rounded p values as one family. If $p_{(j)}$ are ordered values, then $\tilde{p}_{(k)} = \min\{1, \max_{j\le k}(11-j+1)p_{(j)}\}$. This checks multiplicity for the displayed column only; it does not validate the original tests or cover an undisclosed search across both tests and additional analyses. Nominal and adjusted values are distinguished throughout.

F. Supervised Classification and Validation

The original experiments report Logistic Regression, linear SVM, RBF SVM, and Random Forest under leave-one-subject-out (LOSO) validation. These model families have been used in EEG-based ASD classification studies, but prior performance reports do not remove the need for leakage-controlled evaluation [3], [11]. Eleven participants would form each training fold and one participant the test fold. However, the described workflow first selects nominally significant features using the complete dataset and then performs LOSO. Unless selection was repeated using training participants alone, the held-out participant's label influenced feature selection, introducing information leakage. Selecting the best feature/classifier combination on the same LOSO results adds selection bias [12].

Accordingly, the retained accuracy table is a record of exploratory results, not a validated performance estimate. A corrected evaluation must fit feature selection and scaling within each outer training fold, tune hyperparameters in an inner subject-level validation loop, and predict the untouched outer participant. It must specify software versions, random seeds, regularization and kernel settings, forest parameters, and candidate search space, and provide predictions per participant, confusion matrices, sensitivity, specificity, balanced accuracy, and uncertainty. These records are absent, so neither leakage-free performance nor its confidence interval is reported here as established.

III. Results

A. Reported Group Summaries and Multiplicity Audit

Five of the eleven displayed comparisons have nominal $p < 0.05$. None has Holm-adjusted $p < 0.05$ (Table I). The absence of corrected significance does not demonstrate equivalence, particularly with six participants per group. These adjustments are conditional on the validity and identification of the original tests, which remain unresolved.

The reported standardized effects for dispersion descriptors are large in magnitude, but their uncertainty is missing and small samples are sensitive to individual observations. They should not be taken as proof of stable population differences.

TABLE I

REPORTED SUBJECT-LEVEL SUMMARIES (MEAN ± SD) AND HOLM AUDIT OF THE ORIGINAL p COLUMN. TEST IDENTITY AND ORIGINAL EFFECT ESTIMATES REQUIRE VERIFICATION; NO ADJUSTED $p < 0.05$.

Feature	ASD	Control	p reported	p Holm	d reported
Mean	0.568 ± 0.063	0.587 ± 0.055	0.6015	1.0000	-0.311
Std	0.302 ± 0.024	0.267 ± 0.018	0.0173	0.1730	1.644
Variance	0.092 ± 0.015	0.072 ± 0.011	0.0230	0.2070	1.548
Energy	21091.992 ± 3156.606	21185.766 ± 3002.738	0.9590	1.0000	-0.030
Entropy	5.368 ± 0.090	5.439 ± 0.121	0.2721	1.0000	-0.671
Skewness	-0.328 ± 0.329	-0.433 ± 0.301	0.5773	1.0000	0.333
Kurtosis	1.920 ± 0.296	2.445 ± 0.390	0.0253	0.2070	-1.517
CoeffVar	0.542 ± 0.096	0.466 ± 0.069	0.1432	0.8592	0.917
Median	0.628 ± 0.116	0.615 ± 0.088	0.8342	1.0000	0.124
IQR	0.520 ± 0.078	0.403 ± 0.091	0.0372	0.2604	1.386
Robust Range	0.797 ± 0.055	0.718 ± 0.033	0.0132	0.1452	1.735

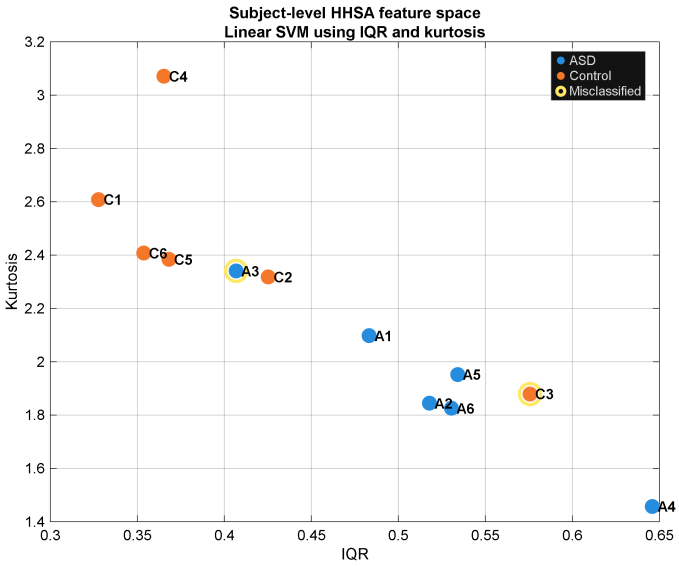

Fig. 4. Supplied subject-level IQR–kurtosis visualization. Error labels refer to the original SVM analysis; validation provenance is unresolved. The plot is descriptive.

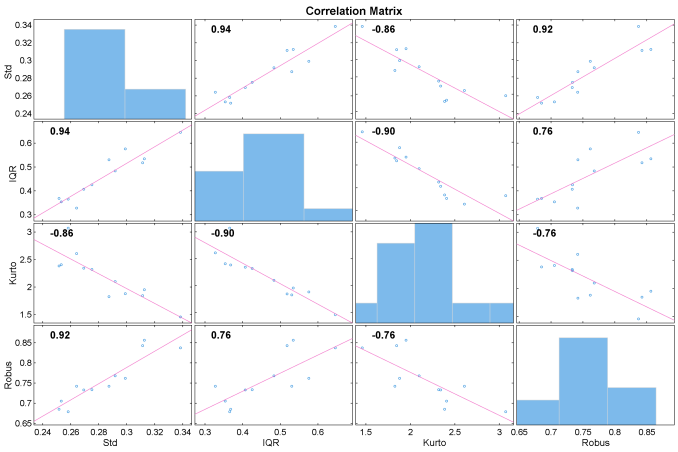

Fig. 5. Supplied Pearson correlations for standard deviation, IQR, kurtosis, and robust range; variance is not displayed. These four descriptors were selected in the original nominal analysis, and none passes the current Holm adjustment. Correlations are descriptive and suggest redundancy.

The original test identity must be checked before assigning inferential meaning to either nominal or adjusted values.

Figure 4 retains the supplied IQR–kurtosis scatter plot as a descriptive visualization. Its labeling of C3 and A3 as classification errors comes from the original analysis and cannot be independently verified without outer-fold predictions. Visible separation does not validate a classifier or measure adaptive reorganization.

The original Pearson correlations include standard deviation–IQR ($r = 0.94$), standard deviation–robust range ($r = 0.92$), kurtosis–IQR ($r = -0.90$), and kurtosis–standard deviation ($r = -0.86$). These are descriptive pooled-sample correlations, not independent evidence of a group effect. Raw data and confidence intervals were not supplied. Group separation itself can contribute to pooled correlations (Fig. 5).

B. Previously Reported Classification Results

Table II retains the originally reported accuracies for traceability. The maximum, 83.33%, represents 10 correct predictions among 12 participants; one prediction changes accuracy by 8.33 percentage points. The feature-selection and model-selection concerns described above prevent interpreting these values as unbiased estimates of generalization.

The original table gives the same maximum accuracy for several feature/model choices. With 12 participants and no independent evaluation, these small differences do not establish a ranking of algorithms or a preferred descriptor. Correlated descriptors may be redundant, but the table alone cannot establish the mechanism behind the reported performance.

TABLE II
ORIGINALLY REPORTED LOSO ACCURACY (%); FEATURE SELECTION WAS DESCRIBED BEFORE LOSO, SO THESE VALUES ARE EXPLORATORY AND POTENTIALLY OPTIMISTIC, NOT INDEPENDENTLY VALIDATED

Feature(s)	Logistic	Linear SVM	Random Forest	RBF-SVM
IQR	**83.33**	**83.33**	66.67	66.67
Kurtosis	75.00	**83.33**	58.33	58.33
Std	75.00	75.00	58.33	66.67
Variance	75.00	75.00	58.33	66.67
Robust Range	75.00	66.67	58.33	58.33
IQR + Kurtosis	**83.33**	**83.33**	75.00	66.67
Five nominal features	**83.33**	**83.33**	66.67	66.67

IV. DISCUSSION

A. Interpretation and Limits

The available summaries suggest descriptive differences in the spread and shape of HHSA matrix values. Similar EEG studies have reported atypical resting-state activity and parietal EEG–fMRI relationships in ASD, but those findings are not direct validation of the present HHSA descriptors [4], [13]. All eleven displayed tests are nonsignificant after Holm correction. Flattened-map descriptors discard the locations of values on the frequency axes; different spectral arrangements can therefore produce the same descriptors. These measures do not operationalize neural flexibility, adaptive reorganization, physiological recovery, synchronization, or theta modulation. No such mechanism or functional marker is established here.

The sample of six participants per group provides imprecise estimates and is sensitive to outliers. Missing clinical and demographic information prevents assessing confounding. Incomplete decomposition, artifact-handling, and normalization records limit reproducibility. Pooled correlations and retrospective selection of favorable features add further uncertainty.

The use of Random Forest and SVM with only 12 subjects creates a substantial risk of overfitting, even under leave-one-subject-out validation. The reported 83.33% accuracy corresponds to only 10 of 12 predictions, and one prediction changes the accuracy by 8.33 percentage points. It should therefore be interpreted as an exploratory, potentially optimistic result rather than evidence of generalizable performance. Independent validation on a larger cohort and leakage-free nested model selection would be required to assess predictive value.

The analysis was restricted to P3 and P4 and therefore does not establish whether other cortical regions contribute to group discrimination. The supplied study also contains no matched quantitative benchmark using conventional spectral or time–frequency features, nor a deep-learning model evaluated on the same subjects and folds. Such comparisons would require the original EEG segments, identical artifact handling, training-only preprocessing, and independent tuning; applying a high-capacity deep-learning model to 12 subjects without those controls would likely increase overfitting risk. Future evaluations should report sensitivity, specificity, balanced accuracy, precision, recall, F1 score, confusion matrices, and uncertainty alongside accuracy. These additional analyses are not available in the present archive, so no superiority of HHSA or of the reported classifiers is claimed.

V. CONCLUSION

This small exploratory study describes subject-averaged HHSA map features from ASD and control participants. Five nominal group differences do not survive Holm correction across the eleven reported comparisons. The maximum originally reported classification accuracy of 83.33% remains unvalidated because of overfitting risk, unresolved feature-selection leakage, and unavailable analytical records. Physiological mechanisms cannot be inferred from the averaged descriptors. Complete numerical data and code, broader channel coverage, leakage-free classification with additional performance metrics, and matched comparisons with conventional and deep-learning approaches are needed before drawing stronger conclusions or considering clinical applications.

***Abstract*—This exploratory study evaluated the feasibility of a protocol to characterize movement-related cortical oscillations and motor performance during peripheral sinusoidal electrical stimulation. Ten right-handed, neurologically healthy volunteers aged 20 to 35 years participated in the study. Participants performed the Archimedean spiral drawing task before, during, and after a 2-kHz sinusoidal stimulation applied alternately over the median and radial nerves. Electroencephalography and accelerometry signals were recorded, along with the coordinates of the drawing trajectory. Event-Related Desynchronization and Synchronization (ERD/ERS) patterns in the alpha (8–13 Hz) and beta (13–30 Hz) bands were analyzed during the Pre-treatment and Treatment stages and statistical comparisons were performed to assess changes relative to the reference period and between stages. Motor parameters were also compared across stages. In both frequency bands, ERD was observed during movement preparation and execution, with greater predominance in contralateral channels. After the task, alpha energy recovery was slow and incomplete, whereas beta power showed an increase consistent with post-movement rebound. No significant differences were identified in ERD/ERS values between stages, although large effect sizes were observed in the post-movement beta response. No significant differences were observed in motor parameters either, and their global effects were small. The results demonstrate the feasibility of the methodology but suggest that further methodological adjustments are required before its application in patients with Parkinson's disease.**

***Index Terms*—ERD/ERS, Peripheral sinusoidal electrical stimulation, Archimedean spiral, Accelerometer.**

I. Introduction

Voluntary movement relies on the complex integration of neurophysiological mechanisms, including the dynamics of cortical oscillations and the coordination of the sensorimotor network [1]. Studies based on electroencephalography (EEG) and magnetoencephalography (MEG) have identified characteristic patterns in the alpha (8–13 Hz) and beta (13–30 Hz) bands during movement preparation, execution, and the post-movement period, known as event-related desynchronization and synchronization (ERD/ERS) [2].

ERD corresponds to a decrease in spectral energy, associated with increased cortical activation, whereas ERS reflects an increase in energy, related to neuronal resynchronization and states of reduced functional demand [2]. During movement preparation and execution, ERD is typically observed in sensorimotor areas, whereas after movement completion, beta-band ERS may occur, known as the post-movement beta rebound [3].

In neurological disorders that affect sensorimotor circuits, such as Parkinson's disease (PD), alterations in ERD/ERS patterns have been reported, reflecting dysfunction in the dynamics of cortical oscillations [4]. In PD, different non-invasive approaches have been investigated to modulate sensorimotor circuits and improve motor control [5], [6]. Among these approaches, transcutaneous afferent patterned stimulation (TAPS) has received, recently, particular attention. This technique consists of alternating stimulation of peripheral nerves, usually the median and radial nerves, adjusted according to the individual tremor frequency, which is estimated from accelerometry signals [7].

TAPS is typically delivered using current pulses with a pulse width of approximately 300 µs at a frequency of 150 Hz, which preferentially activate $A\beta$ fibers involved in the transmission of somatosensory information [6], [8], [9]. As an alternative to pulsed waveforms, a sinusoidal waveform may be used. Previous studies indicate that stimulation in the 2000–3000 Hz range may promote more selective activation of $A\beta$ fibers without causing pain or discomfort [10]–[12]. In a recent study, high-frequency sinusoidal peripheral electrical stimulation (10 kHz) was applied to patients with PD using

current intensities close to the motor threshold for 20 minutes. The results showed a reduction in kinetic tremor immediately after stimulation, with effects persisting for up to 10 minutes after the intervention [13].

In addition to EEG analysis, it is important to complement the results with objective measures of motor performance. For this purpose, the Archimedean spiral drawing task has been used as a standardized test to assess tremor and fine motor control, particularly in patients with PD. Through digitization of the drawing trajectory, metrics related to movement smoothness, regularity, and drawing accuracy can be computed, providing a quantitative and objective measure of motor performance [14]–[16].

To the best of our knowledge, cortical oscillations during the Archimedean spiral drawing task under TAPS-inspired sinusoidal peripheral electrical stimulation have not yet been investigated. Therefore, this study aimed to evaluate the feasibility of an experimental protocol to characterize ERD/ERS patterns and motor performance before, during, and after this type of stimulation. As this was a preliminary and exploratory study, the protocol was first applied to neurologically healthy participants in order to optimize the stimulation, acquisition, and processing procedures before its application in patients with PD.

II. Materials and Methods

A. System for the Assessment of Cortical Oscillations

The system for the assessment of cortical oscillations comprises different subsystems that operate in an integrated manner, as illustrated in Figure 1.

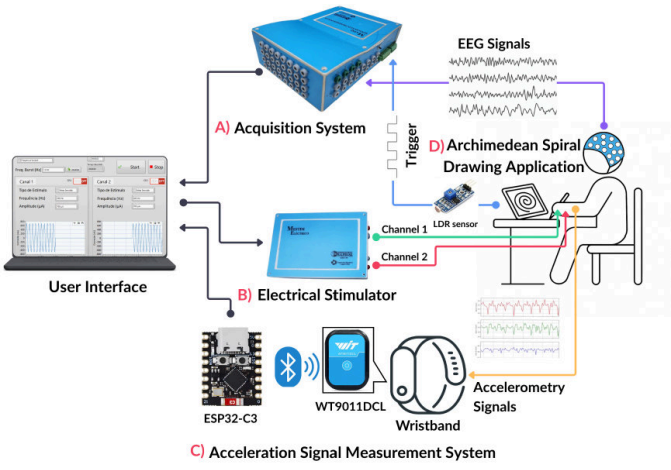

Fig. 1. System for the assessment of cortical oscillations. A) Acquisition system; B) Electrical stimulator; C) Acceleration signal measurement system; and D) Archimedean spiral drawing application.

1) ***MADQ Acquisition System*** *(Fig. 1A):* The MADQ biological signal acquisition system comprises 40 channels, 24-bit analog-to-digital converters, programmable gain, and a sampling rate of up to 16 kHz, in addition to integrated *anti-aliasing* filters. In this study, a sampling frequency of 8 kHz and a gain of 6 were configured. The acquired signals are transmitted to a computer for storage and subsequent processing. Device configuration and signal visualization are performed through an interface developed in LabVIEW [17].

2) ***MESTIM_ELECT Electrical Stimulator*** *(Fig. 1B):* The MESTIM_ELECT is a dual-channel current source capable of generating sinusoidal, square, triangular, sawtooth, and arbitrary waveforms. Each channel can deliver up to 10 mA. It includes a LabVIEW interface for configuring stimulation protocols and adjusting parameters such as frequency, amplitude, duration, and signal type [18]. The MADQ acquisition system and the MESTIM_ELECT electrical stimulator were developed in collaboration between the Federal University of Rio de Janeiro (UFRJ) and Salesian Polytechnic University (UPS, Ecuador).

3) ***Acceleration Signal Measurement System*** *(Fig. 1C):* The system consists of a WT9011DCL inertial sensor, an ESP32-C3 microcontroller, and a graphical interface developed in LabVIEW. The sensor integrates a triaxial accelerometer, gyroscope, and magnetometer (±16 g) and was configured with a cutoff frequency of 20 Hz and a sampling rate of 50 Hz. The device was attached to a wristband to facilitate its use during the experiment. Communication between the sensor and the ESP32-C3 is performed through Bluetooth Low Energy (BLE), with the microcontroller being responsible for data acquisition and retransmission. The acquired signals are visualized and stored in real time, allowing both time-domain signals and frequency spectra to be analyzed. In this study, the system was used to estimate the power spectral density (PSD) of the acceleration signals and identify the dominant frequency during the motor task [19].

4) ***Archimedean Spiral Drawing Application*** *(Fig. 1D):* The application was developed in HTML5 and JavaScript, based on the TRSPER application [16], and can be run directly in a web browser without installation. In the initial interface, the participant identifier is requested and a button is provided to start the experiment. After activation, a reference Archimedean spiral is displayed on the screen.

The protocol starts when the participant places the digital pen at the center of the spiral. This event automatically starts a 3-second countdown corresponding to the motor preparation phase. At the end of this phase, drawing is enabled for a 10-second period, during which the participant must follow the spiral trajectory displayed on the screen. Throughout task execution, the spatial coordinates (x, y), in pixels, of both the reference spiral and the trajectory drawn by the participant are continuously recorded, along with the execution time in milliseconds

After each trial, drawing is disabled and a 10 second rest period begins. A new spiral is then presented to the participant. This procedure is repeated until seven consecutive drawings are completed. At the end of the experiment, all recorded data can be exported in `.csv` format for subsequent analysis.

In addition to recording the motor task, the application incorporates a temporal synchronization mechanism based on visual stimuli. For this purpose, a 1 cm $\times$ 1 cm square was added to the lower-left region of the screen and was

used exclusively to generate temporal markers detected by an external LDR sensor. At the beginning of the motor preparation phase, the square changes its color from black to white for 2 s, producing a first temporal marker associated with the onset of movement preparation. Subsequently, when the participant begins tracing the spiral, the square remains white throughout task execution and returns to black at movement completion. The changes in luminosity were converted into trigger signals and sent to the acquisition system, allowing temporal synchronization between the task and the EEG signal recordings.

The application was run on a Samsung Galaxy Tab S10 Lite tablet equipped with a 10.9-inch display and an Exynos 1380 processor. Interaction with the interface was performed using the S Pen digital stylus, which has a 0.7-mm tip, 4096 pressure levels, a sampling rate of 240 Hz, and low latency.

B. Participants

An exploratory study was conducted with 10 right-handed participants, with a balanced distribution between sexes, aged 20 to 35 years (24.9 $\pm$ 4.4 years). Participants had no history of neurodegenerative diseases, diabetes, or upper-limb injuries. In addition, they had no biomedical implants and were not using medications or other substances that could interfere with the functioning of the sensorimotor system.

The experiments were conducted in quiet rooms free of distractions, with controlled ambient temperature (24 ºC $\pm$ 1 ºC), within the facilities of the Neural Engineering Laboratory of LAPIS (Laboratory of Biomedical Image and Signal Processing), at NTIEB (Center for Technology in Biomedical Engineering / COPPE). Before the experimental procedures began, participants were informed about the study procedures and signed the Informed Consent Form (TCLE). The study was approved by the Research Ethics Committee under CAAE number 58744222.2.1001.5257. The experimental protocol consisted of three stages: Pre-treatment, Treatment, and Post-treatment (Fig. 2).

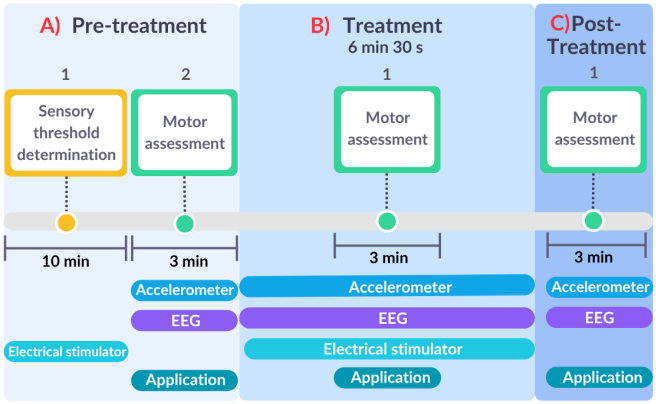

Fig. 2. General overview of the experimental protocol. A) Pre-treatment stage; B) Treatment stage; and C) Post-treatment stage.

1) ***Pre-treatment Stage*** *(Fig. 2A):* At the beginning of the experiment, participants were instructed to sit in a comfortable position, with their forearms resting on a table and their arms extended and relaxed. The sensory thresholds (ST) for a 2-kHz sinusoidal stimulus were then determined (Fig. 2A.1). For this purpose, disposable gel electrodes (1 cm in diameter) were positioned over the median and radial nerves of the dominant hand and fixed with microporous tape. Before electrode placement, the contact areas were cleaned with 70% alcohol to reduce skin impedance. The ST values were determined as described in [10], [18].

During the motor assessment (Fig. 2A.2), EEG and accelerometry signals were recorded. For EEG acquisition, silver/silver chloride (Ag/AgCl) electrodes were positioned according to the international 10-10 system, using an EEG cap and conductive gel to ensure low impedance. Fifteen derivations were used (F3, F4, FC3, FCz, FC4, C3, C4, CP3, CPz, CP4, P3, Pz, P4, O1, O2), with Cz used as the reference and a ground electrode located between Fz and FPz. In addition, an electrode was placed at Erb's point contralateral to the stimulated limb, located in the supraclavicular fossa approximately 1–2 cm above the midpoint of the clavicle, in order to monitor the artifact introduced by electrical stimulation into the EEG signals. To record motor activity, an accelerometer was placed on the dorsum of the participant's dominant hand.

Participants were then asked to remain with the forearm pronated and relaxed on the table for 10 seconds. After this period, participants were instructed to hold the S Pen naturally at the center of the Archimedean spiral and to start drawing along the reference spiral when the countdown reached zero, using the application described previously. Each participant performed a continuous tracing for 10 seconds, without supporting the arm or forearm. After the 10-second tracing period, the participant returned to the resting position for another 10 seconds. This procedure was repeated seven consecutive times.

2) ***Treatment Stage*** *(Fig. 2B):* The treatment stage consisted of the application of TAPS-inspired electrical stimulation using a 2-kHz sinusoidal waveform, with the amplitude defined as $C{\times}ST$, where C corresponded to a constant adjusted for each nerve (median and radial) so that the stimulus was tolerable and did not cause discomfort. The value of C was determined incrementally, starting at $C = 1$ and increasing in steps of 0.25 until the participant's tolerance threshold was reached. Across participants, the applied stimulation current ranged from 0.80 to 3.09 mA for the median nerve and from 1.04 to 4.33 mA for the radial nerve.

The stimulation lasted approximately 6 min 30 s. During this period, the median and radial nerves were stimulated alternately using a standardized *burst* frequency (f_b) of 3 Hz, which was chosen based on the oscillatory characteristics of Parkinsonian rest tremor. Thus, each nerve was stimulated for half of the burst period, corresponding to $\frac{1}{2*f_b}$, or approximately 167 ms at 3 Hz. Ninety seconds after stimulation onset, participants completed seven Archimedean spiral tracings (Fig. 2B.1), following the same procedure described for the Pre-treatment stage. After the seven tracings were completed,

electrical stimulation continued until the full 6 min 30 s period had elapsed.

*3) **Post-treatment Stage** (Fig. 2C):* After the stimulation period ended, participants were asked to perform seven Archimedean spiral tracings again (Fig. 2C.1), following the same procedure described for the Pre-treatment stage.

C. Signal Processing

Data processing was performed using MATLAB software, version R2023b.

*1) **EEG Signal Processing**:* Initially, preprocessing was performed according to the following steps:

- The mean and linear trend were removed from each channel.
- A notch filter was applied to attenuate power-line interference (60 Hz).
- A second-order Butterworth band-pass filter (1–45 Hz) was applied in the forward and reverse directions to ensure zero-phase filtering.
- The signal was resampled to 400 Hz.
- The EEG signals corresponding to the motor assessments performed during the Pre-treatment, Treatment, and Post-treatment stages were segmented (Fig. 2A.2, 2B.1, and 2C.1). Seven segments, corresponding to repetitions of the motor task, were obtained per participant in each stage. Each segment had a total duration of 20 s, comprising 2 s of rest, used as the reference period, 3 s of motor preparation, 10 s of task execution, and 5 s of the post-movement period.
- For artifact identification, each segment was subdivided into 0.1 s windows. In each window, the samples were compared with a threshold of ± 3 standard deviations computed from a 20 s reference signal previously considered artifact-free. A window was classified as containing artifact when more than 5% of its consecutive samples or more than 10% of its total samples exceeded these limits.

Considering only the windows classified as artifact-free, event-related desynchronization/synchronization (ERD/ERS) was calculated according to the method described by Pfurtscheller & Lopes da Silva [2]. The initial 2 s of each segment were used as the baseline, and ERD/ERS values were expressed as the percentage change in power relative to the mean power of this baseline. For the comparison between the Pre-treatment and Treatment stages, a common reference was established, calculated from the mean baseline power obtained across both stages. This common reference was used to compute ERD/ERS under both conditions.

*2) **Accelerometry Signal Processing**:* Preprocessing was performed according to the following steps:

- The mean and linear trend were removed from each orthogonal axis.
- A fourth-order Butterworth band-pass filter (3–12 Hz) was applied in the forward and reverse directions to ensure zero-phase filtering.
- The 10 s segments corresponding to motor task execution during the Pre-treatment, Treatment, and Post-treatment stages were extracted (Fig. 2A.2, 2B.1, and 2C.1).
- Each 10 s segment was divided into five consecutive 2 s windows.

The amplitude of physiological tremor was estimated by considering a three-dimensional random vector whose components corresponded to the accelerometry signals from the three axes [19]. For this purpose, the power spectral density (PSD) was estimated for each axis using Welch's method, with 50% overlap between windows. Subsequently, the magnitude of this vector was obtained, and the physiological tremor frequency was estimated using a weighted average based on the spectral amplitudes, considering the frequency associated with the highest peak and its four nearest neighboring frequencies, according to the procedure described by Cevallos et al. [19].

*3) **Archimedean Spiral Trace Processing**:* For the analysis of the spiral trace, preprocessing was performed according to the following steps:

- Linearization of the spirals by converting the Cartesian coordinates (x, y) of both the trace performed by the participant and the reference spiral into polar coordinates (r, θ), considering the center of the spiral as the origin $(0, 0)$.
- Interpolation of the radius of the spiral traced by the participant to the θ values of the reference spiral, using cubic spline interpolation with $\Delta\theta = 0.04$ rad.

Subsequently, quantitative metrics were calculated to characterize motor control, including *smoothness*, *zero-crossing*, and radial error, as described by Pullman [14] and Surangsrirart & Thanawattano [15]. The radial error was converted from pixels to millimeters using a spatial factor of 0.167 mm/pixel, experimentally determined on the tablet used in the study. The metrics were calculated separately for each trial and subsequently averaged across the seven spirals performed by each participant in each stage of the protocol. Thus, a single mean value was obtained for each metric in the Pre-treatment, Treatment, and Post-treatment stages.

D. Statistical Analysis

*1) **Statistical Analysis of EEG Signals**:* To identify significant ERD/ERS periods in the EEG signal during motor task execution, the spectral F-test (SFT) was used following the adaptation described by Molina [20]. This test assesses whether spectral estimates obtained at the same frequency or within a frequency band of interest differ significantly [21]. A significance level of $\alpha = 0.05$ was adopted, with Bonferroni correction for multiple comparisons. To compare ERD/ERS magnitudes between the Pre-treatment and Treatment stages, the Wilcoxon signed-rank test was applied. The p-values were adjusted using Holm's method for multiple comparisons, and the corresponding effect sizes were estimated using the rank-biserial correlation.

*2) **Statistical Analysis of Accelerometry Signals and Archimedean Spiral Drawings**:* The analysis of motor performance parameters was conducted in RStudio (version

2025.5.0.496) using the R programming language (version 4.4.3). Descriptive statistics were calculated for each variable and stage of the experimental protocol. Data normality was then assessed using the Shapiro-Wilk test. Dominant frequencies, their corresponding PSD values, and the metrics extracted from the spiral drawings were compared among the Pre-treatment, Treatment, and Post-treatment stages using the Friedman test for repeated measures, with a significance level of 5%. The global effect size was estimated using Kendall's W coefficient. When applicable, pairwise comparisons between stages were performed using the Wilcoxon signed-rank test for related samples, with p-values adjusted using Holm's method for multiple comparisons.

III. Results

A. ERD/ERS Patterns During a Motor Task

Figure 3 presents the results of the grand-average ERD/ERS analysis in the alpha (8–13 Hz) and beta (13–30 Hz) bands during the Pre-treatment and Treatment stages, calculated using a common reference. To maintain visual clarity, the post-treatment stage is not shown, as its patterns were highly similar to those observed during pre-treatment stage.

In the alpha band (Fig. 3A), a similar pattern was observed between the Pre-treatment and Treatment stages. ERD was predominant in central, centroparietal, and parietal channels, with greater evidence over the hemisphere contralateral to the limb used in the motor task. This pattern began during movement preparation, between -3 and 0 s, and persisted throughout movement execution, between 0 and 10 s. In both stages, ERD periods significantly different from the common reference were identified ($p < 0.0001$).

After completion of the spiral drawing task (10 s), ERD values were generally maintained or became more pronounced across all analyzed channels, with this behavior being more evident in ipsilateral channels. From approximately 2 s ($t = 12$ s) after the end of the spiral drawing task, corresponding approximately to the time at which the participant returned to rest, a tendency toward power recovery was observed. In the comparison between the Pre-treatment and Treatment stages, no statistically significant differences were identified ($p > 0.19$). In addition, the estimated effect sizes were predominantly small ($r_{rb} < 0.3$).

In the beta band (Fig. 3B), ERD patterns showed similar behavior between the Pre-treatment and Treatment stages. ERD was observed in most channels from the preparation period and persisted throughout the spiral drawing task, being more evident in channels contralateral to the limb used. In general, this response was statistically significant ($p < 0.0001$) relative to the common reference.

Approximately 2 s ($t = 12$ s) after the end of the spiral drawing task, an increase in beta power toward baseline or positive values was observed, being more evident in the Pre-treatment stage. However, the comparison of ERD/ERS values between stages did not reveal statistically significant differences ($p > 0.07$). Nevertheless, large effect sizes were observed in the final seconds ($t = 14$–15 s), particularly in channels C3 ($r_{\mathrm{rb}} = 0.96$), C4 ($r_{\mathrm{rb}} = 0.96$), CP3 ($r_{\mathrm{rb}} = 0.81$), and CP4 ($r_{\mathrm{rb}} = 0.60$).

B. Motor Assessment

Table I presents the descriptive statistics and Friedman test results for the parameters extracted from the accelerometry signals and the metrics obtained from the Archimedean spiral drawing.

TABLE I
Descriptive statistics and comparison of motor performance parameters across the stages of the experimental protocol.

	Treat.	6.37 (2.05)	6.87 [5.22–7.71]		
	Post	6.47 (2.15)	6.75 [5.44–8.10]		

Note. Pre = Pre-treatment stage; Treat. = Treatment stage; Post = Post-treatment stage

Regarding the accelerometry parameters, in the Pre-treatment stage, the dominant frequency was 7.72 $\pm$ 1.30 Hz, with a PSD of 32.3 $\pm$ 14.1 $(\mathrm{cm/s^2})^2/\mathrm{Hz}$. During Treatment, these values decreased to 7.35 $\pm$ 1.48 Hz and 31.8 $\pm$ 19.8 $(\mathrm{cm/s^2})^2/\mathrm{Hz}$, respectively. In the Post-treatment stage, the dominant frequency was 7.38 $\pm$ 1.55 Hz, whereas the PSD showed a mean value of 27.1 $\pm$ 27.0 $(\mathrm{cm/s^2})^2/\mathrm{Hz}$. Overall, the dominant frequency remained similar across stages ($p = 0.38$), whereas the PSD showed a numerical reduction throughout the protocol, although this difference was not statistically significant ($p = 0.15$).

In relation to the metrics extracted from the Archimedean spiral trace, first and second order *smoothness* values remained similar across stages: Pre-treatment (10.45 $\pm$ 0.49 and 17.87 $\pm$

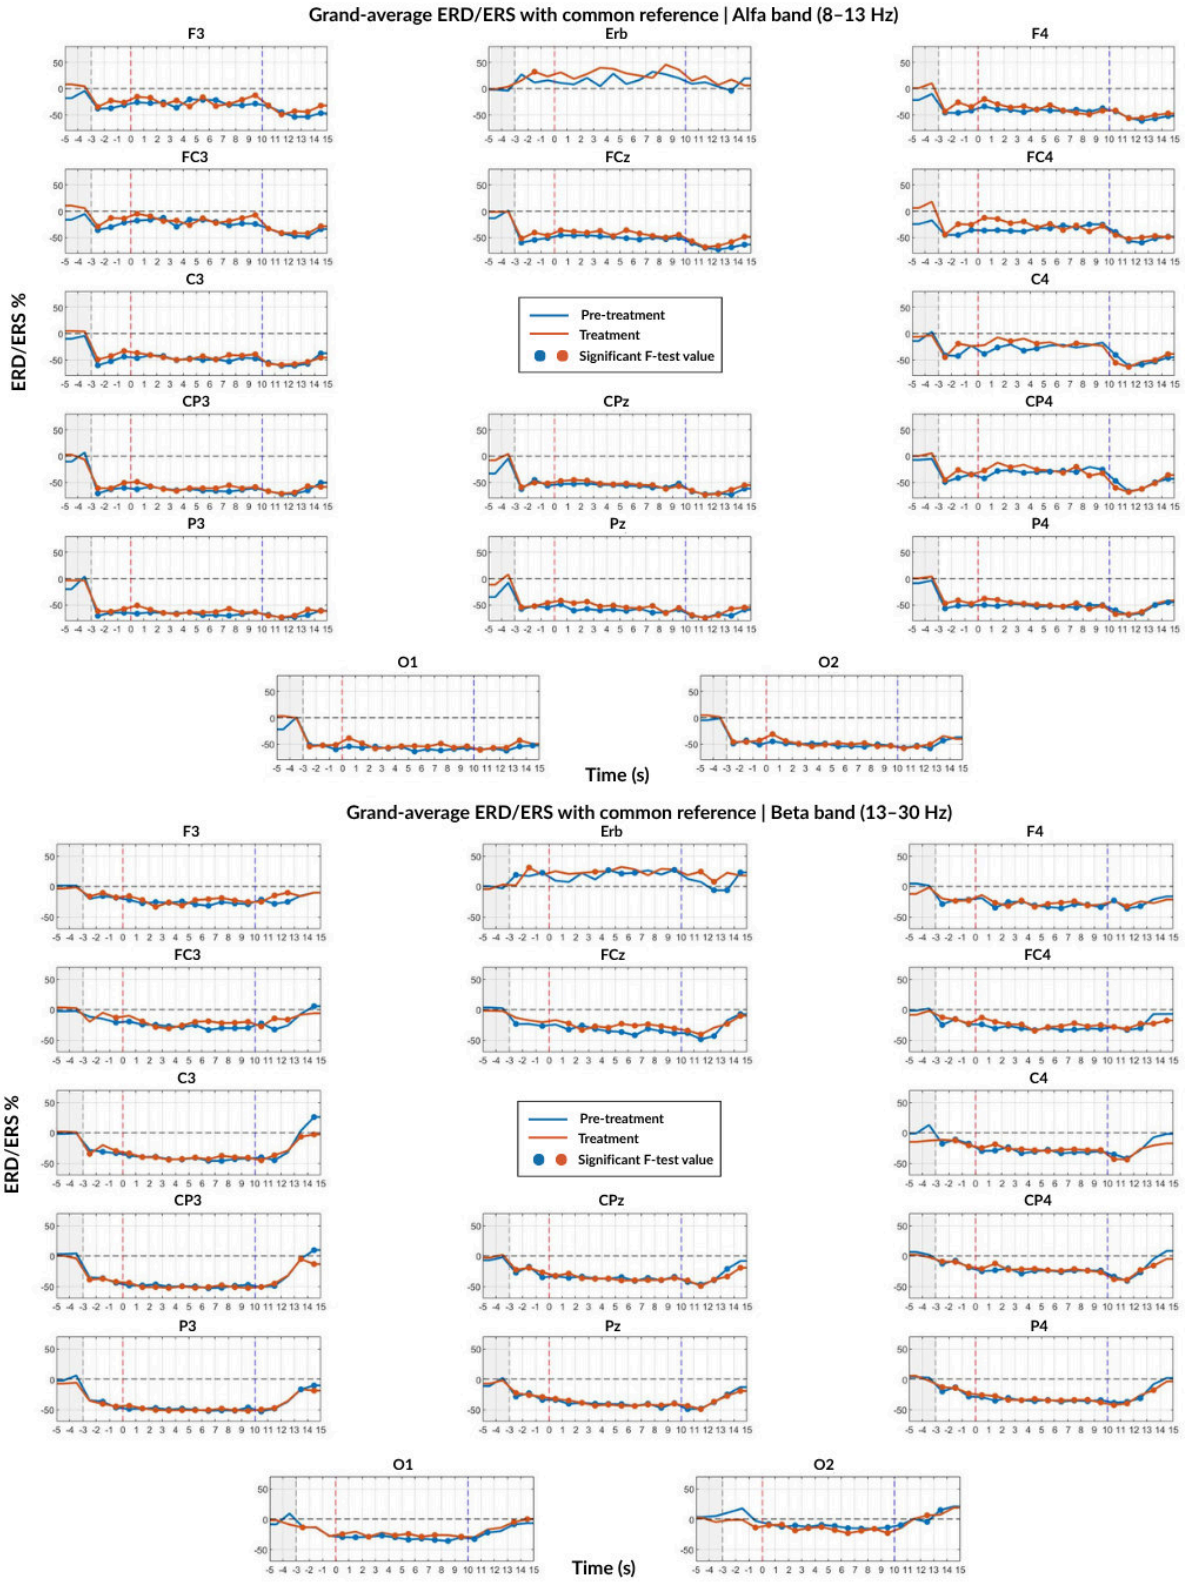

Fig. 3. Results of the ERD/ERS analysis during the Pre-treatment and Treatment stages. A) Alpha band (8–13 Hz); B) Beta band (13–30 Hz). The dots indicate time points at which ERD/ERS values were statistically different from the common reference, according to the spectral F-test.

0.46), Treatment (10.52 ± 0.42 and 17.96 ± 0.41), and Post- treatment (10.50 ± 0.48 and 17.90 ± 0.47), with no significant

differences observed for either metric ($p = 0.53$). Similarly, radial error and first and second order *zero-crossing* parameters showed no significant differences across stages ($p > 0.23$). Kendall's W coefficients indicated small global effect sizes for all analyzed variables ($W < 0.17$).

IV. Discussion and Conclusion

The results showed the presence of ERD/ERS patterns associated with movement preparation, execution, and the post-movement period in the alpha and beta bands, in agreement with responses widely described in the literature [2], [3]. In the Pre-treatment and Treatment stages, periods were identified in which ERD/ERS values differed significantly from the common reference. These findings demonstrate that the experimental protocol and the adopted processing strategy were able to detect changes in cortical oscillatory activity related to voluntary movement.

Overall, ERD was observed in the alpha and beta bands during movement preparation and execution, with greater predominance in channels contralateral to the limb used in the task. This observation is in line with Tang et al. [22], who identified a greater ERD magnitude in contralateral sensorimotor regions, especially during movements performed with the dominant hand. In the present study, the motor task was also performed with the dominant limb, which may have contributed to the observed lateralization.

After movement completion, alpha-band power remained reduced or showed a further decrease. Approximately 2 s after the end of the spiral drawing, a tendency toward recovery to baseline was observed, although this recovery was slow and incomplete. In the beta band, a progressive increase in energy was observed starting approximately 2 s after the end of the drawing, reaching its maximum values about 4 s after the end of the motor task. In some channels, this increase exceeded baseline, characterizing a response compatible with the post-movement beta rebound.

The findings observed after movement completion, in both the alpha and beta bands, differed from the patterns described in the literature, in which power recovery tends to occur shortly after task completion [2], [3]. This difference may be related to the characteristics of the task performed. Whereas classical ERD/ERS studies generally use simple and discrete movements, spiral drawing is a continuous visuomotor task that requires fine trajectory control, visual guidance, and successive movement corrections [15], [23]. These demands may have contributed to the sustained alpha desynchronization and to the delayed emergence of the post-movement beta response.

The characteristics of the experimental protocol may also have influenced this behavior. The 10 s time point corresponded to the end of the spiral drawing, but not necessarily to the actual cessation of all motor activity. After completing the spiral trace, the participant still had to place the pen on the table and return the upper limb to the resting position. Since the speed of return to rest varied among participants, the beta rebound showed a delay of approximately 1 s ($t \approx 14$ s) relative to the expected time point of $t \approx 13$ s, corresponding to 1 s after movement completion [2]. This delay may be due to the temporal misalignment of participants' cortical responses in the grand average.

In this context, the 5-s period analyzed after the end of the spiral drawing may have been insufficient to fully characterize the recovery of cortical activity, considering that the literature recommends intervals of approximately 10 s between movements [2]. The sustained alpha desynchronization and the delayed emergence of the beta rebound suggest that part of this response may have occurred beyond the analyzed interval. In future studies, it is recommended to record the effective time point at which all motor activity ends, including the return of the limb to the resting position, and to extend both the post-movement analysis period and the interval between the end of one spiral and the beginning of the next.

The comparison between the Pre-treatment and Treatment stages revealed similar ERD/ERS patterns in both the alpha and beta bands, with no statistically significant differences. The main distinction was observed in the beta band, between 4 and 5 s after the end of the motor task, when the ERS response showed greater magnitude in the Pre-treatment stage than in the Treatment stage, especially in central and centroparietal channels. Although this difference did not reach statistical significance, the estimated effect sizes were large, suggesting a possible modification of the post-movement beta response associated with sinusoidal peripheral electrical stimulation.

Consistent evidence on the effect of transcutaneous peripheral stimulation on beta rhythm, specifically during voluntary movement, was not found in the literature. However, in a study involving movements induced by functional electrical stimulation (FES) [24], ERD/ERS patterns similar to those described during voluntary movements were observed, characterized by alpha- and beta-band ERD during movement and beta ERS after movement completion. Nevertheless, because the protocol involved stimulation-induced movements rather than voluntary movements performed during peripheral stimulation, these findings do not allow conclusions to be drawn regarding whether electrical stimulation modifies ERD/ERS magnitude during a voluntary motor task.

However, these findings should be considered exploratory. The small sample size may have limited the statistical power to detect differences between stages. Moreover, the absence of a control condition limits the attribution of the observed changes to stimulation, since post-movement beta ERS has been shown to change during repeated motor practice [25]. Future studies should therefore include a larger sample and sham stimulation, to determine whether the observed pattern is maintained and specifically associated with stimulation. In addition, a prospectively defined baseline comparable across stages should be used to avoid retrospective reference estimation.

In the motor assessment, no statistically significant differences were observed in dominant frequencies, their corresponding PSD values, or the metrics extracted from the spiral drawings. Kendall's W coefficients also indicated small

global effects, reflecting a low magnitude of change across stages. This may be explained by the fact that the study was conducted with young participants with no history of neurological disorders or clinical conditions that could affect motor control. Therefore, their baseline performance may have already been within the expected range, reducing the possibility of detecting additional improvements.

Before applying the protocol to a larger clinical sample, a pilot study with patients with PD is recommended to evaluate the sensitivity of the selected metrics in detecting changes in motor control across the different treatment stages. This step may help identify more informative variables and adjust the acquisition, processing, and analysis parameters.

Overall, the results showed cortical ERD/ERS patterns associated with movement preparation, execution, and the post-movement period. Although no statistically significant differences were observed between the Pre-treatment and Treatment stages, large effect sizes were identified in the post-movement beta response, indicating a pattern that should be further investigated. These findings demonstrate the feasibility of the adopted methodology, while also highlighting the need for further optimization of the experimental protocol before its application in patients with PD, in order to increase the sensitivity of the analyses and improve the detection of potential effects of sinusoidal peripheral electrical stimulation during the Archimedean spiral drawing task.

Abstract*—This pilot study evaluated an individualized peripheral electrical stimulation protocol for tremor modulation applied to the median and radial nerves and examined two stimulation waveforms: biphasic pulse bursts (BPB) and sinusoidal bursts (SB). A burst frequency was individualized according to each participant's dominant tremor frequency. Ten participants with Parkinson's disease were randomly assigned to two groups of five ($n = 5$). Hand acceleration was recorded during a postural task at Pre-stimulation, Intra-stimulation (measured at 10, 20, and 30 minutes; denoted as Intra 1, Intra 2, and Intra 3), and Post-stimulation (measured after 40 minutes of stimulation). Tremor magnitude was quantified from the power spectral density (PSD) as the total power within the parkinsonian tremor band ($3.5 - 12$ Hz). Tremor-band power was evaluated using a within-session temporal analysis independently for each waveform. The BPB group showed no statistically significant temporal variation or large effect size ($p = 0.606$, Kendall's $W = 0.136$). Conversely, the SB group demonstrated statistically significant differences across assessment periods with a strong effect size ($p = 0.013$, Kendall's $W = 0.632$). Post-hoc pairwise comparisons (Holm-Bonferroni correction) revealed that significant differences relative to baseline (Pre) were concentrated during the Intra 2 and Intra 3 periods ($p \leq 0.008$). To quantify the magnitude and direction of power differences, relative changes (RC %) were calculated with respect to baseline (Pre). These metrics indicated median power reductions during stimulation (-46.9% for BPB; -47.1% for SB) and post-stimulation (-17.25% for BPB; -29.66% for SB). Furthermore, exploratory correlation analyses between RC % and participant characteristics, including dominant tremor frequency and applied current intensity parameters, yielded null to weak correlations, indicating no clear association with individual power variations. The small sample size limits the generalizability of these preliminary findings, and the results do not establish clinical efficacy, optimal stimulation parameters. Therefore, preliminary results encourage further investigation into the use of sinusoidal waveforms for tremor reduction.

I. Introduction

Parkinson's disease (PD) is a progressive neurodegenerative disorder and the second most common neurodegenerative disease worldwide. Its clinical presentation includes both motor and non-motor symptoms [1]. Bradykinesia, rigidity, tremor, and postural instability are among its main motor manifestations. The progression and severity of these symptoms vary considerably among individuals and may impair upper-limb control, mobility, and independence in activities of daily living [2].

Tremor in PD is characterized by involuntary, rhythmic, and oscillatory movements and may occur at rest or during voluntary action. Classical parkinsonian rest tremor predominantly occurs at approximately $4 - 6$ Hz when the affected body segment is relaxed and fully supported [3]. Action tremors include postural tremor, which occurs while maintaining a position against gravity, and kinetic tremor, which is present during voluntary movement. These manifestations may coexist within the same individual and exhibit partially overlapping frequency ranges, reflecting the heterogeneity of parkinsonian tremor [4], [5].

Levodopa is one of the pharmacological treatments for the motor symptoms of PD and is considered effective for controlling troublesome tremor in most patients [1]. However, tremor response to levodopa can vary among individuals, and the pharmacological response of different tremor components is not fully established [6]. Re-emergent tremor appears to be closely related to rest tremor, including in its response to levodopa, whereas the response of other postural or kinetic tremor components may be more variable [6], [7]. Consequently, some individuals may continue to present clinically relevant tremor despite pharmacological treatment.

For selected patients, deep brain stimulation is an established neurosurgical treatment, particularly for medication-refractory tremor and motor complications that cannot be adequately managed pharmacologically [8], [9]. Nevertheless, its invasive nature, potential surgical risks, and clinical eligibility requirements limit its applicability. Non-invasive mechanical approaches, including wearable damping devices and tremor-suppression orthoses, have also been investigated. Although these systems can attenuate tremor, their clinical and home use may be limited by their weight, bulk, wearability, and potential interference with voluntary movement [10], [11].

In this context, peripheral electrical stimulation has been investigated as a non-invasive neuromodulation approach for tremor reduction. One technique is Transcutaneous Afferent Patterned Stimulation (TAPS), which applies alternating bursts of electrical stimulation to the median and radial nerves at the wrist [12], [13]. The timing of the alternation between the nerves is individualized according to the participant's dominant tremor frequency. It has been hypothesized that the resulting peripheral afferent activity modulates central structures within tremor-related networks, including the cerebello-thalamo-cortical pathway, although the mechanisms underlying its clinical effects have not been fully established [14], [15].

Published TAPS protocols have primarily employed bursts of charge-balanced biphasic pulses, and most of the available clinical evidence has been obtained in individuals with essential tremor [13], [16]. More recently, reductions in action tremor have also been reported in people with PD; however, the evidence in this population remains comparatively limited [12]. Furthermore, the effects of alternative stimulation waveforms have received little investigation.

As an alternative to biphasic pulses, high-frequency sinusoidal stimulation has been investigated because its sensory effects may vary according to the applied frequency. Previous studies have associated sinusoidal currents between 2 and 3 kHz with the preferential recruitment of large myelinated Aβ fibers, particularly when stimulation is applied near the sensory threshold [17], [18]. This provides a physiological basis for exploring a 3 kHz sinusoidal waveform as an alternative form of peripheral sensory stimulation.

Triaxial accelerometry provides an objective method for characterizing tremor and can be used to estimate its dominant frequency and quantify acceleration amplitude and spectral power [19]. Within TAPS-based protocols, accelerometry can support the individualization of stimulation timing by estimating the participant's tremor frequency [12]. These quantitative measurements complement clinical instruments such as the Movement Disorder Society–Unified Parkinson's Disease Rating Scale (MDS-UPDRS). Although the MDS-UPDRS is a widely used and validated clinical instrument, its motor items are scored using ordinal categories assigned through clinical observation [20]. Accelerometry provides continuous measurements that may help identify subtle or short-term changes that are not fully represented by an ordinal clinical score.

Accordingly, this pilot study aimed to characterize the preliminary effects of two individualized peripheral electrical stimulation conditions on tremor in individuals with PD: Biphasic Pulse Burst (BPB), composed of charge-balanced biphasic pulses, and Sinusoidal Burst (SB), composed of a 3 kHz sinusoidal waveform. Given the exploratory design and small sample size, the study aimed to identify preliminary within-group response patterns rather than establish clinical efficacy or determine the superiority of one waveform over the other.

II. Materials and Methods

A. Participants and Ethical Considerations

This pilot study was conducted at the Clementino Fraga Filho University Hospital of the Federal University of Rio de Janeiro (HUCFF/UFRJ). The study protocol was approved by the Research Ethics Committee under approval number CAAE 58744222.2.1001.5257. Before participating, all individuals were informed about the objectives and procedures of the study and provided written informed consent.

The final sample comprised ten men with idiopathic Parkinson's disease. Participants were between 58 and 75 years of age, with a mean age of 66 ± 5.8 years. The diagnosis of Parkinson's disease had previously been established by a neurologist specializing in movement disorders.

The predefined exclusion criteria included dementia associated with Parkinson's disease, other neurodegenerative disorders, diabetes mellitus, and orthopedic conditions affecting the upper limbs that could interfere with performance of the experimental tasks. For safety reasons, individuals with a cardiac pacemaker, a deep brain stimulation system, or another implanted electronic medical device were also excluded. In addition, participants using anticoagulants, antidepressants, sedatives, or other substances likely to interfere with attention, alertness, or motor performance during the experiments were excluded.

Participants were randomly assigned to either the Biphasic Pulse Burst (BPB) or Sinusoidal Burst (SB) waveform group using a draw-lots procedure, with a predefined allocation of five participants per group. Once one group reached this limit, the remaining participants were assigned to the other.

B. Experimental Protocol

For the experimental protocol, one participant was evaluated in the medication OFF state, 13 h 42 min after the last dose, whereas the remaining participants were evaluated in the ON state, 2 h 02 min [Q1–Q3: 1 h 40 min–3 h 50 min] after the last dose. The protocol was conducted in a temperature-controlled room ($24 \pm 1\,^{\circ}\mathrm{C}$). Participants were seated comfortably in a chair with their forearms supported on a table positioned in front of them. The upper limb exhibiting the most pronounced tremor was identified and selected for stimulation and acceleration recording.

Two bipolar electrode pairs were positioned to target the median and radial nerves using a methodology adapted from

previous peripheral stimulation protocols [14], [16]. Disposable circular adhesive electrodes containing conductive gel and measuring 1 cm in diameter were used. Before electrode placement, the skin over the wrist was cleaned with 70% alcohol.

For radial nerve stimulation, the cathode was positioned over the dorsolateral aspect of the wrist, near the anatomical snuffbox, and the anode was placed $2\ \mathrm{cm}$ proximally. For median nerve stimulation, the cathode was positioned over the palmar aspect of the wrist, and the corresponding anode was placed $2\ \mathrm{cm}$ proximally. The separation between the median and radial stimulation paths was adjusted according to wrist circumference, adapting the wrist-size categories described by [13]. A separation of $2.5\ \mathrm{cm}$ was used for wrist circumferences of 13.5–$15.4\ \mathrm{cm}$, $3.0\ \mathrm{cm}$ for circumferences of 15.5–$17.4\ \mathrm{cm}$, and $3.5\ \mathrm{cm}$ for circumferences of 17.5–$19.5\ \mathrm{cm}$.

The MESTIM_ELECT system [21], used for stimulus generation, comprises two independent current sources capable of generating arbitrary stimulation waveforms. The system is controlled through a graphical user interface (GUI) developed in LabVIEW, which enables the configuration and adjustment of the electrical stimulation parameters. The maximum output current was limited to 10 mA per channel.

An accelerometer was subsequently attached to the dorsum of the selected hand using a wrist strap. Using this device, adapted from [22], triaxial acceleration signals were acquired at a sampling frequency of $50\ \mathrm{Hz}$ and used for real-time tremor-frequency estimation during the experimental session and for subsequent offline analysis.

To evaluate the effects of stimulation, the protocol was organized into three assessment periods: Pre-stimulation, Intra-stimulation, and Post-stimulation.

The Pre-stimulation assessment served as the participant's baseline measurement and consisted of the initial recording of a complete six-task sequence. These tasks were adapted from selected items of Part III of the Movement Disorder Society–Unified Parkinson's Disease Rating Scale (MDS-UPDRS) [20]: item 3.4 - finger tapping between the index finger and thumb (Fig. 1.A), item 3.5 - hand opening and closing (Fig. 1.B), item 3.6 - pronation–supination movements of the hand (Fig. 1.C), item 3.16 - the finger-to-nose maneuver as a kinetic tremor task (Fig. 1.D), item 3.15 - outstretched-arm postural task (Fig. 1.E), and item 3.17 - seated rest for rest tremor task (Fig. 1.F). Each task was recorded for 20 s, with 10 s rest intervals between consecutive tasks.

Acceleration signals were recorded continuously throughout the six-task sequence.The participant's individual tremor frequency was estimated by using the outstretched-arm postural task (Fig. 1.E). For this real-time estimation, the acceleration signals were filtered between 3 and 12 Hz. Then, the power spectral density (PSD) was estimated using a Welch periodogram and a random three-dimensional vector derived from the 3-axis accelerometer, as proposed by [22]. The most prominent spectral peak was identified as the dominant tremor frequency (f_{tremor}). The resulting value was subsequently used to configure the burst frequency of the stimulation protocol,

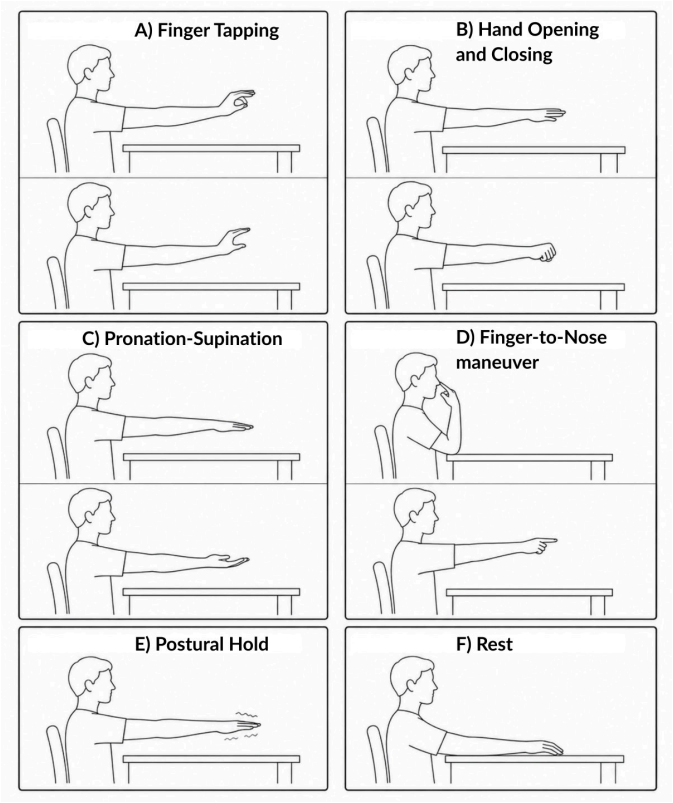

Fig. 1. Experimental motor tasks adapted from selected items of Part III of the MDS-UPDRS [20]: A) finger tapping; B) hand opening and closing; C) pronation-supination movements of the hand; D) finger-to-nose maneuver; E) outstretched-arm postural task; and F) seated rest for rest tremor task.

such that $f_{\text{burst}} = f_{\text{tremor}}$. The burst period was defined as $T_{\text{burst}} = \frac{1}{f_{\text{burst}}}$. Each channel remained active for half of this period as $T_{\text{on}} = \frac{T_{\text{burst}}}{2}$, alternating stimulation between the medial and radial nerves.

Treatment current intensities (TCI) for the median and radial nerves were determined independently by applying a multiplication factor (MF) to the sensory threshold (ST). This factor was progressively increased to the highest level comfortably tolerated by the participant, ensuring no visible muscle contraction or involuntary movement occurred. The ST was obtained following the procedure described by [17], [18].

During Intra-stimulation period, electrical stimulation was delivered for 40 min. Participants exclusively executed the outstretched-arm postural task for approximately 20 s (Fig. 1.E) at the 10-, 20-, and 30-min marks following the onset of stimulation to assess tremor. These three assessments were designated Intra 1, Intra 2, and Intra 3, respectively.

Following the stimulation period, the six-task sequence performed during the Pre-stimulation baseline was repeated. This final recording was defined as the Post-stimulation assessment.

The waveform delivered depended on the stimulation condition assigned to the participant. In the BPB waveform, each burst consisted of a train of symmetric, charge-balanced biphasic pulses. Each pulse comprised a $300\ \mu\mathrm{s}$ positive phase,

followed by a 50 μs interphase interval and a 300 μs negative phase. The positive and negative phases had equal current amplitudes, and the pulses were repeated within each burst at an internal pulse frequency of 150 Hz [12]–[14]. Under the SB waveform, each burst consisted of a continuous 3 kHz sine wave.

C. Signal Processing and Feature Extraction

Offline processing and analysis of the acceleration signals were performed in MATLAB (MathWorks, Inc., Natick, MA, USA). During preprocessing, a fourth-order Butterworth high-pass filter with a cutoff frequency of 0.5 Hz was applied separately to the acceleration signals from the X, Y, and Z axes. The filtering step was used to attenuate the static gravitational component and other slowly signal components.

Although the experimental protocol included all six motor tasks described previously, the present analysis focused on the outstretched-arm postural task. This posture was selected to evaluate tremor power across all assessment periods: Pre-stimulation, Intra 1, Intra 2, Intra 3, and Post-stimulation.

The segments of interest were identified using the temporal markers inserted during the experimental protocol, and a continuous 20 s interval was extracted from each signal.

Spectral features were subsequently extracted from each preprocessed segment, as described below. The resulting dataset was organized according to participant identifier, stimulation waveform (BPB or SB), and assessment period. Spectral features were subsequently extracted from each preprocessed segment, as described below.

1) Power Spectral Density: Following the methodology in [22], the Power Spectral Density (PSD) for the X, Y, and Z axes was estimated using Welch's method (4 s Hann window, 50% overlap) and combined into a triaxial PSD by summing the orthogonal components (omitting the square-root operation to retain power density values). From this spectrum, tremor-band power was calculated by integrating across a predefined frequency band of $3.5-12$ Hz [23], [24], which encompasses the frequency components associated with parkinsonian tremor.

2) Relative Change: To quantify variations in tremor-band power across assessment periods relative to the pre-stimulation baseline, the Relative Change (RC, %) was calculated as:

$$\mathrm{RC}_i = \frac{\mathrm{Power}_i - \mathrm{Power}_{\mathrm{Pre}}}{\mathrm{Power}_{\mathrm{Pre}}} \times 100\% \tag{1}$$

where Power_i represents the power during a given assessment period (Intra 1, Intra 2, Intra 3, or Post-stimulation) and $\mathrm{Power}_{\mathrm{Pre}}$ represents the power during the pre-stimulation period. Here, negative values indicate a reduction in tremor-band power, positive values denote an increase, and zero represents no change.

D. Statistical Analysis

Statistical analyses were performed using R software. Data were analyzed independently for each group defined by the stimulation waveform (BPB and SB). Due to the small sample size ($n = 5$ per group) and to avoid assuming a normal distribution, a non-parametric approach was adopted. Descriptive statistics were reported as median and 1st and 3rd quartiles [Q1, Q3] for treatment current intensity (TCI), multiplier factor (MF), and the relative change percentage (RC) of tremor band power (3.5–12 Hz). To evaluate the temporal changes in tremor band power across the five assessment periods (Pre, Intra 1, Intra 2, Intra 3, and Post), a repeated-measures Friedman test was performed separately for each stimulation waveform, with the significance level set at $\alpha = 0.05$. When the Friedman test indicated a statistically significant overall difference across the assessment periods ($p < 0.05$), post-hoc pairwise comparisons were performed using the Conover's test with a Holm-Bonferroni correction, with Pre-stimulation defined as the reference period. Moreover, the magnitude of the overall effect was quantified using Kendall's coefficient of concordance (W), with 95% confidence interval (CI) estimated via bootstrap resampling (10,000 iterations). Finally, an exploratory analysis of individual responses was conducted across both groups to evaluate the relationship between participant parameters (f_{tremor}, TCI and MF) and tremor band power changes. For this purpose, Spearman's rank correlation coefficient (ρ) was computed between the relative change percentage (RC) during (Intra-mean, calculated as the average across Intra 1–3), and after stimulation (Post).

III. Results

The multiplication factor and treatment current intensity for each experimental group are presented as the median (first–third quartiles). In the BPB group, the multiplication factor was 1.3 (1.3–1.5) for median nerve stimulation and 1.5 (1.3–1.5) for radial nerve stimulation. These multiplication factors corresponded to treatment current intensities of 2.54 mA ($2.22-2.74$) for the median nerve and 1.87 mA ($1.79-3.85$) for the radial nerve. In the SB group, the multiplication factor was 1.2 (1.1–1.2) for the median nerve and 1.2 (1.2–1.4) for the radial nerve. The corresponding treatment current intensities were 3.83 mA ($3.63-5.35$) for the median nerve and 3.95 mA ($3.94-4.70$) for the radial nerve.

Figure 2 illustrates the postural tremor power across the assessment periods. To facilitate the visual representation of tremor power values, which span several orders of magnitude among participants, a logarithmic scale (base 10) was applied to the power values expressed in $(\mathrm{cm/s^2})^2$. In the BPB group (participants P01–P05), participant P01 generally registered the lowest power values within the group, ranging from 53.81 to 166.76 $(\mathrm{cm/s^2})^2$, whereas participant P02 exhibited substantially higher magnitudes, oscillating between 90,960.81 and 309,686.07 $(\mathrm{cm/s^2})^2$. When evaluating changes during the stimulation period (Intra 1 to Intra 3) relative to baseline (Pre), participants P03 and P04 demonstrated a reduction in power values, with P04 exhibiting the most pronounced and sustained attenuation. In contrast, participants P01, P02, and P05 displayed a fluctuating response characterized by alternating periods of power increase and reduction. During the Post-stimulation assessment period, most participants

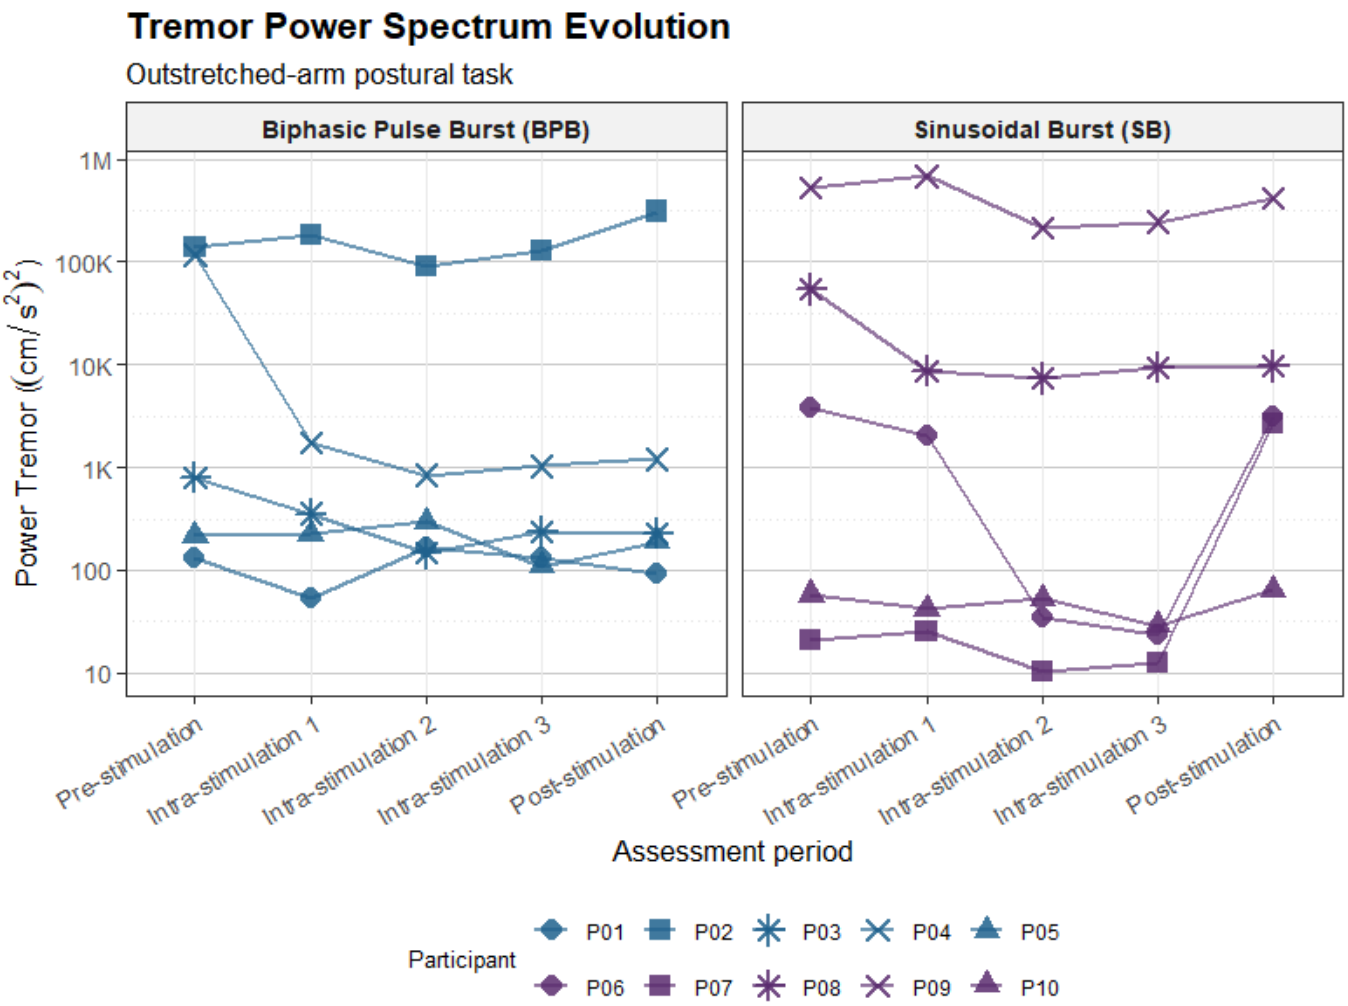

Fig. 2. Postural tremor power in the 3.5–12 Hz frequency band across evaluation periods, represented on a logarithmic scale (base 10). The left panel shows the BPB group (blue), and the right panel shows the SB group (purple). Individual markers represent participants (P01–P10).

maintained values below their baseline, with the exception of participant P02. Evaluating temporal progression using the Friedman test revealed no significant main effect for this group ($\chi^2_F = 2.72$, $p = 0.606$). The effect size for this group was small ($W = 0.136$) with a wide 95% confidence interval ([0.06, 0.81]), reflecting substantial heterogeneity in the participants' trajectories.

In the SB group (participants P06–P010), the baseline (Pre) power range was wider than in the BPB group. Participant P09 maintained the highest magnitudes in the group, ranging from 212,764 to 682,920.45 $(\text{cm/s}^2)^2$ across all assessment periods. Meanwhile, participant P07 registered the lowest values during stimulation, between 10.23 y 25.04 $(\text{cm/s}^2)^2$, though exhibiting a sharp increase during the Post-stimulation assessment period to reach 2,652.34 $(\text{cm/s}^2)^2$. Relative to baseline (Pre), the response during stimulation also showed power fluctuations: P06 achieved the highest relative attenuation in the group, whereas P08 displayed a relatively stable power reduction. During the Post-stimulation assessment period, participants P06, P08, and P09 maintained attenuated values, in contrast to P07 and P10, who experienced an increase (moderate for P10 and pronounced for P07). Unlike the BPB group, the temporal evaluation of the SB group revealed a statistically significant difference in tremor band power across assessment periods ($\chi^2_F = 12.64$, $p = 0.013$). Post-hoc comparisons using Conover's test with Holm-Bonferroni correction demonstrated significant differences between Intra 2 and Intra 3 periods compared to baseline ($T = -3.83$, $p = 0.006$ and $T = -3.54$, $p = 0.008$, respectively). In contrast, the Intra 1 and Post assessment periods did not reach statistical significance compared to Pre ($T = -1.47$, $p = 0.319$ and $T = 0$, $p = 1.000$, respectively). The effect size in this waveform was large ($W = 0.632$) with a 95% CI of [0.58, 0.86].

To complement the comparisons against the baseline (Pre) with RC, Table I summarizes the median and 1st and 3rd quartiles [Q1, Q3] in tremor band power relative to baseline (Pre). Overall, during stimulation (mean of Intra periods), both groups yielded an equivalent general power reduction value

TABLE I
SUMMARY OF RELATIVE CHANGE PERCENTAGE (%) IN TREMOR-BAND POWER COMPARED TO BASELINE (PRE)

	BPB Group		SB Group	
Assessment	**Median (%)**	**IQR [Q1; Q3]**	**Median (%)**	**IQR [Q1; Q3]**
Intra 1	-55.82	$[-58.76; 3.83]$	-27.45	$[-46.51; 21.45]$
Intra 2	-35.67	$[-81.75; 27.83]$	-59.85	$[-86.44; -50.38]$
Intra 3	-49.90	$[-70.65; -8.41]$	-53.63	$[-82.64; -49.80]$
Post	-29.66	$[-71.58; -13.34]$	-17.25	$[-20.92; 10.86]$

(BPB: -47.13%; SB: -46.97%). However, in the BPB group, Intra 1 registered the greatest reduction (median of -55.82%), whereas subsequent periods exhibited lower reduction values. A minor dispersion was observed in Intra 3, its interquartile interval [Q1, Q3] indicate only reduction. On the other hand, in the SB group, the median reduction became more pronounced from Intra 1 to Intra 2, reaching its largest value at Intra 2 (59.85%). The interquartile interval [Q1, Q3] at both Intra 2 and Intra 3 were entirely below zero. Following the end of stimulation (Post), smaller median reductions were observed in both groups compared with their intra-stimulation values. The BPB group showed a median RC of 29.66%, with an interquartile range entirely below zero, and the SB group showed a median RC of 17.25%, with a wider interquartile range spanning both negative and positive values.

Finally, exploratory analyses revealed no clear monotonic relationships between RC and the participant parameters (f_{tremor}, TCI, and MF). During stimulation (Intra-mean), Spearman correlation coefficients demonstrated no monotonic association for f_{tremor} ($\rho = 0$) and weak negative associations for stimulus amplitude parameters, TCI ($\rho = -0.224$) and MF ($\rho = -0.353$). Post-stimulation period revealed a similar pattern with weak associations (f_{tremor}: $\rho = -0.225$; TCI: $\rho = 0.224$; MF: $\rho = -0.322$).

IV. DISCUSSIONS AND CONCLUSIONS

This pilot study evaluated the preliminary effects of two peripheral electrical stimulation waveforms–Biphasic Pulse Burst (BPB) and Sinusoidal Burst (SB) on tremor-band power during an extended-arm postural task in patients with Parkinson's disease.

The treatment current intensities applied in this study showed distinct variability patterns depending on the waveform and the stimulated nerve, being generally higher in the sinusoidal burst (SB) group than in the biphasic pulse burst (BPB) group. In the BPB group, the median current intensity was $2.54\ mA$ for the median nerve and $1.87\ mA$ for the radial nerve, whereas Pahwa et al. [13] reported a higher mean current (5.4 ± 2.9 mA). In the study by Pahwa et al. [13], patients with essential tremor were evaluated, and a single overall current value was reported per participant, adjusted directly based on comfort sensation. In contrast, the present study focused on Parkinson's disease and characterized the current intensity independently for each nerve, considering each subject's sensory threshold and adjusting it to achieve comfortable paresthesia. Although both protocols shared a conceptually similar stimulation waveform and aimed to remain strictly below the motor threshold, the discrepancies in the recorded current intensity values could be attributed to these methodological differences.

In the SB group, the median current intensities were $3.83\ mA$ for the median nerve and $3.95\ mA$ for the radial nerve, which were substantially lower than the initial mean current of $82.3\ mA$ (with a final mean of $105\ mA$) reported by Fernández-Pérez et al. [25] in patients with Parkinson's disease. These differences can be explained because their protocol applied a continuous 10 kHz sinusoidal current, increasing the intensity via a 30-second ramp-up with continuous readjustments throughout the session to achieve a comfortable tingling sensation just below the motor threshold, using electrodes positioned near the medial (targeting median and ulnar nerves) and lateral (targeting radial nerve) epicondyles. In contrast, the present study employed 3 kHz sinusoidal bursts according to each patient's tremor frequency, set relative to the individual sensory threshold, and delivered via surface bipolar electrodes placed over the target nerves.

For both waveforms, tremor-band power showed median reductions relative to baseline (RC) during electrical stimulation (Intra 2 and Intra 3 periods) and after stimulation (Post). In the BPB group, these reductions were not significant ($p = 0.606$). In contrast, the SB group demonstrated statistically significant temporal variations across assessment periods ($p = 0.013$), specifically during the stimulation periods, Intra 2 and Intra 3 ($p = 0.006$ and $p = 0.008$, respectively). The combined intra-stimulation (Intra-mean) exhibited a median reduction of 47.1% and 46.9% for BPB and SB groups, respectively. These findings suggest that that reduction, represented by tremor-band power, achieved significance in the SB group during sustained stimulation. In this context, [14] monitored tremor power using accelerometers before, during, immediately after, and at 30 and 60 min post-stimulation with transcutaneous afferent patterned stimulation (TAPS) during postural hold, spiral drawing and pouring tasks. Their findings indicate that the postural hold task has the most pronounced attenuation, with median reductions of approximately 70% immediately post-stimulation and 83% at 30 min. However, direct quantitative comparison with intra-stimulation periods remains limited due to key methodological differences. Specifically, their study was conducted in patients with essential tremor, quantified tremor power within a narrower frequency band around the dominant frequency without a combined triaxial PSD, and reported detailed numerical reductions primarily for post-stimulation periods. Consequently, while their work reinforces the utility of longitudinal accelerometric monitoring, it represents a distinct clinical and analytical framework.

At the end of stimulation (Post) median power reductions were 29.66% and 17.25% for BPB and SB groups, respectively. In the BPB group, these post-stimulation results can be cautiously contextualized with previous evidence evaluating TAPS in Parkinson's disease. For instance, [12] reported a substantially higher median tremor power reduction of 64% at the end of stimulation, with 79% of participants exhibiting

reductions of at least 50% and 97% showing some degree of improvement. However, their study differed substantially from the present work, since it included a larger sample, two sessions per day over 4 weeks, and pre–post measurements for each session per participant. Consequently, these substantial differences in protocol duration and clinical setting preclude direct quantitative comparisons with previous home-use TAPS studies. On the other hand, for the SB group, evidence concerning the post-stimulation effects of this waveform in Parkinson's disease remains limited. In this context, [25] evaluated a 10 kHz sinusoidal current stimulation in patients with Parkinson's disease, reporting benefits primarily for kinetic tremor. Regarding postural or resting tremor, they observed a reduction no greater than to the sham treatment. This outcome provides a rationale for exploring sinusoidal waveform configurations targeting tremor reduction, such as the SB signal implemented in this work. Thus, while the responses in the SB group must be interpreted as exploratory, the results warrant further investigation of this waveform as a potential alternative or complementary therapeutic approach for managing postural tremor. The exploratory analysis revealed no clear monotonic relationships between RC and participant parameters (f_{tremor}, TCI or MF). Similarly, [26] reported no significant association between dominant tremor frequency and tremor suppression, although their stimulation protocol and study population differed substantially from those used here. Regarding stimulation intensity, [27] reported greater tremor-power reductions at higher stimulation amplitudes under phase-locked peripheral nerve stimulation. In contrast, the weak association observed in the present study suggests that stimulation intensity alone did not clearly account for the interindividual variability in tremor power reduction. Several limitations of this study must be acknowledged. High inter-individual variability was observed in baseline tremor characteristics, which may have been influenced by factors such as disease severity, medication status, and individual responsiveness to peripheral stimulation. Furthermore, the experimental design did not include a sham stimulation condition or blinding. Additionally, direct statistical comparisons between the two waveforms were not performed; as an exploratory pilot study with a small sample size ($n = 5$ per group), the protocol was focused on evaluating changes within each group and lacked the statistical power required for inter-group hypothesis testing. Collectively, these methodological constraints and the preliminary nature of the data preclude definitive conclusions regarding clinical efficacy or the superiority of one waveform over the other.

The results demonstrate the feasibility of peripheral electrical stimulation for modulating postural tremor in Parkinson's disease using BPB and SB waveforms. The individual evaluation of each group revealed median reductions in tremor-band power (3.5–12 Hz), with the SB group achieving statistically significant variations at the end of the intra-stimulation periods. Furthermore, exploratory analyses indicated that relative changes were not associated with individual characteristics such as f_{tremor}, TCI, and MF. Given the small sample size and the lack of statistical significance during post-stimulation periods, these findings must be interpreted as preliminary. Consequently, future studies should incorporate larger sample sizes using randomized, double-blind, sham-controlled crossover designs. This methodological approach will isolate stimulation-specific effects, enable direct quantitative comparisons between waveforms, and incorporate additional assessment periods to evaluate the clinical durability of the treatment.

ACKNOWLEDGMENT

The authors wish to thank CAPES (PROEX), FINEP (grant 01.24.0122.00), CNPq, and FAPERJ (grant E-26/204.393/2024 and SEI-260003/020273/2025) for their financial support. Additionally, the authors would like to express their gratitude to SisAssistiva-MCTI for its collaboration.

***Abstract*—Automatic identification of mosquito species is central to vector surveillance and to the timely deployment of disease-control interventions. This paper proposes an ensemble learning framework built on lightweight convolutional neural networks (CNNs) for classifying mosquito species from wingbeat audio recordings. Six state-of-the-art lightweight architectures—MobileNetV3-Large, ShuffleNetV2, GhostNetV2, EfficientNet-Lite0, MobileOne-S1, and MobileNetV4 Conv Medium—are trained on log-Mel spectrogram representations of the Wingbeats dataset, whose training partition is augmented with realistic environmental noise drawn from the TUT Acoustic Scenes 2017 dataset. Individual model predictions are combined through a weighted soft-voting ensemble, in which each classifier's weight is proportional to its validation F1-score. Performance is assessed under a 5-fold cross-validation protocol with fixed fold assignments, each fold further evaluated under three controlled random seeds, for a total of 15 fold-seed configurations per model. Under this protocol, the proposed ensemble reaches a macro F1-score of $95.5\% \pm 0.29$ on the Wingbeats test set, surpassing every individual classifier with low variability across runs; pairwise Wilcoxon signed-rank tests with Holm correction confirm that this advantage is statistically significant against all individual models and against most alternative ensemble strategies. Cross-dataset validation on Tiny MosquitoSong+, HumBugDB, and ABuzz provides evidence of generalization across the evaluated recording conditions, with the ensemble attaining the highest ROC-AUC on all three external benchmarks (0.901, 0.951, and 0.963, respectively). These results support weighted soft voting as a promising approach to mosquito classification on the evaluated benchmarks; readiness for field or embedded deployment remains to be established.**

***Index Terms*—mosquito classification, wingbeat sound, lightweight convolutional neural networks, ensemble learning, log-Mel spectrogram, acoustic surveillance, IoT**

I. Introduction

Mosquito-borne diseases – including dengue, malaria, Zika, chikungunya, and yellow fever – impose a substantial public health burden, particularly across tropical and subtropical regions [1]. Effective vector control depends on continuous population surveillance, yet conventional trapping and manual, expert-driven identification are labor-intensive and difficult to scale to the continuous, large-area monitoring that timely interventions require.

Acoustic monitoring offers a non-invasive alternative, exploiting the characteristic wingbeat frequencies that mosquitoes produce in flight [5]. Coupled with low-cost microphones and embedded processing, this approach could support continuous, automated identification within smart traps and Internet of Things (IoT) surveillance devices. Convolutional neural networks (CNNs) trained on time-frequency representations, such as log-Mel spectrograms, have already achieved high classification accuracy on this task [6], [7]. Two obstacles nonetheless stand between these results and field-ready systems: the computational demands of many CNN architectures can be prohibitive for embedded deployment, and evaluation restricted to a single acquisition protocol offers limited evidence of robustness to different recording devices, environmental noise, and mosquito populations.

Lightweight CNNs may help mitigate the first obstacle by reducing computational requirements while retaining competitive predictive performance [21], [22], [24], [25]. Because architectures of this kind differ in their design strategy, combining their complementary predictions through ensemble learning may further improve robustness [19]; likewise, training with realistic environmental noise may help narrow the gap between laboratory and deployment conditions [16]. Ensembling several networks, however, multiplies the inference cost of a single model, so the computational footprint of the complete ensemble still warrants dedicated evaluation before such a system can be considered for embedded deployment.

Building on these observations, this work proposes a framework that combines six lightweight CNN architectures, noise-augmented wingbeat recordings, log-Mel spectrogram representations, and a validation-F1-weighted soft-voting ensemble. Models are evaluated on the Wingbeats dataset using five fixed cross-validation folds and three controlled random seeds per fold, keeping data partitions consistent across architectures while explicitly assessing sensitivity to training stochasticity. External validation on the Tiny MosquitoSong+, HumBugDB, and ABuzz datasets further probes the framework's generalization under recording conditions the models never encountered during training. Individual architectures and multiple ensemble strategies are systematically compared in terms of predictive performance and result stability, with statistical testing used to establish which differences are robust rather than incidental.

II. Related Work

Automatic mosquito identification has been investigated through multiple sensing modalities, including morphological imaging, spectroscopic analysis, and acoustic monitoring. This section reviews representative contributions across these areas, with emphasis on wingbeat-based acoustic methods and the machine learning techniques employed for classification.

A. Mosquito Classification from Visual Data

Early automated approaches to mosquito identification relied on image-based analysis of captured specimens. Transfer learning with standard CNN architectures such as VGG16 has been applied to morphological mosquito images, achieving high classification accuracy even with compact training sets [2]. More recently, vision transformers trained on curated image datasets have outperformed CNN baselines in multi-species classification, with a Swin Transformer reaching 96.3% accuracy across 17 species [3]. Nazari et al. [4] took a hybrid route, combining a compact ensemble of three CNNs—EfficientNet-V2-S, MobileNetV3-Large, and ResNet-50—with a Swin-T Transformer branch for *Aedes* mosquito recognition, reporting in-domain accuracies of 99.3–99.5% together with evidence of cross-dataset generalization. Despite these encouraging accuracies under laboratory conditions, image-based methods generally require physical specimen collection and expert handling, which constrains their applicability to continuous, large-scale field surveillance.

B. Acoustic Monitoring and Wingbeat-Based Classification

The characteristic wingbeat sound that mosquitoes produce during flight offers a non-invasive cue for species identification. Early studies established that flight tones carry spectral features that are discriminative across species and sexes [5], and subsequent work by Kiskin et al. showed that CNNs trained on spectrogram representations of this audio achieve high classification accuracy under controlled laboratory conditions [7].

Building on these findings, several studies investigated low-cost acoustic sensing suitable for IoT deployment. Joelianto et al. [8] proposed an IoT solution that differentiates both the sex and species of *Culex quinquefasciatus* and *Aedes aegypti*, using a custom CNN to extract features from the Mel-Frequency Cepstral Coefficients (MFCCs) of wingbeat Mel spectrograms and reporting accuracies of 91.76% and 87.16% for species and sex differentiation, respectively; the model, however, was trained on a limited species set recorded with mobile phones under controlled laboratory conditions. Paim et al. [9] instead targeted a smartphone application, using residual CNNs to identify *Aedes aegypti* from a benchmarking dataset of smartphone-recorded wingbeat sounds augmented with controlled levels of random and background noise; deployed on-device as a proof of concept, the model reached 80% test accuracy.

Other efforts moved away from spectrogram-based pipelines altogether. Yin et al. proposed two lightweight models—a 1D-CNN and a 1D-CNN combined with an LSTM—that operate directly on raw audio at low sampling rates without any preprocessing, achieving classification accuracy above 93% across five mosquito species [10]. Luna-González et al. explored yet another representation, transforming wingbeat features into images before training CNN classifiers on these transformed inputs [12]. Returning to spectrogram-based features, Fanioudakis et al. applied DenseNet121 to wingbeat spectrograms, demonstrating the effectiveness of time-frequency representations for distinguishing medically relevant species and reaching 96% accuracy on the Wingbeats dataset [6].

A different architectural direction is represented by WbNet, a ResNet augmented with a self-attention mechanism that combines Mel-spectrogram inputs with data augmentation and residual connections, achieving 98.9% accuracy on the ABuzz dataset for species of the *Aedes* and *Culex* genera [13]. Closer to the present work, Fernandes et al. investigated CNN-based binary and multiclass classifiers alongside ensembles of binary classifiers for *Aedes aegypti* detection from smartphone recordings, providing early evidence that ensemble strategies can improve robustness under noisy acoustic conditions [14].

C. Noise Robustness and Cross-Dataset Generalization

A recurring limitation of acoustic mosquito classification is the domain gap between clean laboratory recordings and noisy field environments, which has motivated several noise-aware training strategies. Kiskin et al. introduced HumBugDB [15], a benchmark of over 20 hours of multi-species recordings

collected with smartphones across different countries and environments, explicitly designed to support more realistic evaluation; models trained exclusively on clean data typically show substantial performance degradation when evaluated on this benchmark.

Targeting this gap directly, the MosquitoSong+ model extended a baseline 1D-CNN with two complementary augmentation strategies – additive noise and wingbeat volume variation [16]. Evaluated across multiple datasets, including HumBugDB and outdoor recordings, MosquitoSong+ maintained species classification accuracy above 80% in the presence of background noise, underscoring the importance of noise-aware training for real-world deployment.

D. Ensemble Learning for Audio Classification

Ensemble methods have been widely adopted to improve the robustness of audio classification systems more broadly [18]. Soft voting and weighted prediction fusion across independently trained models consistently outperform single-model baselines in environmental sound classification [19], and within bioacoustics specifically, ensembles of CNNs trained with diverse augmentation protocols have been applied to animal audio classification, showing that combining models trained under different data conditions reduces isolated classification errors [20].

E. Lightweight CNN Architectures for Edge Deployment

Deploying deep learning models on embedded devices requires architectures that balance classification performance against low computational cost. MobileNetV3-Large combines depthwise separable convolutions with neural architecture search and squeeze-and-excitation attention to optimize mobile inference [21]. ShuffleNetV2 instead reduces memory-access overhead through channel splitting and shuffling, improving practical inference throughput on mobile processors [22]. GhostNetV2 generates redundant feature maps via inexpensive linear transformations and adds a decoupled fully connected attention mechanism to capture long-range dependencies at low cost [23]. EfficientNet applies compound scaling jointly across depth, width, and resolution; its Lite variant removes hardware-unfriendly operations to enable deployment on edge accelerators [24]. MobileOne relies on structural reparameterization during training, which collapses into a single efficient branch at inference time to target ultra-low latency on mobile hardware [25]. MobileNetV4, finally, integrates hardware-aware architectural design to maximize accuracy under strict latency constraints [26].

Despite their maturity on computer vision benchmarks, a systematic comparison of these architectures on bioacoustic tasks – and their combination through ensemble learning – remains largely unexplored. The present work addresses this gap, evaluating all six architectures under a unified experimental protocol and combining their predictions through a weighted soft-voting ensemble.

III. Methodology

Figure 1 presents an overview of the proposed mosquito species classification framework, whose pipeline comprises seven stages: (i) acquisition of mosquito wingbeat recordings, (ii) audio preprocessing, (iii) data augmentation with realistic environmental noise, (iv) log-Mel spectrogram generation, (v) training of the lightweight convolutional neural networks, (vi) weighted soft-voting ensemble learning, and (vii) performance evaluation on the Wingbeats and external datasets.

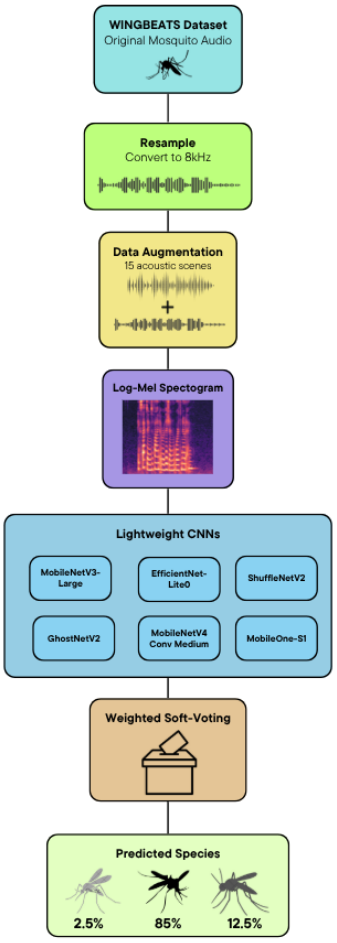

Fig. 1. Overview of the proposed pipeline

A. Dataset

The experiments were conducted on the Wingbeats dataset, which comprises mosquito wingbeat recordings from six medically relevant species. As shown in Table I, the original dataset is markedly imbalanced across species.

Before any data augmentation or spectrogram generation, 4,500 original recordings per species were reserved for validation and a further 4,500 for testing; from the remaining recordings, 7,200 per species were selected for training. All assignments were made at the level of the original recording (*source recording*), so that no source recording was shared across subsets.

Data augmentation was applied exclusively to the training recordings: for each species, 28,800 noise-augmented samples were generated from the 7,200 selected training recordings, yielding 36,000 training samples in total – 7,200 original recordings (20%) plus 28,800 augmented samples (80%). The validation and test subsets, by contrast, retained only their 4,500 original recordings per species and were not subjected to augmentation or synthetic noise addition. Each species therefore contributed 16,200 original and 28,800 augmented samples, for a combined total of 45,000 samples across the three subsets.

Aggregated across the six species, the final balanced dataset comprises 216,000 training samples, 27,000 validation samples, and 27,000 test samples, for a total of 270,000 samples. Although this corresponds nominally to an 80/10/10 split, the ratio actually results from the fixed per-species validation/test allocation combined with training-set augmentation, rather than from a proportional division of the original Wingbeats recordings. As detailed in Section III-F, this partitioning scheme defines one of five fixed folds used throughout the repeated cross-validation protocol, with the same fold assignments held constant across all models and random seeds.

TABLE I
CLASS DISTRIBUTION OF THE ORIGINAL WINGBEATS DATASET AND THE FINAL BALANCED DATASET ACROSS TRAINING, VALIDATION, AND TEST SUBSETS.

Species	**Original**	**Balanced**
Ae. aegypti	85,553	45,000
C. quinquefasciatus	74,599	45,000
An. gambiae	49,471	45,000
C. pipiens	30,415	45,000
Ae. albopictus	20,231	45,000
An. arabiensis	19,297	45,000

B. Audio Preprocessing

The proposed framework operates directly on mosquito wingbeat audio recordings. All recordings were first standardized to a common audio format by resampling the signals to a fixed sampling frequency and applying amplitude normalization, a step that reduces variability caused by different recording conditions while preserving the spectral characteristics of mosquito wingbeats.

To improve model robustness, data augmentation was applied exclusively to the training subset, adding realistic environmental sounds directly to the time-domain signals [19]. Noise samples were drawn at random from the TUT Acoustic Scenes 2017 dataset and mixed with mosquito recordings at randomly selected signal-to-noise ratio (SNR) values. Performing this augmentation before feature extraction allows the resulting spectrograms to reflect more realistic acoustic scenarios, which is expected to improve generalization to unseen recording environments [16].

Each audio signal was then converted into a log-Mel spectrogram. Validation and test recordings underwent the same standardization and feature-extraction steps but bypassed augmentation. The Short-Time Fourier Transform (STFT) was first computed to obtain a time-frequency representation; the resulting power spectrum was projected onto the Mel scale and compressed logarithmically to produce the log-Mel spectrogram. Finally, spectrograms were resized to match the input dimensions required by each lightweight CNN architecture.

C. Lightweight CNN Architectures

Six lightweight CNNs were evaluated: MobileNetV3-Large [21], ShuffleNetV2 [22], GhostNetV2 [23], EfficientNet-Lite0 [24], MobileOne-S1 [25], and MobileNetV4 Conv Medium [26]. As reviewed in Section II, these architectures pursue complementary design strategies – depthwise convolutions, channel shuffling, inexpensive feature generation, compound scaling, structural reparameterization, and hardware-aware design – which motivates their use as diverse ensemble members. All six models received identical log-Mel spectrogram inputs and were compared under the same data partitions and training protocol.

D. Weighted Soft-Voting Ensemble

Although each lightweight CNN provides high classification accuracy on its own, its particular design leads it to learn a somewhat distinct feature representation, so that prediction errors across architectures are often complementary rather than correlated [20]. The proposed framework exploits this diversity by combining the outputs of all trained CNNs through a weighted soft-voting ensemble.

Let $P_i(c|x)$ denote the posterior probability estimated by the i-th CNN for class c, where x represents the input log-Mel spectrogram. The final probability assigned to class c is computed as

$$P(c|x) = \sum_{i=1}^{N} w_i P_i(c|x), \tag{1}$$

where N is the number of CNN models and w_i is the weight assigned to the i-th classifier, satisfying

$$\sum_{i=1}^{N} w_i = 1. \tag{2}$$

The weights were computed from the validation F1-score of each model and normalized as

$$w_i = \frac{F1_i}{\sum_{j=1}^{N} F1_j}, \tag{3}$$

where $F1_i$ denotes the validation F1-score achieved by the i-th CNN.

The predicted mosquito species corresponds to the class with the highest aggregated probability,

$$\hat{y} = \arg\max_{c} P(c|x). \tag{4}$$

Unlike hard voting, which considers only each classifier's predicted label, weighted soft voting exploits the confidence scores produced by the networks and assigns greater influence

to models with stronger validation performance [19]. This combination aims to exploit complementary feature representations and reduce isolated classification errors; any robustness gains must be assessed under the intended operating conditions.

E. Experimental Setup and Hyperparameters

All architectures were trained on the source-recording-level partitions described in the Dataset subsection; derived spectrograms and augmented samples always remained within their source subset, so that only training data were augmented and no leakage into validation or testing could occur.

Training used AdamW with weight decay 10^{-4}, batch size 64, and a maximum of 50 epochs. With a peak learning rate $\eta = 10^{-3}$, a OneCycleLR schedule increased the learning rate from $\eta/10$ to η over the first 30% of training before applying cosine decay down to $\eta/1000$. Early stopping monitored validation loss with a patience of 10 epochs and restored the best-performing model weights.

F. Evaluation Protocol

Five fixed folds were used for cross-validation, with four folds allocated to training and the remaining fold to evaluation at each iteration; identical fold assignments were maintained across all models and ensemble configurations. Each fold was further evaluated under three controlled random seeds, yielding 15 fold-seed configurations per model. Seeds governed weight initialization, data shuffling, and other randomized training operations without altering the partitions themselves; preprocessing, training-only augmentation, and hyperparameters followed the settings described in the preceding subsections.

Results are reported as mean $\pm$ standard deviation across the 15 configurations, with corresponding 95% confidence intervals (CIs) computed from these statistics to summarize estimation uncertainty. This protocol jointly captures performance variation across fixed partitions and across stochastic training runs, while its paired structure enables direct statistical comparison between models.

Statistical comparisons paired results from identical fold-seed configurations. A two-sided Wilcoxon signed-rank test compared the Soft Voting Ensemble against each alternative at $\alpha = 0.05$, with Holm correction applied for multiple comparisons; effect sizes were expressed as rank-biserial correlation. A method was considered superior only when it combined a higher mean performance with a statistically significant paired difference, with effect sizes providing complementary evidence on the magnitude of that difference.

G. Evaluation Metrics

On the Wingbeats test set, the classification performance of the individual lightweight CNNs and of the proposed weighted soft-voting ensemble was evaluated using five metrics: Accuracy, Macro Precision, Macro Recall, Macro F1-score, and ROC-AUC. Accuracy captures the overall proportion of correctly classified samples, whereas Macro Precision and Macro Recall assign equal importance to each class regardless of its frequency. The Macro F1-score, computed as the harmonic mean of Macro Precision and Macro Recall, was adopted as the primary evaluation metric throughout the paper.

F1-score and the area under the receiver operating characteristic curve (ROC-AUC) were additionally reported for the cross-dataset validation, alongside the Wingbeats test set.

Accuracy, Macro Precision, Macro Recall, and Macro F1-score are defined as follows:

$$\text{Accuracy} = \frac{\sum_{c=1}^{K} TP_c}{\text{Total Number of Samples}} \tag{5}$$

$$\text{Precision}_M = \frac{1}{K} \sum_{c=1}^{K} \frac{TP_c}{TP_c + FP_c} \tag{6}$$

$$\text{Recall}_M = \frac{1}{K} \sum_{c=1}^{K} \frac{TP_c}{TP_c + FN_c} \tag{7}$$

$$\text{F1}_M = 2 \cdot \frac{\text{Precision}_M \cdot \text{Recall}_M}{\text{Precision}_M + \text{Recall}_M} \tag{8}$$

IV. Results and Discussion

The proposed methodology was evaluated using six lightweight CNN architectures and the weighted soft-voting ensemble, under the fixed-fold cross-validation protocol described in Section III-F. Performance was first assessed on the Wingbeats test set and then examined through cross-dataset validation on Tiny MosquitoSong+ [16], HumBugDB [15], and ABuzz. Wingbeats performance was evaluated using Accuracy, Precision, Recall, F1-score, and ROC-AUC, whereas cross-dataset performance was assessed using F1-score and ROC-AUC only; accordingly, Table II reports all five metrics, while Table IV reports F1-score and ROC-AUC.

A. Performance on the Wingbeats Dataset

Table II compares the six individual lightweight CNN architectures against hard voting, bagging, stacking, and the proposed weighted soft-voting ensemble on the Wingbeats dataset. All values are reported as mean $\pm$ standard deviation across the 15 fold-seed configurations; Accuracy, Precision, Recall, and F1-score are expressed as percentages, while ROC-AUC is reported on a 0–1 scale.

All six lightweight CNNs achieved high classification performance individually, confirming that log-Mel spectrograms are a highly discriminative representation for mosquito wingbeat sounds [6], [13]. Accuracy ranged from 90.6% for ShuffleNetV2, the lightest and least accurate architecture evaluated, up to $94.4\% \pm 0.47$ for MobileNetV4 Conv Medium, closely followed by MobileOne-S1 and GhostNetV2 – a pattern broadly consistent with the added representational capacity of the more recent architectures.

Every ensemble strategy outperformed every individual architecture, and among them the proposed weighted soft-voting ensemble achieved the best results across all five reported metrics: accuracy of $95.6\% \pm 0.28$, precision of $95.3\% \pm 0.31$,

TABLE II

PERFORMANCE COMPARISON USING 5-FOLD CROSS-VALIDATION WITH FIXED FOLD ASSIGNMENTS AND THREE CONTROLLED RANDOM SEEDS PER FOLD. EACH CELL REPORTS THE MEAN ± STANDARD DEVIATION ON THE FIRST LINE AND THE 95% CONFIDENCE INTERVAL ON THE SECOND, ACROSS 15 FOLD-SEED CONFIGURATIONS.

Model	**Accuracy (%)**	**Precision (%)**	**Recall (%)**	**F1-score (%)**	**ROC-AUC**
MobileNetV3-Large	91.3 ± 0.82	90.8 ± 0.87	91.5 ± 0.76	91.1 ± 0.81	0.963 ± 0.004

TABLE III

PAIRWISE STATISTICAL COMPARISON OF THE SOFT VOTING ENSEMBLE AGAINST INDIVIDUAL MODELS AND ALTERNATIVE ENSEMBLE STRATEGIES. COMPARISONS WERE PERFORMED OVER 15 PAIRED FOLD-SEED CONFIGURATIONS USING THE WILCOXON SIGNED-RANK TEST. HOLM-ADJUSTED p-VALUES RETAIN THE ORIGINAL TEN-COMPARISON FAMILY. EFFECT SIZES ARE REPORTED AS RANK-BISERIAL CORRELATION (r_{rb}).

Comparison	**Δ Acc. (pp)**	**p-value**	**Holm p**	r_{rb}	**Sig.**
Soft Voting vs. MobileNetV3-Large	+4.3	< 0.001	< 0.001	0.94	Yes
Soft Voting vs. EfficientNet-Lite0	+2.9	< 0.001	< 0.001	0.91	Yes
Soft Voting vs. ShuffleNetV2	+5.0	< 0.001	< 0.001	0.96	Yes
Soft Voting vs. GhostNetV2	+2.5	< 0.001	< 0.001	0.89	Yes
Soft Voting vs. MobileOne-S1	+1.8	< 0.001	0.001	0.82	Yes
Soft Voting vs. MobileNetV4 Conv Medium	+1.2	0.002	0.010	0.71	Yes
Soft Voting vs. Hard Voting	+1.0	0.003	0.012	0.69	Yes
Soft Voting vs. Bagging	+0.7	0.009	0.027	0.58	Yes
Soft Voting vs. Stacking	+0.2	0.118	0.118	0.27	No

recall of $95.8\% \pm 0.27$, F1-score of $95.5\% \pm 0.29$, and ROC-AUC of 0.991 ± 0.001. Its ROC-AUC of 0.991 compares favorably with the 0.985 obtained by MobileNetV4 Conv Medium, the strongest individual model. This margin, small as it is in absolute terms, is consistent with the individual CNNs having learned complementary feature representations that the ensemble exploits to correct isolated classification errors through probabilistic fusion [20]. The comparatively low standard deviations observed across fold-seed configurations further indicate that the ensemble's performance is stable under controlled variations of the training process, suggesting that its advantage over individual models reflects the modeling strategy itself rather than a favorable fold or seed.

B. Confidence Intervals and Statistical Significance

Table II also reports the corresponding 95% confidence intervals, computed across the 15 fold-seed configurations for each model and ensemble strategy.

The confidence intervals in Table II indicate low variability for the Soft Voting Ensemble: its F1-score interval is $[95.3, 95.7]$, compared with $[93.5, 94.1]$ for MobileOne-S1 and $[90.1, 91.1]$ for ShuffleNetV2. Paired Wilcoxon signed-rank tests, described in Section III-F, assessed its advantage over each alternative method.

Table III reports accuracy gaps, raw and Holm-adjusted Wilcoxon p-values, and rank-biserial effect sizes (r_{rb}). After Holm correction, the comparison with Stacking does not reach significance at $\alpha = 0.05$, consistent with its confidence intervals overlapping those of weighted soft voting in Table II. The advantage over every individual CNN and the Hard Voting and Bagging ensembles remains significant.

C. Cross-Dataset Validation

To evaluate robustness under acquisition conditions never seen during training, all trained models were additionally tested on the Tiny MosquitoSong+ [16], HumBugDB [15], and ABuzz datasets. Table IV reports the F1-score and ROC-AUC obtained by each model on these three external datasets.

TABLE IV
CROSS-DATASET VALIDATION RESULTS. BEST VALUES FOR EACH DATASET ARE SHOWN IN BOLD.

Model	F1-score (%)	ROC-AUC
Tiny MosquitoSong+		
MobileNetV3-Large	72.4	0.806
EfficientNet-Lite0	74.8	0.827
ShuffleNetV2	71.3	0.793
GhostNetV2	75.6	0.839
MobileOne-S1	77.1	0.851
MobileNetV4 Conv Medium	78.3	0.864
Soft Voting Ensemble	**80.7**	**0.901**
HumBugDB		
MobileNetV3-Large	74.1	0.831
EfficientNet-Lite0	76.5	0.851
ShuffleNetV2	73.0	0.816
GhostNetV2	77.2	0.862
MobileOne-S1	78.8	0.876
MobileNetV4 Conv Medium	80.1	0.889
Soft Voting Ensemble	**87.4**	**0.951**
ABuzz		
MobileNetV3-Large	77.8	0.861
EfficientNet-Lite0	79.1	0.878
ShuffleNetV2	75.9	0.842
GhostNetV2	81.0	0.893
MobileOne-S1	80.4	0.886
MobileNetV4 Conv Medium	83.2	0.914
Soft Voting Ensemble	**89.1**	**0.963**

Among the individual architectures, MobileNetV4 Conv Medium again achieved the highest ROC-AUC on all three external datasets (0.864 on Tiny MosquitoSong+, 0.889 on HumBugDB, and 0.914 on ABuzz), mirroring its lead on the in-domain Wingbeats evaluation.

The ensemble achieved the highest F1-score and ROC-AUC on all three external datasets: F1-scores of 80.7%, 87.4%, and 89.1%, and ROC-AUC values of 0.901, 0.951, and 0.963 on Tiny MosquitoSong+, HumBugDB, and ABuzz, respectively. Its ROC-AUC gains over the best individual model were 0.037, 0.062, and 0.049, exceeding the 0.006 gain on Wingbeats. This pattern suggests potential benefits under the acquisition-related shifts represented by these benchmarks, but does not establish robustness in operational field settings.

D. Overall Discussion

The low variability across 15 fold-seed configurations indicates stable classification performance under controlled changes in data partition and training stochasticity. External-dataset results are consistent with improved robustness from realistic noise augmentation [16], [19], but this contribution cannot be isolated without the augmentation ablation discussed in Section IV-E.

Weighted soft voting outperformed all individual CNNs, consistent with complementary acoustic representations [20]. Architectural differences—including channel shuffling, attention, hardware-aware design, and structural reparameterization—provide a plausible basis for this diversity [21], [22], [25], [26]; their individual contributions nevertheless require ablation studies.

Table III reports significant advantages over every individual model and the Hard Voting and Bagging ensembles after Holm correction, but not over Stacking. Unlike stacking, weighted soft voting requires no additional meta-classifier: it combines model probabilities using normalized validation F1-scores. It therefore offers a simpler combination procedure with higher mean performance, without establishing statistical superiority over stacking. Reusing existing lightweight architectures avoids designing a new network, but does not establish real-time feasibility on embedded hardware.

E. Limitations

Although the proposed methodology achieved promising results, some limitations should be acknowledged, both to contextualize the present findings and to guide future work. The models were trained primarily on the Wingbeats dataset, which consists of recordings acquired under controlled laboratory conditions. Realistic environmental noise from the TUT Acoustic Scenes 2017 dataset was incorporated during augmentation, but the acoustic characteristics of field recordings may still differ due to environmental factors. The framework was evaluated combining noise augmentation with the full six-architecture ensemble, so the individual contribution of each design choice cannot be isolated from the results reported here. In particular, no augmentation ablation was performed to contrast models trained with and without noise-augmented samples;likewise, no architecture ablation, such as a systematic leave-one-out analysis removing each CNN from the ensemble in turn, was conducted. None of the datasets used in this study, including the three external benchmarks, was collected through a deployed acoustic trap operating continuously in an uncontrolled field environment. Real-world monitoring introduces additional challenges that curated datasets only partially capture, such as wind noise, sounds from co-occurring insect species, variable microphone hardware and placement, and natural mosquito flight behavior. Field trials with prototype smart traps, evaluated over extended periods and multiple sites, are therefore necessary before the practical robustness of the proposed framework can be considered validated. End-to-end latency, memory use, and energy consumption on target hardware were not measured; real-time embedded feasibility therefore remains unestablished.

Finally, the present study focused exclusively on species classification from isolated, single-insect wingbeat recordings. Future work should extend the framework to the simultaneous detection of multiple insects, complete the ablation and computational-cost analyses outlined above, and assess deployment feasibility through target-hardware benchmarks and field trials under real environmental conditions.

***Abstract*—Task-based image quality assessment plays an important role in digital mammography, as conventional objective image quality metrics do not necessarily reflect lesion detectability. Model Observers, such as the Channelized Hotelling Observer (CHO), provide a practical alternative to human reader studies by quantitatively assessing signal detectability in medical images. This study proposes a machine learning approach to estimate the CHO response from quantitative image descriptors and acquisition parameters. Four regression algorithms (XGBoost, Random Forest, KNN, and SVR) were trained on radiomic features extracted with the PyRadiomics library, combined with microcalcification size and exposure level (mAs). Among the evaluated models, tree-based ensemble methods substantially outperformed instance- and kernel-based approaches. XGBoost achieved the best overall performance ($R^2 = 0.922$, NRMSE $= 5.1\%$), followed by Random Forest ($R^2 = 0.864$, NRMSE $= 6.8\%$), whereas KNN and SVR exhibited limited generalization capacity ($R^2 < 0.47$). Analysis across experimental conditions indicates that predictive performance was independent of physical acquisition parameters, as lower doses and smaller microcalcifications did not systematically degrade prediction accuracy. Feature importance analysis suggests that first-order radiomic descriptors (skewness and kurtosis) were the primary predictors but the physical acquisition parameters contributed with important information, especially to the tree-based methods. These findings suggest that radiomic features combined with acquisition-related physical parameters can be used to estimate model observer responses, indicating that image characteristics and acquisition conditions contain information related to signal detectability.**

***Index Terms*—Digital mammography, image quality assessment, Channelized Hotelling Observer, radiomics, machine learning models.**

I. Introduction

Breast cancer is one of the leading causes of cancer-related death among women, and early detection is essential for improving the chances of successful treatment [1]. Globally, approximately one in every 20 women will be diagnosed with breast cancer during their lifetime, and it is estimated that by 2050, 3.2 million new cases will be diagnosed, resulting in approximately 1.1 million breast cancer-related deaths [2]. Medical imaging plays a crucial role in the early detection of breast cancer, enabling timely and appropriate treatment and thereby significantly reducing breast cancer mortality [3], [4].

Digital Mammography (DM) is currently the standard imaging modality for detecting masses, microcalcifications, and other breast abnormalities. In this technique, a two-dimensional image of the compressed breast is acquired using X-rays [5]. X-ray imaging examinations inevitably involve exposure to ionizing radiation, and the associated risks must be carefully considered. Therefore, clinical practice seeks to balance image quality and radiation dose in order to minimize

This work was supported by the São Paulo Research Foundation (FAPESP; Grants No. 2021/12673-6 and 2026/18409-2), the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES; Finance Code 001), and the Brazilian National Council for Scientific and Technological Development (CNPq; Grant No. 303251/2025-5).

patient risk while ensuring that the acquired image is adequate for its intended diagnostic task [6], [7].

Image quality plays a critical role in mammography, as both the presence of diagnostically relevant information in the image and the radiologist's ability to interpret it are essential for an accurate diagnosis. Studies have shown that image noise directly affects the detectability of microcalcifications and the discrimination of breast masses [8], [9].

Therefore, assessing the quality of a medical image involves evaluating the observer's ability to interpret the image and detect lesions. However, many studies rely solely on objective image quality metrics based on the images visual characteristics. The limitation of this approach is that such metrics do not always capture image features that are relevant to lesion detection by human observers, whose performance ultimately determines the diagnostic effectiveness of image restoration techniques [10].

Another approach to assessing the diagnostic quality of medical images is through clinical reader studies, in which expert radiologists evaluate clinical images for the presence or absence of lesions [11], [12]. Depending on the study design, readers may also identify lesion locations and assign confidence scores to their detection decisions. However, this type of evaluation has several limitations, including the logistical complexity of conducting reader studies. Such studies require the availability of experienced readers, dedicated image-viewing workstations, and sufficiently large clinical image datasets, while also being time-consuming, particularly when a large number of images must be evaluated.

To address these limitations, model observers have been developed to simulate human observer performance using mathematical and statistical methods based on signal and noise properties [13], [14]. Their use provides a practical approach to image quality assessment while reducing the reliance on human observers.

In this study, we propose estimating the response of a model observer using four regression models trained on quantitative image descriptors and imaging parameters, including radiomic features, microcalcification size, and the product of tube current and exposure time (mAs). The objective is to investigate whether these image descriptors and acquisition-related parameters contain sufficient information to reproduce the model observer response, thereby evaluating their potential as a quantitative representation of image quality for diagnostic tasks.

II. Materials and Methods

A. Dataset

The dataset used in this study was developed from images acquired at the Breast Clinic of Skåne University Hospital, Malmö, Sweden, using a Mammomat Inspiration full-field digital mammography (FFDM) system (Siemens Healthineers, Forchheim, Germany). The images were obtained from an anthropomorphic breast phantom (PhantomX GmbH, Berlin, Germany) [18].

Images were acquired at five tube current–time products: 90, 110, 125, 200, and 250 mAs. The 125 mAs setting was the standard exposure automatically selected by the Automatic Exposure Control (AEC) system.

To generate images containing microcalcifications of different sizes, a uniform polymethyl methacrylate (PMMA) phantom with an insert sheet containing microcalcification patterns was used. The microcalcification diameters ranged from 150 to 310 μm, with increments of 40 μm. Ten images were acquired at 200% of the AEC exposure using the PMMA phantom with the microcalcification insert sheet.

Subsequently, the microcalcifications were cropped and artificially inserted into the mammographic images using a method developed by our research group [19], [20]. The method identifies dense breast regions using the software package developed by the Laboratory for Breast Radiodensity Assessment [21] and inserts the microcalcification cluster into the selected region. Each insertion was performed within a 150 × 150-pixel region of interest, at different locations in the breast image, to provide variability in background tissue and texture for the detection task. An example of the dataset is shown in Fig. 1.

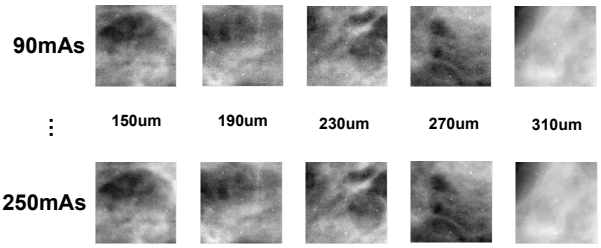

Fig. 1: Representative image patches illustrating the experimental conditions considered in this study. Images are shown for five microcalcification sizes (150–310 μm) and five exposure levels (90–250 mAs).

B. Model Observer

Model Observer is a mathematical and statistical approach based on signal and noise properties that aim to simulate the performance of human observers in diagnostic tasks. Rather than replacing clinical reader studies, they are intended to efficiently identify and address potential issues before investing the time and resources required for evaluations involving human observers [22].

One of the most widely used model observers for medical imaging and detectability assessment is the Channelized Hotelling Observer (CHO). Originally proposed by Kyle J. Myers and Harrison H. Barrett in the 1980s [23], the CHO processes input images through a set of frequency-domain channels designed to model the response of the human visual system. These channels extract task-relevant information from the image and may be implemented using Gabor filters, Difference-of-Gaussians (DoG) channels, Laguerre–Gauss (LG) channels, among others.

Initially, the input signal is processed by the channels, and an internal noise term, is added to the output of each channel to simulate the perceptual inefficiency of the human visual system. The channel outputs are then multiplied by the transposed

CHO template to obtain the decision variable. The template is computed as the product of the inverse covariance matrix of the channel output vectors and the difference between the mean channel responses for the two classes.

The CHO template depends on the channel type employed. The choice of channel is determined by the detection task and influences both the realism and the performance of the model observer. For example, Gabor channels are commonly used in tasks where orientation is an important feature, making them suitable for images containing directional structures. In contrast, Laguerre–Gauss (LG) channels are typically employed to detect radially symmetric signals, such as circular objects. Difference-of-Gaussians (DoG) channels, like LG channels, are rotationally symmetric but are more sensitive to edges and image contrast [25].

The CHO implementation adopted in this study was provided by the VICTRE framework, which employs Laguerre–Gauss (LG) channels [26]. LG channels are particularly suitable for detecting radially symmetric signals, such as microcalcifications, making them appropriate for the detection task investigated in this work.

The CHO is calibrated using a set of training images containing both signal-present and signal-absent cases. From these images, it estimates a template that characterizes the microcalcification cluster in the channelized feature space. During testing, each image is projected onto this template to produce a decision variable (or t-score), which quantifies the evidence for signal presence. Higher t-scores indicate a greater likelihood that the image contains a microcalcification cluster, whereas lower t-scores indicate little or no evidence of signal presence.

C. Radiomic Features

Radiomic features are quantitative metrics designed to describe and characterize medical images properties, transforming medical image analysis from a qualitative assessment into a data-driven quantitative approach [27]. These features provide objective measurements of intensity distribution, spatial relationships between different intensity levels, texture heterogeneity, shape descriptors, and other image properties, allowing subtle image characteristics to be numerically represented, thereby transforming visual information into structured, analyzable data [28].

Radiomic features were extracted using the PyRadiomics library. PyRadiomics is an open-source python package for the extraction of Radiomics features from medical imaging. The extracted radiomic features comprised first-order statistics and texture descriptors derived from gray-level matrices, including the Gray-Level Co-occurrence Matrix (GLCM), Gray-Level Run Length Matrix (GLRLM), Gray-Level Size Zone Matrix (GLSZM), Gray-Level Dependence Matrix (GLDM), and Neighboring Gray Tone Difference Matrix (NGTDM) [29]. Together, these features quantify different aspects of image appearance, such as intensity distribution, local texture, spatial organization, and structural heterogeneity.

To reduce feature redundancy and retain only informative radiomic descriptors, a two-step feature selection procedure was applied. First, features with a variance below 0.01 were removed using the VarianceThreshold method, excluding near-constant features. Then, the Pearson correlation coefficient was calculated among the remaining features using the training set only. When two features exhibited an absolute correlation coefficient greater than 0.95, one of the correlated features was removed to reduce redundancy. The same selected feature set was then applied to the test set without recalculating the selection criteria. The resulting radiomic features were combined with microcalcification size and mAs as additional predictors for the regression models, and the complete set of features is listed in Table II.

D. Regression Models

To estimate the Channelized Hotelling Observer (CHO) response, four supervised regression algorithms were evaluated: Random Forest (RF), Support Vector Regressor (SVR), K-Nearest Neighbors (KNN) and Extreme Gradient boosting (XGBoost). These methods were selected because they represent different regression strategies, such as ensemble tree-based learning, kernel-based regression, instance-based learning anda gradient boosting, respectively.

Random Forest is an ensemble learning algorithm that combines the predictions of multiple decision trees to improve predictive performance and reduce overfitting [30]. Support Vector Regression estimates nonlinear relationships by mapping the input data into a high-dimensional feature space through kernel functions, enabling non-linear relationships to be modeled as linear in the transformed feature space [31]. K-Nearest Neighbors predicts the target value based on the responses of the most similar training samples according to a distance metric [32]. XGBoost is a gradient boosting algorithm that sequentially builds decision trees to minimize prediction error, providing high predictive accuracy and robustness for structured tabular data [33].

To optimize the predictive performance of each regression model, hyperparameter tuning was performed using an exhaustive grid search combined with five-fold cross-validation on the training set. For each algorithm, multiple combinations of hyperparameters were evaluated, and the configuration yielding the highest mean coefficient of determination (R^2) across the validation folds was selected. The optimized models were subsequently retrained using the complete training set and evaluated on the independent test set.

For all models, the input variables consisted of radiomic features extracted from the images, together with acquisition-related parameters, including microcalcification size and mAs. The target variable was the CHO t-score computed for each image. Model performance was evaluated by comparing the predicted and reference CHO responses using the following regression metrics: coefficient of determination (R^2), root mean squared error (RMSE), normalized RMSE (NRMSE) and mean absolute error (MAE).

E. Pipeline

First, the model observer was applied to the dataset to compute the detectability of each image, producing a corresponding t-score that served as the reference response. Next, radiomic features were extracted from each image using the PyRadiomics library, and the most informative features were selected through a feature selection algorithm. The selected radiomic features, together with the microcalcification size and exposure level, were used as input variables for the regression models, while the model observer t-score was used as the target variable. The hyperparameters of the regression models were optimized using Grid Search with five-fold cross-validation on the training set. Finally, the optimized models were evaluated on an independent test set by comparing the predicted and reference t-score values. Figure 2 illustrates the pipeline adopted in this study.

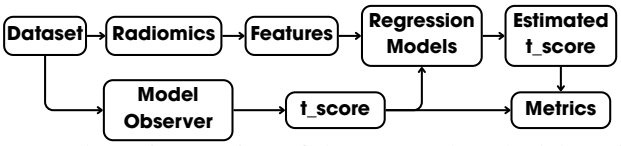

Fig. 2: Schematic overview of the proposed methodology for estimating the CHO response.

III. Results and Discussion

Table I summarizes the quantitative performance of the evaluated regression models.

TABLE I: Performance metrics of the evaluated regression models for CHO t-score prediction.

Models	R^2	NRMSE	RMSE	MAE
XGBoost	0.922	0.051	7.12	4.89
Random Forest	0.864	0.068	9.43	6.49
KNN	0.471	0.163	18.57	12.31
SVR	0.323	0.152	21.012	15.57

Among all approaches, XGBoost achieved the best predictive performance, with the highest coefficient of determination ($R^2 = 0.922$), indicating that approximately 92% of the variability in the observer t-score was explained by the input variables. It also yielded the lowest prediction errors, with an RMSE of 7.12, an NRMSE of 5.1%, and an MAE of 4.89, demonstrating its superior ability to estimate the model observer response.

Random Forest also demonstrated strong predictive performance, achieving an R^2 of 0.864 and relatively low error metrics, although it was outperformed by XGBoost. KNN and SVR models exhibited substantially lower predictive accuracy, with R^2 values of 0.471 and 0.323, respectively, together with considerably higher RMSE and MAE values. These results suggest that tree-based ensemble methods were more effective in modeling the relationship between the selected radiomic features and the model observer response than the instance-based and kernel-based regression approaches.

Figure 3 compares the parity plots obtained for the evaluated

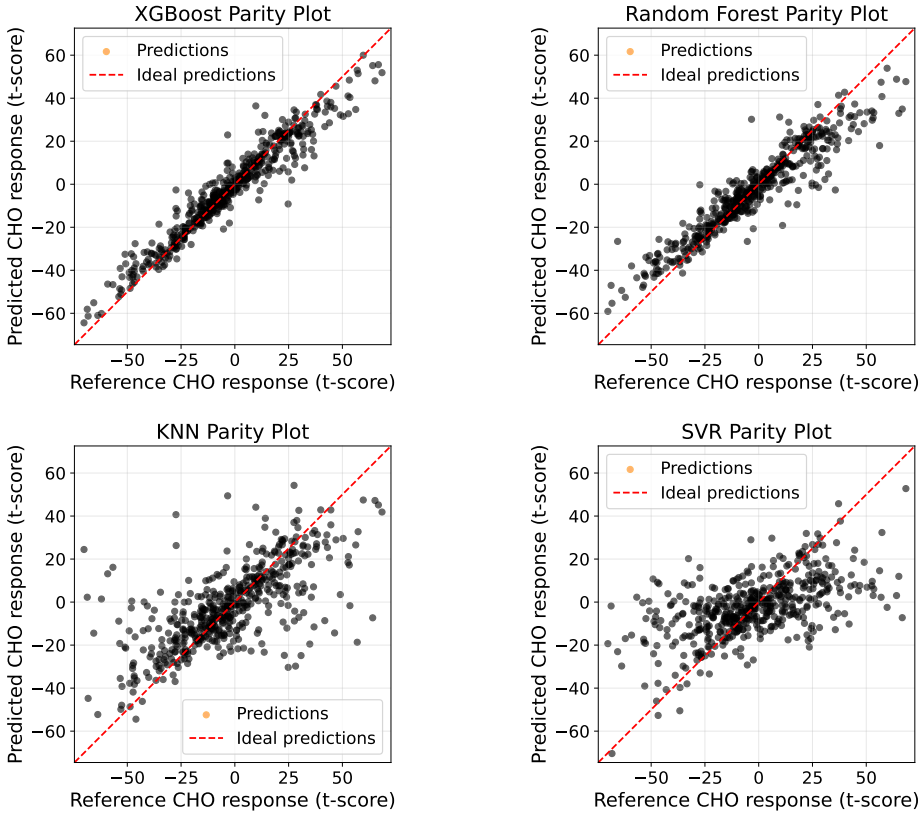

Fig. 3: Parity plots comparing the predicted and reference t-score values for the evaluated regression models: (a) XGBoost, (b) Random Forest, (c) K-Nearest Neighbors (KNN), and (d) Support Vector Regression (SVR). The dashed red line represents the ideal agreement between predicted and reference values.

regression models. XGBoost (Fig.3(a)) exhibited the highest agreement between the predicted and reference t-score values, with most samples closely distributed around the identity line. Random Forest (Fig.3(b)) also demonstrated good predictive performance, although a slightly larger dispersion was observed, particularly for samples with very high and very low t-score values.

KNN (Fig. 3(c)) and SVR (Fig. 3(d)) presented greater deviations from the identity line. For both models, the predictions were concentrated around the central range of the t-score distribution, indicating limited ability to reproduce extreme values. This behavior resulted in the underestimation of high t-score values and the overestimation of low t-score values, which is consistent with their lower coefficients of determination and higher prediction errors reported in Table I.

Despite the superior performance of XGBoost and Random Forest, all models exhibited a slight tendency to overestimate low t-score values and underestimate high t-score values, indicating reduced prediction accuracy under conditions associated with both low and high detectability. This behavior may be partially attributed to the lower number of samples available at the extremes of the t-score distribution, which can limit the ability of the regression models to predict these less represented conditions.

Figure 4 shows the local R^2 values across all experimental conditions, evaluating whether model performance is systematically influenced by physical acquisition parameters. Overall, predictive performance showed no consistent dependence on either exposure level (mAs) or microcalcification size. Lower radiation doses and smaller microcalcifications did not systematically degrade R^2 values, suggesting that these physical factors alone are not determinants of prediction accuracy. However, the results across the experimental matrix varied considerably by algorithm. Tree-based ensemble models (XGBoost and Random Forest) exhibited higher and more consistent R^2 scores across combinations, indicating that these models can maintain robust predictions regardless of noise level or signal scale. KNN and SVR displayed lower overall

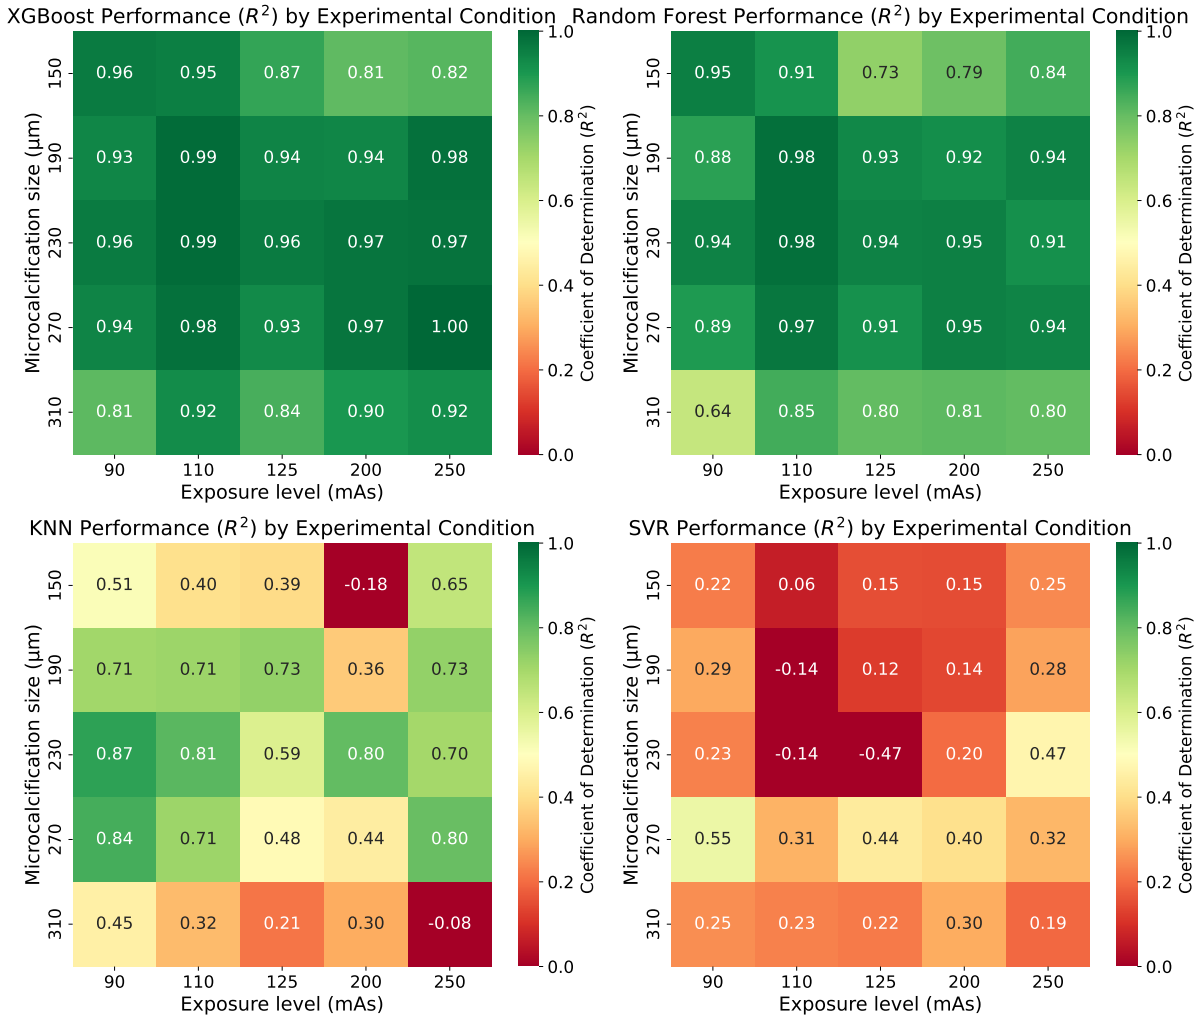

Fig. 4: Heatmaps of the coefficient of determination (R^2) obtained for (a) XGBoost, (b) Random Forest, (c) K-Nearest Neighbors (KNN), and (d) Support Vector Regression (SVR) as a function of exposure level (mAs) and microcalcification size. Higher values indicate higher prediction accuracy.

R^2 values and pronounced local fluctuations across conditions. Rather than a systematic physical trend, this variability reflects the limited generalization capacity of these two algorithms for this task.

The superior performance of Random Forest and XGBoost can be attributed to their ability to model complex nonlinear relationships between the selected features and the CHO t-score while naturally capturing interactions between radiomic features and acquisition-related physical parameters. These tree-based ensemble methods are particularly well suited to representing the heterogeneous characteristics of mammographic images, allowing them to produce more accurate predictions than KNN and SVR. In contrast, KNN relies on local similarity between samples and tends to produce predictions biased toward the average response when neighboring samples exhibit substantial variability. Similarly, although SVR can model nonlinear relationships through kernel functions, its performance is highly dependent on the choice of kernel and hyperparameters, which may limit its ability to accurately represent the complex relationship between these features and the CHO t-score.

Since Random Forest and XGBoost were the best-performing models and provided native feature importance measures, their feature importance rankings are shown in Table II, and the four highest values were highlighted. KNN and SVR do not provide directly interpretable feature importance measures and therefore were not included in this analysis.

TABLE II: Feature importance scores obtained from the Random Forest and XGBoost models.

Feature Classes	Features	Feature Importance Values	
		XGBoost	Random Forest
firstorder	Skewness	**0.157**	**0.226**
firstorder	Kurtosis	**0.132**	**0.218**
glrlm	LRHGLE	**0.103**	**0.108**
-	mAs	**0.095**	0.008
glrlm	LRLGLE	0.061	0.038
glrlm	GLNU	0.056	0.051
firstorder	Variance	0.053	0.016
firstorder	InterquartileRange	0.050	0.030
glcm	ClusterProminence	0.048	0.016
glcm	Autocorrelation	0.044	0.027
firstorder	Entropy	0.035	0.016
glrlm	LongRunEmphasis	0.034	0.026
ngtdm	Busyness	0.033	0.024
firstorder	10Percentile	0.030	0.034
-	MC_size	0.025	**0.109**
gldm	DN	0.023	0.033
firstorder	Range	0.021	0.017

In particular, Skewness and Kurtosis received the highest importance scores in both models. These features describe the shape of the gray-level intensity distribution, suggesting that the asymmetry and peakedness of the image histogram are strongly associated with the CHO t-score. Also, the Long Run High Gray Level Emphasis indicates that the presence of large, homogeneous, and bright areas in the image is a critical factor in the algorithm's decision. The inclusion of microcalcification size and mAs among the most relevant predictors indicates that the physical parameters also contribute to the prediction, as these factors directly influence detectability.

To assess the contribution of acquisition- and signal-related parameters, an additional experiment was performed using only radiomic features as predictors. The local R^2 values across the same experimental conditions are shown in Figure 5.

The exclusion of mAs and microcalcification size reduced the predictive performance of Random Forest and XGBoost, particularly for the smaller microcalcifications, suggesting that the acquisition and signal-related parameters provide relevant complementary information for predicting the CHO response under these conditions. In contrast, KNN showed an overall improvement in predictive performance when these parameters were excluded, with the most pronounced improvement observed for larger microcalcification sizes. SVR maintained a relatively poor predictive performance and showed a further reduction in R^2 across most experimental conditions when the physical parameters were excluded.

Overall performance metrics for this experiment are shown in table III.

TABLE III: Performance metrics of the evaluated regression models for CHO t-score prediction without physical parameters.

Models	R^2	NRMSE	RMSE	MAE
XGBoost	0.756	0.091	12.62	9.67
Random Forest	0.769	0.089	12.27	9.50
KNN	0.745	0.093	12.91	10.09
SVR	0.258	0.159	22.01	16.89

For Random Forest, the R^2 decreased from 0.864 to 0.769, while for XGBoost it decreased from 0.922 to 0.756. In contrast, KNN exhibited an improvement when only radiomic features were used, with the R^2 increasing from 0.471 to 0.745, while the RMSE decreased from 18.57 to 12.91. This different behavior may be related to the sensitivity of distance-based methods to the predictor space. The inclusion of additional acquisition-related variables changes the geometry of the feature space and may affect the distances between samples used by KNN, even when the variables are appropriately scaled.

SVR showed a decrease in performance when the acquisition parameters were excluded, from $R^2 = 0.323$ to $R^2 = 0.258$. Overall, these results indicate that radiomic features alone contain substantial information related to the CHO response, while the contribution of acquisition-related parameters depends on the regression model used.

IV. Conclusion

This study investigated whether the response of the Channelized Hotelling Observer (CHO) can be estimated using machine learning regression models based on radiomic features together with acquisition-related parameters. Among the evaluated approaches, XGBoost achieved the best predictive performance, with an R^2 of 0.922 and an NRMSE of 5.1%, followed by Random Forest with an R^2 of 0.864 and an

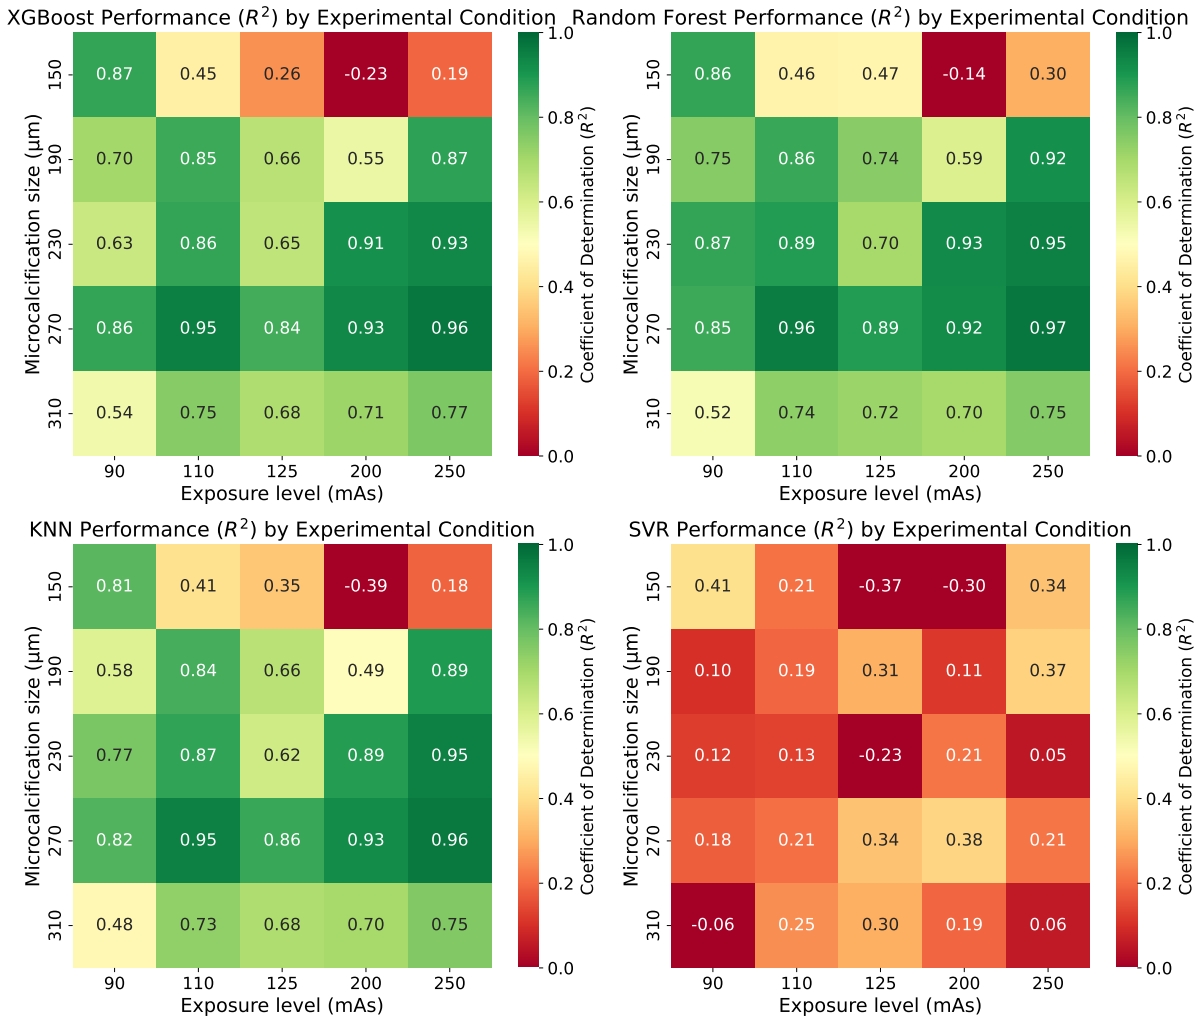

Fig. 5: Heatmaps of the coefficient of determination (R^2) obtained for (a) XGBoost, (b) Random Forest, (c) K-Nearest Neighbors (KNN), and (d) Support Vector Regression (SVR) across different microcalcification sizes and exposure levels (mAs), trained using radiomic features only. Higher values indicate higher prediction accuracy.

NRMSE of 6.8%. The analysis using radiomic features alone showed that these descriptors contain substantial information related to the CHO response, although the inclusion of microcalcification size and mAs further improved the performance of the tree-based models. Feature importance analysis indicated that first-order radiomic descriptors, particularly skewness and kurtosis, were among the most relevant predictors, suggesting that radiomics can capture image characteristics associated with observer detectability. Error analysis also revealed a tendency to overestimate low t-scores and underestimate high t-scores, indicating a regression-to-the-mean behavior across the evaluated models. Future work should focus on improving prediction accuracy at the extremes of the t-score distribution by acquiring additional samples under low- and high-detectability conditions and including greater variation in background complexity, such as denser and less dense breast regions.

***Abstract*—Dysphagia is a common complication in neurodegenerative diseases such as Amyotrophic Lateral Sclerosis and Parkinson's disease, requiring accessible diagnostic tools for telemedicine applications. Acoustic analysis of swallowing sounds using laryngophones offers a promising non-invasive approach, but current automatic detection methods remain below human-level agreement. This study investigates whether representations from audio foundation models pre-trained on general-domain data can improve swallowing event detection when transferred to this specialized domain. We propose lightweight adaptation strategies using frozen CLAP encoder weights, comparing zero-shot classification, linear probing, and a shallow MLP head against a classical energy detector baseline under a common leave-one-subject-out protocol. On 16 healthy subjects, zero-shot classification fails (MCC = 0.303), while both adapted heads reach MCC = 0.743–0.768 against 0.696 for the baseline. Under subject-clustered inference these differences in mean MCC are not significant at this sample size; what the data do resolve is dispersion, with adaptation roughly halving the inter-subject standard deviation from 0.13 to 0.07–0.08. The contribution is a fair subject-independent evaluation of transfer to a contact-sensor domain, and evidence that the benefit of adaptation lies in consistency across individuals rather than in mean performance. The validated scope is swallowing-event detection in healthy subjects with a single laryngophone setup; extension to dysphagia monitoring would require validation on patients, devices and sites.**

***Index Terms*—swallowing detection, CLAP, audio foundation models, laryngophone, transfer learning, linear probe**

I. Introduction

Neurodegenerative disorders such as Amyotrophic Lateral Sclerosis (ALS) and Parkinson's disease progressively impair motor functions, including the ability to swallow safely [1], [2]. Dysphagia affects a substantial proportion of these patients and carries risks of aspiration pneumonia and malnutrition. Traditional diagnostic methods require specialized equipment, limiting accessibility in remote settings. Acoustic analysis of swallowing sounds captured by laryngophones offers a non-invasive, low-cost alternative suited for telemedicine [3], [4].

Previous work established a band-limited energy detector for swallowing events, achieving MCC of 0.71 against manual annotations from three observers [5]. The gap between automatic detection and human agreement defines the improvement target. However, the baseline was evaluated in-sample, without cross-validation, meaning performance is optimistically biased.

Biomedical acoustic datasets are typically small due to the cost of clinical data collection and expert annotation. Training deep learning models from scratch on such low-resource datasets risks overfitting, motivating the use of transfer learning from pre-trained representations. Audio foundation models trained on large-scale datasets have shown strong transfer capabilities in diverse downstream tasks [6]–[8]. The CLAP model learns joint audio-text representations through contrastive learning, enabling zero-shot classification. Whether such representations transfer to laryngophone signals is unclear, given the domain mismatch between air microphones used in pre-training and contact sensors.

This work contributes a fair subject-independent evaluation of foundation model transfer to laryngophone signals, in four parts: (i) we re-evaluate a band-limited energy detector under leave-one-subject-out (LOSO) cross-validation, providing an unbiased performance estimate; (ii) we show that zero-shot classification with CLAP fails on laryngophone signals due to domain mismatch; (iii) we show that lightweight adaptation (linear probe or MLP head) with frozen encoders roughly halves the inter-subject standard deviation from 0.13 to 0.07–

0.08 under subject-clustered inference, improving consistency across unseen subjects, while the accompanying differences in mean MCC do not reach significance with 16 subjects; and (iv) we visualize the learned representations to characterize class separability and identify where errors concentrate in the embedding space.

II. Related Work

Acoustic analysis of swallowing has been investigated as a diagnostic and monitoring tool for dysphagia. Dudik et al. [3] reviewed the effects of dysphagia on swallowing sounds and vibrations, highlighting the potential of acoustic features for distinguishing healthy from impaired swallowing. Da Silva et al. [4] applied acoustic analysis to swallowing sounds in Parkinson's disease patients, demonstrating differences in spectral characteristics. Machine learning approaches to swallowing detection date back to Sazonov et al. [9], who used mel-scale features and SVMs for automatic detection of swallowing events in wearable devices. More recently, Khalifa et al. [10] applied deep learning to high-resolution cervical auscultation recordings, demonstrating the potential of CNNs for swallowing identification. The use of throat microphones, or laryngophones, offers advantages in noise rejection and signal quality for swallowing sound acquisition [11]. Sanchez-Gendriz et al. [5] developed a band-limited energy detector for swallowing events and established inter-observer agreement metrics using the Matthews Correlation Coefficient.

Foundation models for audio have emerged as powerful feature extractors for diverse tasks. General-purpose models like CLAP [6], [12], WavLM [7], and BEATs [8] learn representations from large-scale datasets and have been systematically evaluated through benchmarks such as HEAR [13]. In the health acoustics domain, Google's HeAR [14] was specifically trained on over 300 million health-related audio clips including coughs, breathing, and speech, demonstrating strong performance on respiratory disease classification. Deep learning has also been extensively applied to respiratory sounds using the ICBHI database [15]. However, most health acoustic foundation models target air-conducted sounds; transfer to contact sensors such as laryngophones remains unexplored. This work addresses this gap by evaluating whether general-purpose audio representations transfer to the distinct acoustic characteristics of contact-sensor recordings.

III. Materials and Methods

A. Dataset and Annotations

This study builds upon the dataset and annotation methodology established by Sanchez-Gendriz et al. [5]. Acoustic signals were collected from 16 healthy subjects (5 males and 11 females, median age 27.5 years) at the University Hospital Onofre Lopes (HUOL) at UFRN. The study was conducted following the guidelines approved by the Research Ethics Committee of UFRN (CAAE No. 25687819.3.0000.5537). A laryngophone, a contact microphone placed on the cervical region, was connected to a mobile phone for signal acquisition. Audio signals were recorded at 22.05 kHz with 32-bit resolution. Recording durations ranged from 14 to 33 seconds (median 26 s), capturing swallowing sounds along with physiological noise such as breathing.

The ground truth construction followed a rigorous multi-observer protocol. Three trained observers, who received specialized training in the detection of swallowing sounds, independently annotated each recording using Audacity software. Observers marked the start and end times of swallowing events based on both auditory playback and visual inspection of spectrograms. To assess reliability, each observer repeated the annotation process three times, yielding nine annotation sets per recording.

Annotations were converted to binary detection masks with temporal resolution of 50 ms per bin. For each observer, a bin was marked positive if at least two of three repetitions indicated a swallowing event (intra-observer aggregation). The final ground truth then took the union across observers: a bin is positive if any one of the three marked it. This is an inclusive criterion, chosen so that events seen by a single annotator are not discarded, and it means the reference is not uniformly certain: 60.3% of positive bins carry all three observers, 17.9% two and 21.8% only one. Section IV-E exploits this gradation to separate label ambiguity from detector error. The original study reported intra-observer MCC values of 0.84, 0.92, and 0.88. To establish a fair performance ceiling for our models, we compute each observer's MCC against the leave-one-out consensus of the other two, yielding MCC = 0.827 ± 0.048 (see Section IV).

The dataset exhibits severe class imbalance: prevalence of positive bins is approximately 9%. This makes accuracy misleading, motivating MCC as the primary metric [16].

B. Evaluation Protocol

All trained models follow leave-one-subject-out (LOSO) cross-validation. In each of 16 folds, one subject is held out for testing while 15 are used for training. This protocol applies to the energy detector baseline, linear probe, and MLP head. To prevent data leakage, every fitting and selection step within a fold uses training data only. The energy detector performs its grid search by pooling the 15 training subjects, and the held-out subject is never scored during selection. The linear probe fits the feature scaler on training embeddings alone and applies the resulting transformation unchanged to the test subject. For the MLP head, one of the 15 training subjects serves as an inner validation set, selected by a fixed rule in which fold k uses subject $(k+1) \bmod 16$. The model is trained on the remaining 14, and the checkpoint maximizing inner-validation MCC is selected; the validation subject is by construction disjoint from the test subject. Head architecture and all hyperparameters were fixed a priori and held identical across the 16 folds, and the decision threshold is fixed at 0.5 for both adapted models with no post-hoc adjustment. The split by subject ensures that no information from the test

subject influences model development, avoiding leakage from temporally correlated bins within the same recording.

The zero-shot experiment constitutes an exception: since no training occurs, LOSO is not applicable. Instead, we optimize the decision threshold directly on all data, providing an upper bound on zero-shot performance.

We report two complementary metrics. The primary metric is pooled MCC, computed by aggregating all predictions and ground truth labels across the 16 folds into a single confusion matrix, then calculating MCC from this pooled matrix. This provides a global measure of performance across the entire dataset. Additionally, we compute MCC separately for each subject and report the standard deviation across subjects, which characterizes how consistently a method performs on individuals it was not trained on.

C. Experiments

We conducted four experiments to systematically evaluate the potential of foundation model representations for swallowing detection.

1) Experiment 1: Baseline Reproduction: The first experiment reproduces the band-limited energy detector from [5] under proper LOSO validation. The detector computes Short-Time Fourier Transform (STFT) coefficients and extracts energy within a frequency band $[f_{\text{low}}, 2000]$ Hz. A moving average filter smooths the energy, and detection occurs when the smoothed energy exceeds a threshold $\theta = r_{\text{std}} \times \sigma(E_{\text{smoothed}})$.

Two hyperparameters are tuned via grid search over the same space as the original study: the lower cutoff frequency $f_{\text{low}} \in \{50, 100, \ldots, 1000\}$ Hz, and the threshold multiplier $r_{\text{std}} \in \{0.05, 0.10, \ldots, 1.00\}$. This yields $20 \times 20 = 400$ parameter combinations per fold. Searching the full grid rather than a restricted range avoids assuming that the optimum reported in-sample by [5] ($f_{\text{low}} = 700$ Hz, $r_{\text{std}} = 0.20$) transfers to every training partition. For each LOSO fold, grid search is performed on the 15 training subjects by pooling their predictions and computing a single MCC score for each parameter combination. The parameters maximizing training MCC are then applied to the held-out subject. This nested procedure ensures that hyperparameter selection does not use test data. This experiment quantifies the bias introduced by in-sample evaluation in the original work. Figure 1 illustrates this processing pipeline.

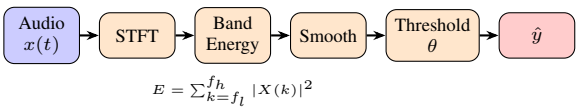

Fig. 1. Energy detector pipeline: STFT followed by band-limited energy extraction, smoothing, and thresholding.

2) Experiment 2: CLAP Zero-Shot Classification: The second experiment evaluates zero-shot classification using LAION-CLAP [6], specifically the `630k-audioset-best.pt` checkpoint with the HTSAT-base audio encoder (`laion-clap` library v1.1.4). We selected CLAP over alternatives such as WavLM [7] or BEATs [8] for three reasons: (1) CLAP produces a single 512-dimensional embedding per audio segment, avoiding the need to aggregate frame-level representations; (2) the joint audio-text embedding space enables zero-shot classification, allowing us to test whether swallowing can be detected without any task-specific training; and (3) CLAP was trained on general audio including environmental sounds, whereas WavLM focuses on speech. Classification uses cosine similarity between audio and text embeddings [12].

Since LAION-CLAP operates at 48 kHz while the recordings were captured at 22.05 kHz, we upsample the audio using linear interpolation before embedding extraction. This upsampling does not create spectral content above the original Nyquist frequency (11 kHz), leaving the upper half of CLAP's expected bandwidth empty. We extract 512-dimensional embeddings using a sliding window of 480 ms with 50 ms hop, aligning with the annotation grid. For classification, we compute the difference between cosine similarity to positive prompts and cosine similarity to negative prompts. Negative prompts include "silence", "breathing sound", "background noise", and "coughing sound". We evaluate four positive prompt categories to assess sensitivity to prompt engineering: simple ("swallowing sound", "gulp sound"), descriptive ("the sound of a person swallowing water" and variants), medical ("deglutition sound", "pharyngeal swallow sound") and a combination of these. The decision threshold is optimized on all data, providing an upper bound on zero-shot performance.

3) Experiment 3: Linear Probe: The third experiment trains a logistic regression classifier on frozen CLAP embeddings, following the linear probing paradigm commonly used to evaluate pre-trained representations. The same 512-dimensional embeddings from Experiment 2 are used, with the CLAP encoder weights kept frozen throughout training. For each LOSO fold, embeddings are standardized to zero mean and unit variance using statistics computed exclusively on the training fold; the same transformation is then applied to the test fold. We use scikit-learn's LogisticRegression with the L-BFGS solver, balanced class weighting (inversely proportional to class frequencies), and default L2 regularization ($C = 1.0$). Critically, no hyperparameter tuning is performed: all settings are fixed a priori, including a decision threshold of 0.5 with no post-hoc adjustment. This deliberate choice makes the linear probe a minimal-adaptation baseline that isolates the contribution of CLAP features. If the probe outperforms the energy detector despite zero tuning effort, the gain is attributable to the quality of the pre-trained representations rather than to careful engineering. The pipeline is that of Figure 2 with the MLP head replaced by logistic regression.

4) Experiment 4: MLP Head: The fourth experiment replaces logistic regression with a shallow multilayer perceptron (MLP) to assess whether non-linear combinations of features improve performance. All hyperparameters were fixed a priori, before any LOSO evaluation, to ensure a fair comparison with the baseline. The architecture consists of three fully-connected layers: $512 \rightarrow 128 \rightarrow 64 \rightarrow 1$, with ReLU

activations and dropout ($p = 0.3$) after each hidden layer. The output uses sigmoid activation for binary classification. We train using binary cross-entropy loss with positive class weighting $w_+ = 10$, which corresponds to the inverse class frequency (negative/positive ratio ≈ 10.3). Optimization uses Adam with initial learning rate 10^{-3} and ReduceLROnPlateau scheduling (patience 3, factor 0.5). Training runs for 20 epochs with batch size 64. Inner validation follows the fixed rule described in Section III-B: the model trains on 14 subjects and the checkpoint maximizing inner-validation MCC is selected. As with the linear probe, the decision threshold is fixed at 0.5 with no post-hoc adjustment. To verify that the result does not depend on a particular initialization, the full LOSO procedure was repeated across five random seeds, yielding MCC $= 0.766 \pm 0.008$. This design tests whether a lightweight non-linear head can extract additional discriminative information from the frozen embeddings. Figure 2 illustrates this architecture.

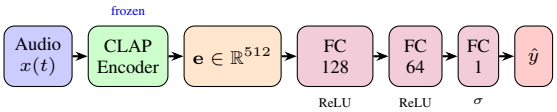

Fig. 2. MLP head pipeline: frozen CLAP encoder with trainable three-layer MLP classifier.

D. Representation Analysis

To understand the structure of CLAP embeddings, we perform dimensionality reduction using UMAP and visualize the embedding space colored by class label and detection outcome. This analysis reveals whether swallowing events form separable clusters and characterizes where classification errors concentrate in the representation space.

IV. Results

A. Main Results

Table I presents the performance of all evaluated methods. The energy detector reproduced under LOSO cross-validation achieves MCC = 0.696 with a standard deviation of 0.13 across subjects. This is below the 0.712 reported in [5], confirming the expected drop when proper cross-validation replaces in-sample evaluation. The bias, 0.015 MCC at full precision, is modest but demonstrates that the original results were optimistically biased.

Zero-shot classification with CLAP embeddings and text prompts yields MCC = 0.303, well below the baseline. This result was obtained with the threshold optimized directly on the test data, meaning it represents an upper bound on zero-shot performance. The failure is unsurprising given the domain mismatch between air microphone recordings in the pre-training data and the contact sensor used here, combined with the absence of swallowing as a concept in the pre-training vocabulary.

The linear probe reaches MCC = 0.743 and the MLP head 0.768, both above the baseline's 0.696 in mean MCC. Subject-clustered inference, however, finds none of the three pairwise contrasts significant at this sample size (all $p \geq 0.21$; see Limitation 6), so we treat the two adaptation strategies as empirically equivalent and read the ordering of means as suggestive rather than established. What the intervals do resolve is dispersion: both adapted methods roughly halve the inter-subject standard deviation, from 0.13 to 0.07–0.08.

To establish a fair comparison ceiling, we apply a leave-one-observer-out procedure analogous to LOSO for models. For each of the three observers, we exclude that observer from the ground truth computation and calculate the consensus using only the other two (a bin is positive if both remaining observers agree). We then compute MCC between the excluded observer's annotations and this two-observer consensus. This yields individual MCCs of 0.852 (Obs1), 0.857 (Obs2), and 0.771 (Obs3), with mean MCC = 0.827 $\pm$ 0.048. Observer 3 scores lower because they marked substantially more positive bins (832 vs. approximately 600 for the others), generating more false positives against the stricter two-observer consensus. This leave-one-out ceiling is the appropriate reference because models are evaluated against the same hierarchical consensus that no single observer fully determined. The MLP reduces the gap to this human ceiling from 0.131 (baseline) to 0.059.

TABLE I
Performance comparison across methods.

Method	MCC	95% CI‡	Std	F1	Rec.	Prec.
Human ceiling*	0.827	–	0.05	–	–	–
Energy (in-sample)	0.712	–	–	0.735	0.694	**0.780**
Energy (LOSO)	0.696	.610–.771	0.13	0.721	0.688	0.757
CLAP Zero-Shot†	0.303	–	–	0.266	0.167	0.657
CLAP Linear	0.743	.702–.781	0.08	0.771	0.821	0.726
CLAP MLP	**0.768**	.717–.806	**0.07**	**0.782**	**0.923**	0.678

*Each observer vs. leave-one-out consensus of other two.
†In-sample threshold optimization (LOSO not applicable).
‡Cluster bootstrap resampling subjects (10,000 replicates). All clustered inference is computed over the 8086 non-padded bins, where the methods score 0.691, 0.743 and 0.763; the MCC column uses the full grid (Limitation 7).

B. Detection Examples

Figure 3 shows the CLAP MLP detector output for the median-performing subject: laryngophone spectrogram, ground truth annotations, and predictions with detection outcomes (TP, FP, FN). The caption gives the counts for the best and worst subjects.

Across the performance range the failure mode is consistent: recall stays high while false positives vary, so errors concentrate on specificity rather than sensitivity.

C. Event-Level Evaluation

A 50 ms bin is not the clinical unit of interest, so we complement the bin-level MCC with an event-level analysis. Consecutive positive bins form events, and a detection counts

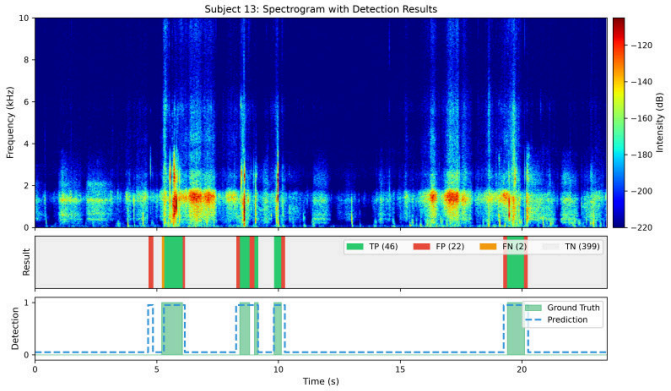

Fig. 3. CLAP MLP detector output for the median-performing subject (S13: 46 TP, 22 FP, 2 FN), showing the laryngophone spectrogram, annotated events and predictions. Performance across the cohort ranges from 24 TP / 10 FP / 0 FN (best, S03) to 57 TP / 76 FP / 0 FN (worst, S08); recall stays high throughout while the false positive rate varies.

as a hit when its onset falls within 250 ms of an annotated onset, matched greedily one-to-one. The tolerance follows from the annotations: the 64 annotated events have a median duration of 0.65 s, so 250 ms lies well inside a typical event.

Table II qualifies the bin-level picture. Without a duration filter the ranking inverts: the energy detector, last by MCC, raises the fewest false alarms per minute. The cause is fragmentation. The CLAP heads recover more true positive bins (787 and 700, against 587) but scatter them across short spurious detections. 33% of the MLP's and 48% of the linear probe's last no longer than 150 ms, against 8% for the energy detector, and each fragment counts as a separate false alarm.

Because the shortest annotated event lasts exactly 150 ms, discarding shorter detections removes no real event. Under that filter the MLP attains both the highest event sensitivity (0.938) and fewer false alarms than the linear probe (2.97 versus 3.86/min), while the energy detector stays most conservative (1.93). Onset error is small and comparable throughout (median $\leq$ 100 ms, IQR 100 ms), so the methods differ in how often they fire, not in when. We report both variants because the fragmentation is real, and a deployed system would have to post-process it.

TABLE II
EVENT-LEVEL PERFORMANCE AT 250 MS ONSET TOLERANCE. FA/MIN IS FALSE ALARMS PER MINUTE OVER 6.7 MINUTES OF RECORDING CONTAINING 64 ANNOTATED EVENTS.

	No filter			$\geq$150 ms		
Method	**Sens.**	**Prec.**	**FA/min**	**Sens.**	**Prec.**	**FA/min**
Energy (LOSO)	0.891	**0.792**	**2.23**	0.859	**0.809**	**1.93**
Linear probe	**0.938**	0.426	12.02	0.906	0.690	3.86
CLAP MLP	**0.938**	0.522	8.16	**0.938**	0.750	2.97

Onset error medians: 0 ms (energy), −50 ms (linear probe), −100 ms (MLP); IQR 100 ms throughout, negative means early.

Figure 4 shows bin-level precision-recall curves, obtained by refitting the heads on the cached embeddings under the same LOSO protocol to recover continuous scores. Average precision is 0.863 for the MLP and 0.850 for the linear probe against a chance level of 0.105, and the curves overlap across most of the operating range, the same equivalence the significance tests report. Markers show the fixed 0.5 threshold, set a priori and not re-tuned here; at that point the MLP favours recall (0.923) over precision (0.678) while the linear probe is more balanced, and the curves show what either method would trade if a different operating point were chosen.

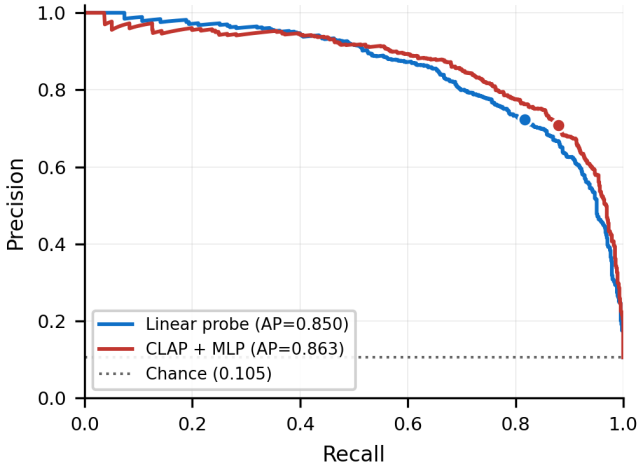

Fig. 4. Bin-level precision-recall curves for the adapted methods. Markers show the fixed 0.5 threshold applied to the refitted heads, which sit up to 0.04 in recall off the Table I operating points.

D. Per-Subject Performance

Figure 5 displays the MCC distribution across subjects for each trained method. The energy detector exhibits high variance, with some subjects yielding MCC above 0.80 and others below 0.55. The CLAP-based methods show a compressed distribution with fewer outliers. This reduction in variance is the central finding of the study: the differences in mean MCC do not survive subject-clustered testing, whereas the gain in predictability across individuals is what the data support.

E. Label Uncertainty and Error Attribution

Because the reference is a union across annotators, the number of observers who marked a bin measures its label confidence, separating two error sources the ceiling alone cannot distinguish. The MLP's recall tracks that measure almost perfectly: 99.6% of the 514 bins all three observers marked, 91.5% of the 153 marked by two, and 72.6% of the 186 marked by only one. It essentially never misses an event the annotators agree on, and its misses concentrate where the label is least certain, so the residual false negatives are largely a property of the reference rather than of the model.

False positives read similarly. All 374 fall, by construction, in bins no observer marked, but they are not scattered: 46.5% lie within 100 ms of an annotated event and 60.7% within

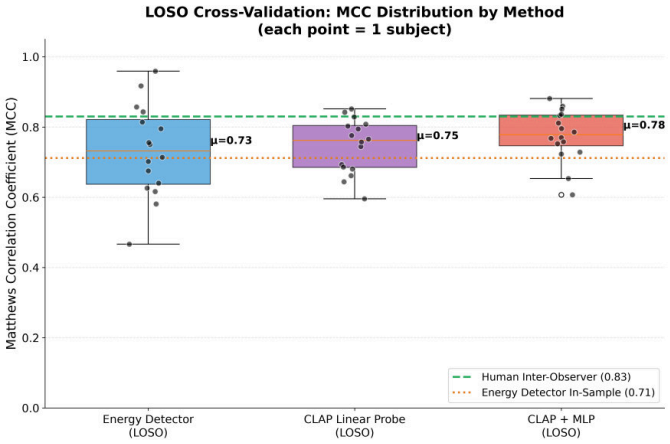

Fig. 5. Per-subject MCC distribution under LOSO cross-validation; the dashed line marks the human ceiling (0.827). Per-subject means differ from the pooled MCC of Table I by construction, since pooling aggregates all predictions into one confusion matrix: 0.696 vs. 0.732 for the energy detector and 0.768 vs. 0.776 for CLAP MLP, the larger gap reflecting higher calibration variability in the baseline.

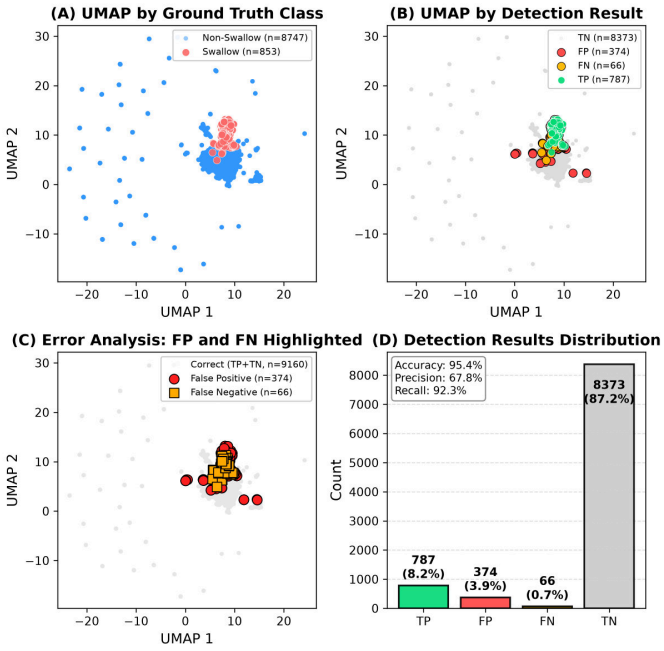

Fig. 6. UMAP projection of the 9600 CLAP embeddings (853 swallowing, 8747 non-swallowing). (A) ground truth class; (B) MLP detection outcome; (C) errors highlighted over correctly classified bins; (D) outcome counts. False positives cluster near class boundaries, indicating partial separability.

200 ms, so most are disagreements about event boundaries rather than detections of unrelated sounds, and a further 29.9% lie within 100 ms of a bin a single annotator marked. We had hypothesised that false positives would concentrate on breathing, the predicted confounder, but the annotations mark only swallowing intervals and carry no event type, so this cannot be tested here.

F. Representation Analysis

Figure 6 projects the CLAP embeddings with UMAP. Positive bins form a cluster only partially separable from negative bins, and the errors mirror the temporal picture above: false positives concentrate at the class boundary while false negatives are rare and scattered.

V. Discussion

A. Why Does Zero-Shot Classification Fail?

Zero-shot classification fails because of a fundamental domain shift between CLAP's pre-training data and laryngophone recordings. Three factors contribute to this failure.

First, CLAP was trained on 48 kHz air-microphone recordings of environmental sounds, music and speech, whereas the encoder here receives upsampled 22.05 kHz signals whose upper spectral band is empty, a distribution shift absent from pre-training. Compounding it, the laryngophone is a contact sensor whose transfer function attenuates high frequencies and emphasizes low-frequency body-conducted vibration, giving spectral characteristics fundamentally unlike air-conducted sound.

Second, biomedical sounds are largely absent from CLAP's pre-training corpus. Concepts like "drinking" or "gulp" were learned from air-microphone recordings in everyday contexts, not the muffled contact-sensor signature of pharyngeal muscle contraction, so the semantic concept of "swallowing" in CLAP's embedding space does not align with the acoustic reality of laryngophone signals.

Third, the failure is not an artifact of prompt engineering. The four prompt strategies yield MCC of 0.286 (simple), 0.303 (descriptive), 0.291 (medical) and 0.295 (combined), a spread of only 0.017, and none approaches the baseline: the limitation lies in the audio encoder's representation of contact-sensor signals rather than in the choice of text anchors. Even this ceiling used a threshold optimized on the test data, so without that unrealistic advantage performance would be worse still. Foundation models therefore do not provide out-of-the-box solutions for physiological sound detection with contact sensors.

B. Why Does Linear Probing Succeed?

Despite the domain shift, an untuned logistic regression on frozen CLAP embeddings matches the energy detector in mean MCC while halving its inter-subject spread. The embeddings therefore already carry discriminative information: the obstacle for zero-shot classification is task adaptation, not representation quality.

CLAP's contrastive pre-training learns to distinguish acoustic events based on spectral and temporal patterns, even if the semantic labels differ from swallowing. Features such as transient energy bursts, frequency modulation patterns, and temporal structure are generic enough to transfer across domains. The linear probe learns a hyperplane that separates swallowing from non-swallowing bins in this 512-dimensional space, bypassing the failed text-audio alignment entirely.

C. Does Non-Linearity Help Over Linear Probing?

The MLP head achieves MCC = 0.768 against 0.743 for the linear probe, a margin of 0.020 on the non-padded bins over which all contrasts are computed (see Table I). With 16 subjects it is not separable from zero: the paired permutation test gives $p = 0.33$ and the MLP wins on only 9 of 16 subjects. We therefore cannot claim that non-linearity helps, and the following reading is offered as a hypothesis for future work with a larger cohort rather than as a conclusion supported by these data.

The UMAP visualization (Figure 6) shows swallowing events forming a cluster that overlaps with non-swallowing bins at irregular boundaries. If that overlap reflects genuine curvature in the class boundary, an MLP's hidden layers could capture it where a linear classifier cannot. The observed margin is at least consistent with this picture, but it is equally consistent with sampling noise.

Whatever the head, the underlying embedding already provides most of the separability, which is why the choice between a linear and a non-linear head has so little room to matter here.

D. What Would Be Required for Clinical Use

Telemedicine motivates this task, but nothing here demonstrates a telemedicine result. What these results support is narrower: foundation model representations can be adapted to a contact-sensor signal with a small cohort and a frozen encoder, and that adaptation makes performance more consistent across individuals. Consistency is a precondition for running without per-patient calibration, which is why we regard it as the practically relevant finding, but a precondition is not a demonstration.

Three gaps separate this evidence from a clinical claim, detailed in Limitations 1 and 2: an all-healthy cohort, a single sensor and setup, and controlled recording conditions. Closing them requires validation on patients, across devices and sites, under realistic conditions, not extrapolation from the numbers reported here. The MLP's operating point (recall = 0.923, precision = 0.678) favors sensitivity, which would be the appropriate trade-off in a screening context, since a missed event costs more than a false positive a clinician can dismiss on review.

E. Limitations

Several limitations constrain the generalizability of these findings.

First, the dataset comprises only 16 healthy subjects. No patients with ALS or Parkinson's disease were included, precluding direct conclusions about the clinical target population. Swallowing patterns in dysphagic patients may differ substantially from healthy individuals.

Second, all recordings come from a single laryngophone and acquisition setup under controlled conditions, so robustness to environmental noise, sensor variability and multi-site acquisition remains untested. Whether the CLAP representation degrades more gracefully than the spectral baseline under such conditions is the robustness question this work leaves open.

Third, the ground truth carries residual label noise, which the leave-one-observer-out ceiling of MCC = 0.827 quantifies: even trained annotators do not fully reproduce their peers' consensus. Rather than leave this as a caveat, Section IV-E stratifies the detector's errors by how many annotators marked each bin, and finds that they track label uncertainty closely. The residual noise therefore bounds what any detector can achieve here, and part of the measured error is a property of the reference rather than of the model.

Fourth, the 50 ms temporal resolution is coarser than the acoustic dynamics of swallowing events, which typically last 500-1000 ms but contain sub-events at finer timescales. This resolution was inherited from the original study for comparability.

Fifth, this study evaluates a single foundation model and so cannot separate what is specific to CLAP from what would hold for audio foundation models generally. Settling that requires comparison against smaller acoustic features and against alternative encoders such as BEATs, WavLM or health-specific models, under an identical protocol and matched compute budget; this is left to future work. Our results therefore show that *a* general-purpose encoder transfers to this domain, not that CLAP is the best such encoder.

Sixth, with 16 subjects the resolution of the comparison between methods is limited, and we quantify that limit rather than assume it. Because consecutive bins within a recording are temporally correlated, all inference is clustered at the subject level, with one recording per subject so that no nesting is required: confidence intervals come from a cluster bootstrap over subjects and method contrasts from paired permutation tests that exchange the two methods' predictions within each subject (10,000 replicates each). None of the three contrasts reaches significance: MLP versus linear probe gives ΔMCC $= +0.020$, 95% CI $[-0.012, +0.055]$, $p = 0.33$; MLP versus energy $+0.072$, $[-0.024, +0.171]$, $p = 0.21$; linear probe versus energy $+0.052$, $[-0.025, +0.130]$, $p = 0.25$. Wilcoxon signed-rank and paired t-tests agree, and in each contrast the nominally better method wins on only 9 of 16 subjects. We therefore treat the two adaptation strategies as empirically equivalent at this sample size and do not claim that either significantly outperforms the energy baseline in mean MCC. What the intervals do separate is dispersion: the bootstrap standard error of the energy detector (0.041) is roughly twice that of the linear probe (0.020) or the MLP (0.023), and its per-subject spread is likewise larger (0.134 versus 0.077 and 0.074).

Seventh, recording durations vary from 13.8 to 32.6 seconds across subjects against a fixed 600-bin (30 s) grid; the two longer recordings are truncated at 30 s, discarding no annotated event. The 1514 padded bins (15.8% of the total) carry no annotated events and are trivially classified as true negatives, which inflates specificity. We quantified this effect by recomputing every metric over the 8086 bins that contain recorded audio: pooled MCC shifts by at most 0.005 (0.005

for the energy detector, 0.005 for the MLP head), and the ordering of methods is unchanged. Specificity, in contrast, is inflated by 0.005 to 0.008, which is one further reason to read MCC rather than specificity under this class balance.

VI. Conclusion

This study shows that audio foundation model representations encode transferable information for swallowing event detection, despite a severe domain mismatch between air-microphone pre-training data and contact-sensor recordings. The transfer, however, is conditional on how the model is used. Zero-shot classification through the text-audio alignment fails at MCC = 0.303, and this failure is robust to prompt formulation, showing that the semantic pathway of the foundation model does not reach laryngophone signals. Bypassing that pathway and training a lightweight head on the frozen embeddings raises MCC to 0.743 for a linear probe and 0.768 for an MLP head, against 0.696 for a band-limited energy detector evaluated under the same leave-one-subject-out protocol.

The central finding is not the gain in mean performance, which subject-clustered testing cannot separate from zero at this sample size, but the reduction in inter-subject variability: the standard deviation falls from 0.13 for the baseline to 0.07–0.08 for the adapted models, and the bootstrap standard error of the pooled MCC falls by roughly half. A detector whose performance is predictable across individuals is a precondition for deployment without per-patient calibration, though demonstrating such deployment is beyond what this study evaluates. Measured against a leave-one-observer-out human ceiling of MCC = 0.827, the adapted models narrow the gap from 0.131 to 0.059.

These conclusions are bounded by the cohort that produced them: 16 healthy adults, one laryngophone setup, no dysphagic patients and no device or site variation. The result to carry forward is that general-purpose audio representations transfer to a contact-sensor domain more consistently than a hand-tuned spectral baseline. Whether that consistency survives contact with patients, devices and recording environments is the question future work must answer, alongside encoders with native frame-level temporal resolution.

Acknowledgment

The data used in this study were collected under the RevELA Project at the Laboratory for Technological Innovation in Health (LAIS), Federal University of Rio Grande do Norte. ***Abstract*—The decomposition of high-density electromyography (HD-EMG) allows estimating the individual activity of the motor units (MUs) recruited during muscle contraction. The resulting firing trains, however, still have to be picked by hand, an essential step that is slow and prone to error. This work evaluates artificial neural networks for the classification of MU firings, using as input the instantaneous pulse trains (IPTs). Three architectures were compared on a single 41-second isometric HD-EMG recording from one participant (64 channels, 17 motor units, with a manually edited reference produced by one experienced evaluator): a one-dimensional convolutional neural network (CNN-1D) acting as a per-unit binary detector, a multiclass two-dimensional convolutional neural network (CNN-2D), and a recurrent Long Short-Term Memory (LSTM) network. The models were compared by the average Rate of Agreement (RoA) with the evaluator's manual editing. The CNN-1D obtained the highest value, with an initial RoA of 55.44%. A hyperparameter search and the consolidation into a single cross-MU model raised the average RoA to 78.48%, reaching approximately 90% for fourteen of the units (all except MUs 15–17). All results were obtained on a single recording with a random partition of windows, so they should be read as a preliminary characterization rather than as an estimate of performance on unseen recordings, motor units or participants.**

***Index Terms*—high-density electromyography, motor units, decomposition, convolutional neural networks, deep learning.**

I. Introduction

The decomposition of high-density electromyography (HD-EMG) signals, whether surface (HD-sEMG) or intramuscular (HD-iEMG), identifies the sources that generate the recorded signals, which correspond to the electrical activity of the motor units (MUs) [1]. Blind source separation methods such as convolution kernel compensation (CKC) [2] and fast independent component analysis (FastICA) [3] have been applied successfully to this task.

The quality of the decomposition depends on the spatio-temporal characteristics of each MU. The spatial distribution of the signals is affected by the volume conductor, the size of the MU, the relative position between the innervation zone and the electrode, and the recording system [4], whereas the temporal properties reflect the firing pattern. When different MUs have similar spatial profiles, the separation can be imperfect, producing mixed firing trains or classification errors.

After the automatic decomposition, manual picking of the firing trains remains an essential step to ensure the validity of the subsequent analyses. Erroneous classifications, such as false positives and false negatives, can compromise standard analyses in the neurophysiology of motor control (synchronization, correlation, and coherence between MUs, as well as individual characteristics such as firing rate and firing variability) and should be avoided. Manual validation is also slow: a trained evaluator takes, on average, about one minute to review the firing train of a single MU in a one-minute recording. Each recording may present dozens of MUs, and each study involves multiple participants and trials, so this step is one of the main bottlenecks in experimental projects [5].

The use of artificial neural networks (ANNs) for HD-sEMG data processing has grown in recent years [6]. ANN models can automate parts of this pipeline, including the picking of firing trains. To our knowledge, however, no ANN model has been dedicated specifically to the correct classification of the firings obtained from decomposition. That step matters as much as the initial separation, especially for applications that require real-time decomposition, such as human-machine interfaces, neurofeedback, and prosthesis control. A network dedicated to firing classification could shorten the analysis and support online applications.

In this work, three architectures are compared using as

input the instantaneous pulse trains (IPTs) estimated by the decomposition. The main contributions are: (i) the comparison between a CNN-1D (per-unit binary detector), a multiclass CNN-2D, and an LSTM network on a single 41-second recording from one participant; (ii) the identification of the CNN-1D as the most suitable of the three; and (iii) a refinement process under which the average RoA rises from 55.44% to 78.48% on this dataset.

II. Methods

A. Dataset

An anonymized HD-sEMG recording from the Neuroengineering Research Laboratory (NERLab, CEB/UNICAMP) database was used [7]. The study analyzed only previously collected, fully anonymized data, with no access to identifiable participant information, so no additional ethical approval was required. The task consisted of isometric contraction of the index finger at 5% of maximal voluntary contraction for 41 s. The signals were acquired with a grid of 13×5 electrodes, totaling 64 active channels (as one electrode position in the grid is empty), at a sampling frequency of 2048 Hz. The decomposition with gCKC identified 17 MUs and 10,781 valid firings, with the number of reference firings per MU ranging from 500 to 797 (median 643). Since the sliding scan covers the whole recording, the number of candidate windows is the same for every MU, and only the positive fraction varies with the firing count. The database contains two versions of the recording, referred to as original and clean; the firing instants of the clean version were manually classified by an experienced evaluator and were adopted here as reference labels.

The dataset was split into 80% for training and 20% for validation, with a fixed seed to ensure reproducibility. All windows originate from a single continuous recording, so the random partition places windows from the same recording and the same MU in both subsets. Because the morphology of the IPT peaks of a given MU is approximately stationary within a recording, the two subsets are not statistically independent, and the values reported here characterize interpolation within a single recording rather than generalization to new recordings, motor units or participants. Two validation schemes would be required to support claims of generality: a time-block split, in which the model is trained on one portion of the recording and evaluated on a later one, and a leave-one-motor-unit-out scheme, in which the evaluated unit contributes no data to training. Neither is reported here, and both are left for future work.

B. Processing HD-sEMG Recordings

The spike-selection task is cast as a supervised binary classification problem at the level of individual firing candidates. After decomposition, each MU is associated with an instantaneous pulse train (IPT), a one-dimensional signal whose local peaks indicate candidate firing instants. Rather than operating on the raw multichannel EMG, the model takes as input a fixed-length window of the IPT (60 samples, $\approx$ 29 ms), which preserves the temporal shape of the event while keeping the input dimensionality low.

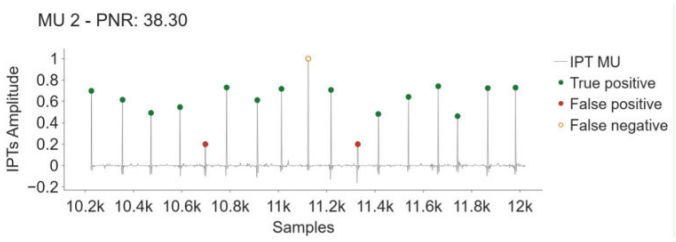

Figure 1. Firing classification from the instantaneous pulse train. In each 60-sample window centered on a candidate, the network decides between firing and non-firing: on the left, a true positive (sharp, isolated peak: accepted); on the right, a false positive (low-amplitude peak associated with noise: rejected).

Candidates were generated by a sliding scan along the IPT with a stride of 2 samples, so that consecutive windows overlap by 58 of their 60 samples. A window was assigned to the positive class when a reference firing of that MU falls within its support, that is, within ± 30 samples of the window center; at the sampling rate of 2048 Hz, where consecutive samples are 0.488 ms apart, this corresponds to ± 14.6 ms. Windows without a reference firing in their support were assigned to the negative class, and therefore correspond to noise, to interference from other units, and to inter-discharge intervals. Because the two classes are not equally represented in the scan, the larger set was randomly subsampled to the size of the smaller one before training. The labeling tolerance is deliberately wide: rather than marking a single instant, it marks the neighborhood of each discharge, so that every reference firing gives rise to a group of consecutive positive windows. A non-maximum suppression (NMS) stage is applied at inference to collapse each group into a single detected firing, and the agreement between detected and reference instants is then assessed with the much tighter tolerance defined in Section II-E. The manually validated firing instants are used as the reference for both training and evaluation. They are treated here as the best available reference rather than as an error-free ground truth, since they reflect the judgment of one evaluator.

C. Preprocessing and Input Representation

The HD-sEMG signals were filtered with a notch filter at 60 Hz and a 20–500 Hz band-pass filter. Each input window was normalized independently by z-score, using its own mean and standard deviation, over an analysis window of 60 samples (2.93×10^{-2} s, or ≈ 29 ms). No statistics computed over the whole recording or over the whole MU were used in this step, so the relative amplitude between windows is not preserved. The input variables of the models correspond exclusively to the IPTs estimated by the decomposition, which contain the temporal information associated with the MU discharges. This choice reduces the input dimensionality and focuses the model on the temporal characteristics of the firings. Fig. 1 illustrates the network's decision on firing candidates from a MU.

D. Evaluated Architectures

Three neural network architectures were compared. In all cases the input is a single 60-sample window, and the per-model design is described below.

- **CNN-1D (binary detector):** A set of 17 independent one-dimensional convolutional neural networks (CNNs), each trained to classify a window as a firing or non-firing of a specific MU (sigmoid output). Each network stacks three convolutional layers with decreasing kernel sizes, with 32 filters (kernel 7), 64 filters (kernel 5) and 128 filters (kernel 3), the first two followed by batch normalization and all with ReLU activation. A global average pooling layer is followed by a 64-unit dense layer with dropout (0.3) and the final sigmoid unit, totaling about 44k parameters. CNNs suit EMG signals because they extract local features and morphological patterns of the action potentials, reduce the number of parameters through weight sharing, and identify relevant attributes without manual engineering. The network was trained with the Adam optimizer (10^{-3}) and binary cross-entropy.
- **CNN-2D (multiclass):** A single two-dimensional CNN that receives the spatio-temporal cube ($13 \times 5 \times 60$) and classifies the window among the 17 MUs (*softmax* output). It first applies a 3D convolution along the temporal axis (32 filters, kernel $1\times1\times7$), and then 2D convolutions over the electrode grid (64 filters with L_2 regularization, followed by 128 filters), which exploit the spatial invariances of the action potentials. A spatial attention block, which combines average- and max-pooled feature maps through a sigmoid-gated convolution, weights the most informative regions before two dense layers (256 and 128 units, dropout 0.5) and the softmax output. It was trained with Adam (3×10^{-4}) and categorical cross-entropy.
- **LSTM (multiclass):** A recurrent *Long Short-Term Memory* (LSTM) network, which processes the window as a single-channel temporal sequence (without spatial information). After batch normalization, it stacks two bidirectional LSTM layers (64 and 32 units, dropout 0.3), followed by a 128-unit dense layer and a 17-class *softmax* output. LSTMs model short- and long-term temporal dependencies, in principle suitable for the physiologically structured firing patterns of the MUs. It was trained with Adam and categorical cross-entropy.

All models were trained for 50 epochs with a batch size of 64, with the two classes balanced by subsampling, in the Google Colab environment using TensorFlow/Keras.

E. Evaluation Metrics

The agreement between the automatically detected firings and the reference firings was quantified with the *Rate of Agreement* (RoA) [3] defined for each motor unit j as

$$\mathrm{RoA}_j = \frac{c_j}{c_j + A_j + B_j} \cdot 100\%, \tag{1}$$

where c_j is the number of firings identified by both methods (reference and automatic classification), and A_j and B_j are the firings identified by only one of them. Two firings were considered coincident when separated by at most 10 samples (4.88 ms at 2048 Hz). Taking the automatic classification as the predictor and the manually validated instants as the reference, c_j corresponds to the true positives (TP), and A_j and B_j to the false positives (FP) and false negatives (FN), from which precision (P) and recall (R) are computed:

$$P = \frac{\mathrm{TP}}{\mathrm{TP}+\mathrm{FP}}, \qquad R = \frac{\mathrm{TP}}{\mathrm{TP}+\mathrm{FN}}, \tag{2}$$

and the F1-score, given by the harmonic mean of the two:

$$\mathrm{F1} = 2\,\frac{P \cdot R}{P + R} = \frac{2\,\mathrm{TP}}{2\,\mathrm{TP}+\mathrm{FP}+\mathrm{FN}}. \tag{3}$$

After estimating these metrics for each MU, a macro average was calculated for each architecture. Per-unit values are reported in Fig. 2, so that the dispersion behind each macro average can be inspected. Precision, recall and F1 are computed at the level of individual windows, whereas the RoA is computed on the reconstructed firing train, after the sliding-window scan and the non-maximum suppression applied at inference. The two sets of values are therefore not directly comparable.

F. Optimization of the CNN-1D

Starting from the most promising architecture, a step-by-step refinement process was carried out. First, the hyperparameter search was automated with Optuna [8], an optimization framework based on the Tree-structured Parzen Estimator (TPE), with early stopping and adaptive learning-rate reduction; its objective was the window-level F1 on the validation set, which is the same set from which the metrics below are reported. Then, an independent optimization was performed for each MU. Finally, a single cross-MU model was consolidated, trained with the concatenated windows of all MUs and applied through a sliding-window search followed by non-maximum suppression (NMS) at the inference stage. The term *cross-MU* denotes a single network shared by the 17 MUs of this recording, in contrast to one detector per unit. It carries no claim of generality across recordings, contractions or participants, which was not evaluated. Two aspects change with respect to the per-unit detectors. First, the identity of the MU is not provided to the network: the input is a single IPT window, with no unit label or embedding, so the same weights are applied to every unit. The unit is determined externally, by the choice of which IPT the model is applied to, which is already available after decomposition. Second, at inference the model no longer receives a pre-selected set of candidates, but scans the IPT and relies on NMS to produce one detection per discharge. The hyperparameter search, the per-unit refinement and the final metrics were all computed on the same partition, so the reported values reflect performance on data that participated in model selection and are optimistic by an unquantified margin. An independent test set is required to confirm the magnitude of the reported differences.

Table I
COMPARISON OF EVALUATED MODELS FOR HD-SEMG FIRING CLASSIFICATION.

Model	Task	Input	No. Params	RoA (macro)	Precision	Recall	F1	No. Models	Loss
CNN-1D (binary)	Firing / non-firing	IPT window (60 samples $\times$1 channel)	43,969	55.44%	86.7%	86.9%	86.8%	17 (sigmoid per MU)	Binary cross-entropy
CNN-2D (unified)	Multiclass (17 MUs)	$13 \times 5 \times 60$	3,304,676	46.64%	63.6%	63.3%	63.4%	1	Categorical cross-entropy
LSTM (unified)	Multiclass (17 MUs)	Window $\times$ 1 channel	$\sim$86k	12.8%	22.9%	23.7%	21.9%	1	Categorical cross-entropy
CNN-1D Optuna General + IPT	Binary	IPT window (60 samples $\times$1 channel)	17 tuned (44k–128k/MU)	60.45%	90%	90%	87.2%	17	Binary cross-entropy
CNN-1D cross-MU model	**Binary**	IPT window (60 samples $\times$1 channel)	**$\sim$128k**	**78.48%**	**98%**	**98%**	**97.9%**	1	Binary cross-entropy

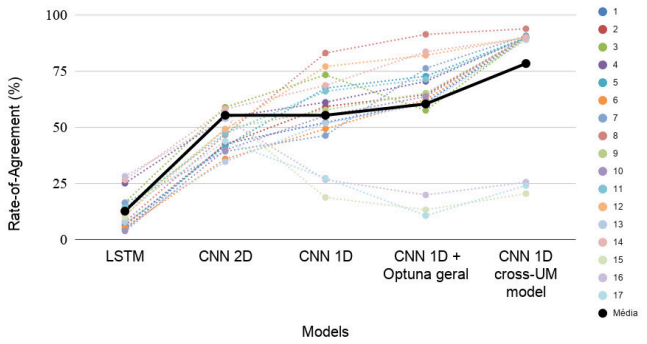

Figure 2. Evolution of the RoA across the architectures and optimization steps (LSTM, CNN-2D, base CNN-1D, general search with Optuna, per-unit optimization, and final cross-MU model). Each light curve corresponds to a MU and the black curve to the average of the 17 units, which rises from 12.8% (LSTM) to 78.48% in the cross-MU model. The fourteen units other than MUs 15–17 reach about 90%, while MUs 15–17 remain below 30%.

III. RESULTS AND DISCUSSION

Table I summarizes the evaluation metrics (macro average) for the three architectures. The CNN-1D, in the form of independent binary detectors, obtained the highest macro RoA (55.44%), as well as balanced precision and recall (86.7% and 86.9%, respectively). The multiclass CNN-2D fell between the other two (RoA of 46.64%; precision 63.6% and recall 63.3%), and the LSTM performed worst, with an RoA of only 12.8%. The LSTM processes the window as a single-channel temporal sequence and discards the spatial information of the electrode grid, which may be important for distinguishing MUs with similar profiles; its low RoA is consistent with that. The CNN-2D, although it explicitly exploits the spatio-temporal cube, showed substantial overfitting: the training accuracy (89.4%) exceeded the validation accuracy (65.0%) by more than 24 percentage points, whereas the CNN-1D kept training and validation practically equal (86.5%). The specialization of one detector per unit reduces the complexity of the problem faced by each network, which motivated the choice of this architecture for the following steps.

The per-MU curves in Fig. 2 show that the CNN-1D obtains higher values than the CNN-2D and the LSTM on most of the units, and that the CNN-2D is ahead only on units 15–17, where the base CNN-1D collapses. For the CNN-1D, the macro precision and recall are both high ($\approx$ 86–87%), but the RoA is, by construction, more conservative: since it simultaneously penalizes false positives and false negatives in the denominator of Eq. (1), units with many false positives (for example, MUs 1, 6, and 9, with recall above 97% but more than a hundred false positives each) end up with an RoA in the 50–58% range, despite good detection. Units 15, 16, and 17 show low RoA across all architectures. The cause was not established in this study, and a source-pairing inconsistency between the two decompositions cannot be ruled out.

The optimization process of the CNN-1D, illustrated in Fig. 2, produced a consistent increase in RoA across the successive stages. No statistical test was applied, since all stages were computed on a single recording and on the same partition, so the differences reported below are descriptive. Starting from the base architecture (average RoA of 55.44%), the general hyperparameter search with Optuna raised the average to 60.45%, the independent per-unit optimization to 69.8%, and the consolidation into a single cross-MU model reached 78.48%. This model was trained with the concatenated windows of all units and applied through a sliding-window scan followed by NMS. Restricting the analysis to the fourteen units other than MUs 15–17, the average RoA rises from 62.1% (base) to 90.2% in the final model, with individual values close to 90%. Units 15, 16, and 17 remained at low levels (about 20–26%) even after optimization. The cross-MU model also replaces the 17 independent detectors with a single network of approximately 128 thousand parameters, which simplifies its use at inference time.

Several limitations apply. The evaluation was restricted to a single 41-second HD-sEMG recording from one participant, so generalizability remains untested. The random partition places windows from the same recording and the same motor unit in both subsets, so the reported RoA characterizes interpolation within a single recording rather than generalization to new

motor units, contractions or participants, and the same partition was also used for model selection, which makes the values optimistic by an unquantified margin. The final average RoA of 78.48% remains well below the $\sim$98% typically required for decomposed firing trains to be used without further manual editing; in its present form the approach is a pre-selection tool that reduces, but does not replace, manual editing. The reference labels were produced by a single evaluator, and no inter-rater agreement was assessed. A relevant next step is to report the comparison of the RoA before (original classification) and after the model, in order to verify whether the network improves, rather than degrades, the original classification.

IV. Conclusion

This work investigated the use of neural networks to automate the classification of MU firings obtained from HD-sEMG decomposition, a step currently performed by manual editing and one of the main bottlenecks of the analysis. Among the three compared architectures, the CNN-1D in the form of a per-unit binary detector obtained the highest RoA and the smallest gap between training and validation. Starting from it, the hyperparameter search and the consolidation into a cross-MU model raised the average RoA from 55.44% to 78.48% on this dataset, reaching about 90% for the fourteen units other than MUs 15–17. These are preliminary results obtained on a single recording, and the final average RoA remains below the $\sim$98% usually required for decomposed firing trains to be used without further manual editing, so the approach reduces rather than replaces that step. Confirming the reported values requires evaluation on independent recordings and on data not used during model selection.

***Abstract*—Atrial fibrillation (AF) is a common cardiac arrhythmia associated with an increased risk of stroke and heart failure. This study compares two ECG-based approaches for automatic AF detection using 86 records from PhysioNet databases. The first method (RR-HRV method) is based on RR interval variability and heart rate variability features, whereas the second method (Hybrid RR-HRV + P-wave Method) extends the baseline model by incorporating P-wave morphological analysis and an abrupt RR-transition detector. Descriptive comparisons showed higher classification performance for the RR-HRV method, although paired statistical analyses did not indicate a significant difference between the methods at a 5% significance level. A class-specific AFIB analysis showed that the hybrid method increased sensitivity from 80.0% to 83.3%, but also increased false positives and reduced precision from 77.4% to 64.1%. These findings suggest that P-wave and RR-transition features provide complementary information for AF detection; however, further improvements may require more robust integration strategies considering signal quality assessment, ectopy control, and evidence fusion.**

***Index Terms*—Atrial fibrillation, electrocardiogram, RR intervals, P-wave, heart rate variability, biomedical signal processing.**

I. Introduction

Atrial fibrillation (AF) is the most common sustained arrhythmia in the adult population, associated with an increased risk of stroke, heart failure, and cardiovascular mortality [1], [15]. Characterized by chaotic atrial electrical activation, its identification on the electrocardiogram (ECG) is based on RR interval irregularity and the absence of organized P waves [3], [4]. However, definitive diagnosis faces challenges due to the intermittent nature of paroxysmal AF and the presence of noise or artifacts that can lead to misclassifications [2], [5].

Historically, automated detection focused on the temporal dynamics of RR intervals [3], [6], driven by classic QRS complex detection algorithms, such as that of Pan and Tompkins [7]. Recently, deep learning-based approaches and wearable devices have expanded continuous monitoring capabilities with high sensitivity [8], [9]. However, these modern models often require high computational cost and suffer from lower clinical interpretability, hindering their implementation in embedded systems.

A critical limitation of methods restricted to RR intervals is that ventricular beat irregularity, expressed by temporal variation between consecutive R peaks, is not exclusive to AF. Alterations such as ectopy, detection artifacts, and other supraventricular arrhythmias can also produce irregular RR series, increasing the occurrence of false positives in classifiers based solely on ventricular dynamics. To mitigate this issue, hybrid approaches emerge as a promising alternative. Integrating P-wave morphology provides complementary atrial information [1], while statistical (RMSSD, pNN50) and non-linear (approximate entropy) metrics provide a balanced quantification of cardiac rhythm complexity [10], [11].

In this context, this work proposes a modular hybrid system to support automatic AF detection, combining RR interval variability and P-wave morphological analysis. ECG records from public databases available on the PhysioNet platform were used, specifically the MIT-BIH Atrial Fibrillation Database, the MIT-BIH Normal Sinus Rhythm Database, and the MIT-BIH Arrhythmia Database [12], [13]. The main contribution of this study consists of comparing two strategies: the RR-HRV Method, based exclusively on RR intervals, and the Hybrid RR-HRV + P-wave Method, a hybrid approach that incorporates P-wave morphological analysis and the detection of abrupt transitions in RR dynamics.

II. Methodology

This study presents the implementation and comparison of two strategies for automatic AF detection in multichannel electrocardiogram (ECG) signals provided by PhysioNet, using the first available channel of each record for processing. The first approach, referred to as the RR-HRV Method, is based exclusively on RR interval variability. The second approach, the Hybrid RR-HRV + P-wave Method, extends the former by incorporating P-wave morphological analysis and an additional module for detecting abrupt transitions in

This work was supported by the Fundo de Apoio ao Ensino, à Pesquisa e à Extensão (FAEPEX) of Universidade Estadual de Campinas (UNICAMP), grant number 3325/24.

RR interval dynamics. The primary objective is to evaluate whether incorporating morphological evidence associated with the presence or organized absence of the P wave enhances the discriminative capability of a system based on RR interval variability

The evaluated methods do not employ supervised learning, training stages, cross-validation, or model tuning. These approaches are deterministic, relying on digital signal processing, handcrafted extraction of physiological heart rate variability features, and heuristic decision rules

A. Databases and Standardization

Records from PhysioNet databases were used, including the MIT-BIH Atrial Fibrillation Database, the MIT-BIH Normal Sinus Rhythm Database, and the MIT-BIH Arrhythmia Database [12], [13]. The signals were resampled to 250 Hz to ensure temporal consistency across records and allow uniform application of the methods. The flowchart of the system for automatic AF detection is presented in Figure 1.

In this study, an experimental reorganization of the original annotations was performed. The AFIB label was used for AF, N for normal sinus rhythm, while other arrhythmic events present in the MIT-BIH Arrhythmia Database were grouped as other arrhythmias (OA). The N-OA class was assigned to records with a predominantly sinus rhythm, but containing episodes of other arrhythmias or events not classified as AF, according to the original annotations of the databases used. The final evaluation set comprised 86 records, organized into four target classes: 36 N-OA records, 17 N records, 30 AFIB records, and 3 OA records. This organization enabled evaluating the behavior of the methods both on records with AF and on pure sinus signals, other arrhythmias, and predominantly sinus records with associated arrhythmias.

B. Preprocessing, R-Peak Detection, and RR Interval Calculation

As presented in Figure 1, preprocessing constitutes the first step of the methodological workflow, serving as the basis for R-peak detection and the subsequent calculation of RR intervals. ECG signal preprocessing was performed using second-order bandpass Butterworth filters. For general inspection of the electrocardiographic trace, a frequency band of 0.5–35 Hz was used to reduce baseline wander and high-frequency noise while preserving the main morphological components of the ECG. For QRS complex detection, a more selective band of 5–18 Hz was employed, suitable for highlighting ventricular activity associated with R peaks.

R-peak detection was performed on the filtered signal, using differentiation, squaring, and moving window smoothing of 120 ms. Next, an adaptive threshold defined by the median of the processed signal plus 1.5 times the standard deviation was applied. To avoid multiple detections associated with the same QRS complex, a refractory period of 250 ms was

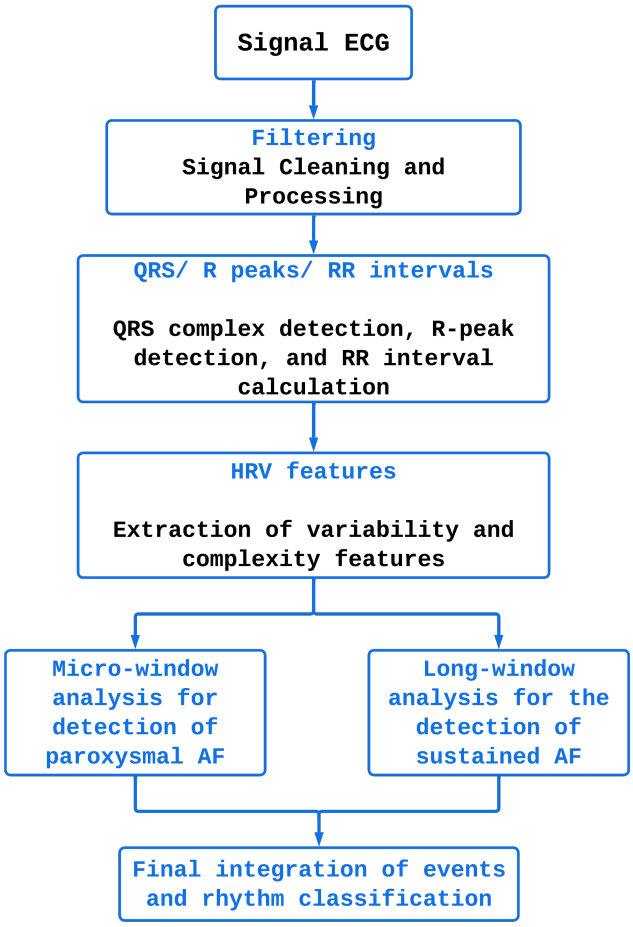

Fig. 1. Methodological architecture of the system for automatic atrial fibrillation detection. The RR-HRV Method uses features derived from RR intervals, whereas the Hybrid RR-HRV + P-wave Method additionally incorporates P-wave morphological analysis and detection of abrupt transitions in the RR series.

imposed. Subsequently, the detected peaks were refined by local search within a window of ± 80 ms, in order to locate more precisely the maximum amplitude point corresponding to the R peak.

After identifying the R peaks, the RR intervals were calculated as the time difference between two consecutive R peaks:

$$RR_i = t_{R_i} - t_{R_{i-1}} \tag{1}$$

After that, the RR intervals were subjected to a physiological validation criterion, keeping only values between 0.25 s and 2.5 s, a range approximately compatible with heart rates between 24 and 240 bpm. Intervals outside this limit were considered likely artifacts, R-peak detection failures, or events not physiologically plausible for the proposed analysis.

C. RR Interval Feature Extraction

Variability and complexity metrics were extracted from the RR series: RMSSD, pNN50, coefficient of variation (CV), approximate entropy (ApEn), lag-1 autocorrelation, and Turning Point Ratio (TPR).

These metrics were selected for their ability to represent different aspects of temporal RR interval irregularity, a relevant feature in automatic AF detection.

The coefficient of variation was used as a normalized measure of dispersion for the RR intervals, defined by:

$$CV = \frac{\sigma_{RR}}{\mu_{RR}}. \tag{2}$$

RMSSD quantifies the magnitude of successive differences between consecutive RR intervals, being sensitive to rapid heart rate variations:

$$RMSSD = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N-1}(RR_{i+1} - RR_i)^2}. \tag{3}$$

pNN50 was calculated as the proportion of consecutive RR interval pairs whose absolute difference exceeds $50\,\mathrm{ms}$, or $0.05\,\mathrm{s}$, when intervals are expressed in seconds:

$$pNN50 = \frac{1}{N-1}\sum_{i=1}^{N-1} I\left(|RR_{i+1} - RR_i| > 0.05\right), \tag{4}$$

where $I(\cdot)$ represents the indicator function, taking a value of 1 when the condition is true and 0 otherwise. When expressed as a percentage, this value is multiplied by 100.

To evaluate the unpredictability of the RR series, approximate entropy was used, calculated over the previously validated RR intervals. In this work, $m = 2$ and $r = 0.2\sigma_{RR}$ were adopted, where σ_{RR} represents the standard deviation of the analyzed RR series in the window.

$$ApEn(m, r, N) = \phi^m(r) - \phi^{m+1}(r). \tag{5}$$

Higher ApEn values indicate greater irregularity and lower temporal predictability of the sequence of RR intervals.

The lag-1 autocorrelation (ρ_1) was employed to estimate the temporal dependence between consecutive RR intervals:

$$\rho_1 = \frac{\sum_{i=1}^{N-1}(RR_i - \mu_{RR})(RR_{i+1} - \mu_{RR})}{\sum_{i=1}^{N}(RR_i - \mu_{RR})^2}. \tag{6}$$

High values of ρ_1 indicate greater similarity between consecutive intervals, while reduced values suggest greater temporal irregularity.

Finally, the Turning Point Ratio was used to quantify the frequency of local trend changes in the RR series. A point RR_i is considered a turning point when it represents a local maximum or minimum relative to its immediate neighbors. TPR was defined as:

$$TPR = \frac{1}{N-2}\sum_{i=2}^{N-1} I\left[(RR_i - RR_{i-1})(RR_i - RR_{i+1}) > 0\right]. \tag{7}$$

Thus, the combination of these metrics allows characterizing different dimensions of cardiac dynamics: global dispersion of RR intervals, beat-to-beat variations, temporal irregularity, unpredictability, and local trend changes.

Candidate AF episodes were identified from the combination of RR-HRV features using fixed thresholds. These values were defined based on literature references on heart rate variability [16], [17] and established during the initial implementation of the method, prior to the experimental evaluation presented in this study. Table I presents the thresholds used in the decision stage.

TABLE I
THRESHOLDS USED IN THE DECISION STAGE BASED ON RR-HRV FEATURES.

Feature	Thresholds used
CV	0.12 (minimum), 0.17 (high)
RMSSD	0.09 s (minimum), 0.13 s (high)
pNN50	0.30 (minimum)
ApEn	0.14 (minimum), 0.20 (high)

This quantitative representation provides the basis for classifying AF episodes in subsequent system stages.

D. Analysis Windows

(i) Long-window analysis for sustained AF detection: evaluation of signals in 30 s windows, with a 10 s step, using RR-HRV features to identify prolonged episodes of irregularity consistent with sustained AF.

(ii) Micro-window analysis for paroxysmal AF detection: evaluation in 12 s micro-windows, with a 3 s step, complemented by beat-to-beat analysis, allowing the identification of short and transient AF episodes that might not be detected in longer time windows.

E. Final Event Integration and Rhythm Classification

To obtain the final AF classification (AFIB), the RR-HRV Method considers the combination of features extracted from the RR series and their respective decision thresholds presented in Table I. When all features meet the defined criteria, the record is classified as AFIB. Otherwise, records are classified considering the OA or N categories according to the number of criteria met.

After detecting events at different temporal scales, individual window results were integrated into continuous intervals of AF events. Consecutive windows classified as compatible with AF were grouped considering the temporal proximity between events, avoiding multiple counts of the same episode. From this aggregation, each record received a final classification subsequently used in the comparison with

the reference annotations from the PhysioNet databases.

To attempt to improve the RR-HRV Method, we added a P-wave analysis, forming a Hybrid Method (RR-HRV + P-wave). The P-wave analysis uses a pre-R-wave window between $-240\,\mathrm{ms}$ and $-60\,\mathrm{ms}$; the P wave was detected using a simple threshold. The ECG signal used in this step was filtered in the 0.5–$12\,\mathrm{Hz}$ range.

In this method, the final AF classification was obtained with the same features as the RR-HRV Method, adding P-wave information as a complementary criterion. The P-wave analysis acts as an additional adjustment in the system decision, increasing or reducing evidence of AF according to the pattern observed in the signal.

F. Statistical Analysis

Statistical evaluation was performed by comparing the classifications obtained by the proposed methods with the reference annotations from the PhysioNet databases. To evaluate classifier performance, confusion matrix elements were considered: true positive (TP), false positive (FP), false negative (FN), and true negative (TN). From these values, precision, sensitivity, and F1-score metrics were calculated.

Precision represents the proportion of positive classifications correctly identified as atrial fibrillation,

$$\mathrm{Precision} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FP}} \tag{8}$$

while sensitivity indicates the ability of the system to identify AF records present in the reference annotation.

$$\mathrm{Sensitivity} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FN}} \tag{9}$$

The F1-score was used to represent the balance between precision and sensitivity.

$$\mathrm{F1} = \frac{2 \times \mathrm{Precision} \times \mathrm{Sensitivity}}{\mathrm{Precision} + \mathrm{Sensitivity}} \tag{10}$$

Statistical analyses were performed using Jamovi software. Initially, the Shapiro-Wilk test was applied to check the normality of paired differences between the methods. Since the data did not follow a normal distribution, the Wilcoxon test for paired samples was used to evaluate whether there were statistically significant differences in performance between the two approaches. In addition, McNemar's test was applied to compare the proportions of correct classifications between the methods, considering the binary and paired nature of the results.

III. Results and Discussion

The experimental evaluation was performed on the same set of 86 records, allowing a direct comparison of the performance of the RR-HRV Method and the Hybrid RR-HRV + P-wave Method under the same conditions of preprocessing, segmentation, and feature extraction.

A. Overall Performance

Each ECG record was considered as an independent experimental unit for statistical and performance analyses. For each of the 86 evaluated records, the variable *Correct* was defined, associated with the outcome of each classification method, taking a value of 1 when the obtained classification matched the PhysioNet reference annotation and a value of 0 when a disagreement occurred. This variable allowed a paired comparison of performance between the RR-HRV and Hybrid RR-HRV + P-wave Methods. Formally, for each record i and method $k \in \{\text{RR-HRV}, \text{RR-HRV+P-wave}\}$, it was defined as:

$$\mathrm{Correct}_{i,k} = \begin{cases} 1, & \text{when } \hat{y}_{i,k} = y_i, \\ 0, & \text{when } \hat{y}_{i,k} \neq y_i, \end{cases} \tag{11}$$

where y_i represents the PhysioNet reference annotation and $\hat{y}_{i,k}$ represents the classification obtained by method k for record i.

The normality of paired differences between *CorrectRR-HRV* and *CorrectRR-HRV+P-wave* was evaluated using the Shapiro-Wilk test. Since the assumption of normality was not met ($W = 0.443$, $p < 0.001$), the Wilcoxon signed-rank test for paired samples was used to check for statistically significant differences in performance between the methods. The test indicated no statistically significant difference between the approaches ($W = 44.0$, $p = 0.066$). As these are paired binary responses, McNemar's test was applied to compare the proportions of correct classifications between the methods (Table II).

TABLE II
PAIRED STATISTICAL ANALYSIS BETWEEN THE RR-HRV METHOD AND THE HYBRID RR-HRV + P-WAVE METHOD.

Analysis	Statistic	p-value	Interpretation
Shapiro-Wilk	$W = 0.443$	< 0.001	Non-normal
Paired Wilcoxon	$W = 44.0$	0.066	Non-significant

B. Paired Comparison by McNemar's Test and Analysis of Contingency Matrices

Since the variables *CorrectRR-HRV* and *CorrectRR-HRV+P-wave* constitute binary and paired outcomes, in addition to the statistical analyses presented previously, McNemar's test was applied, which is specifically indicated for comparing proportions of responses in paired data. For this analysis, the classification of each method on each record was coded as correct (1) or incorrect (0). Since the RR-HRV Method and the Hybrid RR-HRV + P-wave Method were evaluated on the same 86 records, the test made it possible to verify whether the overall proportions of correct classifications differed significantly between the two approaches.

In the paired comparison, both methods correctly classified 62 records and incorrectly classified 14 records. In 8 cases, only the RR-HRV Method produced a correct classification,

whereas in 2 cases only the Hybrid RR-HRV + P-wave Method was correct. Thus, the RR-HRV Method obtained 70 correct classifications, corresponding to 81.4% of the records, while the Hybrid RR-HRV + P-wave Method presented 64 correct classifications, equivalent to 74.4%.

As presented in Table III, the uncorrected McNemar test yielded a result close to the significance level, but not significant ($\chi^2(1) = 3.60$, $p = 0.058$). The exact analysis, considered especially due to the small number of discordant pairs, also showed no statistically significant difference between the methods ($\ln(OR) = 1.39$, $p = 0.109$). Therefore, although there is a descriptive trend favoring the RR-HRV Method, it was not possible to confirm its statistical superiority at the 5% significance level.

TABLE III
MCNEMAR TEST RESULT FOR THE PAIRED COMPARISON OF CORRECT CLASSIFICATIONS BETWEEN THE RR-HRV METHOD AND THE HYBRID RR-HRV + P-WAVE METHOD.

Analysis	Value	df	p-value
McNemar (asymptotic)	$\chi^2 = 3.60$	1	0.058
Exact McNemar	$\ln(OR) = 1.39$	–	0.109

$N = 86$.

Table IV presents the contingency matrices of the RR-HRV Method and the Hybrid RR-HRV + P-wave Method. Although the reference classes were organized into four categories (N-OA, N, AFIB, and OA), the analysis of method outputs focused on the detection of AF-compatible events. Thus, the records were compared based on the presence or absence of AF, while the remaining categories were used to characterize the different rhythmic scenarios present in the databases.

This analysis highlights an important shift in the decision profile of the hybrid method. Under the RR-HRV Method, 31 records were classified as AFIB, of which 24 corresponded to reference AFIB records and 7 to false positives. Under the Hybrid RR-HRV + P-wave Method, 39 records were classified as AFIB, of which 25 corresponded to true AFIB records and 14 to false positives.

TABLE IV
CONTINGENCY MATRICES OF THE RR-HRV METHOD AND THE HYBRID RR-HRV + P-WAVE METHOD. ROWS: REFERENCE CATEGORIES; COLUMNS: CATEGORIES ASSIGNED BY THE METHODS.

Method	Reference	Classification assigned by method			
		N	OA	AFIB	Total
RR-HRV	N-OA	23	10	3	36
RR-HRV	N	13	1	3	17
RR-HRV	AFIB	1	5	24	30
RR-HRV	OA	1	1	1	3
	Total	38	17	31	86
RR-HRV + P-wave	N-OA	21	7	8	36
RR-HRV + P-wave	N	11	1	5	17
RR-HRV + P-wave	AFIB	1	4	25	30
RR-HRV + P-wave	OA	1	1	1	3
	Total	34	13	39	86

Considering the AFIB class as the main target, the RR-HRV Method showed 24 true positives, 7 false positives, and 6 false negatives. In contrast, the Hybrid RR-HRV + P-wave Method showed 25 true positives, 14 false positives, and 5 false negatives. Thus, the hybrid model recovered one additional AFIB case and slightly reduced false negatives; however, it doubled the number of false positives associated with the AFIB class.

This redistribution explains the observed decrease in the overall performance of the Hybrid RR-HRV + P-wave Method and, in particular, the decline in precision for the AFIB class. The Hybrid RR-HRV + P-wave Method became more permissive in classifying records as AFIB, especially in N-OA and N records. Specifically for the AFIB class, sensitivity increased from 80.0% to 83.3%, while precision dropped from 77.4% to 64.1%. Therefore, the local gain in sensitivity was accompanied by an increase in false positives and a reduction in precision, indicating that incorporating the P-wave and the RR-transition detector modified the decision profile of the system without yielding an overall improvement in the evaluated configuration.

C. AFIB Class-Specific Performance

Table V presents the performance metrics of the RR-HRV Method and the Hybrid RR-HRV + P-wave Method for the AFIB group ($N = 30$). This analysis allows for an isolated evaluation of the behavior of both methods on records containing AF.

The Hybrid RR-HRV + P-wave Method showed an increase in sensitivity for the AFIB class, accompanied, however, by a higher number of false positives and a reduction in precision. These results indicate a shift in the balance between detection and the occurrence of false positives after incorporating P-wave information and RR transitions.

TABLE V
PERFORMANCE OF THE RR-HRV AND HYBRID RR-HRV + P-WAVE METHODS FOR THE AFIB CLASS.

Metric ($N = 30$)	RR-HRV	RR-HRV + P-wave
True positives	24	25
False negatives	6	5
False positives	7	14
Precision	77.4%	64.1%
Sensitivity	80.0%	83.3%
F1-score	78.7%	72.4%

Thus, the incorporation of the P wave and the RR-transition detector modified the decision profile of the hybrid method, favoring the identification of AFIB records, but with a higher occurrence of incorrect positive classifications.

D. Analysis of Error Mechanisms Associated with the Hybrid Method

The use of the P wave as a complementary criterion is clinically justified. In sinus rhythm, the P wave reflects coordinated atrial depolarization and tends to precede the QRS complex in an organized manner. In AF, this atrial organization is lost, and the absence of an organized P wave, associated with RR interval irregularity, constitutes a relevant

electrocardiographic criterion for arrhythmia diagnosis [1], [14].

Thus, the problem observed in the Hybrid RR-HRV + P-wave Method lies not in the choice of the P wave as a physiological marker, but in how this information was incorporated into the decision-making process. The analysis of patterns observed in error cases suggests three mechanisms associated with the performance of the Hybrid RR-HRV + P-wave Method:

(i) Predominance of sinus rhythm in paroxysmal records: In records containing paroxysmal AF episodes, the predominant presence of sinus rhythm periods hindered the overall classification of the record. This characteristic led to incorrect classifications in some cases, as short AF episodes may have been insufficient to alter the predominant pattern observed in the signal.

(ii) Influence of signal morphological quality: In records with a higher presence of noise or morphological changes, the complementary atrial information presented limitations. In these situations, residual components of the QRS complex or artifacts in the PR segment may have contributed to incorrect classifications, reducing the reliability of P-wave-based evidence.

(iii) Limitations of local temporal analysis: Analysis based on local transitions between windows presented limitations in records with abrupt rhythm changes, ectopies, or artifacts. In these situations, transient changes in RR variability can present behavior similar to the patterns expected during AF episodes, contributing to the increase in false positives in the hybrid method.

E. General Interpretation and Comparison with Literature Approaches

The obtained results should be interpreted considering the differences among databases and validation scenarios used in the literature. Several studies on automatic AF detection range from classical methods based on RR interval analysis, such as the one proposed by Tateno and Glass [6], to recent approaches based on machine learning, wearable systems, and continuous monitoring [5], [8]. These works frequently use public databases specifically oriented toward AF identification, such as the MIT-BIH Atrial Fibrillation Database, in which records contain sustained and paroxysmal arrhythmia episodes with rhythmic annotations used as clinical reference. This type of database is necessary to evaluate the sensitivity of methods in the presence of AF, but it may not fully represent situations where the arrhythmia appears associated with other rhythmic patterns or more heterogeneous signals.

In this study, in addition to the MIT-BIH Atrial Fibrillation Database, records from the MIT-BIH Arrhythmia Database and the MIT-BIH Normal Sinus Rhythm Database were used to expand the variability of the analyzed signals. This choice made the classification task more challenging, as the records can contain sinus rhythm, AF, other arrhythmias, ectopies, and artifacts. For this reason, the target classes were organized into N, AFIB, OA, and N-OA, allowing the differentiation of pure sinus records from those predominantly sinus with other associated arrhythmias.

This methodological choice limits direct comparison, in absolute terms, with studies evaluated in less heterogeneous scenarios or focused exclusively on AF-specific databases. Classical methods based on RR intervals, such as those proposed by Moody and Mark [3] and Tateno and Glass [6], demonstrated that RR interval irregularity constitutes a relevant feature for automatic AF detection. Subsequently, Tateno and Glass explored metrics based on RR and ΔRR intervals, reporting a sensitivity of 86.6% for the RR interval coefficient of variation and 94.4% for the Kolmogorov-Smirnov test applied to ΔRR intervals on the MIT-BIH Atrial Fibrillation Database. However, when applying the method to the MIT-BIH Arrhythmia Database, the authors observed a performance drop associated with an increase in false positives in records with complex arrhythmias and premature ventricular contractions.

In more recent approaches, studies such as Xie et al. [9] indicate that machine learning and deep learning models can achieve high sensitivities in AF detection. However, these models generally involve higher computational complexity and lower physiological interpretability when compared to strategies based on explicit RR interval and atrial morphology features.

This behavior is consistent with the findings of the present study. Although the Hybrid RR-HRV + P-wave Method increased sensitivity for AFIB from 80.0% to 83.3%, this gain was accompanied by a reduction in precision from 77.4% to 64.1%, mainly due to an increase in false positives in N-OA and N records. The performance of the RR-HRV Method indicates that features based on RR intervals demonstrated adequate capacity for AF detection even across different rhythmic scenarios. However, the inclusion of the P wave and RR transitions increased the identification of some AF cases, but also generated more incorrect classifications in records without AF.

In summary, comparison with the literature suggests that hybrid architectures can be promising, but their effectiveness depends on more rigorous fusion strategies between temporal and morphological evidence. In particular, future versions should incorporate additional signal quality criteria, multiple physiological evidences, and decision mechanisms capable of reducing false positives in records with complex arrhythmias.

IV. Conclusion

This study presented a comparative analysis between an automatic AF detection method based exclusively on RR interval variability (RR-HRV Method) and a hybrid approach that incorporates P-wave morphological analysis and abrupt transitions in the RR series (Hybrid RR-HRV + P-wave Method). The results indicated that the RR-based approach showed better overall descriptive performance in precision, sensitivity, and F1-score; however, the paired statistical analysis showed no significant difference between the methods.

Although the inclusion of atrial information is clinically justified, its implementation in the Hybrid RR-HRV + P-wave Method did not produce an aggregate improvement in the evaluated configuration. The increase in the identification of AFIB records was accompanied by a higher number of incorrect positive classifications, indicating that the integration of additional information still requires adjustments.

It is concluded that the P wave should be used as a complementary criterion to the analysis of RR intervals, contributing to a decision based on multiple physiological indicators, rather than as an isolated rule for exclusion or confirmation. These findings provide guidelines for future versions of the system, in which the integration among RR variability, atrial morphology, signal quality control, and multiple physiological evidences may favor a better balance among sensitivity, precision, and clinical interpretability, especially in records with complex arrhythmias.

***Abstract*—Static postural control (PC) involves maintaining postural stability while standing on a fixed surface, whereas dynamic postural control (DPC) requires maintaining or recovering stability during movement or in response to external perturbations. Temporomandibular Disorders (TMD) encompass a range of musculoskeletal and neuromuscular conditions involving the temporomandibular joint, masticatory muscles (MM), and associated structures. This pilot study evaluated movement smoothness using the Log Dimensionless Jerk (LDLJ) and directional control during the Four-Way Leaning Limits of Stability (LOS) test in patients with TMD under different visual, surface, and MM maximal voluntary contraction (MVC) conditions. Dynamic postural performance was strongly influenced by sensory conditions, particularly support surface and visual input. Large effects were observed for support surface and vision on movement smoothness, whereas masticatory muscle MVC showed no significant main effect on either mean velocity or LDLJ. However, moderate effects were observed for interactions involving contraction, suggesting that the effect of masticatory muscle activation may depend on sensory conditions.**

***Index Terms*—Temporomandibular Disorders, Dynamic Postural Control, Limits of Stability, Movement Smoothness, Log Dimensionless Jerk.**

I. Introduction

Static Postural Control (PC) involves maintaining postural stability while standing on a fixed surface. Dynamic Postural Control (DPC) requires maintaining or recovering stability during movement or in response to external perturbations, such as standing on unstable surfaces or walking [11].

Temporomandibular Disorder (TMD) is an umbrella term encompassing a group of musculoskeletal and neuromuscular conditions involving the Temporomandibular Joint (TMJ), masticatory muscles (MM), and associated structures [12]. The Diagnostic Criteria for Temporomandibular Disorders (DC/TMD) are widely used and provide a standardized approach for classifying these conditions, covering both pain-related and intra-articular disorders (e.g., disc displacement, degenerative joint disease) [7], [12].

Postural control results from the continuous integration of information from visual, vestibular, and proprioceptive systems by the central nervous system, enabling the generation of motor responses that maintain the center of mass within the base of support. Proprioception constitutes the primary source of information during upright posture, providing data on body position and movement through mechanoreceptors in muscles, tendons, and joints. The visual system contributes to postural stabilization by detecting environmental references and distinguishing self-motion from external movement. The relative contribution of each system varies according to the task and the reliability of available sensory information, with multisensory integration enabling adaptations and compensations when one system is altered [13].

Current evidence suggests that TMDs may be associated with alterations in postural stability; however, the relationship with DPC is less established and appears to depend on the specific TMD subtype and assessment methods employed [3], [10], [14]. Studies demonstrate that individuals with myogenic TMD show increased sway area and velocity during posturostabilometric tests, indicating impaired postural stability compared to healthy controls [9]. However, these findings predominantly pertain to static balance evaluations rather than DPC tasks.

Additionally, jaw clenching and MM contraction, which are relevant in the context of TMD, have been associated with acute improvements in steady-state DPC performance in healthy adults, although this effect has not been directly investigated in populations with TMD or self-reported bruxism. Available literature supports a potential association between TMD and changes in DPC, particularly through mechanisms involving occlusal changes and neuromuscular control [2], [4]–[6]. Nevertheless, additional studies are required to elucidate the causality and clinical relevance of this relationship.

The primary objective of this pilot study was to estimate the effect size associated with maximal voluntary contraction (MVC) of the MM during the Four-Way Leaning LOS test to guide sample size calculations for a future adequately powered study. The secondary objective was to explore the influence of MM MVC on DPC performance, focusing primarily on movement smoothness using the Log Dimensionless Jerk (LDLJ) and directional control, while also examining changes in movement velocity and maximum excursion under different visual and surface conditions. Furthermore, this knowledge

may support therapeutic strategies to improve functionality and quality of life in adults with TMD.

II. Materials and Methods

This was a pilot, quantitative, observational, analytical, and cross-sectional study conducted with adults of both sexes aged between 18 and 60 years. Participants were recruited by convenience sampling through social media announcements and underwent a single in-person evaluation lasting approximately 60 minutes.

The evaluation consisted of physical therapy and dental examinations, standardized questionnaires, and the Four-Way Leaning Limits of Stability (LOS) test. Characterization of the sample regarding the presence of TMD was performed by trained researchers using the DC/TMD protocol, including an interview and standardized clinical examination.

Dynamic PC was evaluated using the Four-Way Leaning LOS test performed on a force platform (AMTI, USA) with a sampling frequency of 100 Hz, and signal processing was conducted via NetForce software (AMTI, USA). During the test, participants stood upright and were instructed to voluntarily displace their center of gravity as far as possible in the anterior, right lateral, posterior, and left lateral directions, keeping their feet fixed on the platform without losing balance. The protocol evaluates the ability to control the center of pressure (COP) and center of gravity within the limits of postural stability.

The test was performed under eight experimental conditions resulting from the combination of three factors: visual condition (eyes open or closed), support surface stability (rigid platform or TempurMed® foam on the platform), and masticatory muscle activation (habitual condition or MVC). The order of conditions was randomized by drawing lots immediately prior to evaluation. To minimize muscle fatigue, conditions with and without MVC were executed alternately.

Prior to data collection, a standardized demonstration was performed, followed by a practice trial. Subsequently, up to three valid trials were recorded for each experimental condition, and the first valid attempt was considered for this analyses. In case of failure, the reason was documented, and if a participant could not complete the task after three attempts, that condition was considered non-executable.

COP signals exported from the force platform were processed in Python (Python Software Foundation, USA). Signals were initially filtered using a 4th-order low-pass Butterworth filter with a cutoff frequency of 6 Hz, following recommendations by Miller et al. [8]. Center of gravity (COG) trajectory was then estimated from filtered COP signals using a 4th-order low-pass Butterworth filter with a 0.5 Hz cutoff frequency, as described by Benda et al. [1]. Each trial was visually inspected to manually identify the start and end of the task, as well as transitions between directions, allowing movement segmentation for feature extraction.

From the segmented signals, variables of interest were calculated, including maximum COG excursion in anteroposterior and mediolateral directions, mean displacement velocity, Directional Control, and Log Dimensionless Jerk (LDLJ), the latter serving as an indicator of movement smoothness and coordination.

Descriptive analysis was conducted in Python. Given the pilot nature of the study, interpretation prioritized effect magnitudes to inform future sample size calculations. Effects of MVC, visual condition, and surface stability, along with their interactions, were evaluated using repeated-measures statistical models, reporting effect sizes and confidence intervals where applicable. Intra-individual differences between habitual and MVC conditions ($\Delta = \mathrm{MVC} - \mathrm{Habitual}$) were visualized using boxplots and paired representations. To evaluate movement smoothness ($\mathrm{General}_L DLJ; lowervaluesindicatesmoothermovement), a2 \times 2 \times 2$ three-way repeated-measures ANOVA was conducted with Vision (Open vs. Closed), Surface (Stable vs. Unstable), and Contraction (Habitual vs. Voluntary) as within-subjects factors, assessing all main effects and their two-way and three-way interactions. Data normality was verified prior to analysis using the Shapiro-Wilk test, applying logarithmic or square-root transformations when necessary; post-hoc comparisons were performed using paired t-tests with Bonferroni correction, and effect sizes were reported as partial eta squared (η_p^2).

The activity flowchart is presented in Fig. 1.

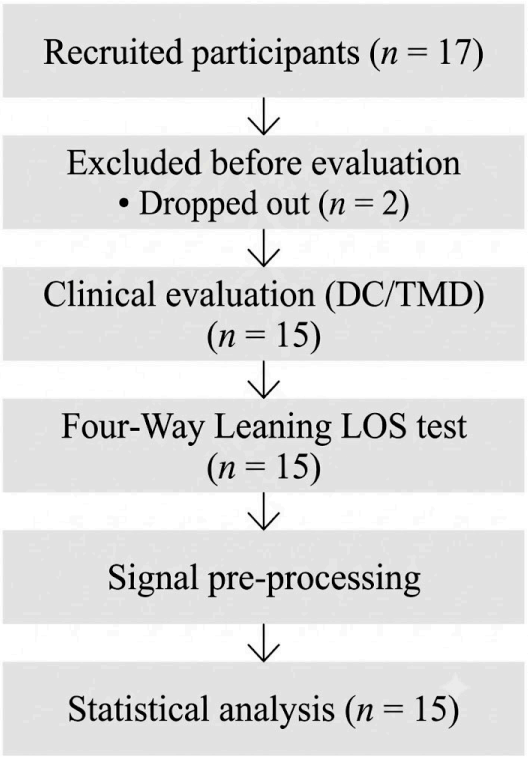

Fig. 1. Flowchart of activities.

III. Results and Discussion

A total of 15 participants (11 female, 4 male) ranging in age from 9 to 52 years were evaluated, with the vast majority presenting with both myalgia and arthralgia associated with TMD

(Table I). Descriptive statistics for all outcome measures across the eight experimental conditions are presented in Table II. Mean LDLJ values ranged from -27.15 to -29.89 across conditions. Lower (more negative) LDLJ values, indicating reduced movement smoothness, were consistently observed during tests on the unstable surface compared to the stable surface.

TABLE I
PARTICIPANT CHARACTERISTICS

Characteristic	Value
Participants	15
Age	Ranging from 9 to 52
Sex	11 Female, 4 Male
TMD Associated Pain	Myalgia e Arthralgia: 12 Myalgia: 2 None: 1

TABLE II
DESCRIPTIVE RESULTS

Condition	Mean Velocity (SD)	LDLJ (COP) Mean (SD)
OESSN	92.88 (18.19)	-27.15 (1.23)
CESSN	86.68 (19.57)	-28.03 (1.54)
OESSC	88.13 (13.22)	-27.48 (1.42)
CESSC	85.28 (13.91)	-28.07 (1.38)
OEUSN	79.25 (14.19)	-29.35 (1.47)
CEUSN	101.43 (19.79)	-29.81 (2.31)
OEUSC	82.67 (15.55)	-28.34 (1.78)
CEUSC	98.48 (19.55)	-29.89 (1.80)

Note: OESSN = open eyes, stable surface, "no contraction"/habitual; CESSN = closed eyes, stable surface, "no contraction"/habitual; OESSC = open eyes, stable surface, "contraction"/MVC; CESSC = closed eyes, stable surface, "contraction"/MVC; OEUSN = open eyes, unstable surface, "no contraction"/habitual; CEUSN = closed eyes, unstable surface, "no contraction"/habitual; OEUSC = open eyes, unstable surface, "contraction"/MVC; CEUSC = closed eyes, unstable surface, "contraction"/MVC.

A three-factor repeated measures ANOVA evaluated the effects of Vision, Surface, and Contraction on mean movement velocity. No significant main effects were found for Vision ($F(1,13) = 3.764$, $p = 0.074$, $\eta_p^2 = 0.225$), Surface ($F(1,13) = 0.847$, $p = 0.374$, $\eta_p^2 = 0.061$), or Contraction ($F(1,13) = 0.373$, $p = 0.552$, $\eta_p^2 = 0.028$). A significant interaction between Vision and Surface was identified ($F(1,13) = 43.727$, $p < 0.001$, $\eta_p^2 = 0.771$). No significant interactions were found for Vision $\times$ Contraction, Surface $\times$ Contraction, or three-factor interactions ($p > 0.05$).

Significant main effects of Vision and Surface were observed for LDLJ (Fig. 2). Vision significantly influenced LDLJ ($F(1,13) = 16.092$, $p = 0.001$, $\eta_p^2 = 0.553$), while Surface showed a larger effect ($F(1,13) = 143.609$, $p < 0.001$, $\eta_p^2 = 0.917$). No significant main effect was identified for Contraction ($F(1,13) = 0.558$, $p = 0.468$, $\eta_p^2 = 0.041$). None of the interaction terms reached statistical significance; however, the Surface $\times$ Contraction interaction showed a moderate estimated effect size ($\eta_p^2 = 0.192$), and the Vision $\times$ Surface $\times$ Contraction interaction demonstrated a moderate-to-large estimated effect size ($\eta_p^2 = 0.261$).

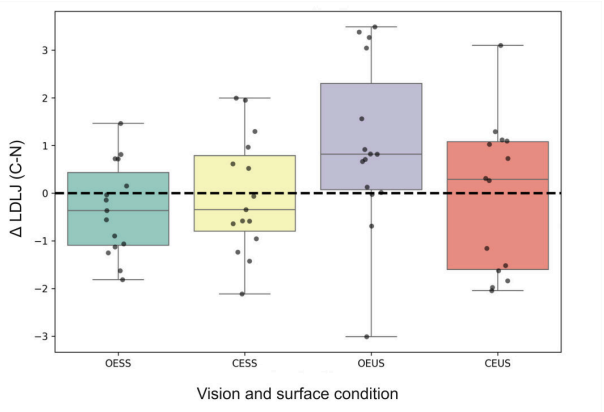

Fig. 2. Intra-individual variation in LDLJ induced by maximal voluntary contraction of the jaw (Δ = MVC − Habitual). Because more negative LDLJ values represent less smooth movement, negative ΔLDLJ values indicate a reduction in movement smoothness following MVC. Dashed horizontal line at $\Delta = 0$ represents no change. OESS = open eyes, stable surface; CESS = closed eyes, stable surface; OEUS = open eyes, unstable surface; CEUS = closed eyes, unstable surface.

Additionally, directional control was analyzed in each direction and condition, yielding no significant differences (Fig. 3, Fig. 4, Fig. 5, Fig. 6). Similarly, an analysis of LDLJ in each condition, visualized using paired line plots, also showed no significant differences (Fig. 7). Directional control was examined separately for the anteromedial (AM), right mediolateral (RML), posteromedial (PM), and left mediolateral (LML) directions under each vision and surface condition (Figs. 3–6).

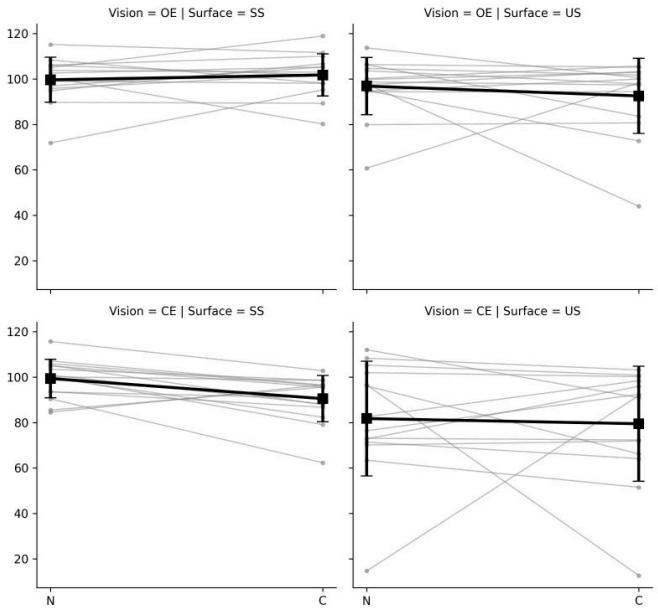

Fig. 3. Directional control analysis (Anteromedial or AM direction). OESS = open eyes, stable surface; CESS = closed eyes, stable surface; OEUS = open eyes, unstable surface; CEUS = closed eyes, unstable surface; N = "No contraction" or Habitual; C: "Contraction" or MVC.

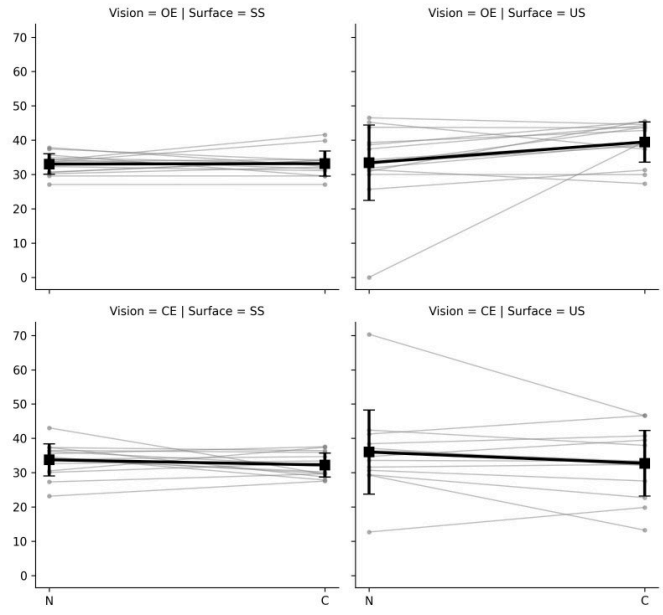

Fig. 4. Directional control analysis (Right Mediolateral or RML direction). OESS = open eyes, stable surface; CESS = closed eyes, stable surface; OEUS = open eyes, unstable surface; CEUS = closed eyes, unstable surface; N = ”No contraction” or Habitual; C: ”Contraction” or MVC.

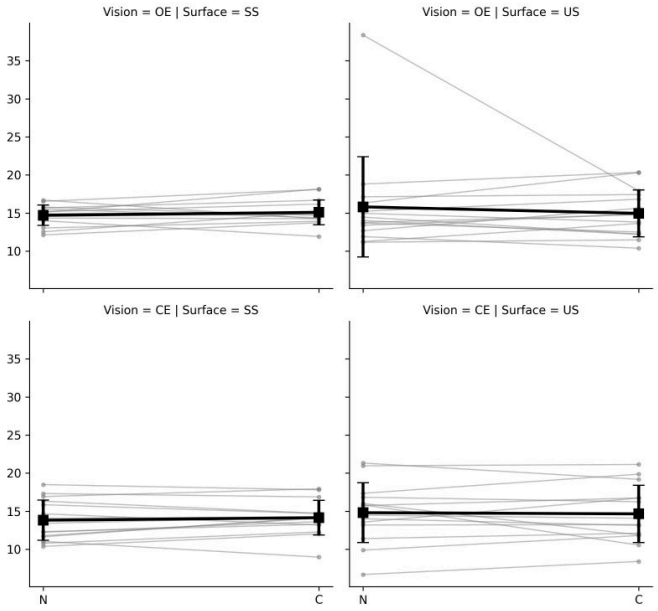

Fig. 6. Directional control analysis (Left Mediolateral or LML Direction). OESS = open eyes, stable surface; CESS = closed eyes, stable surface; OEUS = open eyes, unstable surface; CEUS = closed eyes, unstable surface; N = ”No contraction” or Habitual; C: ”Contraction” or MVC.

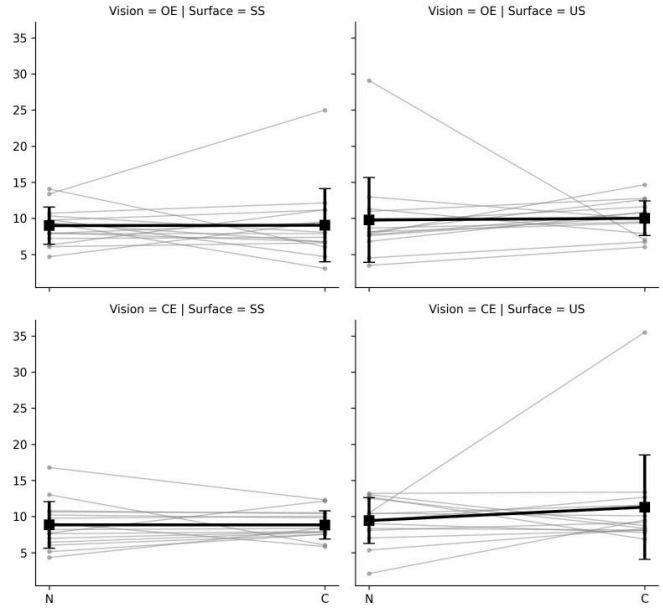

Fig. 5. Directional control analysis (Posteromedial or PM direction). OASE = open eyes, stable surface; OESS = open eyes, stable surface; CESS = closed eyes, stable surface; OEUS = open eyes, unstable surface; CEUS = closed eyes, unstable surface; N = ”No contraction” or Habitual; C: ”Contraction” or MVC.

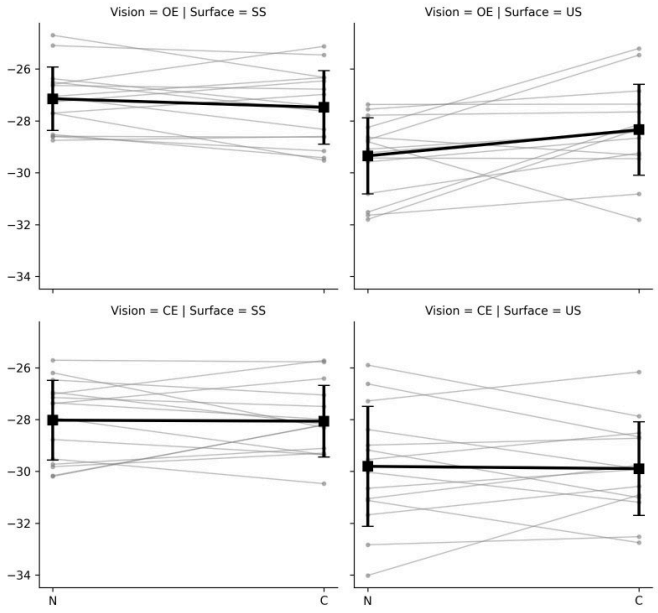

Fig. 7. Paired line plots illustrating LDLJ across all experimental conditions. OESS = open eyes, stable surface; CESS = closed eyes, stable surface; OEUS = open eyes, unstable surface; CEUS = closed eyes, unstable surface; N = ”No contraction” or Habitual; C: ”Contraction” or MVC.

Effect size estimation was the primary objective of this pilot study. Partial eta squared values ranged from negligible ($\eta_p^2 = 0.028$) to very large ($\eta_p^2 = 0.917$). The largest estimated effects were observed for Surface on LDLJ ($\eta_p^2 = 0.917$), Vision on LDLJ ($\eta_p^2 = 0.553$), and the Vision $\times$ Surface interaction on mean velocity ($\eta_p^2 = 0.771$).

The large effects observed for Surface on LDLJ ($\eta_p^2 = 0.917$), Vision on LDLJ ($\eta_p^2 = 0.553$), and the Vision $\times$ Surface interaction on mean velocity ($\eta_p^2 = 0.771$) indicate that sensory manipulation should be carefully considered in the design and sample size estimation of future studies. In contrast, the small effect associated with the main effect of contraction on LDLJ ($\eta_p^2 = 0.041$) suggests that substantially larger samples may be required to detect a clinically or statistically meaningful effect of masticatory muscle activation, if such an effect exists. First, the absence of a matched healthy control group prevents determining whether the observed responses are specific to individuals with TMD. Future studies should include matched controls to distinguish disease-related alterations from normal responses to sensory manipulation and masticatory muscle activation. Second, the relatively small sample size precluded robust subgroup analyses according to TMD subtype and severity. Future adequately powered studies should consider stratification by TMD diagnosis and clinical severity, as different clinical phenotypes may present distinct neuromuscular and postural responses. Third, movement segmentation was performed manually based on visual inspection of the COP/COG trajectories. Although this approach allowed identification of task phases, it may introduce observer-dependent variability. Future studies should investigate automated segmentation methods and/or establish inter- and intra-rater agreement for the identification of movement onset, termination, and directional transitions.

IV. Conclusion

In this pilot sample, dynamic postural performance showed large effects associated with sensory conditions, particularly support surface and visual input. Masticatory muscle MVC did not show a significant main effect on mean velocity or movement smoothness. However, moderate effect sizes for interactions involving contraction suggest that its contribution may depend on sensory conditions. These findings provide preliminary effect-size estimates to inform the design and sample size of future adequately powered studies.

***Abstract*—This study applies Explainable Artificial Intelligence techniques (SHAP and LIME) to a multimodal classifier (SVM-RBF) to support the differential diagnosis of dementia syndromes. Using EEG, clinical, and sociodemographic data from the GeronGnosis dataset (n=50), global and local explainability analyses revealed that the model bases its decisions predominantly on cognitive and functional scores (MMSE, Pfeffer Questionnaire, and Mini-BESTest), followed by sociodemographic variables and, to a lesser extent, frontotemporal neurophysiological attributes. In conclusion, the integration of multimodal data with XAI imparts transparency and clinical coherence to the algorithm, validating its alignment with traditional diagnostic criteria and suggesting its applicability as a diagnostic support tool, particularly in cases of cognitive decline that remain poorly defined.**

***Index Terms*—Explainable Artificial Intelligence, Dementia Syndromes, Electroencephalography, Machine Learning.**

I. Introduction

Global population aging is projected to increase the proportion of individuals aged 60 years or older from 12% to 22% between 2015 and 2050, with two-thirds of this demographic concentrated in low- and middle-income countries [1]. This scenario projects a substantial increase in dementia syndromes, neurodegenerative conditions that progressively impair cognition and functional capacity [2]. Consequently, the number of individuals with dementia is estimated to reach 152.8 million by 2050 [3]. Alzheimer's disease (AD), the most prevalent form, is associated with the accumulation of beta-amyloid peptide and hyperphosphorylated tau protein, leading to progressive synaptic and neuronal loss [4], [5].

Frontotemporal dementia (FTD), also classified as a neurodegenerative dementia, predominantly affects the frontal and temporal lobes, causing behavioral and language alterations [6]. Mild Cognitive Impairment (MCI) represents an intermediate condition characterized by measurable cognitive decline and relative preservation of functional capacity, particularly in the performance of instrumental activities of daily living (IADL) [7], [8].

The early identification of dementia syndromes is highly relevant for prognosis, as therapeutic intervention in early stages can delay disease progression. However, the differential

Coordination for the Improvement of Higher Education Personnel (CAPES), Brazil; Science and Technology Support Foundation of the State of Pernambuco (FACEPE), Brazil; and the National Council for Scientific and Technological Development (CNPq), Brazil.

diagnosis of dementia syndromes encounters cultural, structural, and economic barriers in clinical practice, given that specialist professionals and high-cost imaging examinations are resources with limited availability in public health systems [9]. This limitation drives the search for lower-cost and more scalable auxiliary methods.

In this context, electroencephalography (EEG) presents favorable characteristics: it is non-invasive, low-cost, and portable. Furthermore, it can capture alterations in cortical activity that precede structural changes detectable by neuroimaging, offering sensitive markers of the synaptic dysfunction characteristic of neurodegenerative processes [10], [11].

When combined with EEG, machine learning (ML) techniques have demonstrated robust performance in differentiating dementia syndromes, particularly when integrated with clinical and sociodemographic variables in multimodal approaches [12]–[15]. However, studies indicate that classifiers such as Support Vector Machines (SVM) operate as black boxes, limiting their clinical adoption [15], [16]. Explainable Artificial Intelligence (XAI) frameworks, such as Local Interpretable Model-agnostic Explanations (LIME) and SHapley Additive exPlanations (SHAP), have been proposed to quantify the contribution of each feature to the model's decision [17], [18]. Nevertheless, their application to multimodal dementia models remains underexplored.

This study applies XAI models, such as SHAP and LIME, to a previously validated SVM classifier trained on the GeronGnosis dataset [15], with the aim of quantifying the contribution of the clinical, neurophysiological, and sociodemographic features that most strongly influence the differential diagnosis of dementia syndromes.

II. Methodology

A. Study Design

The present study builds upon the work of Oliveira et al. (2026) [15], who tested and validated various machine learning models using the multimodal GeronGnosis dataset. Based on the Particle Swarm Optimization (PSO) configuration and the best-performing classifier identified by those authors, the SHAP and LIME explainability frameworks were applied to investigate the features that most significantly influenced the algorithm's decision-making process. Figure 1 presents a flowchart illustrating the methodological steps of both the study by Oliveira et al. (2026) [15] and the present study.

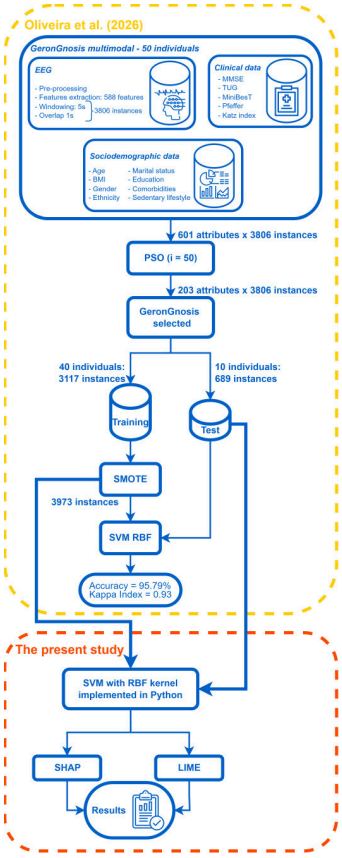

Fig. 1. Flowchart of the experiments.

B. GeronGnosis

The GeronGnosis dataset [15] comprises 50 older adults distributed across four groups: Healthy Controls (HC, n=20), Alzheimer's disease (n=15), Mild Cognitive Impairment (n=10), and Frontotemporal dementia (n=5). Recordings were performed using the EEG module of the Brain Wave III Neurovirtual polysomnograph, with participants in a resting state. Impedance was maintained below 5 kΩ and monitored through the software interface. The sampling rate was 300 Hz, with 16-bit analog-to-digital conversion and a resolution of $9.74 \times 10^{-2} \mu V$.

Participants are followed up at the Cognitive Neurology Outpatient Clinic of Hospital das Clínicas at the Federal University of Pernambuco (HC/EBSERH-UFPE), where cognitive and behavioral neurologists perform clinical evaluation and classification according to current guidelines established by the Brazilian Academy of Neurology. All data collection procedures were conducted only after approval by the Ethics and Research Committee (CEP) of the Health Sciences Center (CCS) at the Federal University of Pernambuco (UFPE), under process number CAAE 71096223.3.0000.5208.

The EEG signal was acquired using 19 electrodes positioned according to the international 10-20 system, supplemented by two auricular electrodes (A1 and A2), totaling 21 recording channels, plus one reference electrode positioned in the frontal region. During acquisition, high-pass filtering at 0.1 Hz, low-pass filtering at 70 Hz, and 60 Hz notch filtering were applied, with no subsequent digital filtering. Only resting-state segments with eyes closed were used, with an average duration of 5 minutes. The continuous signal was segmented into 5-second windows with 1-second overlap. For each window, 28 time-frequency features described in Table I were extracted from each of the 21 electrodes, resulting in 588 features per instance and 3,806 instances [19].

The dataset features a multimodal structure, comprising 28 time- and frequency-domain features for each of the 21

EEG electrodes; clinical data for assessing cognition (Mini-Mental State Examination [MMSE]), functionality (Katz Index and Pfeffer Functional Activities Questionnaire), and mobility/balance (Timed Up and Go [TUG] and Mini-Balance Evaluation Systems Test [Mini-BESTest]); and sociodemographic data, including age, body mass index (BMI), gender, ethnicity, marital status, education level, comorbidities, and level of sedentary behavior. The GeronGnosis EEG dataset was previously compared with the OpenNeuro dataset (which also consists exclusively of EEG recordings), achieving satisfactory classification performance among the evaluated groups, as reported by Oliveira et al. (2026) [15].

The authors randomly divided the dataset into training (80%) and test (20%) sets, performing a subject-level partition. This division resulted in 40 subjects (3,117 instances) for the training set and 10 subjects (689 instances) for the test set. The training set was balanced using the Synthetic Minority Oversampling Technique (SMOTE), resulting in a total of 3,973 instances.

C. Baseline Model and Experimental Setup - Oliveira et al. (2026) [15]

The present study builds upon the investigation initiated by Oliveira et al. (2026) [15], in which a multimodal classification pipeline was developed for the differential diagnosis of dementia syndromes using the GeronGnosis dataset. In that study, various classifiers were evaluated under two experimental configurations (binary and multiclass) combined with different feature selection strategies employing PSO. The binary configuration consisted of the classification between the control group (CS) and the dementia group (grouping individuals diagnosed with AD and FTD), whereas the multiclass configuration involved the CS, MCI, and dementia classes.

For the multiclass scenario, results demonstrated that the SVM classifier with Radial Basis Function (RBF) kernel, combined with PSO configured with 50 iterations, achieved the best performance on the test set, with an accuracy of 95.79% and a Kappa index of 0.93. This configuration resulted in a subset of 203 selected features, composed of EEG-derived features and clinical and sociodemographic variables, as detailed in Table II.

TABLE II
ATTRIBUTES SELECTED AFTER PSO.

D. Classifier Reimplementation for Interpretability Analysis

Since the study by Oliveira et al. (2026) [15] used the SVM classifier implementation available in Weka software (version 3.8.6), and considering that XAI libraries—particularly SHAP

and LIME—require direct access to output probabilities and the internal structure of the trained model, the SVM-RBF classifier was reimplemented in Python.

The reimplemention was performed using the scikit-learn library (version 1.8.0), maintaining the following hyperparameters in accordance with the original configuration whenever possible:

- **Kernel**: RBF;
- **Regularization parameter (C)**: 1;
- **Kernel parameter (gamma)**: 0.01;
- **Probabilities**: enabled (`probability=True`), a requirement for applying SHAP via `KernelExplainer` and LIME via `LimeTabularExplainer`;
- **Stopping tolerance**: 0.001;
- **Random seed** (`random_state`): 1;
- **Data standardization**: parameters fitted on the training set and applied to the test set.

This reimplementation step was essential to enable the application of explainability techniques, since Weka does not offer native integration with the SHAP and LIME frameworks. The model was trained on the same subset of 203 features selected by PSO with 50 iterations, in order to ensure direct comparability with the results reported in the preceding study. The reimplementation was validated by comparing performance metrics with those of the original study, obtaining an accuracy of 95.79% and a Kappa index of 0.93 on the test set, values identical to those originally reported.

E. XAI Implementation

To address the black-box problem of SVM and enable clinical interpretation of decision-making, this study implemented two XAI frameworks: (i) SHAP, grounded in Game Theory, which quantifies the influence of each variable on the decision, operating at both global interpretation (summary plots) and local interpretation (waterfall plots for individual instances); and (ii) LIME, focused on local interpretation, which generates synthetic perturbations around a specific instance to provide a simplified explanation of that isolated prediction [17], [18].

LIME, by default, explains one instance at a time. Since each individual is represented by multiple instances due to temporal signal windowing, the algorithm was adapted to calculate the average of importance values across all instances of the same individual. The average importance values were calculated preserving the sign of each feature's weights. For each class, one individual from the test set was randomly selected for local analysis.

SHAP was implemented using the `KernelExplainer`, with 100 samples from the training set as background reference. LIME, in turn, employed the `LimeTabularExplainer` with random seed 42, configured with 15 features and 1,000 perturbations per explained instance.

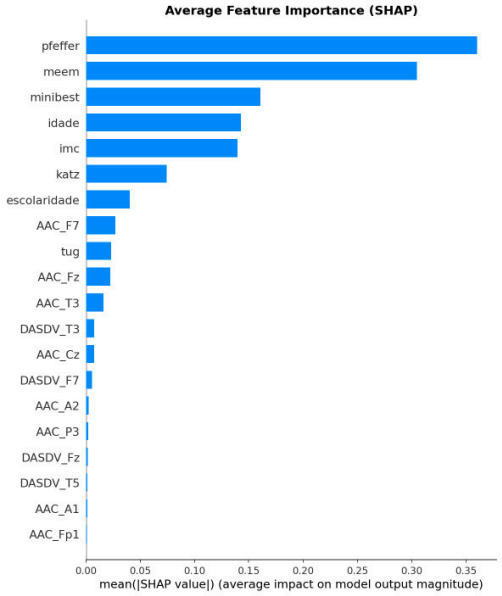

Fig. 2. Absolute mean importance of the main attributes in the global prediction.

III. Results

A. Global Explainability via SHAP

As a means to overcome the inherent interpretability limitation of black-box algorithms, the SHAP framework was applied to the test set predictions, enabling the mapping of the exact contribution of each feature to the model's mathematical decision. The mean absolute importance analysis demonstrated that the model anchored its primary decisions mainly on clinical and functional markers, as shown in Figure 2.

As evidenced by the global ranking, the Pfeffer Functional Activities Questionnaire, the MMSE, and the Mini-BESTest were the main determinants of the classifier's decisions. It is worth noting that the MMSE and the Pfeffer questionnaire are part of the assessment protocol used by neurologists for the diagnostic classification of participants. Thus, the fact that these features predominate in the global ranking suggests that the classifier reproduces the very instruments that originated the labels, which does not represent independent evidence of its discriminative power. Added to this clinical basis, sociodemographic variables (age and BMI) demonstrated a secondary weighting factor for classification. In the neurophysiological domain, frontal and temporal electrodes (especially AAC_F7, AAC_Fz, and AAC_T3) emerged as most influential. To understand the impact of these features on class differentiation, SHAP density values were segmented by predictive class.

In the HC group, the features that stood out most in classification were those related to cognitive assessment scores (MMSE) and IADLs, represented by the Pfeffer questionnaire (Figure 3). The results reflect how the preservation of such variables can contribute to the correct assignment of participants to their respective group by the model. In parallel, the high motor performance evidenced in the Mini-

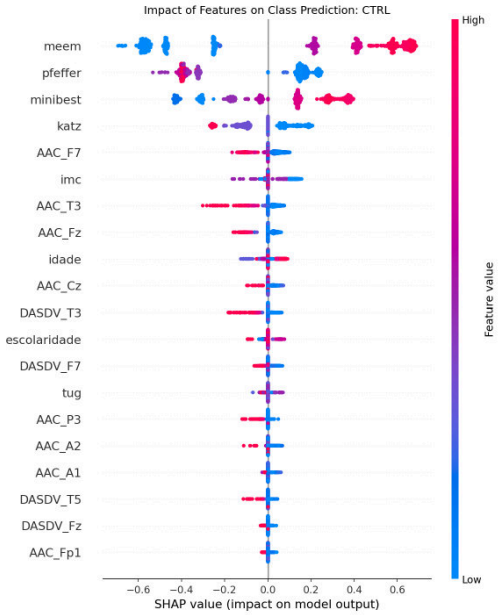

Fig. 3. SHAP for the control class.

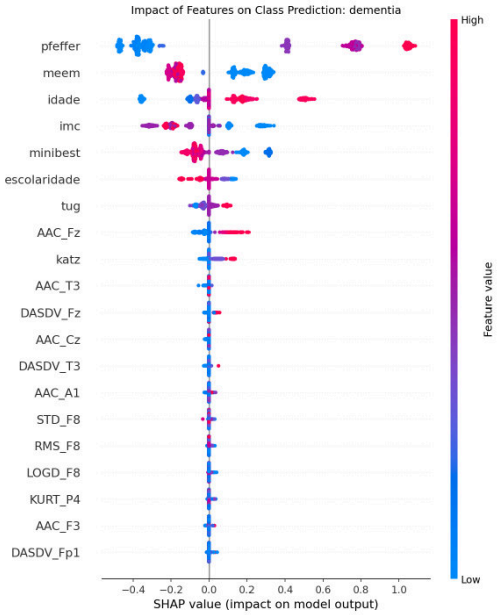

Fig. 4. SHAP for the dementia class.

BESTest consolidated the classification of individuals in the control group. Regarding EEG activity, it is noteworthy that its contribution was more modest compared to that observed in the clinical variables, with a pattern of greater relevance in the frontal and temporal areas (AAC_F7 and AAC_T3).

As in the HC group classification, the MMSE and Pfeffer questionnaire scores stood out as the main predictors for model accuracy in the Dementia group (Figure 4). The low scores obtained by this group in the assessments likely facilitated discrimination between the healthy control profile and the profile with a dementia diagnosis. Additionally, advanced age and balance deficits (assessed by the Mini-BESTest) also contributed significantly to classification. The prominence of EEG activity appears in relation to midline electrodes (AAC_Fz and AAC_Cz), which, according to the model's results, developed greater weight in classification. Similarly to what was found in the other groups, the electrode located in the temporal region (AAC_T3) also contributed to the result, however, with lower weight compared mainly to MCI.

In the SHAP analysis of the MCI group (Figure 5), the Pfeffer questionnaire, age, MMSE score, and BMI stood out as the most relevant features for algorithm performance. This result demonstrates that clinical and sociodemographic variables were determinant for the classification of this group. However, the weight distribution pattern for the group reveals an overlap among the most relevant variables, unlike what was found in the other groups. Furthermore, electrode activity, although more modest, still presented relevance (as evidenced by signal intensity on the right side), especially in the left frontotemporal regions (AAC_F7, AAC_T3, DASDV_F7, and DASDV_T3).

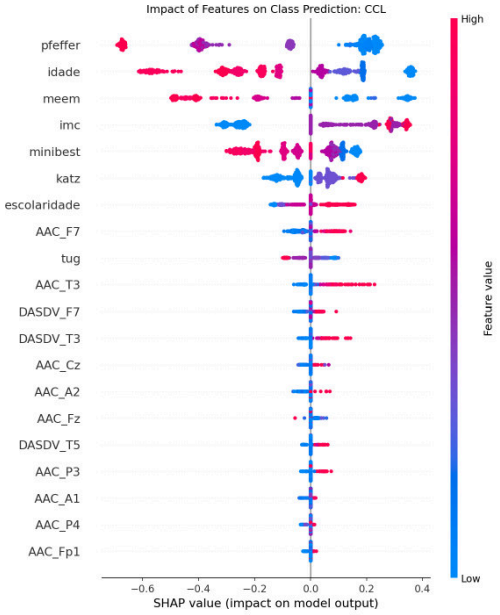

Fig. 5. SHAP for the MCI class.

B. *Local Explainability via LIME*

A locally-targeted analysis through the LIME framework was also implemented, with the objective of deepening the predictions for individual participants. When conducting this type of experiment, it is expected that the results previously achieved will be maintained when specifically testing one participant from each research group.

The analysis of case P018 (HC group) illustrates the classifier's behavior for a participant from this group, whose prediction was obtained by averaging 76 temporal windows (Figure

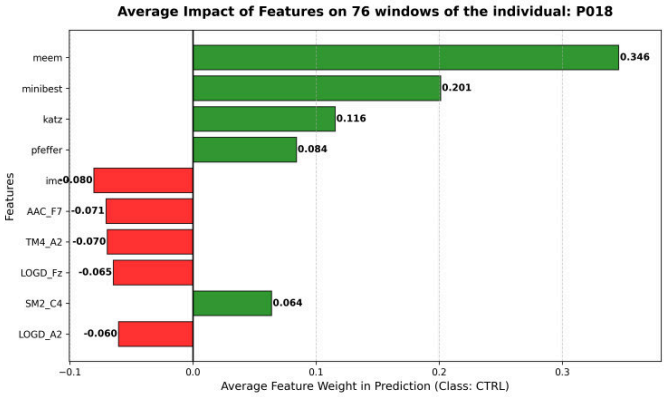

Fig. 6. Interpretability of individual P018 using LIME – control class.

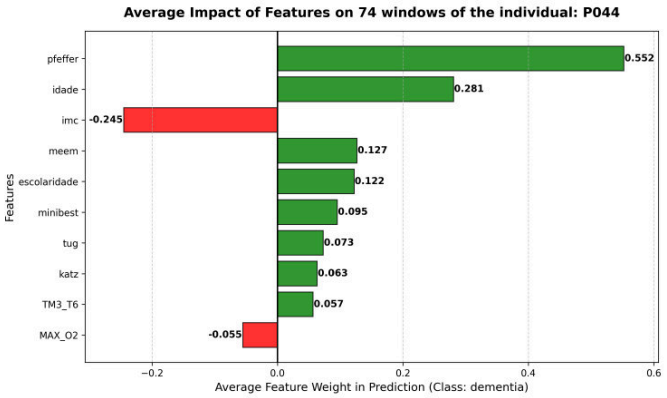

Fig. 7. Interpretability of individual P018 using LIME – dementia class.

6). The results demonstrate that clinical variables, particularly the MMSE score (average impact weight of 0.346), were determinant for the classification of the participant into their respective group.

In addition to cognitive function, adequate performance on the balance scale and instruments related to functional assessment also positively influenced the correct classification of case P018. This result highlights that the preservation of these domains is essential for characterizing cognitively intact individuals.

The LIME model evaluation for a patient in the dementia group (patient P044) was conducted across 74 windows. Analysis of the plot in Figure 6 clearly demonstrates the influence of the Pfeffer questionnaire on the classification of this patient (weight of 0.552). This finding corroborates the clinical importance of assessing the loss of IADLs, which serves as a key criterion in diagnostic decision-making. In addition to the Pfeffer questionnaire score, age (weight of 0.281) and the MMSE score (weight of 0.127) were decisive factors in the classification of patient P044..

In the MCI group, patient P023 was selected for LIME data processing. In this case, 77 windows were analyzed, and the results are presented in Figure 8. The explainability plot highlights that the BMI variable most favored the classifier's

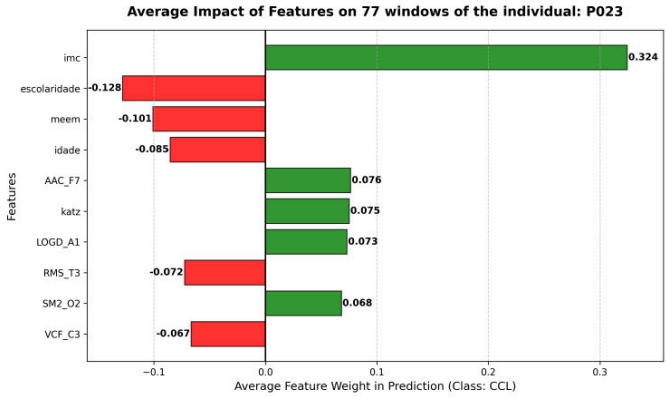

Fig. 8. Interpretability of individual P023 using LIME – MCI class.

final decision for patient P023 (weight of 0.324). The education level (-0.128) and MMSE (-0.101) variables contributed negatively to the MCI group score; that is, they reduced the predicted probability of classification as MCI by the model. It is also noteworthy, albeit with lower impact, the influence of electrodes F7 (frontal lobe, weight of 0.076), A1 (temporal lobe, weight of 0.073), and O2 (occipital, 0.068) for the correct classification of P023 in the MCI group.

IV. Discussion

The results of this study indicate that the integration of multimodal data, analyzed through machine learning algorithms combined with XAI, provides support for adequate classification among individuals in the HC, MCI, and dementia groups. The subject-level stratified partition adopted in this work stands out, which confers greater reliability to the reported metrics compared to approaches that segment data by epochs. The global analysis using the SHAP framework revealed that the results of the clinical assessment battery performed with participants from the dataset (use of MMSE, Pfeffer questionnaire, Mini-BESTest) exerted greater mean influence on the model's predictions. Furthermore, the local analysis performed by LIME largely reinforced the main relevant variables in the classification tasks, according to what had been found in the SHAP analysis.

For the HC group, the preservation of cognitive scores (MMSE), functional capacity (Pfeffer), and balance (Mini-BESTest) were crucial for the final classification. This result reinforces that the high performance found in participants from this group enables the employed models to differentiate a profile of good clinical performance from those with some type of deficit (as found in the dementia group) [20]. The repetition of the variables found in SHAP in the LIME result reinforces that cognitive and functional integrity are, in fact, determinant for adequately classifying participants from the control group. Previous studies report that discrimination between clinically well-defined groups, such as patients with dementia and matched controls, tends to be less challenging than differentiation in intermediate conditions, which can be observed in the MCI group pattern [15], [21]–[23].

In the dementia group, given that patients already presented more evident cognitive and functional impairments, their lower clinical performance facilitated their discrimination compared to the other groups. Regarding EEG activity, we observed a greater weight in midline electrodes (Fz and Cz), which may suggest diffuse alterations in cortical activity related to an advanced stage of cognitive impairment [24], [25]. Once again, the individual assessment results from LIME confirmed the predominance of clinical and sociodemographic variables. Particularly for the dementia group, the alterations in the Pfeffer questionnaire score that facilitated classification establish a close relationship with the diagnostic investigation performed in clinical practice [26]. The results of the present study reinforce that functional losses characterize the profile of patients with dementia, beyond the already established cognitive impairment. Another relevant finding in the individual analysis was the high weight of the education variable for classification (a value close to that of the MMSE). This finding is consistent with the results of a Brazilian study, which detected that educational level presented the highest relative risk for cognitive impairment [27]. Lower educational attainment often serves as a proxy for reduced cognitive reserve accumulated throughout life; conversely, cognitive reserve is directly proportional to the level of education, acting as a protective factor against pathological processes such as dementia [28].

In the MCI group, the overlap of feature weights among clinical, sociodemographic, and neurophysiological variables is consistent with the characterization of this phase as a heterogeneous continuum, marked by greater interindividual variability [29]. In the global analysis, as revealed by the SHAP algorithm, the considerable influence of frontotemporal electrodes on the classification stands out. This may indicate that subtle alterations in cortical electrical activity were already detectable by EEG, even before any overt impairment in global functional capacity becomes apparent. Once again, cognitive reserve can help explain the discrepancy observed between cortical electrical activity patterns and clinical assessment results. Simfukwe et al. (2025) [30] demonstrated that greater cognitive reserve is associated with delayed onset of cognitive decline, lower dementia risk, and better clinical outcomes, despite a similar neuropathological burden.

Given that EEG can provide relevant information at the cortical level, its application is justified by the detection of electrophysiological alterations that may precede the clinical manifestations of dementia syndromes or even MCI. Therefore, even though clinical variables were more prominent in the XAI results, other types of EEG processing, such as those related to the investigation of more or less active cortical areas, can provide valuable information for the characterization of each clinical condition studied.

The study presents methodological limitations that require cautious interpretation. The primary limitation concerns the small size of the original clinical sample (n=50 participants), which may restrict the generalizability of the findings. Despite the increase in the number of computational instances achieved through EEG signal windowing into 5-second segments, there remains a possibility that the heterogeneity of the general population was not fully represented. To mitigate the risk of overfitting and data leakage, rigorous protocols were implemented. These include subject-level stratified partitioning, which prevents windows from the same participant from appearing simultaneously in both the training and test sets, alongside the application of the SMOTE technique strictly restricted to the training set.

Future investigations with larger sample sizes and longitudinal designs are necessary to evaluate whether the patterns identified by the multimodal model are reproducible and robust. Temporal follow-up studies could determine whether patients with MCI, classified based on the bioelectrical signature detected by the algorithm, progress to dementia, thereby validating the early predictive potential of this approach.

V. Conclusion

To overcome the interpretability limitations of the models, XAI frameworks such as SHAP and LIME were employed, providing greater transparency and clinical coherence to the classifier's decisions. The results suggest that the integration of EEG and clinical data can offer complementary information for diagnostic assessment, particularly when traditional neuropsychological evaluation proves inconclusive due to the effects of cognitive reserve, as seen in MCI. Furthermore, XAI revealed the model's reliance on the instruments of the diagnostic criteria themselves, an insight that performance metrics alone would not have identified. The combination of multimodal data with interpretable ML algorithms has demonstrated potential, albeit preliminary, as a resource to support the differential diagnosis of electrophysiological and clinical alterations in a patient population with cognitive deficits.

***Abstract*—Nowadays, gas vesicles (GVs) have been studied for the development of improved contrast agents for ultrasound biomedical imaging. When GVs receive US pulses, the acoustic responses of the GVs are captured by US transducers as radio-frequency (RF) signals which are analyzed by digital processors to get tissue information. These RF signals have to be denoised before being analyzed since noise and electromagnetic interference usually affect these signals. Conventional linear filters are not suitable for non-stationary signals, such as the GV responses. This paper evaluates different wavelet filters for the denoising of the GV responses. Wavelet filtering allows a better denoising of non-stationary signals, for different detail levels (decomposition levels). Tests performed on experimental ultrasound GV responses using a piezoelectric transducer and an oscilloscope show the characteristics of applying different wavelets for the denoising process of the GV ultrasound responses. The results indicate that wavelets with low vanishing moments are not adequate for RF signal denoising, while increasing the number of decomposition levels resulted in a marginal improvement of the denoising process. However, using fewer decomposition levels reduces the required processing time. Hence, the number of decomposition levels must be properly selected.**

***Index Terms*—Biomedical imaging, data acquisition, ultrasound imaging, wavelet filtering.**

I. Introduction

Wavelet transform is a powerful tool for signal processing in biomedical applications [1]–[5] Among these signal processing applications, biomedical imaging based on ultrasound requires processing the radio-frequency (RF) signals produced during the acquisition of the ultrasound waves [6]–[9].

On the other hand, contrast agents are required in biomedical imaging systems for getting adequate tissue images. Nowadays, gas vesicles (GVs) have been studied for their application as contrast agents for ultrasound (US) imaging systems. GVs are air-filled protein nanostructures with a width between 45–250 nm and a length of hundreds of nm [10]. Besides, GVs scatter the received sound waves, due to their low density and high compressibility, producing a ultrasound contrast. As a result, GVs have better tissue penetration (due to their nano-scale dimensions) and give stronger acoustic responses than other conventional microbubble contrast agents [11], [12].

The GV acoustic responses are acquired by the transducer as RF signals. Noise and electromagnetic interference can affect the acquired RF signals. Even when using analog filters in the data acquisition system, digital filtering is commonly applied. Conventional digital filters (Butterworth, Chebyshsev, finite impulse response filters, among others) operate mainly in the frequency domain, with poor time localization and their performance is not good for non-stationary signals (such as electrocardiograms and ultrasound signals).

On the other hand, wavelet filtering has many advantages over conventional filters [13], [14]. This method has good performance for stationary and non-stationary signals, the time and frequency resolution can be adjusted, which is useful to detect spikes and irregularities in the signal, and allows multi-resolution signal analysis:the signal is analyzed at different levels of detail (decomposition levels).

This paper explores the application of wavelet filtering in the denoising of RF signals obtained from the ultrasound responses of GVs. An adequate RF signal denoising allows an improved analysis of the ultrasound properties of GVs, aiming for their further application as contrast agent. A phantom was prepared using a combination of agarose with GVs produced by Halobacterium salinarum NRC–1, until reaching an optical density (OD) of 0.8. A piezoelectric ultrasound transducer was used to send ultrasound pulses to the phantom, and also to

This research was supported in part by CAPES, CNPq and FAPERJ.

acquire the GV responses as RF signals. These RF responses were amplified, filtered using a low pass filter and sent to a oscilloscope to save the samples. Each RF response of the phantom was visualized and saved by the oscilloscope using two different acquisition modes for: single mode (the oscilloscope acquires only one waveform after the trigger event) and 128-average mode (the oscilloscope acquires 128 waveforms and the average of these waveform is stored and visualized). The wavelet filtering is applied to the single-mode-acquisition waveform, while the 128-average-acquisition waveform is used as a reference signal (an approximation of the RF signal in the absence of noise). Wavelet filters with different mother wavelets (Daubechies, Symlets, Coiflets) and decomposition levels were applied to filter the RF signal.

The performed tests indicate that mother wavelets with low vanishing moments are not adequate for the filtering of the RF signals, while increasing the number of decomposition levels does not significantly improve the denoising process. The filtering using the wavelet Symlet 8 with 6 decomposition levels gives the best noise attenuation.

II. Theoretical Foundations

A. Wavelets

A wavelet is a function with limited duration that can be used to decompose a signal, similarly to the Fourier analysis that decomposes a signal into a set of sinusoidal functions. However, the sinusoidal functions are regular and periodic, being not adequate to detect transients. On the other hand, a wavelet function can be symmetrical or asymmetrical, sharp or smooth, being better for the analysis of peaks, instantaneous changes of amplitude or frequency, irregularities or other signal transients. A function $\Psi(t)$ can be used as a wavelet if the signal has zero mean and finite energy. These conditions can be mathematically expressed as follows [15], [16]:

$$\int_{-\infty}^{+\infty} \Psi(t)dt = 0, \tag{1}$$

$$\int_{-\infty}^{+\infty} |\Psi(t)|^2 dt = 0. \tag{2}$$

Fig. 1 shows some wavelets used for signal processing.

The wavelet transform uses translated and scaled versions of a function called mother wavelet $\Psi(t)$;

$$\Psi_{a,b}(t) = \frac{1}{\sqrt{a}}\Psi\left(\frac{t-b}{a}\right), \quad 0 < a \in \Re, b \in \Re, \tag{3}$$

where a and b are the scale and translation factors, respectively. The continuous-time wavelet transform (CWT) of the signal $x(t)$ with respect to the mother wavelet $\Psi(t)$ is defined as

$$w(a,b) = \frac{1}{\sqrt{a}}\int_{-\infty}^{\infty} x(t)\Psi\left(\frac{t-b}{a}\right)dt. \tag{4}$$

A wavelet coefficient shows the similarity (correlation) between a segment of $x(t)$ and the scaled/translated version of $\Psi(t)$. Therefore, the set of wavelet coefficients $w(a,b)$ is the wavelet representation of $x(t)$ with respect to the wavelet mother.

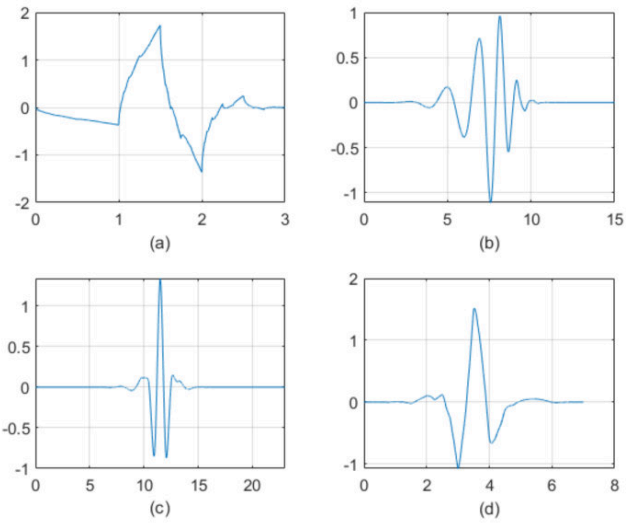

Fig. 1. Examples of wavelets used in denoising. a) Daubechies 2; b) Daubechies 8; c) Coiflet 4; d) Symlets 4

In the CWT, the mother wavelet is continuously scaled and translated, producing a great quantity of redundant information. A more efficient approach is to translate this wavelet in dyadic positions (positions which are powers of two). This approach is called the discrete wavelet transform (DWT), which is defined as follows:

$$w(m,k) = \frac{1}{\sqrt{a_0^m}}\sum_n x[n]\Psi\left(\frac{k - nb_0ba_0^m}{a_0^m}\right), \tag{5}$$

where $a = a_0^m$ and $b = nb_0ba_0^m$, being $x[n]$ the discrete-time version of $x(t)$, n is the discrete time, while m and k are integer. The vanishing moment of a wavelet $\Psi(t)$ is the number M such that

$$\int_{-\infty}^{+\infty} t^k\Psi(t)dt = 0, \quad k = 0, 1, \ldots, M-1. \tag{6}$$

For example, the mother wavelet Daubechies 8 has 8 vanishing moments.

B. Wavelet Filtering through Multi-Resolution Analysis

DWT allows a multi-resolution analysis (MRA) of the signal, since DWT gives time and frequency (through the scale parameter) information. MRA consists on a recursive operation to represent a discrete-time signal $x[n]$ at different levels of resolution [15], [16].

The signal denoising process based on MRA is composed by the following steps:

1) Decomposition: Fig. 2 shows the wavelet decomposition process for signal denoising. Recursive filtering and down-sampling procedures give the DWT coefficients at different detail levels. The approximation signal at level $j-1$ (for level $j = 1$, the approximation signal is $x[n]$). is filtered using a low-pass filter (L) and a high-pass filter (H). The output of each filter suffers a dyadic decimation (down-sampled by two): for each two

samples of the filter output, one is discarded. Therefore, the low-pass and high-pass filtering processes produce the set of approximation coefficients (cA_j) and the set of detail coefficients (cD_j), respectively:

$$cA_j = \{cA_j[1],\ cA_j[2],\ cA_j[3], \ldots\}, \tag{7}$$

$$cD_j = \{cD_j[1],\ cD_j[2],\ cD_j[3], \ldots\}, \tag{8}$$

where $cA_j[k]$ and $cD_j[k]$ are the k-th approximation and detail coefficients, respectively. The structures of the low-pass and high-pass filters depend on the selected mother wavelet.

2) Thresholding: the aforementioned detail coefficients *cD* are substituted by zero if they are less than a threshold value (c_{th}). Consequently, new detail coefficients ($c'D_j$) are created. There are different thresholding methods used in wavelet denoising techniques, including fixed and adaptive approaches. The hard thresholding method was selected in this paper as it is simple to compute, being easier to implement in real-time applications than adaptive approaches. The hard thresholding is defined as follows [17]:

$$c'D_j[k] = \begin{cases} cD_j[k], & |cD_j[k]| \geq c_{th} \\ 0, & |cD_j[k]| < c_{th} \end{cases}, \tag{9}$$

where c_{th} is a threshold. The proposed denoising approach applies the universal threshold formula [17]:

$$c_{th} = \sigma\sqrt{2ln(N)}, \tag{10}$$

where N is the number of signal samples, and σ is the standard additive gaussian white noise (it can be considered that $\sigma = 1$ if information of the gaussian white noise is not available). This thresholding process reduces the noise that affect the signal.

3) Reconstruction: Fig. 3 presents the reconstruction signal process, which is done using the approximation coefficients (cA_j), the detail coefficients after the thresholding process ($c'D_j$) and the reconstruction low-pass and high-pass filters (L' and H', respectively).

The length of the low-pass and high-pass filters, when Coiflet, Daubechies and Symlet wavelets are used, is directly related to the number of mother wavelet vanishing moment.

III. Methodology

A. Experimental Acquisition Setup

A phantom was prepared using a combination of agarose with GVs produced by Halobacterium salinarum NRC–1, until getting an optical density (OD) of 0.8. The GVs were prepared according to the methodology described in [18].

A piezoelectric transducer (C190210; Capistrano Labs Incorporated, CA, USA) was used to produce and receive US waveforms. A 50 MHz electrical voltage pulse is applied to the transducer, generating an ultrasound (US) wave with a central frequency of 50 MHz to the phantom. The GVs receive the US signal and produce an acoustic response which is acquired by the transducer as RF signals which are amplified, filtered (using an analog low-pass filter with a cutoff frequency of 70 MHz) and sent to an oscilloscope (DSO-X 0334A, Agilent Technologies, CA, USA). The oscilloscope acquire the data using a sampling rate of 2 GHz. This data is sent to a computer to be analyzed using a numerical software.

B. Evaluation of Wavelet Denoising Methods

The RF response of the phantom was visualized and saved by the oscilloscope using two different acquisition modes for:

- Single mode: the oscilloscope captures single waveform of the input channel after the trigger event.
- M-Average mode: the oscilloscope captures M consecutive waveforms, synchronized with the trigger events. The point-by-point average of these waveforms is calculated and visualized. This acquisition mode is used to attenuate noise effects in the visualized signal.

Figs 4 and 5 show the RF response of the GVs acquired using the single and 128-average acquisition modes of the oscilloscope. The RF signal acquired using the single-acquisition mode is contaminated by noise and is used to evaluate the performance of the wavelet-based denoising methods. In contrast, the RF signal acquired using the 128-average acquisition mode exhibits a significantly higher signal-to-noise ratio and is adopted as the reference RF signal (an approximation of the RF signal in the absence of noise).

The objective of the wavelet-based filtering process is to reduce the noise in the signal shown in Fig. 4, obtaining a filtered signal that closely matches the reference waveform presented in Fig. 5. Different mother wavelets and decompo-

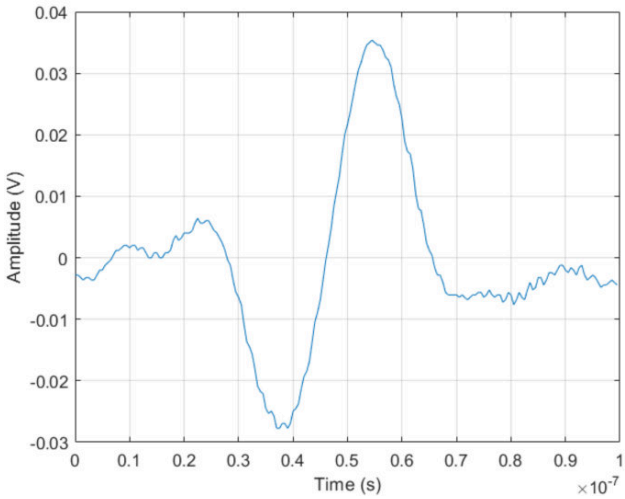

Fig. 4. RF response of GVs acquired using single acquisition mode.

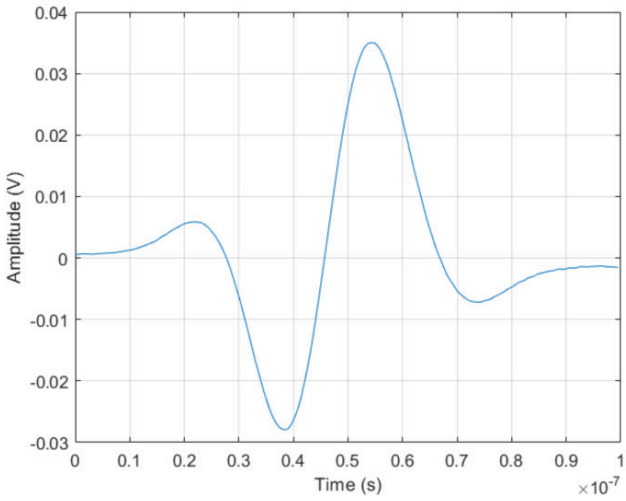

Fig. 5. RF response of GVs acquired using 128-average acquisition mode.

sition levels will be tested to evaluate the influence of these parameters into the RF signal denoising.

IV. Results

The RF signals of the GV acoustic responses were analyzed in MATLAB. The command *wden* was used to apply different types of wavelet filters. The option *sqtwolog* of this command allows using the hard thresholding method defined in (9) and (10).

Figs. 6–17 show the results for different mother wavelets (Coiflet 1, Coiflet 4, Daubechies 2, Daubechies 3, Symlet 3 and Symlet 8), and for 3 and 6 decomposition levels. According to these results, Coiflet 1 and Daubechies 2 produce spikes at the filtered pulse peak (instead of the soft peak presented in Fig. 5, as shown in Figs. 6, 7, 10, and 11. Mother wavelets with too low vanishing moments are not adequate for RF signal denoising.

The pulse peaks in Figs. 11 and 12 present an interesting case: using mother wavelets whose vanishing moments differ

by one unit can produce different filtering performance. For that reason, the selection of an adequate vanishing moment of the mother wavelets is important. A mother wavelet with low vanishing moment gives inadequate filtering results. However, a mother wavelet with a high vanishing moment produces low-pass and high-pass filters with many coefficients, increasing the computational complexity of the denoising process.

Wavelet filtering (using mother wavelets with adequate vanishing moments) allows reducing the high-frequency noise, with a negligible delay, and the pulse shape of the filtered signal is similar to the pulse of the reference waveform given in Fig. 5. After the pulse, sinusoidal perturbation is still present before and after the RF pulse. Other techniques such a notch filter could be used to remove that interference. However, usually the information of the GV responses is concentrated in the pulse whose shape is recovered through wavelet filtering.

Fig. 18 shows the result when a first-order stop-band Butterworth filter (with cut-off frequencies of 55 MHz and 65 MHz) is used for filtering the RF pulse. The delay between the reference signal and the filtered signal has increased compared to the results obtained through wavelet filters, since a linear filter adds a delay to the signals. Moreover, high-frequency oscillations can still be observed in the filtered signal.

Table I shows the signal-to-noise ratio (SNR), the root mean square error ($RMSE$) and the correlation coefficient (C_{corr}) for each test. These results show that increasing the number of decomposition levels (from 3 to 6) resulted in only a marginal improvement in the *SNR*, the correlation coefficient and reduction in the *RMSE*. Filtering using Symlet 8 and 6 decomposition levels gives the highest SNR and correlation coefficient, and the lowest $RMSE$.

The processing time of the wavelet filter based on Symlet 8 (which has the best performance) for 3 and 6 decomposition levels was measured. For each decomposition level, the command *wden* was executed 1000 times and the average time was computed. The results in Table II prove that using more decomposition levels increases the processing time. However,

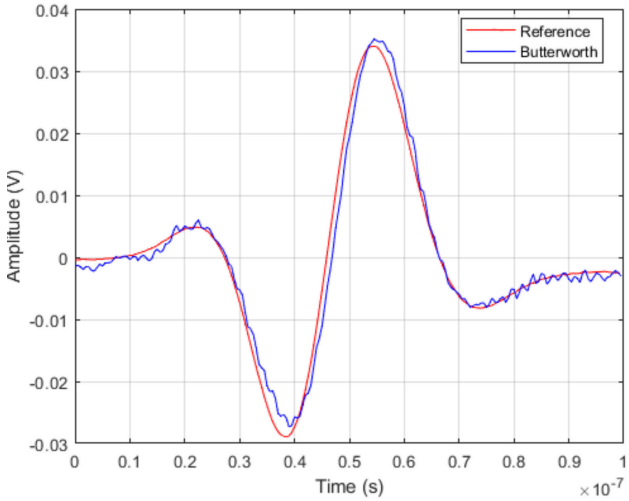

Fig. 18. Result for the Butterworth filter.

TABLE I
SNR, $RMSE$ AND C_{corr} FOR THE TESTS

Wavelet	***SNR***	***RMSE*** $\times 10^3$	C_{corr}
Coiflet 1, level 3	14.311	1.330	0.982
Coiflet 1, level 6	15.775	1.124	0.987
Coiflet 4, level 3	14.163	1.353	0.981
Coiflet 4, level 6	15.685	1.135	0.986
Daubechies 2, level 3	14.252	1.339	0.981
Daubechies 2, level 6	15.984	1.097	0.987
Daubechies 3, level 3	14.240	1.341	0.981
Daubechies 3, level 6	15.820	1.118	0.987
Symlet 3, level 3	14.240	1.341	0.981
Symlet 3, level 6	15.820	1.118	0.987
Symlet 8, level 3	14.166	1.352	0.981
Symlet 8, level 6	16.359	1.051	0.988
No filter	13.561	1.450	0.978
Butterworth	13.801	1.409	0.979

TABLE II
PROCESSING TIME OF THE WAVELET FILTER

Wavelet	Processing time (ms)
Symlet 8, level 3	0.681
Symlet 8, level 6	1.026

Table I shows that increasing the decomposition level could improve the denoising process. For that reason, it is important to select properly the number of decomposition levels.

V. CONCLUSION

This paper evaluated the performance of different wavelet filters for denoising the RF signals obtained from the acoustic responses of the GVs. Mother wavelets with low vanishing moments are not adequate for the filtering of the RF signals. In general, wavelets with a vanishing moment greater than or equal to three can be used. However, a high vanishing moment gives low-pass and high-pass filters with many coefficients, increasing the computational complexity of the wavelet denoising process. Filtering using the Symlet 8 wavelet with 6 decomposition levels provides the best noise reduction. In all tests, increasing the number of decomposition levels resulted in only a marginal improvement in the denoising process. However, using fewer decomposition levels reduces the required processing time. Hence, the number of decomposition levels should be carefully selected to achieve an appropriate tradeoff between noise reduction performance and computational cost. As future work, other kinds of filters (e.g., notch filters) will be applied together with the wavelet denoising process to improve the denoising of the GVs responses.

ACKNOWLEDGMENT

The authors would like to thank the Ultrasound Laboratory (LUS) and the Biomedical Engineering Program of COPPE/UFRJ for providing the infrastructure, technical support, and research environment that made this work possible.

Abstract— **Child physical abuse is a major public health concern and one of the leading causes of preventable morbidity and mortality in the pediatric population. Forensic radiology plays a critical role in the identification and documentation of skeletal injuries associated with non-accidental trauma. This study aimed to experimentally reproduce fracture patterns commonly associated with child physical abuse and evaluate the influence of radiographic exposure parameters on image quality and diagnostic performance. An experimental study was conducted using a juvenile porcine model (Sus scrofa domesticus), selected due to its anatomical and biomechanical similarities to the pediatric skeleton. Spiral, greenstick, rib, and cranial fractures were experimentally induced and assessed using a GE XR-6000 and direct digital radiography detector. Different exposure protocols were evaluated through adjustments using the 15% rule, enabling comparative analysis of image quality and fracture visualization. The results demonstrated that the porcine model successfully reproduced radiographic patterns consistent with those reported in the literature for suspected child abuse. Optimized exposure parameters improved image quality and fracture detection, while inadequate techniques increased image noise and reduced diagnostic performance. The study also highlighted the importance of proper positioning and the acquisition of complementary radiographic projections for accurate lesion characterization. These findings reinforce the need for individualized pediatric exposure charts and adherence to the ALARA principle (As Low As Reasonably Achievable), contributing to improved diagnostic quality, reduced repeat examinations, and enhanced radiation protection in pediatric forensic radiology.**

I. INTRODUCTION

Since the discovery of X rays by Wilhelm Conrad Roentgen in 1895, forensic radiology has become an important tool for trauma assessment and medico-legal investigations, including the identification of injuries related to child abuse [1]. Pediatric forensic radiology is particularly relevant for detecting fractures at different stages of healing and documenting findings compatible with non-accidental trauma [2].

Between 2020 and 2023, violence-related records increased in Brazil across the Information System for Children and Adolescents (Sistema de Informação para a Infância e Adolescência – SIPIA), the Notifiable Diseases Information System (Sistema de Informação de Agravos de Notificação – SINAN), and Disque 100. SIPIA monitors violations of the rights of children and adolescents; SINAN compiles mandatory notifications submitted by health services; and Disque 100 receives reports of human rights violations. Reports registered through Disque 100 increased from 366,032 in 2020 to 1,311,044 in 2023. Although these databases may contain overlapping records, the data demonstrate the magnitude of violence and the need for prevention, early identification, reporting, and victim protection [3], [4].

Radiological assessment contributes to fracture identification, evaluation of trauma mechanisms, injury chronology, and comparison between imaging findings and the reported clinical history, supporting the differentiation between accidental and non-accidental trauma [4], [5]. The fracture patterns selected for this study were defined according to their forensic relevance in suspected child

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

physical abuse. Spiral fractures present a helical fracture line produced by torsional forces; greenstick fractures are incomplete injuries of immature bone, characterized by cortical disruption and bending; posterior rib fractures are associated with thoracic compression; and cranial fractures may result from direct impact or acceleration–deceleration mechanisms. The interpretation of these findings must consider the child's age, developmental stage, clinical history, associated injuries, and consistency between the reported mechanism and radiological findings [6], [7].

The differentiation between accidental and abusive injuries requires integrated clinical, radiological, and medico-legal assessment, including the exclusion of conditions associated with bone fragility. Conventional radiography, computed tomography, and magnetic resonance imaging are complementary methods for identifying occult fractures and associated injuries [7]. Proper documentation, ethical conduct, and a child-centered approach are essential during imaging examinations [8], [9]. Radiation protection is particularly important in pediatric imaging because of increased tissue radiosensitivity and longer lifetime risk; therefore, the principles of justification, optimization, and dose limitation, as well as pediatric-specific protocols and individualized exposure adjustments, must be applied [10].

In addition to diagnostic aspects, professional conduct in suspected cases of child abuse requires ethical, technical, and legal rigor, as radiologists and healthcare professionals play a strategic role in identifying, documenting, and reporting findings [9]. Proper documentation of injuries through precise descriptions and high-quality imaging is essential to support medico-legal investigations and ensure evidentiary integrity. Simultaneously, a humanized approach is indispensable during examinations, considering the physical and emotional vulnerability of abused children. This includes patient welcoming, minimization of suffering, respect for dignity, and strategies aimed at reducing fear, pain, and revictimization during procedures [10]. From a technical perspective, the fundamental principles of radiological protection are particularly relevant in pediatric populations due to greater tissue radiosensitivity and longer lifetime risk. Therefore, the principles of justification, optimization, and dose limitation must be strictly applied to ensure safe imaging practices. Optimization must be widely understood and applied by professionals in order to ensure diagnostic image quality while keeping radiation doses as low as possible, since children are more sensitive to radiation and have a longer life expectancy [11].

The X ray absorption and transmission depend primarily on the composition and, above all, the thickness of the body part being imaged; patient age is a poor surrogate for thickness [12]. Pediatric imaging protocols must therefore be designed for each anatomical region and individualized according to patient anthropometry. Standardized exposure protocols should be used as reference guidelines but must allow adjustments for patient body thickness, positioning and clinical indication [13], [14]. And also, the protocols should be specific to each detector [12]. Optimized protocols also require careful beam collimation, appropriate selection of exposure parameters, and periodic review based on radiation dose indicators and image quality assessment. These measures reduce exposure variability, minimize dose to radiosensitive organs, prevent unnecessary repeat examinations, and support establishment of pediatric Diagnostic Reference Levels (DRLs) [13], [14].

Identifying the correct protocol for obtaining an X ray is not a simple task. And it is also necessary to consider the lack of experience or training of the radiology professional in optimizing image quality while managing radiation doses in different technologies from different manufacturers with different sensitivity of the detection system [15]. Therefore, there are many failures in choosing the ideal protocol, and it is necessary to repeat exposures, often by trial and error. This causes an increase in the patient's doses. Then it is important to ensure all radiation doses from an imaging examination are kept As Low As Reasonably Achievable (ALARA) [16].

In this context, the optimization of radiographic exposure parameters becomes essential to ensure diagnostic image quality while minimizing unnecessary radiation exposure in pediatric patients. One practical approach for adjusting exposure techniques is the 15% rule. According of Carrol (2007), the "15% rule" (radiography): Increasing the tube voltage (kVp) by about 15% produces approximately the same effect on receptor exposure as doubling the tube current time product (mAs). Conversely, decreasing kVp by 15% is roughly equivalent to halving the mAs. The 15% rule has derivations for when the necessary changes in the exposure technique are subtle. It is also possible to change around 10% in the kV value, is roughly equivalent to modify the mA in 30%. When applied appropriately, this principle may assist in selecting exposure parameters according to the anatomical region and diagnostic objective, contributing to image-quality optimization, reduction of repeat examinations, and compliance with the ALARA principle [17].

This rule has some limitations and caveats: the rule is empirical and approximate; exact relation depends on generator type (single vs. high frequency), beam filtration, kVp range, receptor sensitivity, patient thickness/composition, geometry; at very low or very high kVp ranges the approximate 15% doubling relation may not hold; for digital detectors with wide dynamic range, maintaining "exposure index" matters; image processing may mask exposure changes. Excessive post-processing should always be avoided. The 15% rule is an important tool for maintaining diagnostic image quality and reducing patient dose, as mAs is the main parameter responsible for dose contribution [17].

When acquiring an image, it is necessary to evaluate which parameter should be changed. kVp directly impacts beam penetrability, and mAs impacts the noise pattern. These parameters must be carefully manipulated to correct exposure flaws that compromise lesion visualization. However, the best balance must also be considered to keep the dose to the pediatric patient as low as possible [17].

Increasing kVp and reducing mAs typically reduces patient entrance skin dose and absorbed dose for many exams (less absorption of low energy photons), but may increase dose to deeper tissues; net effect usually lower dose for same image receptor exposure. Beware: if mAs is not reduced appropriately, patient dose will increase [17].

The protocol adopted in this study was to work with fixed kVp values. That is, to identify the energy value that provides adequate contrast for that anatomical region (optimal kVp).

According with Carrol (2011), a fixed kVp protocol is therefore composed of the selection of a kVp value considered optimal – the value required to penetrate a given anatomical part, with the production of long-scale contrast

radiograph. When the kVp is determined for each examination, it does not vary with the difference in thickness in the anatomical part. The change will occur in the mAs value used, to obtain the desired noise level. The primary goals of the fixed kVp method, is to (1) assure sufficient penetration, (2) keep image contrast consistent, and (3) simplify and standardize for accuracy [18].

In light of this context, this study aimed to investigate the experimental reproduction and radiographic characterization of fracture patterns associated with suspected child physical abuse using a juvenile porcine model, with emphasis on evaluating the application of the 15% rule for the optimization of radiographic exposure parameters. The study sought to improve the diagnostic quality of the images while preserving the visualization of osseous findings and using the lowest radiation doses reasonably achievable.

II. Methodology

The experimental phase of this study was conducted to reproduce radiographic fracture patterns frequently described in the literature as suggestive of child physical abuse and to evaluate the influence of technical exposure parameters on the diagnostic quality of the acquired images. All procedures were performed at DAPI Clinic, located in Curitiba, Paraná, Brazil, using a GE XR-6000 radiographic system (General Electric Healthcare) equipped with a direct FUJI D-EVO flat-panel detector for digital radiography (DR). The equipment was manufactured in 2012 and installed at the institution in 2013, remaining in regular clinical use for radiographic examinations. All radiographic acquisitions were performed using equipment operating under the institution's routine quality assurance program, in accordance with the applicable requirements established by Brazilian Health Regulatory Agency (ANVISA) Resolution RDC No. 611/2022, ensuring proper system performance and quality control throughout the experimental procedures [19]. The system enabled immediate image acquisition, reduced processing time, and the use of post-processing tools, including brightness and contrast adjustment and image magnification. These features were particularly relevant to the present study, as they enabled comparative analysis among different exposure protocols and detailed assessment of the simulated injury patterns.

Given the need for an experimental model comparable to the pediatric skeleton, a juvenile pig (*Sus scrofa domesticus*), approximately five weeks of age, weighing about 14 kg and measuring approximately one meter in length, was obtained from a commercial slaughterhouse after routine commercial slaughter for food production and used exclusively as an experimental anatomical model. The juvenile porcine specimen was selected because its skeletal characteristics allow the experimental reproduction of fracture patterns in immature bone, making it suitable for evaluating radiographic acquisition techniques under controlled conditions. The use of commercially obtained post-mortem biological material enabled the standardized simulation of different fracture mechanisms under controlled conditions, ensuring reproducibility throughout the experimental procedures. No live animals were subjected to restraint, anesthesia, euthanasia, or any other experimental procedures for research purposes. Accordingly, in compliance with Brazilian Federal Law No. 11,794/2008 (Arouca Law) and the Brazilian Guidelines for the Care and Use of Animals in Teaching or Scientific Research Activities (DBCA), the study was considered exempt from review by the Animal Use Ethics Committee (CEUA), as it did not constitute animal experimentation under the applicable legislation [20].

Following the definition of the experimental model, four fracture patterns frequently described in the specialized literature and recognized for their relevance in the radiological investigation of suspected child physical abuse were selected: spiral fractures, greenstick fractures, rib fractures, and cranial fractures. The inclusion of these lesions aimed to encompass different biomechanical mechanisms and radiographic patterns encountered in clinical practice.

For spiral fracture induction the limb segment was stabilized using metallic clamps and subjected to controlled torsional force using a pipe wrench until a fracture line was produced and for greenstick fracture induction the selected bone segment was subjected to controlled bending force using a pipe wrench, aiming to produce incomplete cortical disruption associated with angular deformation (Fig. 1).

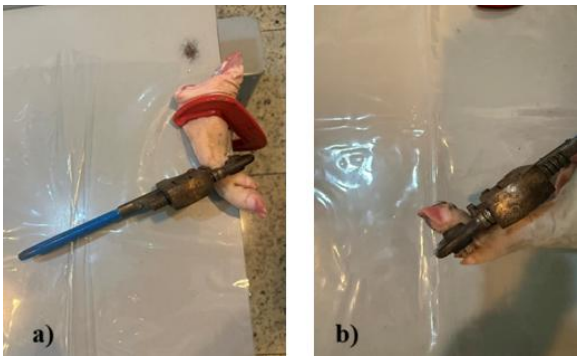

Fig. 1 - Simulation of a) Spiral Fracture and b) Greenstick Fracture.

Rib fractures were simulated by applying controlled blunt compressive force with the rib cage positioned on a rigid surface, reproducing the compression mechanism of pediatric blunt thoracic trauma. Cranial fractures were induced by a controlled perpendicular impact with a metallic hammer to the cranial vault of a juvenile porcine skull supported on a rigid surface. Fig. 2 presents the experimental simulation of these trauma mechanisms, showing (a) blunt compressive force applied with a baseball bat to induce a rib fracture and (b) a controlled impact with a metallic hammer to simulate a cranial fracture. The figure was digitally modified using an artificial intelligence (AI) exclusively to improve the visual representation of the injury-production mechanisms and facilitate understanding of the experimental setup [21].

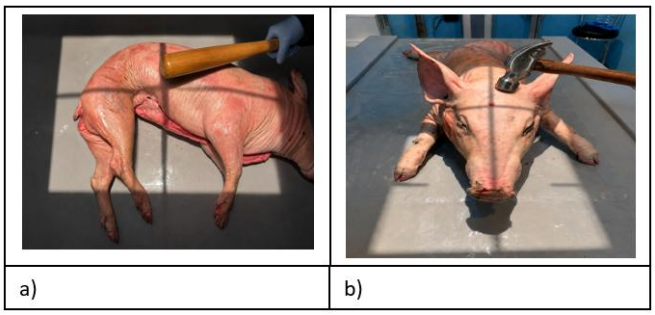

Fig. 2 - Simulation of a) Rib fracture, b) Cranial fracture

Radiographic examinations were performed after lesion induction in each anatomical region evaluated. For the upper and lower limbs, posteroanterior (PA) and lateral (P) projections were obtained; for the rib fractures, an anteroposterior (AP) projection was performed; and for the skull, PA and P projections were acquired. The complementary projections were used to assess fracture-line morphology, cortical discontinuity, anatomical alignment, possible displacement, and lesion extent from different planes, thereby reducing the limitations associated with anatomical superimposition. Image acquisition was initially performed using the exposure charts routinely adopted by DAPI Clinic for each anatomical region.

Exposure parameter optimization was performed through sequential adjustments of tube potential (kVp) and tube current–time product (mAs), using the initial exposure chart adopted for each anatomical region as the reference. Following the acquisition of the baseline radiograph, image quality was visually assessed based on radiographic contrast, cortical definition, fracture-line conspicuity, and the presence of quantum noise. Whenever image limitations related to beam penetration or contrast were identified, kVp adjustments were performed using the 15% rule as an operational guideline, with proportional mAs modifications whenever necessary to maintain adequate detector exposure. When excessive image noise or insufficient photon flux was observed, only the mAs value was adjusted while maintaining a constant tube potential. This sequential optimization procedure was repeated for each anatomical region and fracture pattern until the combination providing the best diagnostic visualization of the simulated lesions was achieved.

The radiographic images were qualitatively evaluated by two experienced radiologic imaging professionals through visual comparison on a 2 MP diagnostic display. The assessment considered fracture pattern visualization, cortical definition, image sharpness, radiographic contrast, image density, the presence of quantum noise, and visualization of anatomical structures. During protocol optimization, only one exposure parameter was modified at a time, beginning with the parameter considered least appropriate while maintaining the other unchanged. Successive adjustments of kVp and mAs were performed until the combination providing the best lesion visualization was identified. The optimized technique was defined as the protocol that achieved the best balance between image sharpness, radiographic contrast, image density, noise reduction, and fracture-line visualization.

Because this investigation was designed as a preliminary proof-of-concept study aimed at experimentally reproducing pediatric fracture patterns and optimizing radiographic exposure parameters, image quality assessment was intentionally based on qualitative visual analysis. Therefore, objective image quality metrics, including the Exposure Index (EI), Deviation Index (DI), Signal-to-Noise Ratio (SNR), Contrast-to-Noise Ratio (CNR), radiation dose measurements, and formal interobserver agreement analysis, were not included. Qualitative visual assessment was considered appropriate for the scope of this preliminary study. Future phases of the project will incorporate quantitative image quality metrics, dosimetric assessment, and interobserver agreement analysis to strengthen the methodological robustness and metrological validation of the proposed radiographic protocol.

The kV and mAs combinations were organized into a comparative exposure table, including the initial protocols, PA, AP, and P projections, as well as the parameters submitted for evaluation, as presented in TABLE I.

TABLE I - Exposure Charts and Optimized Technical Parameters.

Region	Projection	Techniques Evaluated (kV/mAs)	Optimized (kV/mAs)
Wrist (Spiral/Greenstick)	PA	40/4 44/12.5	44/12.5
Wrist (Spiral/Greenstick)	P	44/8	44/8
Ribs	AP	65/40 55/40 55/80 60/80 55/100 60/100	55/100
Skull	PA	65/10 65/20	65/20
Skull	P	55/5 65/10	65/10
Lower Limb	AP	44/12.5 50/12.5 44/20	44/20

III. RESULTS and DISCUSSION

The present study demonstrated that the experimental model using a juvenile porcine specimen was capable of reproducing radiographic patterns comparable to those described in the literature for fractures frequently associated with suspected child physical abuse. Fracture patterns consistent with spiral fractures, greenstick fractures, rib fractures, and cranial fractures were successfully simulated, allowing not only the morphological characterization of these injuries but also the evaluation of how exposure parameters, patient positioning, and radiographic projections influenced image quality and fracture visualization.

Although the experimental model provided a controlled and reproducible environment for fracture simulation, some limitations were observed and should be considered when extrapolating the findings to clinical pediatric practice. Anatomical and histological differences between porcine and human bone, as well as variations in bone geometry and surrounding soft tissues, may influence fracture morphology and radiographic appearance. Therefore, the optimized exposure parameters obtained in this study should be interpreted as experimental references rather than universal clinical protocols. Nevertheless, the reproducibility of the proposed model and its ability to simulate different fracture mechanisms support its application in experimental investigations, professional training, and the development of radiographic protocols for pediatric forensic imaging [22-24].

Furthermore, the literature review conducted for this study did not identify recent publications specifically investigating the use of juvenile porcine models to reproduce fracture patterns associated with suspected child physical abuse in combination with the optimization of radiographic exposure parameters. Although juvenile porcine models have been employed in orthopedic, biomechanical, and trauma research, their application integrating the simulation of

abuse-related fracture mechanisms with the systematic evaluation of radiographic techniques appears to remain scarcely explored in the recent literature. This gap reinforces the originality of the experimental approach adopted in the present study and indicates its potential contribution to future research, professional training, and the development of optimized imaging protocols in pediatric forensic radiology.

The simulated lesions exhibited radiographic characteristics consistent with patterns described in the literature, allowing the evaluation not only of fracture identification but also of factors related to image acquisition. Throughout the study, it was observed that obtaining diagnostically adequate images depends directly on the combination of optimized radiographic technique, correct positioning of the anatomical segment, and the acquisition of complementary radiographic projections.

This study reinforced the importance of obtaining at least two orthogonal radiographic projections for the assessment of bone injuries, as fracture visualization was limited when based on a single projection due to anatomical superimposition or the orientation of the fracture line relative to the X ray beam. The use of complementary projections enabled a more accurate assessment of fracture extent, bone alignment, fragment displacement, and the spatial relationship between affected structures, thereby increasing diagnostic reliability and reducing the likelihood of false-negative findings, in accordance with international recommendations for the radiographic investigation of suspected child physical abuse.

During the simulation of spiral fractures, radiographically, a helical fracture line was observed, characterized by sharp margins and rotational displacement of the distal fragment, consistent with a torsional mechanism of injury. Fig. 3 shows the simulated spiral fracture in the posteroanterior (a) and lateral (b) projections, demonstrating the characteristic helical fracture line and improved visualization of the fracture trajectory using complementary projections.

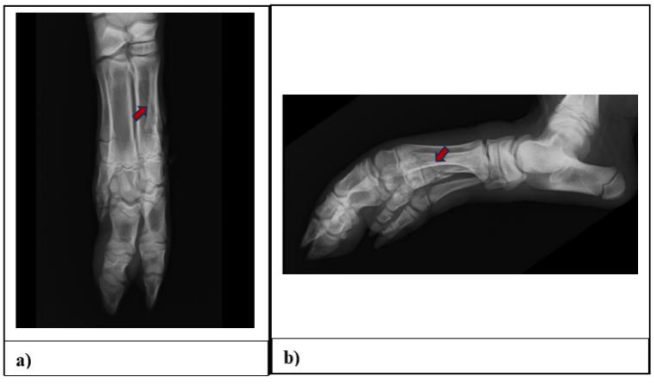

Fig. 3 - Spiral Fracture: a) PA Projection and b) Lateral Projection.

This type of fracture is associated with rotational forces acting along the longitudinal axis of the bone, resulting in progressive cortical shear stress. Accurate identification of this pattern was facilitated by the use of complementary projections and careful selection of technical parameters.

The initial exposure protocol was 40 kVp/4 mAs, resulting in insufficient beam penetration, high image noise, and poor visualization of the fracture extent. The tube potential was then increased to 44 kVp, while maintaining the 4 mAs setting. Although this adjustment provided adequate beam penetration, image noise remained high. Therefore, the mAs value was doubled to 8 mAs, resulting in improved cortical definition and enhanced visualization of the fracture lines.

Greenstick fractures exhibited characteristics compatible with those observed in immature skeletons, demonstrating partial disruption of one cortex associated with deformation of the opposite cortex. This pattern is directly related to the increased elasticity and higher collagen content of pediatric bone tissue. Although it presents lower specificity for non-accidental trauma, its association with other suspicious findings may significantly contribute to the overall assessment of the case and the interpretation of the clinical-forensic context. Radiographic evaluation demonstrated angular deformity and unilateral cortical disruption, while the periosteum remained intact on the opposite side, a characteristic finding of incomplete fractures in immature bone. Fig. 4 shows the simulated greenstick fracture in the posteroanterior (a) and lateral (b) projections, demonstrating incomplete cortical disruption and angular deformity characteristic of immature bone.

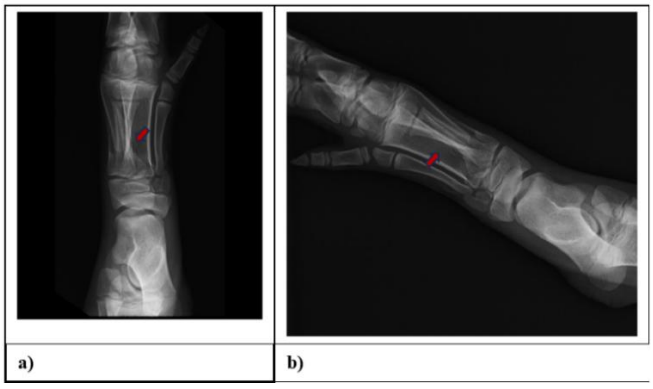

Fig. 4 - Greenstick Fracture: a) PA Projection and b) Lateral Projection.

Regarding the simulated rib fractures, small adjustments in radiographic parameters directly influenced the ability to identify fracture lines. The initial exposure protocol was 65 kVp/40 mAs, with a low contrast scale and difficulty in characterizing the fractures. The kVp was reduced by 15% (55 kVp) and the mAs value was maintained. The higher contrast scale better demonstrated the fracture edges, but still with a noise level that needed to be reduced. Doubling the mAs still did not bring the expected result, and the best result was achieved with 100 mAs, that is, doubling the initial value plus 30%. This protocol providing adequate radiographic density, increased contrast between anatomical structures, and improved visualization of the ribs. Conversely, indiscriminate increases in exposure factors resulted in detector saturation and deterioration of image quality, demonstrating that optimization must be individualized and carefully controlled. Fig. 5 compares the rib radiographs obtained using the non-optimized technique (a) and the optimized technique (b). Image (b) demonstrates improved contrast, reduced noise, and better fracture visualization.

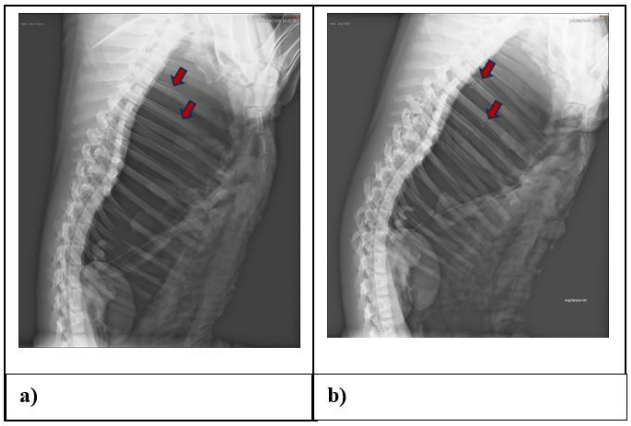

Fig. 5- Rib Radiograph: a) Non-Optimized Technique and b) Optimized Technique.

Radiographically, the lesion was characterized by posterior cortical discontinuity. In chronic stages, prominent periosteal callus formation may be observed. This morphological pattern is recognized as a radiological marker of severe thoracic compression and is considered a finding of high forensic specificity.

A similar behavior was observed in the evaluation of posteroanterior cranial lesions. The initial technique using 65 kV and 10 mAs produced images with reduced definition of osseous details. Doubling the mAs to 20 while maintaining the same kV value reduced quantum noise and improved the signal-to-noise ratio, resulting in enhanced sharpness and improved visualization of fracture lines. Fig. 6 compares the posteroanterior skull radiographs obtained using the non-optimized technique (a) and the optimized technique (b). Image (b) shows reduced image noise and improved visualization of the fracture line.

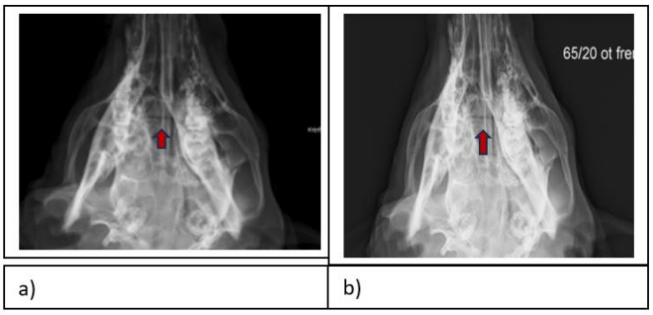

Fig. 6 - Cranial Radiograph: a) Non-Optimized Technique and b) Optimized Technique.

For lateral skull radiographs, the technique using 65 kV and 10 mAs provided the best diagnostic image quality among the parameters evaluated. The resulting image demonstrated adequate radiographic density, good contrast, and excellent sharpness of osseous structures, allowing better delineation of the cranial cortices and more accurate visualization of the simulated fracture pattern. This combination of parameters provided a satisfactory signal-to-noise ratio, facilitating the identification of anatomical details and contributing to greater diagnostic reliability. In contrast, the use of 55 kV and 5 mAs compromised image quality, characterized by increased image noise, a granular appearance, and reduced sharpness of the evaluated structures. The lower number of photons reaching the detector resulted in a decreased signal-to-noise ratio, impairing cortical delineation and adequate characterization of the lesion. This finding has significant clinical relevance, as cranial fractures may present subtle fracture lines whose identification depends directly on the technical quality of the acquired image. Fig. 7 compares the lateral skull radiographs obtained using the the optimized technique (a) and non-optimized technique (b). The optimized image provides greater sharpness and improved cortical definition, facilitating fracture identification.

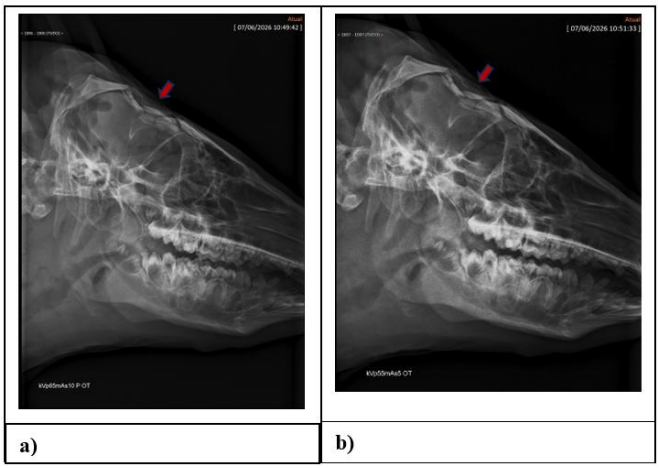

Fig. 7 - Cranial Fracture in the Lateral Projection a) Optimized Technique and b) Non-Optimized Technique.

In the analysis of appendicular lesions, the initial technique using 40 kV and 4 mAs proved insufficient for adequate demonstration of anatomical details. After parameter optimization, using 44 kV and 12.5 mAs in the posteroanterior projection, a significant improvement in contrast and cortical definition was observed. For the lateral projection, the use of 44 kV and 8 mAs allowed adequate visualization of the fracture line. Subsequently, the technique employing 44 kV and 20 mAs yielded the best diagnostic image quality, with reduced image noise, increased sharpness, and improved visualization of osseous structures.

The findings of this study demonstrated that minor modifications in technical parameters directly influence the diagnostic quality of radiographic images. From a physical standpoint, excessive reduction of mAs is associated with increased quantum noise due to the lower number of photons reaching the detector, compromising the signal-to-noise ratio and hindering the visualization of fine details. Conversely, indiscriminate increases in kV may reduce radiographic contrast, impairing differentiation between structures of similar densities. Therefore, achieving an appropriate balance between kV and mAs proved essential for obtaining images with adequate sharpness, density, and contrast.

The ribs region was the most complex in terms of technique adjustment, probably because the pig was not whole, as the internal organs had been removed and the internal air layer compromised the definition of the ideal technique without so many adjustments.

Another relevant aspect identified in this study was the importance of correct positioning during image acquisition. Even when appropriate technical parameters were employed,

small variations in positioning interfered with fracture visualization. This finding has important implications in pediatric practice, where pain, functional limitation, and lack of patient cooperation frequently hinder optimal examination performance. Consequently, the technical expertise of the radiologic technologist becomes a determining factor in obtaining reliable diagnostic examinations.

The findings reinforce the need for the development of specific exposure protocols for the radiographic investigation of suspected child abuse. Standardized yet flexible protocols allow individualized adjustments according to patient age, body habitus, anatomical thickness, and the body region being examined, facilitating the acquisition of high-quality images without unnecessary exposure to ionizing radiation. In this context, optimization of radiographic parameters should be aligned with radiation protection principles, particularly the ALARA principle, always seeking a balance between diagnostic quality and dose minimization.

The findings of the present study are consistent with those reported in the international literature regarding radiographic image repeat analysis and radiation protection. Hasaneen *et al.* (2023), when evaluating the causes of image repetition in digital radiography, reported that 48.4% of repeated examinations were associated with positioning errors, whereas 9.7% were related to the inappropriate selection of exposure factors. The authors emphasized that repeat examinations constitute an important source of unnecessary exposure to ionizing radiation and highlighted the need for continuous quality assurance programs and technical optimization strategies to reduce such occurrences. Furthermore, the study demonstrated that the ALARA principle should be incorporated into radiology department routines, aiming to minimize radiation dose while maintaining adequate diagnostic image quality [25].

Similar findings were reported by Bantas, Sweeney & Mdletshe (2023), who analyzed more than 76,000 images acquired using direct digital radiography systems. The authors identified image rejection rates ranging from 5.91% to 7.86%, with positioning errors accounting for approximately 77% to 79% of repeated examinations. The study highlighted that systematic analysis of rejected images represents an important quality assurance tool, enabling the identification of acquisition protocol deficiencies, the review of exposure charts, and the development of educational strategies aimed at reducing image repetition and, consequently, patient radiation exposure. The authors further emphasized that optimization of radiographic protocols should consider the specific characteristics of each examination and imaging department, as no single universal exposure chart can be applied to all clinical situations [26].

Complementarily, O'Keefe (2023) reported that image rejection rates in digital radiography systems remain close to 9%, despite technological advances associated with direct digital radiography. The author demonstrated that the primary causes of image rejection continue to be inadequate positioning, anatomical cut-off, and inappropriate exposure parameters. The study also emphasized that each repeated examination results in additional radiation exposure to the patient while negatively affecting departmental workflow efficiency. According to the author, rejected image analysis should be incorporated as a continuous quality improvement strategy, contributing to professional development and reducing unnecessary radiation exposures [27].

This discussion becomes even more relevant when applied to the pediatric population. Children exhibit increased radiosensitivity due to the higher mitotic activity of developing tissues and possess a longer life expectancy, factors that increase the probability of stochastic effects associated with ionizing radiation manifesting throughout life. Therefore, reducing repeat examinations through the implementation of appropriately designed exposure charts becomes an essential radiation protection strategy. In this context, the findings of the present study reinforce that the combination of proper patient positioning, appropriate selection of exposure parameters, and the use of examination-specific radiographic protocols represents one of the most effective approaches for ensuring diagnostic image quality, patient safety, and compliance with radiation protection principles [28-30].

A limitation of the present study is the absence of quantitative image quality metrics, dosimetric assessment, and formal interobserver agreement analysis. Although the proposed protocol demonstrated satisfactory qualitative performance, future studies should incorporate these objective parameters to further strengthen its methodological robustness and metrological validation.

Finally, the results of this study demonstrate that the accurate identification of bone injuries related to child abuse depends not only on recognizing classical radiographic patterns but also on the proper execution of radiographic technique. The combination of appropriate positioning, acquisition of orthogonal projections, and individualized optimization of protocols proved fundamental for maximizing the diagnostic sensitivity of radiographic examinations. And the 15% rule is good tool to orientate the radiology team to work and to know the response of the detector. Furthermore, the use of the porcine experimental model enabled the development of an educational product applicable to the training and continuing education of radiologic technologists, contributing to the strengthening of pediatric forensic radiology as an essential tool for the early detection of suspicious findings, the production of technical and scientific evidence, and the comprehensive protection of children who are victims of violence.

IV. Conclusions

Overall, this study demonstrated that the identification of radiographic findings associated with suspected child physical abuse depends on both the recognition of characteristic fracture patterns and the technical quality of image acquisition. The juvenile porcine model enabled the experimental reproduction and radiographic characterization of spiral, greenstick, rib, and cranial fractures, supporting its use as an educational and research tool in pediatric forensic radiology.

Optimized exposure charts, appropriate positioning, and complementary radiographic projections improved fracture visualization and diagnostic image quality. Small adjustments in kV and mAs influenced contrast, sharpness, image noise, and the visibility of fracture lines. These findings reinforce the importance of pediatric-specific exposure protocols and the ALARA principle, particularly

because children are more radiosensitive and have a longer lifetime risk associated with ionizing radiation exposure.

The 15% rule, using fixed and predefined kV values for anatomical regions, and making fine adjustments to mAs to improve lesion sharpness has a direct impact on image quality and patient dose as defined by ALARA principle.

This study has limitations that should be considered. The pig may not have been the ideal phantom for defining the rib protocol, but for the extremities it proved to be a valuable and inexpensive phantom for simulating fractures. In addition, the findings cannot be directly extrapolated to clinical pediatric populations without further validation studies. Nevertheless, the study establishes an experimental model that may support future research on image-quality optimization, training of radiologic technologists, and the development of pediatric forensic radiology protocols.

V. ACKNOWLEDGMENTS

The authors express their sincere gratitude to DAPI Clinic, Curitiba, Paraná, Brazil, for providing the facilities and radiographic equipment required for the experimental procedures conducted in this study. The authors also acknowledge the Graduate Program in Biomedical Engineering (PPGEB) for its academic support and valuable contribution to the development of this research.

***Abstract*—This paper presents a feature-based sEMG signal processing pipeline for prosthetic control applications, combining time- and frequency-domain descriptors with an unsupervised clustering stage for automated label generation. The generated pseudo-labels train a supervised classifier to distinguish muscle contraction and relaxation states across four forearm electrode configurations. The results demonstrate high classification performance and accurate pattern detection, supporting the feasibility of the proposed unsupervised labeling strategy under the evaluated experimental conditions.**

I. Introduction

Surface electromyography (sEMG) is a non-invasive technique widely used to record the electrical activity associated with muscle contraction. By means of electrodes placed on the skin, this technique enables the analysis of muscle activation patterns and the extraction of features related to activation intensity, timing, and coordination among different muscles. Consequently, sEMG has been applied in several areas, including motor rehabilitation, clinical assessment, human–machine interfaces, and, particularly, myoelectric prosthetic control systems. In these systems, muscle signals are processed to identify the user's intended movement and convert it into commands capable of controlling prosthetic devices [1].

Despite the large number of studies and advances in this field, many solutions developed for the acquisition and processing of myoelectric signals rely on expensive equipment and devices. These characteristics may hinder the reproducibility of results, the adaptation of systems to different applications, and access to myoelectric control technologies by researchers, students, and low-income users. In this context, the development of low-cost and open-source systems is relevant, as it promotes knowledge dissemination, enables hardware and software modifications according to the requirements of each application, and contributes to expanding access to sEMG-based assistive technologies

From a physiological perspective, sEMG signals result from the spatiotemporal superposition of motor unit action potentials (MUAPs) recruited during muscle contraction [1], [2]. In anatomical regions with high muscle density, such as the forearm, surface electrodes capture activity from adjacent muscles (cross-talk), representing a primary limitation for signal analysis [3], [6]. Therefore, proper electrode placement is essential to maximize the signal-to-noise ratio and ensure high-quality sEMG measurements.

In addition to physiological challenges, Electromyography signals are characterized by low amplitude and high susceptibility to noise, even when differential acquisition techniques are employed. These characteristics make signal processing and reliable classification particularly challenging. Traditional approaches often rely on threshold-based methods for label generation, [8]; however, such methods may be sensitive to noise and signal variability [7], [9].

To address these limitations, this work proposes a feature-based pipeline for sEMG signal processing, combining time- and frequency-domain features with an unsupervised learning stage for automatic pattern identification and label generation. The generated labels are then used to train a supervised classification model. This approach aims to reduce dependency on manually labeled datasets while providing an alternative strategy for handling signal variability, contributing to the development of accessible approaches for sEMG-based prosthetic control.

Therefore, the main contribution of this work is a semi-automatic labeling strategy for sEMG datasets based on feature engineering and unsupervised clustering, reducing the dependency on manually annotated data while preserving the ability to identify muscle contraction patterns for prosthetic control applications. Although a quantitative comparison with conventional threshold-based labeling methods was considered, such a comparison was beyond the scope of the present study, which focuses on investigating the feasibility of the proposed feature-based unsupervised approach and evaluating its use for pseudo-label generation and subsequent supervised classification. In this context, the present study is framed as a proof-of-concept study, focusing on the feasibility of the proposed labeling pipeline rather than on establishing its superiority over threshold-based methods or validating a complete prosthetic control system.

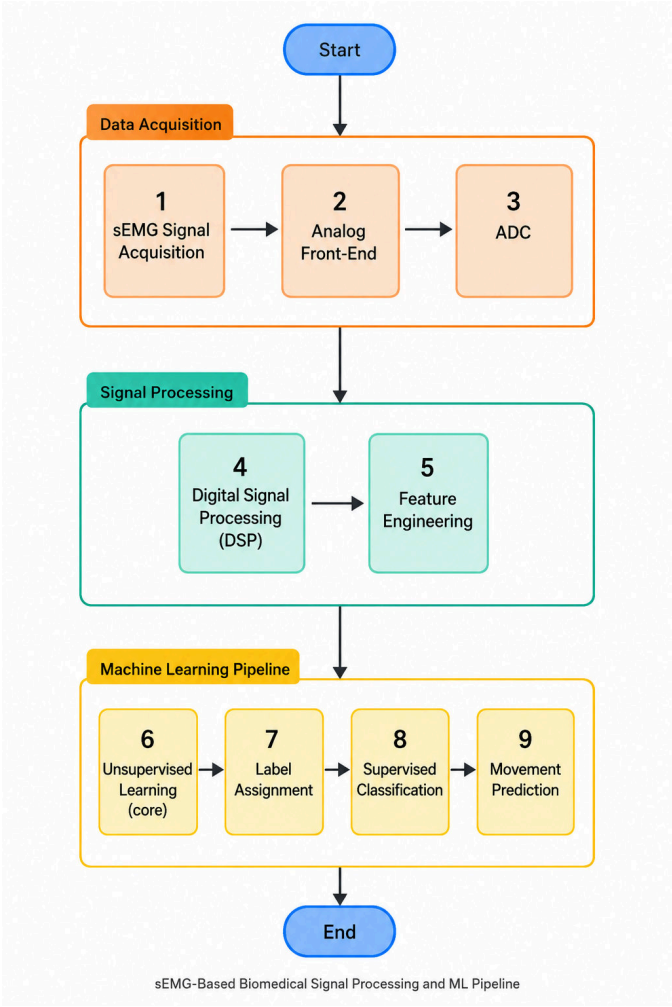

Fig. 1. Proposed EMG processing pipeline.

The remainder of this paper is organized as follows: Section II details the architecture of the proposed feature-based pipeline for sEMG signal processing. Section III presents the algorithm performance analysis. Finally, Section IV summarizes the conclusions of the study.

II. Materials and Methods

A. Proposed classification system

Fig. 1 presents the proposed sEMG processing and classification pipeline. The proposed method is composed of nine sequential stages, ranging from signal acquisition to movement prediction. Each stage is described in the following subsections.

1) sEMG Signal Acquisition: Differential surface electromyography (sEMG) acquisition was adopted in order to reduce common-mode noise and improve signal quality during hand movement acquisition [10]. Multiple electrode configurations were experimentally evaluated to identify muscle activation patterns associated with different hand and finger movements.

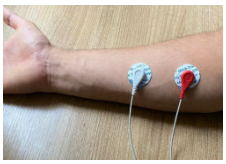
Since hand and finger movements result from the coordinated activation of multiple forearm muscles, a single sEMG acquisition channel is generally insufficient to represent all possible hand gestures [4]. In the present study, only one sEMG acquisition module was available; therefore, the four muscle configurations were acquired independently rather than simultaneously. Each recording corresponded to a single muscle configuration, and the resulting activation states were subsequently analyzed and combined at the processing stage. Therefore, this work investigates individual electrode configurations as independent muscle activation detectors and subsequently proposes a strategy to combine their outputs. Moreover, practical myoelectric prostheses do not require the recognition of every anatomically possible hand movement, but rather a reduced set of functional gestures that are sufficient for the execution of activities of daily living (ADLs) [5]. Based on this premise, the acquisition protocol was designed to generate independent datasets for each muscle configuration while preserving the possibility of future multi-channel integration.

The target movements considered in this study were selected according to their relevance for prosthetic control and daily-life activities, including hand opening, hand closing, pointing, pinch grasp, and thumb extension. Rather than directly acquiring these movements as classification labels, the proposed methodology focused on identifying whether each monitored muscle was in a contraction or relaxation state.

To build the database, an acquisition protocol composed of different activation patterns was defined for every electrode configuration. Each recording included: (i) relaxed muscle activity, (ii) sustained muscle contraction, (iii) cyclic contraction-relaxation movements with an approximate period of 10 s, (iv) cyclic contraction-relaxation movements with an approximate period of 5 s, and (v) individual finger activation experiments designed to evaluate cross-talk effects and muscle selectivity.

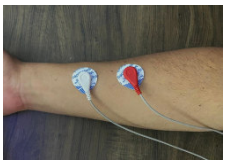
For the individual finger activation experiments, a discrete movement encoding scheme was adopted, as summarized in Table I. The encoded sequence defines the temporal movement protocol executed during data acquisition and enables a direct comparison between the expected muscle activation pattern and the corresponding EMG responses.

The adopted encoding is defined as follows: 1—Little finger contraction; 2—Ring finger contraction; 3—Middle finger contraction; 4—Index finger contraction; 5—Thumb contraction; 6—All fingers extended; and 7—All fingers flexed.



To ensure repeatability, approximately five recordings were acquired for each electrode configuration and acquisition protocol. Each recording lasted between 1 and 2 min, resulting in independent datasets representing different muscle activation conditions.

Consequently, the complete database consisted of multiple independent datasets for each muscle, covering all predefined activation protocols. These datasets constituted the basis for the subsequent feature extraction, unsupervised clustering, and supervised classification stages.



The monitored muscles were selected according to their anatomical relevance to hand and finger movements, consid-

ering the anatomical descriptions presented by Waldman [11] and Netter [12]. The electrode placement was experimentally optimized by positioning the differential pair over the muscle belly in order to maximize signal quality and reduce interference from adjacent muscles. A reference electrode was positioned near the elbow region. The selected muscles included the Flexor Carpi Radialis (FCR), Flexor Pollicis Longus (FPL), Flexor Digitorum Superficialis (FDS), and Extensor Digitorum (ED), as illustrated in Fig 2.

All datasets were acquired using non-invasive surface electromyography (sEMG) from a single healthy volunteer (one of the authors, aged 25, with no history of neuromuscular disorders) under the same experimental conditions, in accordance with the Declaration of Helsinki and with written informed consent. The objective of this work was to validate the proposed signal processing and machine learning methodology rather than to evaluate inter-subject variability. Therefore, the results should be interpreted as an intra-subject proof of concept, and no conclusions regarding the generalization or robustness of the proposed approach across different individuals can be drawn from the present dataset.

2) Analog Front-End: A commercial sEMG acquisition module was employed for the acquisition and analog conditioning of muscle signals. The module uses a differential input architecture consisting of two measurement electrodes positioned over the target muscle and a reference electrode. This configuration attenuates noise components that are simultaneously present at both measurement electrodes, thereby improving signal quality through a high Common-Mode Rejection Ratio (CMRR).

The commercial module was selected for its simplicity, high CMRR, and suitability for rapid experimental prototyping. Although adequate for single-channel evaluation, its use presents limitations for multi-channel expansion due to lack of direct control over internal conditioning stages and synchronization. For future multi-channel applications, a dedicated integrated acquisition system would be more appropriate.

3) Analog-to-Digital Conversion (ADC): The analog-to-digital conversion stage was implemented using the Arduino Uno board, which is based on the ATmega328P microcontroller. Its built-in successive-approximation-register (SAR) ADC provides a 10-bit resolution. Furthermore, the device was also used for serial data transmission, operating at a baud rate of 230400 bps.

According to [13], most of the useful sEMG signal energy is concentrated within the 0–500 Hz frequency range, with the dominant spectral content typically located between 50 and 150 Hz. Based on the Nyquist criterion, the sampling frequency of 2 kHz was initially adopted for signal acquisition.

But, due to limitations associated with serial communication and software-based timing, sampling jitter was observed during acquisition. Therefore, timestamps were recorded alongside ADC values, and the effective sampling frequency was estimated as $f_{s,\text{eff}} = 1/[\frac{1}{N-1}\sum_{n=2}^{N}(t_n - t_{n-1})]$, where N is the total sample count and t_n is the n-th timestamp. The effective sampling frequency was approximately 1.5 kHz across all datasets, satisfying the Nyquist criterion.

The acquired signals were stored in CSV format for subsequent digital signal processing and feature extraction stages.

4) Digital Signal Processing (DSP): After signal acquisition and digitization, the mean component was removed to eliminate the influence of the direct-current (DC) offset. Subsequently, an 8th-order Butterworth IIR band-pass filter with cutoff frequencies of 20 Hz and 500 Hz was applied to remove motion artifacts while retaining only the spectral components of interest in the signal. Additionally, during the validation stages, a zero-phase filter was used to compare the temporal behavior of the filtered signals and evaluate possible phase-related distortions.

The IIR filter was selected because of its lower computational complexity and reduced number of coefficients compared with an FIR filter, which are desirable characteristics for real-time embedded applications. Although IIR filters introduce nonlinear phase distortion, the classification model was trained directly using a dataset composed of filtered signals, allowing the model to naturally adapt to the temporal characteristics introduced by the filter.

Figure 3 illustrates the spectrogram obtained from a representative dataset corresponding to the fourth electrode configuration during cyclic hand opening and closing movements

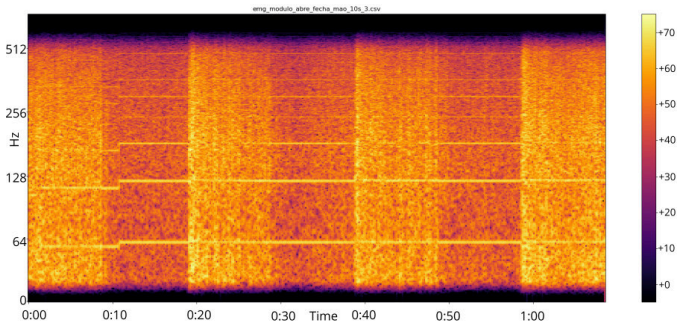

Fig. 3. Spectrogram obtained from the processed EMG signal acquired using the fourth electrode configuration during cyclic hand opening and closing movements with an approximate period of 10 s. The horizontal axis represents elapsed time (min:s), while the vertical axis represents frequency in hertz (Hz). The color scale indicates signal power in decibels (dB), where brighter colors correspond to higher energy concentrations and darker colors correspond to lower energy levels.

with an approximate period of 10 s. The spectrogram was computed after the application of the proposed DSP stages.

It can be observed that the power-line interference components are centered mainly around 60 Hz, 120 Hz, and 180 Hz. Although notch filters are commonly used to remove these components, their use was intentionally avoided in this work, since the implementation of multiple band-stop filters would increase computational complexity and introduce additional phase distortions, which are undesirable characteristics for embedded real-time applications.

At the same time, periods of muscle contraction are characterized by an overall increase in signal energy across the sEMG frequency range, making activation events clearly distinguishable in the time–frequency representation. During these periods, the useful sEMG signal exhibits considerably higher energy than the approximately constant power-line interference, allowing relevant physiological information to be reliably extracted even without explicitly removing these components. Since the interference remains nearly constant throughout the acquisition, the proposed learning pipeline is able to naturally adapt to its presence. This behavior supports the decision to preserve these components and allow the subsequent learning stages to operate under realistic acquisition conditions.

However, the signal energy during relaxation states was significantly lower than the power-line interference energy. To address this behavior, specific spectral features were developed to quantify these variations and assist the unsupervised clustering process. Therefore, the proposed system was designed to operate under realistic acquisition conditions, allowing the learning models to naturally adapt to the residual interference components present in the acquired signals.

5) Feature Engineering: In order to extract representative features from the sEMG signals, a framing process was employed. Frame size was set to 1024 samples (approx. 0.68 s) with a hop length of 256 samples (approx. 0.17 s), yielding an average spectral resolution of 1.46 Hz per frame under a Hann window [14].

Features were extracted using Python (*librosa* [14] and custom routines). The extracted time-domain features included: Amplitude Envelope, Root Mean Square (RMS), Zero Crossing Rate (ZCR), Mean Absolute Value (MAV), Waveform Length (WL), mean value, variance, standard deviation, Slope Sign Changes (SSC), and MAV with Slope Weighting. Frequency-domain features included: Band Energy Ratio (BER), Spectral Centroid, Bandwidth, fundamental frequency dominance (f_0 dominance), Median Frequency, Mean Frequency, harmonic energy relations, spectral energy distribution metrics, and interference-sensitive spectral descriptors.

The extracted features were organized into normalized dataframes for subsequent unsupervised clustering and supervised classification.

6) Unsupervised Learning: Based on the extracted features, unsupervised learning techniques were employed to identify muscle activation patterns and generate pseudo-labels corresponding to contraction and relaxation states. The adopted strategy consisted of constructing binary models for each electrode configuration individually, considering muscle contraction as state 1 and muscle relaxation as state 0.

This binary approach was adopted due to the acquisition limitations of the experimental setup, which employed only a single sEMG acquisition module. Consequently, simultaneous multi-channel acquisition using multiple electrode configurations was not possible. Nevertheless, the proposed methodology was designed to be scalable and directly applicable to future multi-channel systems.

Two clustering algorithms were evaluated for label generation: K-Means Clustering and Gaussian Mixture Models (GMM). These methods were applied mainly to datasets containing temporal muscle activation variations, while datasets containing only a single muscular state received manually assigned labels. Before clustering, all feature matrices were normalized using the Min-Max scaling technique. Since unsupervised learning algorithms are sensitive to the statistical properties of the input data, the clustering strategy, including algorithm selection and feature combinations, was optimized individually for each dataset.

7) Label Assignment: The optimization strategy involved feature selection, temporal filtering of extracted features, and post-processing of the generated cluster labels. Temporal smoothing techniques, including moving average filtering, median filtering, and run-length smoothing, were employed to reduce spurious classifications and improve temporal consistency.

Different combinations of time-domain and frequency-domain features were evaluated according to the analyzed movement and muscle activation pattern. In specific cases, minor manual interventions were performed after automatic processing stages in order to correct label inversion or isolated temporal inconsistencies.

After the clustering optimization process, the generated labels were assigned to the original feature dataset. The final labeled datasets preserved the extracted features in their

original scale, while the normalized representations were used exclusively during the clustering stage. These labeled datasets were subsequently employed for supervised classifier training.

8) Supervised Classification: After the label assignment stage, the resulting datasets were employed for supervised learning. Each electrode configuration generated an independent binary classification dataset, in which the target variable represented muscle contraction and relaxation states.

To handle class imbalance, the RandomOverSampler technique was applied to the training set. Feature values were normalized using Min-Max scaling, with scaling parameters computed exclusively on training data and saved to ensure consistent evaluation during inference. Multiple supervised learning algorithms were evaluated using the extracted feature vectors and the unsupervised pseudo-labels to identify the most suitable classifier for each muscle configuration.

The datasets were divided into training (20%) and testing (80%). Unlike conventional random splits, the adopted datasets were formed by concatenating multiple independent acquisition sessions performed at different time instants under the same protocol. Therefore, a reduced training subset was intentionally adopted, while the majority of the data were reserved for testing to evaluate the model's performance on recordings not included in the training subset and to reduce the likelihood of overfitting. Hyperparameter optimization was also performed when applicable.

9) Movement Prediction: The binary classifiers generated for each muscle configuration were designed to operate as independent activation detectors. Each model estimates whether the corresponding muscle is in a contraction or relaxation state.

The final movement prediction strategy is based on the combination of these individual muscle activations. By analyzing the activation patterns obtained from multiple muscles, it becomes possible to infer more complex hand and finger movements than those represented by a single binary classifier.

For each time frame, the outputs of the individual classifiers are combined into a binary activation vector

$$\text{Label}_t = [b_1\ b_2\ b_3\ b_4], \qquad b_i \in \{0, 1\}$$

where C1, C2, C3, and C4 correspond to the FCR, FPL, FDS, and ED muscles, respectively.

The binary activation vector provides a compact representation of the muscular activation pattern, allowing functional hand movements to be inferred from the simultaneous activation of multiple muscles. Table II summarizes the movement mapping adopted in this work.

Although the experimental validation of this work was performed using independent datasets acquired from individual muscle configurations, the proposed methodology was designed to support future multi-channel implementations, where several sEMG acquisition modules operate simultaneously. In this scenario, the same feature extraction, clustering, label assignment, and classification pipeline can be directly extended to real-time multi-channel movement recognition systems.

This architecture enables the construction of scalable movement recognition systems, allowing the transition from binary muscle-state detection to multi-class gesture and movement prediction.

TABLE II
BINARY VECTOR MAPPING FOR TARGET HAND MOVEMENTS. THE TABLE REPRESENTS A CONCEPTUAL SIMULATION BASED ON THE INDEPENDENT BINARY ACTIVATION STATES OBTAINED FROM EACH MUSCLE CONFIGURATION.

C1 (FCR)	C2 (FPL)	C3 (FDS)	C4 (ED)	Predicted Movement

1	1	1	0	Closed Hand
0	1	1	1	Pinch
1	0	1	0	Thumb Extension

B. Evaluation Methodology

The performance of the proposed methodology was evaluated in two stages.

For the unsupervised learning stage, the quality of the generated labels was primarily assessed through visual inspection of the recorded sEMG signals, clustering results, and temporal consistency of the contraction and relaxation patterns. A fully objective quantitative evaluation is difficult in the present experimental setting because no independent physiological ground truth was available. In particular, the time intervals defined by the experimental protocol cannot be directly considered ground-truth labels, since they represent the intended task periods rather than the exact physiological onset and offset of muscle activation. In recordings from a human subject, these transitions may occur before or after the predefined intervals and may also develop gradually, making the assignment of an exact transition point inherently uncertain.

For this reason, visual inspection of the recorded signals was adopted as the primary means of assessing whether the identified clusters were consistent with the observed contraction and relaxation patterns. This assessment considers the temporal behavior of the signal and the resulting cluster assignments, rather than relying on a single signal characteristic or a predefined amplitude threshold to determine the expected state.

As a complementary quantitative assessment, a representative subset of the acquired signals was manually annotated through visual inspection and compared with the corresponding clustering-based labels. The experimental protocol was used as a temporal reference during this annotation, while the recorded sEMG signal was considered when determining the observed contraction and relaxation intervals. The annotations were aligned with the same analysis frames used by the clustering stage, allowing a frame-by-frame comparison.

The manual annotations were therefore treated as an independent reference rather than an absolute physiological ground truth, since the precise boundaries of muscle activation remain subject to interpretation. The agreement between the reference and generated labels was quantified using Accuracy, Precision, Recall, F1-score, Cohen's Kappa, and the confusion matrix. Thus, the quantitative analysis provides an objective measure of agreement for the evaluated subset, while the visual analysis remains the primary evaluation criterion for the overall clustering results.

Subsequently, the generated labels were employed to train supervised binary classifiers for each electrode configuration. The classification performance was evaluated using the Accuracy, Precision, Recall, and F1-score metrics, which were computed according to their standard definitions [15].

where TP denotes true positives, TN true negatives, FP false positives, and FN false negatives. Precision (P) measures the proportion of predicted positive samples that are correctly classified, Recall (R) measures the proportion of actual positive samples correctly identified, Accuracy (Acc) represents the overall classification performance, and the F1-score ($F1$) corresponds to the harmonic mean of Precision and Recall.

Finally, the binary outputs of the four classifiers were combined according to the movement prediction strategy described previously, allowing the feasibility of recognizing functional hand gestures from independent muscle activation detectors to be analyzed.

III. Results and Discussion

A. Unsupervised Label Generation

The clustering strategy was optimized individually for each dataset due to the inherent variability of sEMG signals and the differences between global hand movements and individual finger activations. Depending on the dataset characteristics, different combinations of time- and frequency-domain features were selected, and label post-processing techniques were applied to improve cluster stability and temporal consistency.

As illustrated in Fig. 4, the generated cluster labels (red dashed line) are superimposed on the zero-phase filtered sEMG signal (blue line), allowing a direct visual comparison between the automatically generated pseudo-labels and the underlying muscle activation periods.

The proposed approach successfully identified contraction and relaxation states across all electrode configurations. For datasets containing periodic contraction-relaxation cycles, the separation between both states was generally well defined, with most ambiguities occurring only during the transition intervals. Occasional short-duration fluctuations within otherwise stable activation periods were effectively mitigated by the proposed label post-processing stage, resulting in temporally consistent cluster assignments.

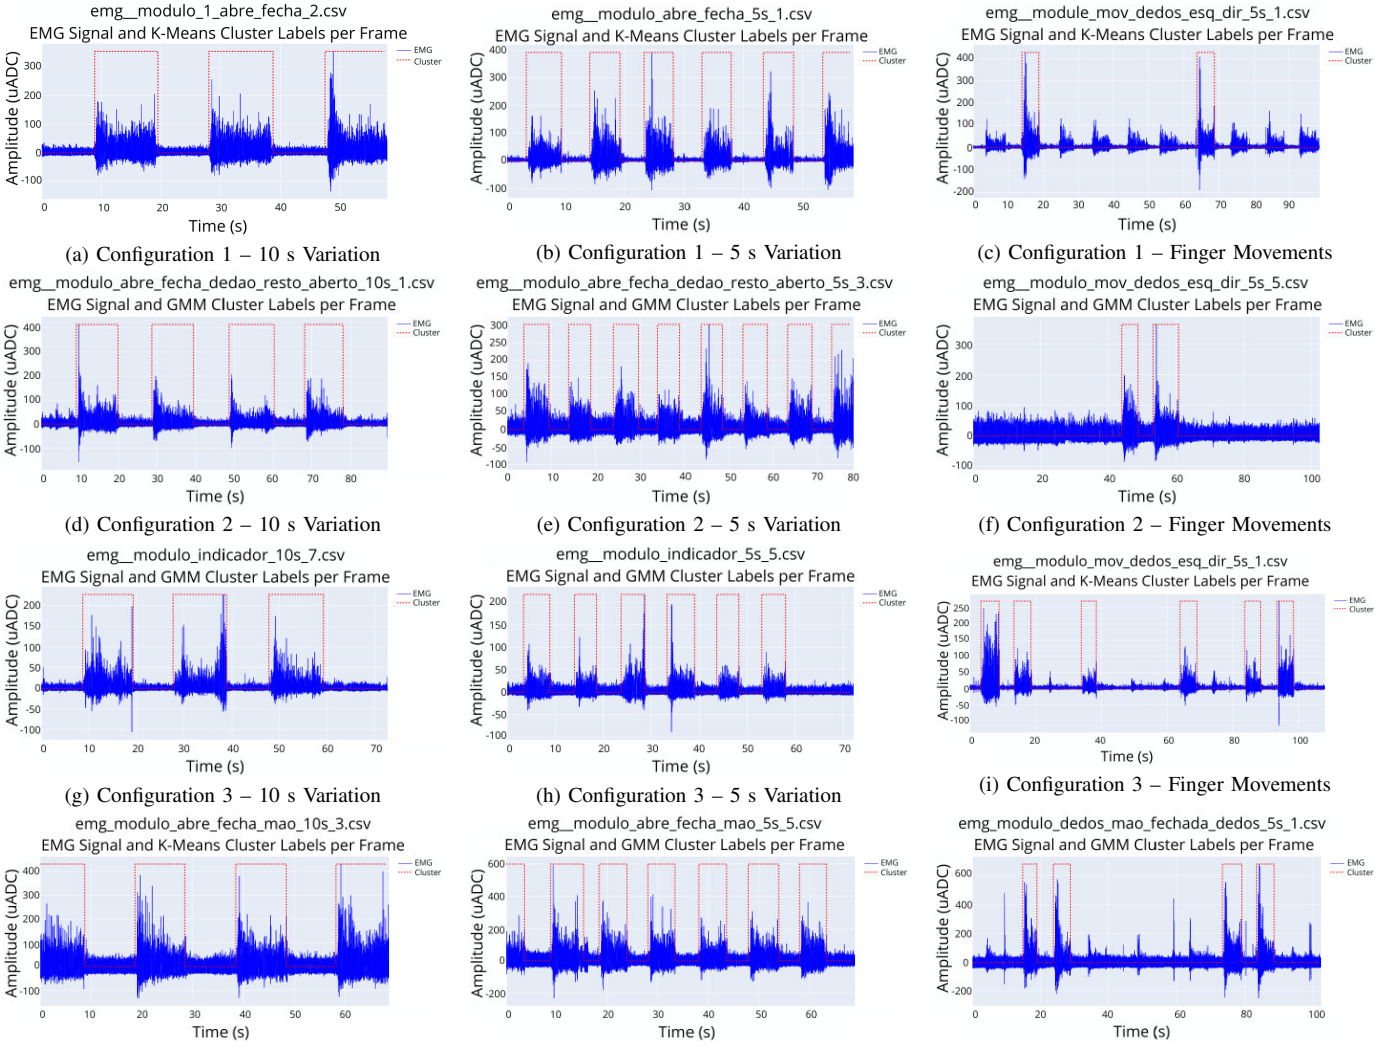
The visual inspection of the generated labels indicated a consistent correspondence between the identified clusters and the activation patterns observed in the filtered EMG signals. This assessment was considered particularly relevant because the experimental protocol defines the intended movement intervals but does not provide an exact physiological ground truth for the onset and offset of muscle activation. Therefore, the observed signal behavior and the temporal consistency of the generated labels were considered when assessing the clustering results.

The most challenging scenarios were observed in the individual finger movement datasets. In these cases, the physiological cross-talk phenomenon produced overlapping muscle activations, reducing the separability between classes. Consequently, feature selection and label post-processing became more important to ensure temporal consistency and reduce isolated false-positive detections.

For flexor muscles, contraction corresponds to the flexion of the target finger while the remaining fingers are extended. For extensor muscles, contraction corresponds to the extension of the target finger while the remaining fingers are flexed, preserving the same encoding.

To complement the qualitative assessment, a quantitative analysis was performed on a representative subset of 3280 analysis frames using the manual reference annotation described in Section II-B. The clustering-based labels achieved an Accuracy of 98.05%, a Cohen's Kappa of 0.961, and an F1-score of 0.98 for both relaxation and contraction. Precision/Recall values were 0.99/0.97 for relaxation and 0.97/0.99 for contraction, respectively. The resulting confusion matrix yielded 1,597 True Relaxations, 51 False Contractions, 13 False Relaxations, and 1,619 True Contractions (rows representing manual reference, columns representing clustering labels).

The quantitative results complement the visual assessment by providing an objective measure of agreement for the selected recordings. However, they should not be interpreted as evidence of an absolute physiological ground truth or as a comprehensive validation of all acquired datasets, since the manual reference itself is subject to interpretation of the recorded sEMG signals.



Furthermore, differences in clustering performance were observed among the electrode configurations. These variations are consistent with the characteristics of the monitored muscles, as larger and more superficial muscle groups generally produced clearer activation patterns and greater cluster separability. In contrast, deeper muscles or regions with significant overlap between muscle groups were more susceptible to cross-talk effects, increasing the complexity of the clustering task.

Overall, the visual and complementary quantitative assessments indicate that the clustering framework was able to identify activation patterns consistent with the observed sEMG signals under the evaluated experimental conditions, supporting the use of the generated labels as pseudo-labels for the subsequent supervised learning stage.

B. Supervised Classification Results

The pseudo-labels generated during the unsupervised learning stage were subsequently used to train supervised classification models. Several classifiers were evaluated and exhibited similar performance. For conciseness, only the results obtained using the Random Forest classifier are presented, as it consistently achieved high performance across all electrode configurations.

Table III summarizes the weighted-average classification metrics for each electrode configuration. Since the classification task consisted of a binary problem, representing con-

(a) Configuration 1 – 10 s Variation
(b) Configuration 1 – 5 s Variation
(c) Configuration 1 – Finger Movements
(d) Configuration 2 – 10 s Variation
(e) Configuration 2 – 5 s Variation
(f) Configuration 2 – Finger Movements
(g) Configuration 3 – 10 s Variation
(h) Configuration 3 – 5 s Variation
(i) Configuration 3 – Finger Movements

(k) Configuration 4 – 5 s Variation
(l) Configuration 4 – Finger Movements

Fig. 4. Comparison of the clustering results obtained for the four electrode configurations and three movement categories. The horizontal axis represents time in seconds, and the vertical axis represents signal amplitude in ADC units (uADC). Cluster labels (red dashed line) are superimposed on the zero-phase filtered EMG signal (blue line), allowing visual assessment of the correspondence between the generated pseudo-labels and the underlying muscle activation periods.

TABLE III
CLASSIFICATION PERFORMANCE (WEIGHTED AVERAGE) FOR EACH ELECTRODE CONFIGURATION USING THE RANDOM FOREST CLASSIFIER

Configuration	Precision	Recall	F1-score	Accuracy
C1 (FCR)	0.96	0.96	0.96	0.96
C2 (FPL)	0.97	0.97	0.97	0.97
C3 (FDS)	0.99	0.99	0.99	0.99
C4 (ED)	0.98	0.98	0.98	0.98

traction and relaxation states, accuracy, precision, recall, and F1-score remained consistently high across all experiments.

The results indicate that the labels generated by the clustering stage provided sufficient consistency for the subsequent supervised classification stage, with classification accuracies ranging from 96% to 99% across the evaluated configurations. These results support the feasibility of using the generated pseudo-labels for supervised learning under the evaluated experimental conditions. The adopted train/test partition allowed the classifiers to be evaluated on recordings not included in the training subset; however, this should not be interpreted as evidence of generalization across subjects or experimental conditions.

C. Movement Prediction

The proposed binary architecture combines the outputs of four independent muscle classifiers to represent functional hand movement patterns, as shown in Table II. Since the four muscle configurations were acquired independently rather than simultaneously, these results represent a conceptual simulation of the proposed framework rather than an experimental validation of simultaneous multi-channel gesture recognition. A multi-channel acquisition system is required to experimentally verify temporal muscle coordination in real time. Nevertheless,

the proposed pipeline is directly scalable to future multi-channel implementations using the same processing steps.

One limitation of the current implementation is its reduced capability to distinguish subtle motor actions involving highly correlated muscles, such as isolated index-finger extension. This limitation arises primarily from anatomical cross-talk and the independent acquisition of each muscle rather than from the proposed processing pipeline. Future multi-channel, multi-class implementations are expected to overcome this limitation while preserving the proposed methodology.

Therefore, the obtained results indicate that combining low-overhead binary classifiers is a viable strategy for representing functional hand movement patterns from independently acquired muscle activations. The proposed features-and-clustering framework achieves high classification performance within the evaluated datasets, supporting the feasibility of the proposed methodology as a proof of concept for future scalable myoelectric control systems.

IV. Conclusions

The main contribution of this work is the development of a feature-based pipeline combined with unsupervised learning for semi-automatic annotation of sEMG signals. By extracting time-, frequency-, and statistical-domain descriptors and applying clustering algorithms, the proposed approach identified contraction and relaxation patterns without relying on a single manually defined amplitude threshold. The generated labels were subsequently used as pseudo-labels for supervised classification, with overall accuracies ranging from 96% to 99% across the evaluated configurations. As a complementary quantitative assessment, a representative subset of 3280 analysis frames achieved 98.05% Accuracy and a Cohen's Kappa of 0.961 when compared with an manual reference annotation. These results indicate that the proposed pipeline was able to generate labels consistent with the observed sEMG activation patterns under the evaluated experimental conditions.

Unlike threshold-based approaches (e.g., [8]), which rely on empirical amplitude thresholds, the proposed methodology leverages multi-domain feature extraction and unsupervised learning. This multidimensional representation allows the pipeline to capture complementary signal characteristics and generate pseudo-labels with reduced manual intervention under the evaluated acquisition conditions, offering a practical end-to-end framework for sEMG dataset annotation with reduced manual effort.

The primary limitation of the present work is the experimental acquisition setup and the limited number of participants. Only a single healthy volunteer was evaluated, and the availability of a single sEMG acquisition module required sequential data acquisition sessions for each muscle configuration, preventing simultaneous multi-channel validation. Additionally, forearm muscle cross-talk limited the separability of highly subtle or isolated finger movements. Therefore, the results should be interpreted as an intra-subject proof of concept and feasibility assessment rather than evidence of generalization or robustness across subjects.

Future work will include simultaneous multi-channel acquisition, evaluation with additional participants, and quantitative comparison with established threshold-based labeling methods. The proposed feature extraction and learning framework can also be adapted to different acquisition hardware and extended to multi-channel configurations, providing a basis for further investigation of automated sEMG dataset annotation and myoelectric control.

Data Availability

The full data processing code, feature engineering scripts, clustering optimization routines, and dataset logs are openly available in our GitHub repository at GitHub repository to ensure transparency, reproducibility, and future open-source improvements by the biomedical engineering community.

Abstract—Introduction: Brain death (BD) is the complete and irreversible loss of all brain function. In Brazil its determination is strictly clinical and legal and follows CFM Resolution No. 2,173/2017, under which electroencephalography (EEG) is an ancillary test used to establish electrocerebral inactivity and has no standing as a criterion on its own. Besides visual inspection, quantifiers such as spectral coherence describe the degree of synchronization between homologous cortical regions. Objective: To describe, in exploratory and descriptive terms, the quantitative behaviour of inter-hemispheric spectral coherence and its temporal and regional dispersion in EEG recordings of neurocritical patients admitted to an intensive care unit (ICU) and undergoing the brain death protocol. No diagnostic criterion is proposed or validated. Methods: A series of four cases (A, B, C and D) comprising seven EEG examinations. In cases A, B and C the protocol was not confirmed and cerebral arteriography showed residual brain perfusion (six examinations); in case D arteriography showed no intracranial arterial opacification and brain death was confirmed (one examination). Ten artefact-free 2 s epochs were selected from each examination, totalling 70 epochs. Magnitude-squared coherence (a dimensionless quantity, 0–1) was estimated by Welch's method in the delta (1–3 Hz), theta (4–8 Hz), alpha (8–13 Hz) and beta (13–35 Hz) bands, over eight homologous inter-hemispheric pairs of the international 10–20 system, using a referential auricular montage. Because epochs are nested within examinations and examinations within patients, they are not independent observations, and no hypothesis test was applied. Results are reported per case and per examination and are also presented graphically. Results: The overall median coherence was 0.18 in case A, 0.17 in case C, 0.13 in case B and 0.11 in case D. Case D showed the lowest median in all four bands and was lower than the three comatose cases in 20 of the 32 electrode-pair/band combinations. Parieto-occipital pairs concentrated the highest values in A and C (ratios of 1.7 and 2.1 relative to the remaining pairs), a pattern absent in B and reversed in D. In the two cases with serial examinations, coherence decreased across recordings. Conclusion: The findings are descriptive, restricted to four patients and to a single examination in the confirmed brain death case, and support no inference about diagnostic performance or about discrimination between coma and brain death. They are offered as an exploratory signal-processing illustration; EEG remains an ancillary test, subordinate to the clinical and legal protocols in force.

Keywords—brain death, electroencephalography, quantitative EEG, spectral coherence, case series, exploratory study

I. Introduction

Brain death (BD) is the complete and irreversible loss of all brain function, including that of the brainstem, and is legally recognized as a criterion of death in many countries [1]. The diagnosis carries high clinical, ethical and legal weight, because it determines the withdrawal of therapeutic support and opens the organ donation and transplantation process. An accurate determination protects the safety of the procedures that follow, the reliability of care protocols and compliance with the legal criteria set by national and international guidelines [2], [3].

In Brazil, brain death determination is governed by CFM Resolution No. 2,173/2017 [2], which requires two clinical examinations by different physicians, an apnoea test and, mandatorily, an ancillary test able to demonstrate absence of cerebral blood perfusion, absence of cerebral metabolic activity or electrocerebral inactivity. EEG belongs to this last category: it establishes electrocerebral inactivity, and its report depends on the clinical prerequisites set out in the regulation, namely body temperature above 35 °C, arterial oxygen saturation above 94 %, systolic blood pressure of at least 100 mmHg or mean arterial pressure of at least 65 mmHg in adults, and exclusion of central nervous system depressant drugs. The technical recording parameters (minimum number of electrodes, sensitivity, filters, recording time, impedance check and integrity tests) follow the recommendations of the International Federation of Clinical Neurophysiology (IFCN) [3]. The diagnosis is therefore clinical and legal, and no quantifier derived from the EEG, including the coherence described here, replaces or alters that determination.

Ancillary tests gain weight when clinical factors limit or hinder neurological assessment. Electroencephalography is non-invasive, widely available and has high temporal resolution, which allows real-time monitoring of cerebral electrical activity and yields information on cortical function [4], [5].

Advances in digital signal processing (DSP) have brought several quantitative approaches to the EEG, as auxiliary tools intended to make neurophysiological analysis more objective. Studies by [6], [7] and [8] described parameters related to spectral energy, entropy and hybrid analysis techniques in patients with brain death and in individuals with severe impairment of consciousness, and [9] observed changes in

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

power spectral density parameters in patients undergoing the brain death protocol.

Alongside spectral approaches, brain functional connectivity has also been investigated. One of its metrics is electroencephalographic coherence, the degree of synchronization between signals recorded at different brain regions within a given frequency band, which informs on the functional integrity of neural networks and on the communication between distinct areas [10], [11]. States of reduced or lost consciousness show a progressive decrease in this connectivity, a sign that the neural integration sustaining cognitive and physiological function is impaired.

Interpreting the EEG within brain death protocols remains difficult despite the technical and methodological advances of recent decades. Artefacts from the intensive care environment, electromagnetic interference, physiological noise and low-amplitude residual activity can hinder signal analysis and disturb the clinical reading [12]. The literature also describes electroencephalographic activity persisting after the clinical diagnosis of brain death: [13] reported low-amplitude theta and beta activity in patients considered clinically dead, and [14] described the persistence of organized patterns, including sleep spindles and residual alpha activity, for prolonged periods after clinical confirmation of BD. In line with these observations, [15] followed a comatose ICU patient throughout the dying process and showed that the temporal dynamics of quantitative EEG features, among them the frequency spectrum and the aperiodic (1/f) component of the signal, can still be observed in the last hour before death.

This work describes the quantitative behaviour of inter-hemispheric spectral coherence and its dispersion in EEG recordings of neurocritical patients in coma and of one patient who progressed to diagnostic confirmation of brain death. It is a series of four cases, analysed in exploratory and descriptive terms, with the data of each patient presented individually. The study does not compare populations, estimate diagnostic accuracy, validate a discrimination method or propose any additional criterion for brain death determination.

To the best of our knowledge, this type of coherence analysis has not been reported for recordings of Brazilian patients undergoing the brain death protocol. That gap motivates the present description but gives the findings no confirmatory value: with four patients, the work is an exploratory signal-analysis illustration and provides no evidence about the condition under study.

II. Methodology

This descriptive study assessed electroencephalography examinations obtained from four patients admitted to the intensive care unit (ICU) with clinical suspicion of brain death. The study was approved by the Research Ethics Committee of the Federal University of Uberlândia (CEP-UFU), under protocol No. 82824017.5.0000.5152.

A. Inclusion criteria

Patients were included if they had at least one EEG examination requested during the investigation for the brain death protocol. Recordings were required to be free of significant artefacts capable of disturbing clinical interpretation and to last at least 18 min. Only patients whose death was subsequently confirmed in the hospital records, and who had cerebral arteriography as an ancillary test, were considered.

B. Cases analysed and terminology

The recordings come from four patients, identified as A, B, C and D, and comprise seven EEG examinations. In cases A, B and C the brain death protocol was not confirmed: cerebral arteriography showed residual brain perfusion, and the patients died between 18 and 33 days after the last EEG analysed. In case D, arteriography showed no intracranial arterial opacification and brain death was confirmed.

The four cases are described individually, and the comparisons presented below are descriptive. Although the database contained other recordings, only those with adequate technical quality and complete clinical information were selected, a criterion that introduces selection bias and is revisited in Section V.

TABLE I. Clinical characterization of the four cases and ancillary test finding. Age in years; BD conf.: brain death confirmed.

Case	Sex	Age	Aetiology	Exams	Days to death	BD conf.	Cerebral arteriography
A	M	53	Haemorrhagic stroke	2	33 e 29	No	Faint opacification of right M1 and A1
B	M	21	Traumatic brain injury	3	22, 20 e 18	No	Faint opacification of carotid, A1 and basilar
C	M	73	Traumatic brain injury	1	26	No	Faint opacification of M1/M2 and basilar “stop”
D	F	53	Haemorrhagic stroke	1	6	Yes	No intracranial arterial opacification

Table I presents the clinical characterization of the four cases. In the three cases in which the protocol was not confirmed there is documented residual arterial opacification, however faint and territorially limited, whereas in case D there was no intracranial arterial opacification. This is a perfusion correlate obtained by a method independent of the EEG, which situates the four cases without resorting to the very quantifier under description.

TABLE II. EEG recordings analysed (seven examinations from four patients).

Case	Examination	Duration (min)	Epochs (n)	Days to death
A	1st	31	10	33
A	2nd	30	10	29
B	1st	30	10	22
B	2nd	30	10	20
B	3rd	30	10	18
C	1st	18	10	26
D	1st	30	10	6

The seven examinations are described in Table II. Durations ranged from 18 to 31 min. Case B contributed three examinations over five days, case A two examinations over four days, and cases C and D one examination each. The brain death protocol set out in CFM Resolution No. 2,173/2017 allows a variable number of EEG examinations, according to the clinical circumstances of each admitted patient. Ten 2 s epochs were extracted from each examination, yielding 70 epochs: 60 in the three comatose cases and 10 in case D (Table III).

TABLE III. Summary of the sample used in signal processing.

Set	Patients (n)	Exams (n)	Epochs (n)	Brain perfusion at arteriography
Comatose cases (A, B, C)	3	6	60	Residual, documented
Confirmed BD case (D)	1	1	10	Absent
Total	4	7	70	—

C. Clinical conditions: sedation, temperature and metabolic factors

All seven examinations were requested and performed within the brain death protocol, and therefore under the clinical conditions that CFM Resolution No. 2,173/2017 [2] requires for the ancillary test: the temperature, oxygen saturation and blood pressure thresholds and the exclusion of central nervous system depressant drugs listed in Section I. Checking these prerequisites is a regulatory condition for performing the test and falls to the attending team, which documents it in the protocol file. The technical recording parameters follow the IFCN recommendations [3].

Compliance with the prerequisites is assured at protocol level, but the individual values of temperature, blood pressure, blood gases, natraemia and glycaemia at the moment of each acquisition, as well as sedative dose and time since withdrawal, cannot be retrieved from the records available for this retrospective study. It is therefore not possible to quantify the margin by which each examination met the thresholds, nor to rule out entirely a residual sedation effect. Residual sedation, borderline hypothermia, hypotension, hypercapnia, hypoglycaemia and hydroelectrolytic disturbances each reduce signal amplitude and synchronization on their own, and can produce coherence drops similar to those described here. No difference observed between cases can therefore be attributed exclusively to the neurological condition, a point revisited in Section V.

Chronology of case D. The single EEG of patient D was recorded during the protocol investigation, six days before death. The cerebral arteriography that supported the diagnostic confirmation, and which showed no intracranial arterial opacification, was performed six days after that EEG, on the same day as death. At the moment the analysed signal was acquired, therefore, brain death had not yet been confirmed. Since confirmation came from arteriography, the EEG examination considered here is the neurophysiological information closest to that outcome and, in that sense, the most representative available. None of the seven examinations analysed corresponds to a confirmatory protocol report.

D. EEG acquisition: montage, reference, impedance and filters

Signals were acquired with electrodes positioned according to the international 10–20 system, in the intensive care environment, for the clinical purpose of supporting the brain death protocol. A referential montage was used, with the auricular electrodes A1 and A2 as reference. Coherence was computed over eight homologous inter-hemispheric pairs derived from this montage: Fp1-Fp2, F7-F8, F3-F4, T3-T4, C3-C4, T5-T6, P3-P4 and O1-O2.

Examinations lasted between 18 and 31 min, with a sampling frequency of 100 Hz and an acquisition sensitivity corresponding to a ±200 μV range. No digital filter was applied before processing, which preserves the original signal characteristics. A 60 Hz notch filter was likewise not used, which does not affect the analysed bands (1 to 35 Hz) but is relevant to the characterization of background noise. The reports do not give the impedance value measured in each examination; since the recordings were performed within the brain death protocol, the technical conditions recommended by the IFCN [3] apply: impedance check between 100 Ω and 10 kΩ, electrode integrity testing and calibration recording.

E. Pre-processing, epoch selection and artefact rejection

Only artefact-free epochs were quantitatively analysed. They were chosen visually and by consensus of two experienced neurologists, who have been responsible for more than ten years for the EEG reports of the brain death protocol at the Hospital de Clínicas of Uberlândia, and who selected the segments of greatest clinical relevance and excluded those with artefacts. Segments with movement artefact, 60 Hz interference from ICU equipment, electrode artefact (saturation or disconnection), electrocardiogram artefact and mechanical ventilation artefact were discarded. Ten 2 s epochs were extracted from each examination: 60 in the comatose cases and 10 in case D, 70 in total.

Beyond segment exclusion, individual electrodes were excluded whenever they showed loss of contact, excessive noise or saturation. Because coherence is computed between homologous pairs, excluding one electrode eliminates the corresponding pair in that examination. Of the 56 possible pairs (7 examinations × 8 pairs), six could not be analysed: F3-F4 in the 2nd examination of case A, O1-O2 in the 1st examination of case B, C3-C4 and P3-P4 in the 3rd examination of case B,

and Fp1-Fp2 and F3-F4 in the examination of case C. In the results tables and figures these pairs appear as missing data, not as zero coherence.

Artefact rejection was visual and not automated, and selection by clinical relevance systematically favours the segments of best quality.

F. Spectral estimation and coherence computation

Coherence evaluates the degree of synchronization between two signals across frequency bands and provides information on the functional interaction between distinct brain regions [10]. The computation is based on the cross power spectral density between two signals, normalized by their individual spectral densities. The resulting values range between 0 and 1: values close to 1 indicate greater synchronization between the electrodes analysed, whereas values close to 0 reflect low synchronization [10].

Coherence between two signals is defined as:

$$|\Gamma_{xy}(e^{j\omega})|_i^2 = \frac{|S_{xy}(e^{j\omega})|^2}{S_x(e^{j\omega})\, S_y(e^{j\omega})} \quad (1)$$

where:

Sxy – Cross power spectral density.

Sx – Power spectral density of signal X.

Sy – Power spectral density of signal Y.

i – Segment considered.

This equation satisfies the following property:

$$0 \leq |\Gamma_{xy}(e^{j\omega})|^2 \leq 1 \quad (2)$$

Magnitude-squared coherence was estimated by Welch's method [16], averaging the ten 2 s epochs of each examination as segments of the spectral average, with a Hann window and no overlap. Each epoch contains 200 samples at 100 Hz. The value assigned to each band is the mean of the coherence values over the spectral components it contains. Coherence is a dimensionless quantity restricted to the interval [0, 1], so the values reported here carry no unit.

The analysis covered the 1 to 35 Hz range, with 1 Hz resolution, divided into four bands: Delta (1 to 3 Hz, 3 spectral components), Theta (4 to 8 Hz, 5), Alpha (8 to 13 Hz, 6) and Beta (13 to 35 Hz, 23). The 8 and 13 Hz limits are shared by adjacent bands. With a sampling frequency of 100 Hz the Nyquist frequency is 50 Hz, and the whole analysed range lies below it. Frequencies above 35 Hz were not analysed, because they approach the sampling limit and because the reports do not document the anti-aliasing filter used at acquisition, which compromises the reliability of estimates in that region. Mains interference at 60 Hz, if present and unfiltered before sampling, folds back to 40 Hz, above the analysed range [11], [17].

Magnitude-squared coherence estimated from a finite number of segments is biased upwards, and its expected value between two statistically independent signals is approximately 1/L, where L is the number of averaged segments [18]. The medians observed in this study lie between 0.10 and 0.27, a magnitude consistent with the floor expected for L on the order of ten. The values described here are therefore close to the level expected in the absence of coupling, particularly the smallest ones, and should not be read as measures of preserved connectivity.

G. Descriptive and exploratory analysis

For each examination and for each of the 32 electrode-pair/band combinations, a complete set of descriptive statistics of the coherence coefficients was computed: mean, median, standard deviation, variance, coefficient of variation, minimum and maximum, first and third quartiles, skewness and kurtosis. Each of these distributions gathers the coherence values of the ten epochs across all spectral components of the band, that is, 30 values in Delta, 50 in Theta, 60 in Alpha and 230 in Beta. The dispersion measured in this way therefore combines temporal variation and variation across the spectrum within the band. The synthesis presented below uses the median as the measure of central tendency and two complementary measures of dispersion, which describe distinct axes: the standard deviation of the coherence coefficients within each band, which measures the variability of synchronization across the spectrum and across the epochs of a given pair, and the range across the eight homologous pairs, which measures spatial heterogeneity over the scalp. All are descriptive measures, not estimates of population parameters.

The data structure is nested: epochs belong to the same examination, electrode pairs share channels and reference, examinations belong to the same patient, and the set comprises four patients, one of them with confirmed brain death. Under these conditions, a hypothesis test would treat as independent observations values that in practice describe four individuals, and the resulting p-value would mostly reflect the number of epochs and pairs considered. An entirely descriptive analysis was therefore adopted, without hypothesis tests and without qualifying results as significant.

For the same reason, percentage differences between sets of examinations are not computed. Such a measure would require pooling the three comatose cases into a single average, which would erase precisely the individual variation the series sets out to show. Results are therefore presented case by case and examination by examination, in tables and in graphs.

III. Results

Results are presented case by case and examination by examination. Table IV summarizes coherence behaviour in each case and band, Table V details the topography pair by pair, and Table VI descends to the level of the individual examination. Figs. 1 and 2 present the same information visually.

TABLE IV. Coherence by case and band: median, range across the eight homologous pairs, and standard deviation within the band. Dimensionless

values (0–1); n = number of electrode-pair × examination combinations effectively analysed, after exclusion of pairs with a discarded electrode.

Case	Band	n	Median	Min–Max across pairs	SD within band
A	Delta	15	0.17	0.08–0.56	0.16
	Theta	15	0.18	0.08–0.61	0.14
	Alpha	15	0.21	0.12–0.47	0.17
	Beta	15	0.14	0.09–0.33	0.15
B	Delta	21	0.14	0.07–0.31	0.15
	Theta	21	0.13	0.07–0.19	0.13
	Alpha	21	0.16	0.09–0.22	0.14
	Beta	21	0.12	0.09–0.17	0.13
C	Delta	6	0.14	0.10–0.31	0.15
	Theta	6	0.23	0.11–0.39	0.15
	Alpha	6	0.18	0.14–0.34	0.17
	Beta	6	0.14	0.12–0.34	0.15
D	Delta	8	0.12	0.07–0.19	0.12
	Theta	8	0.11	0.08–0.12	0.12
	Alpha	8	0.12	0.10–0.22	0.13
	Beta	8	0.11	0.11–0.14	0.14

Each row of Table IV gathers the values of one case in one band. Column n reports how many electrode-pair and examination combinations entered the computation, already discounting the pairs lost to electrode exclusion. Median is the central coherence value in that band, the value that splits the observations in half. Min–Max across pairs gives the smallest and the largest value observed among the eight homologous pairs: in case A, for instance, coherence in Delta ranged from 0.08 in the least synchronized pair to 0.56 in the most synchronized one, and this range measures how much synchronization differs from one scalp region to another. SD within band is the standard deviation of the coherence coefficients inside the band, computed over the ten epochs and all the spectral components that compose it; it measures how much coherence fluctuates over time and frequency within a given pair, not between different pairs.

TABLE V. Median [Q1–Q3] coherence by electrode pair, in each case (pooling the four bands and the examinations of the case).

Electrode pair	A	B	C	D
Fp1-Fp2	0.16 [0.07–0.28]	0.15 [0.06–0.29]	—	0.13 [0.05–0.22]
F7-F8	0.15 [0.09–0.27]	0.12 [0.05–0.25]	0.15 [0.06–0.30]	0.11 [0.05–0.21]
F3-F4	0.16 [0.07–0.26]	0.13 [0.07–0.25]	—	0.12 [0.05–0.21]
T3-T4	0.18 [0.08–0.29]	0.16 [0.08–0.29]	0.22 [0.11–0.33]	0.12 [0.06–0.22]
C3-C4	0.24 [0.11–0.41]	0.14 [0.05–0.25]	0.14 [0.07–0.25]	0.12 [0.05–0.23]
T5-T6	0.16 [0.06–0.23]	0.13 [0.06–0.21]	0.12 [0.06–0.24]	0.11 [0.06–0.22]
P3-P4	0.19 [0.10–0.34]	0.13 [0.06–0.22]	0.19 [0.09–0.34]	0.10 [0.05–0.16]
O1-O2	0.27 [0.16–0.42]	0.13 [0.05–0.23]	0.34 [0.20–0.50]	0.10 [0.05–0.22]

In Table V, each cell gives the median coherence of that electrode pair in that case, followed in brackets by the first and third quartiles, Q1 and Q3. Below Q1 lie 25 % of the observations and below Q3, 75 %; together they delimit the central half of the distribution and indicate how concentrated the values are around the median. A dash marks a pair not analysed because of electrode exclusion. Unlike Table IV, here the four bands and the examinations of each case are pooled: the reading is spatial, comparing scalp regions rather than frequency bands.

TABLE VI. Median coherence in each of the seven examinations, by band.

Examination	Delta	Theta	Alpha	Beta
A, 1st	0.21	0.24	0.26	0.17
A, 2nd	0.12	0.13	0.16	0.12
B, 1st	0.18	0.16	0.16	0.12
B, 2nd	0.13	0.13	0.13	0.11
B, 3rd	0.13	0.11	0.17	0.13
C, 1st	0.14	0.23	0.18	0.14
D, 1st	0.12	0.11	0.12	0.11

Table VI gives the median coherence of each of the seven examinations, band by band. It is the only table in which the examinations of the same patient appear separately, which allows the evolution of cases A and B across successive recordings to be followed.

The overall median coherence was 0.18 in case A, 0.17 in case C, 0.13 in case B and 0.11 in case D. Case D showed the lowest median in all four bands (0.12 in Delta, 0.11 in Theta, 0.12 in Alpha and 0.11 in Beta), although the margin over case B was small, 0.01 in Beta. Considering the 32 electrode-pair/band combinations, the median of case D was lower than that of the three comatose cases in 20 of them; in the remaining 12, at least one comatose case showed an equal or lower value.

Heterogeneity among the three comatose cases is evident and argues against treating them as a single set. The overall median of B (0.13) is closer to that of D (0.11) than to those of A (0.18) and C (0.17). The same holds for spatial dispersion: the range across the medians of the eight homologous pairs was wide in A (0.13 to 0.22 depending on the band) and in C (0.20 to 0.28), and narrow in D (0.04 to 0.13), but also in B (0.05 to 0.10). The spatial homogeneity of case D therefore does not distinguish it from all comatose cases.

The largest difference between cases appeared in the topographic distribution. In cases A and C, posterior pairs concentrated the highest values: the median of P3-P4 and O1-O2 was 1.7 times that of the remaining pairs in A and 2.1 times in C, with O1-O2 reaching 0.27 and 0.34, respectively. This postero-anterior gradient did not appear in B (ratio 1.0) and was reversed in D (ratio 0.9), where P3-P4 and O1-O2 recorded the lowest values of all pairs, 0.10 in both.

In the two cases with serial examinations, coherence fell across recordings (Table VI). The medians of case A went from 0.21 to 0.12 in Delta, from 0.24 to 0.13 in Theta, from 0.26 to 0.16 in Alpha and from 0.18 to 0.12 in Beta, between the first and the second examination. In B, the drop concentrated between the first and the second examination (Delta 0.18 to 0.13; Theta 0.16 to 0.13), with relative stability in the third. At the end of these trajectories, the medians of A and B approach the values observed in case D.

All values lie between 0.07 and 0.61, and the vast majority between 0.10 and 0.25, a range which, as set out in Section II-

F, is of the order of the floor expected for signals without coupling. In case D, the medians of the four bands (0.11 to 0.12) are practically indistinguishable from each other and from that level.

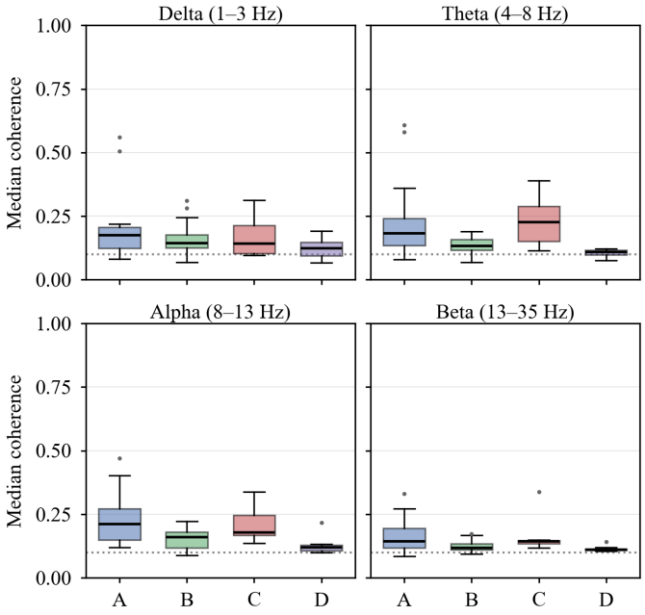

Fig. 1. Dispersion of median coherence across the eight homologous pairs, in each case and band. Each point forming the box is the median of one electrode pair in one examination. The box therefore describes the spatial heterogeneity of synchronization, not the variability within the band, which is given in Table IV. Dotted line: estimation floor (1/L ≈ 0.10 for L = 10 epochs).

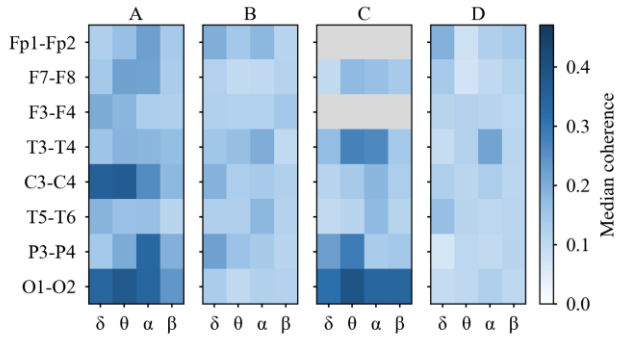

Fig. 2. Median coherence by electrode pair and band, in each patient (δ: delta; θ: theta; α: alpha; β: beta). Colour scale common to the four panels. Dimensionless values; in cases A and B, the median across examinations. Grey cells: pair not analysed because of electrode exclusion.

IV. Discussion

Electroencephalographic coherence is widely used as a metric of brain functional connectivity, decreasing progressively as states of impaired consciousness deepen. This reduction reflects the loss of functional synchronization between cortical regions, particularly in diffuse cerebral dysfunction [5], [19]. Quantitative studies in comatose patients show coherence values generally lower than those observed in neurologically healthy individuals [20], [21], varying with the electrode pair and the band considered.

One feature sets this series apart from purely electroencephalographic descriptions: all four cases have cerebral arteriography, a perfusion measure that does not depend on the EEG. In the three comatose cases there is documented residual arterial opacification, however faint; in case D there is no intracranial opacification. Any coherence difference between them can therefore be read against an objective circulatory finding as well as against the clinical label. The comparison remains descriptive: with a single case of absent perfusion, no association can be estimated.

The pathophysiological reading of the findings remains plausible. In the absence of organized neuronal activity, the recorded signal tends to be dominated by instrumental and environmental noise, and coherence indices settle at low, weakly varying values. In comatose patients, by contrast, the persistence of irregular electrical activity favours larger fluctuations in these indices. The observed values, however, approach the level expected for electrical and instrumental noise in the ICU environment. With L = 10 epochs, the coherence expected between two independent signals is of the order of 0.10 [18], a magnitude comparable to the medians described here. Low coherence in this regime is compatible both with the collapse of corticocortical integration and with the mere absence of signal above the noise, and the two situations cannot be separated by the available data.

The smaller standard deviations observed in case D are consistent with a low-amplitude signal of little dynamics, as expected when no organized detectable cortical electrical activity remains [1], and consistent here with the absence of intracranial arterial opacification. The same signature, however, may arise from deep sedation, hypothermia or better technical recording quality, factors that could not be controlled (Section V). The pathophysiological reading is therefore one among several explanations compatible with the data.

The spatial distribution separates the cases more sharply than any other measure, and is also the hardest to interpret. In cases A and C, the parieto-occipital pairs concentrated the highest coherence values, with ratios of 1.7 and 2.1 relative to the remaining pairs. In case D, these same pairs recorded the lowest values, reversing the gradient. One possible reading links this pattern to the involvement of parieto-occipital regions in cortical integration and in the maintenance of consciousness levels, particularly in the alpha and theta bands [22]: loss of the gradient would accompany the collapse of posterior corticocortical integration.

Two facts from the material itself weigh against this reading. The first is case B, comatose and with documented residual perfusion, which likewise shows no posterior gradient (ratio 1.0) and whose overall median is the closest to that of case D. The topographic finding therefore does not separate the cases by outcome. The second is that posterior pairs are the most exposed to decubitus artefact in the ICU bed and to variations in electrode contact, and it was precisely among them that exclusions for discarded electrodes occurred. With a single case of confirmed brain death, the observed topography cannot be distinguished from individual variation.

The material also allows a limited longitudinal reading, restricted to the comatose cases. In A and in B coherence decreased across successive examinations, and at the end of

both trajectories the values approach the level observed in case D. The observation is suggestive, as it would be compatible with progressive deterioration of cortical synchronization, but both patients had documented residual brain perfusion and neither had confirmed brain death. The decrease cannot therefore be read as a trajectory towards brain death. For case D no longitudinal reading is possible, since only one examination is available, obtained six days before death and during the protocol investigation. The electrophysiological evolution towards brain death, which would be the finding of greatest interest, cannot be described from this material.

V. Limitations

This is a series of four cases, and its limitations determine the reach of what can be asserted. Part of them stems from the practical difficulty of obtaining ethical authorization from the patients' families. By determination of the UFU Ethics Committee, the request for authorization took place during the family's visit to the patient, a moment ill-suited to such a request given the relatives' distress and anxiety for news.

Sample size and design. Four patients and seven examinations, of which only one corresponds to confirmed brain death, do not allow between-patient variability to be estimated nor the effect of the clinical condition to be separated from individual effects. Any difference observed is entirely compatible with variation between individuals.

Single examination in the brain death case. Case D contributes one examination and 10 epochs. Since the methodology followed the ICU care protocol, the clinical circumstances of this patient led to a single EEG recording.

Absence of additional metrics. The analysis is restricted to spectral coherence, without comparison with other EEG quantifiers such as entropy, phase synchronization (PLV), graph connectivity metrics or machine learning approaches, which could characterize the electrophysiological behaviour of the cases more completely [7], [8]. The space limit imposed by the conference rules did not allow their inclusion in this description.

Confounding factors documented only at protocol level. The clinical prerequisites of CFM Resolution No. 2,173/2017 (temperature, oxygenation, blood pressure and exclusion of central nervous system depressants) are a regulatory condition for performing the test and were verified by the attending team (Section II-C), but the individual values at the moment of each acquisition are not in the retrieved records. The margin by which each examination met the thresholds cannot be quantified, and residual sedation, borderline hypothermia or minor metabolic disturbance, each capable of producing the patterns described here, cannot be ruled out.

VI. Conclusion

In this exploratory case series, EEG spectral coherence behaved differently in the patient who progressed to diagnostic confirmation of brain death and in the patients with severe neurological injury: in the former, coherence stood at the lowest level of the series in all bands, and the parieto-occipital gradient present in two of the comatose cases did not appear. Given the small sample, the overlap with one of the comatose cases and the descriptive design, coherence should be understood as an investigative signal-processing metric.

The contribution is therefore methodological: an exploratory illustration of how quantitative coherence analysis can be applied to recordings obtained within the brain death protocol, with a detailed description of the processing and of the limitations, and with the uncommon benefit of cerebral arteriography for all four cases. No diagnostic criterion is proposed, and EEG remains an ancillary test, subordinate to the clinical criteria and to the legislation in force.

Future studies require a substantially larger and multicentre sample, prospective recording of clinical confounders, standardization of montage and impedance, automated artefact rejection, inclusion of other quantifiers (entropy, phase synchronization, graph metrics), serial acquisition in cases progressing to brain death, and patient-level analysis with models that respect the nested structure of the data. Only then could the discriminative value of coherence be investigated.

Acknowledgment

The authors thank the Coordination for the Improvement of Higher Education Personnel – Brazil (CAPES) for financial support, and the Hospital de Clínicas of the Federal University of Uberlândia (UFU), in particular its Department of Neurology, for the support and collaboration that made this research possible. The authors also thank Liliana Silva for her valuable collaboration in this work.

***Abstract*— Melanoma is the most aggressive form of skin cancer, making early diagnosis crucial to increasing the chances of successful treatment. This work proposes a methodology based on Digital Image Processing for the computational quantification of criteria A (asymmetry), B (border), and C (color) of the ABCD rule through the automatic extraction of geometric and pigmentation descriptors, aiming to evaluate its potential in differentiating between melanomas and non-melanomas. The methodology comprises the steps of automatic lesion segmentation in the CIELAB color space using the k-means algorithm, complemented by intensity-based thresholding in more complex cases, extraction of computational descriptors, and individual evaluation of their discriminatory power. The methodology was validated on a set of 20 images (10 melanomas and 10 non-melanomas), showing promising results. Among the descriptors evaluated, the asymmetry index showed the best performance, reaching 90% accuracy, while the border and pigmentation descriptors obtained accuracy of up to 70% and 75%, respectively. The results indicate that geometric descriptors, especially the asymmetry index, exhibit greater discriminatory capacity, reinforcing the potential of the proposed methodology as an interpretable computational tool to support the early diagnosis of melanoma. However, studies with larger image sets are needed to validate the robustness and generalizability of the approach.**

Keywords*— *Melanoma. Digital Image Processing. Skin Lesions. Border Signature.

I. Introduction

Skin cancer is one of the most common types of cancer worldwide, with melanoma being its most aggressive form due to its high metastatic potential. Although it represents a smaller proportion of cases, it is responsible for the majority of deaths associated with the disease, making early diagnosis fundamental to increasing the chances of successful treatment [1], [2].

With the advancement of imaging technologies, Digital Image Processing (DIP) techniques have been widely used to aid diagnosis, allowing the automatic extraction of relevant characteristics from skin lesions and reducing the subjectivity of visual assessment [2], [3], [4]. More recently, methods based on deep learning have achieved high performance in the classification of skin lesions [2], [4], [11]. However, these approaches generally require large labeled databases, high computational costs, and exhibit lower interpretability when compared to methods based on computational descriptors.

In this context, methods based on computational descriptors inspired by clinical criteria remain relevant because they allow for greater interpretability of results, lower computational complexity, and potential application in scenarios with limited data availability. However, studies that automatically quantify the clinical criteria of the ABCD rule using geometric and pigmentation descriptors capable of supporting the differentiation between melanomas and benign lesions are still scarce.

Given this scenario, this work proposes a methodology for the computational quantification of criteria A, B, and C of the ABCD rule through the automatic extraction of geometric and pigmentation descriptors. The methodology quantifies these characteristics and evaluates their discriminatory potential in differentiating between melanomas and non-melanomas, aiming to contribute to the development of computational tools to support diagnosis.

II. Materials And Methods

The proposed methodology performs computational quantification of the ABCD rule's clinical criteria of asymmetry, border, and color through the automatic extraction of geometric and pigmentation descriptors from dermatoscopic images. To this end, the method comprises the steps of image acquisition, automatic lesion segmentation, extraction of computational descriptors, and evaluation of the discriminatory power of these characteristics in differentiating between melanomas and non-melanomas. Fig. 1 presents the general flowchart of the developed methodology.

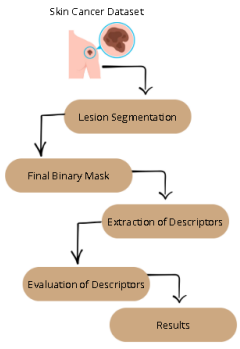

Fig. 1. – General flowchart of the proposed methodology

A. The Database

The images used in this study were obtained from the public Melanoma Skin Cancer Dataset [15], available on the Kaggle platform. This dataset consists of dermatoscopic images of skin lesions classified as melanoma and non-melanoma, and is widely used in research related to the development and evaluation of computational methods for the diagnosis of skin cancer. The original database contains approximately 10,000 images, encompassing different morphological and pigmentation characteristics of the lesions.

For the evaluation of the proposed methodology, a set of 20 randomly selected images was used, 10 melanomas and 10 non-melanomas, selected to represent both classes. This set was used to evaluate the behavior of the computational descriptors of asymmetry, border irregularity and pigmentation, as well as their discriminatory power in differentiating between melanoma and non-melanoma lesions.

B. Lesion Segmentation

Initially, all images were standardized to a resolution of 256 × 256 pixels and had their intensity levels normalized, aiming to standardize processing conditions and reduce variations resulting from image acquisition. Then, the images were converted from the RGB color space to the CIELAB space, whose separation between the luminance component (L) and the chromatic components (a and b) provides greater robustness against variations in illumination, favoring lesion segmentation [5], [13].

Segmentation was performed using the k-means algorithm, applied to the chromatic components of the CIELAB space. After the clustering step, the resulting binary mask was refined using morphological opening and closing operations, with the aim of removing small spurious regions and smoothing the lesion contour [3], [8], [10], [13].

When the segmentation obtained by the k-means algorithm did not present satisfactory quality due to the high heterogeneity of the lesion pigmentation, a complementary strategy based on contrast enhancement, conversion to grayscale, intensity thresholding and morphological operations was employed, allowing to obtain a mask more representative of the region of interest [12], [13].

The final mask obtained was used in subsequent steps to extract the computational descriptors related to the asymmetry, border and pigmentation criteria of the ABCD rule.

C. Extraction of Computational Descriptors

The extraction of computational descriptors aimed to automatically quantify the clinical criteria of asymmetry (A), border (B), and color (C) of the ABCD rule [7]. To this end, quantitative metrics were developed based on geometric properties and the pigmentation distribution of the lesion, allowing computationally representation of characteristics traditionally evaluated qualitatively during dermatoscopic examination [3], [5], [13].

The extraction of descriptors was performed from the binary mask obtained in the segmentation step. Initially, the geometric properties of the lesion were determined, including area, perimeter, centroid, and contour. This information served as the basis for constructing the radial signature and for calculating the descriptors related to asymmetry and border irregularity. In parallel, pigmentation analysis was performed using the luminosity component (L) of the CIELAB color space, allowing the acquisition of metrics associated with the color distribution in the segmented region [5], [13].

C.1 Asymmetry Descriptors

Asymmetry constitutes one of the main criteria of the ABCD rule for clinical evaluation of melanocytic lesions. In general, benign lesions have a more uniform geometric distribution, while melanomas tend to exhibit irregular growth, producing differences between opposite regions of the lesion [7]. To computationally represent this criterion, the radial signature was used, defined by the distances between the centroid of the segmented lesion and its contour in different angular directions [5], [13].

Initially, the centroid of the segmented region was determined based on the geometric properties of the binary mask. Next, 360 radial samples were obtained, corresponding to the distances between the centroid and the edge of the lesion for angles between 0° and 359°. This representation allows each angular direction θ to be associated with the diametrically opposite direction $\theta+\pi$.

For each pair of opposite directions, the local symmetry error was calculated, defined as the absolute difference between the respective radial distances, as presented in Eq. (1).

$$e(\theta) = |r(\theta) - r(\theta + \pi)| \quad (1)$$

where $r(\theta)$ represents the distance between the centroid and the edge of the lesion in the θ direction, $r(\theta+\pi)$ corresponds to the radial distance in the diametrically opposite direction, and $e(\theta)$ represents the local symmetry error. In approximately symmetrical lesions, opposite rays have similar values, producing low values of $e(\theta)$. More pronounced differences indicate less correspondence between opposite regions and, consequently, greater geometric asymmetry [3], [5].

After calculating the local symmetry error for each of the 180 diametrically opposite pairs of the radial signature, the Asymmetry Index (AI) was determined. To reduce the influence of the absolute size of the lesion, the sum of the errors was normalized by the sum of the radial distances corresponding to the evaluated pairs, as presented in Eq. (2).

$$IA = \frac{\sum e(\theta)}{\sum r(\theta)} \quad (2)$$

This normalization makes the index independent of the lesion scale, allowing for direct comparison of images with different dimensions and reducing the influence of absolute size on the asymmetry measurement.

C.2 Border Irregularity Descriptors

Border irregularity constitutes the second criterion of the ABCD rule for clinical evaluation of melanocytic lesions. While benign lesions tend to have smooth and continuous contours, melanomas frequently exhibit irregular borders,

characterized by indentations, protrusions, and abrupt changes along the contour [7].

To computationally represent this criterion, the discrete derivative of the radial signature obtained in the previous step was used. Since the radial signature describes the distance between the centroid of the lesion and its border as a function of the polar angle, its derivative allows quantifying local variations in the contour. Considering that the radial signature represents a closed curve, the derivative was calculated in a circular manner, including the difference between the last and first sample, ensuring the continuity of the signal along the entire perimeter of the lesion [13].

Initially, the Average Border Irregularity Index (IB_1) was determined, which corresponds to the average of the magnitudes of the differences between consecutive radial samples. This descriptor provides an estimate of the average intensity of contour variations and was calculated according to Eq. (3).

$$IB_1 = \frac{1}{N}\sum_{i=0}^{N}|\Delta r_i| \quad (3)$$

where N represents the total number of samples of the radial signature and Δr_i corresponds to the difference between two consecutive radial distances. High IB_1 values indicate greater average intensity of edge variations, being associated with geometrically more irregular contours [3], [5].

In addition to the average intensity of variations, the Irregularity Dispersion Index (IB_2) was calculated, obtained by the standard deviation of the discrete derivative of the radial signature, as presented in Eq. (4).

$$IB_2 = std(\Delta r_i) \quad (4)$$

This descriptor quantifies the dispersion of radial variations along the contour. Reduced values indicate relatively uniform border behavior, while high values show greater geometric heterogeneity, a characteristic frequently observed in melanoma lesions [3], [5].

Although the IB_1 and IB_2 descriptors characterize the overall behavior of the border, they do not fully represent localized irregularities. Therefore, automatic peak detection was performed on the absolute derivative of the radial signature using the findpeaks function of MATLAB®, considering an adaptive threshold defined by the sum of the mean and one standard deviation of the absolute derivative, in addition to a minimum distance between consecutive peaks to avoid multiple detections of the same irregularity.

From this analysis, three additional descriptors were extracted: number of peaks, corresponding to the number of significant irregularities present along the border; average peak amplitude, which represents the average intensity of the detected irregularities; and maximum peak amplitude, corresponding to the greatest local variation observed in the lesion contour.

Thus, the proposed methodology combines global descriptors, represented by IB_1 and IB_2 , with local descriptors, obtained by peak detection, providing a more complete quantitative representation of the geometric complexity of the lesion border.

C.3 Pigmentation Descriptors

Color variation constitutes the third criterion of the ABCD rule for evaluating melanocytic lesions. While benign nevi tend to have relatively homogeneous pigmentation, melanomas frequently exhibit multiple shades distributed irregularly, a characteristic associated with the heterogeneity of melanin concentration and structures present in the lesion [7].

In this work, this criterion was analyzed by means of the distribution of luminosity within the segmented region. For this, the CIELAB color space was used, which separates the luminosity component L from the chromatic components, allowing the analysis of intensity variations with less influence from color information [5], [13]. After segmentation, only the pixels belonging to the binary mask of the lesion were considered, excluding the adjacent skin.

To characterize the heterogeneity of pigmentation, the L-channel values were divided into five equally spaced intervals between the minimum and maximum values observed in the lesion itself. Each pixel was associated with one of these intervals, producing a pigmentation map composed of up to five luminosity levels.

The first descriptor, called the Pigmentation Level Index **(IC_1)**, corresponds to the number of levels actually present in the lesion. To reduce the influence of small regions resulting from noise, a level was considered present only when it represented at least 5% of the total segmented area. Thus, IC_1 expresses the diversity of luminosity levels with a relevant participation in the composition of the lesion.

In addition to the number of levels, the Luminosity Dispersion Index **(IC_2)** was calculated, corresponding to the standard deviation of the L-channel values within the lesion, as shown in Eq. (5).

$$IC_2 = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(L_i - \bar{L})^2} \quad (5)$$

where N represents the number of pixels belonging to the lesion, L_i corresponds to the luminosity of the i-th pixel, and $\bar{L}$ represents the average luminosity of the segmented region. High IC_2 values indicate greater dispersion of luminosity levels and, consequently, greater heterogeneity of pigmentation, while reduced values characterize lesions with a more uniform distribution.

Finally, the Luminosity Amplitude IC_3 was calculated, defined by the difference between the maximum and minimum values of the L channel inside the lesion, as shown in Eq. (6).

$$IC_3 = L_{max} - L_{min} \quad (6)$$

This descriptor represents the maximum contrast of pigmentation. High values indicate a greater difference between the lighter and darker regions of the lesion.

The three descriptors provide complementary information about pigmentation: IC_1 quantifies the number of relevant lightness levels, IC_2 measures the dispersion of these values, and IC_3 represents the maximum contrast observed. Subsequently, the descriptors were individually evaluated for

their ability to differentiate melanoma and non-melanoma lesions.

D. Exclusion of Criterion D from the ABCD Rule

Criterion D of the ABCD rule corresponds to the lesion diameter, traditionally considered suspicious when greater than 6 mm [7]. However, its use in computer systems depends on the spatial calibration of the image, requiring reliable information on resolution and scale for converting measurements into physical units. As the database used in this study gathers images obtained under different acquisition conditions, it was not possible to guarantee the standardization of this information, compromising the reliability of this parameter.

In addition to the limitations related to image acquisition, recent studies demonstrate that melanomas can be identified in early stages, even when they have a diameter smaller than the classic limit of 6 mm [2], [7]. Thus, the use of this criterion could reduce the sensitivity of the method for identifying small lesions, contradicting the objective of favoring early diagnosis.

Due to these limitations, it was decided not to use criterion D in the proposed methodology, prioritizing quantitative descriptors related to the geometry of the lesion and the distribution of its pigmentation. This decision makes the method less dependent on image acquisition conditions and potentially more suitable for analyzing lesions in different databases, regardless of their absolute size.

E. Evaluation of Descriptors

After extracting the computational descriptors, each metric was individually evaluated for its ability to differentiate melanoma and non-melanoma lesions. For this step, an evaluation set composed of 20 images was used, 10 melanomas and 10 non-melanomas, selected from the database described in Section II-A.

Initially, the descriptors for asymmetry (IA), border irregularity (IB_1 , IB_2 and peak-based descriptors) and pigmentation (IC_1, IC_2 and IC_3) were calculated for each image. Then, descriptive statistics were obtained for each class, allowing for the analysis of the individual behavior of each metric and the identification of differences between melanoma and non-melanoma lesions.

To assess the discriminatory power of the descriptors, each metric was analyzed individually using Leave-One-Out cross-validation (LOOCV). In each iteration, one image was reserved for testing, while the remaining images (N−1) were used to calculate the descriptor averages in each class and establish the separation threshold between them. The reserved image was then classified based on this threshold. This procedure was repeated for all samples, preventing the evaluated image from being used in defining the decision criterion itself.

As a performance measure, accuracy was used, defined as the ratio between the number of correct classifications and the total number of images evaluated, as presented in Eq. (7).

$$Acurácia = \frac{VP+VN}{VP+VN+FP+FN} \quad (7)$$

where VP represents the number of true positives, VN the number of true negatives, FP the number of false positives, and FN the number of false negatives. In addition to accuracy, sensitivity, specificity, precision, F1-score, and area under the ROC curve (AUC) were calculated. While accuracy represents the overall proportion of correct classifications, precision indicates the proportion of cases classified as melanoma that actually belonged to that class. The AUC was used to assess the discriminatory capacity of the descriptors considering different decision thresholds.

The significance of the differences between the melanoma and non-melanoma groups was evaluated using the Wilcoxon rank-sum test (Mann–Whitney U), with Bonferroni correction for multiple comparisons. This analysis allowed the identification of the descriptors with the greatest capacity to differentiate between the groups.

Finally, the most discriminatory descriptors for each criterion A, B, and C were combined using logistic regression, also evaluated by Leave-One-Out (LOOCV) cross-validation. This approach allowed us to compare the performance of the combined model with that obtained by the descriptors analyzed individually.

III. Results And Discussion

A. Evaluation of the Proposed Methodology

The proposed methodology was evaluated using a set of 20 dermatoscopic images, composed of 10 melanomas and 10 non-melanomas, processed entirely by the developed pipeline. As a representative example, the analysis of Image 5 (AUG_0_1114.jpeg), illustrated in Fig. 2, is presented, showing the main processing steps, including lesion segmentation, centroid determination, radial signature extraction, comparison between diametrically opposed rays, radial signature derivation, and pigmentation distribution analysis.

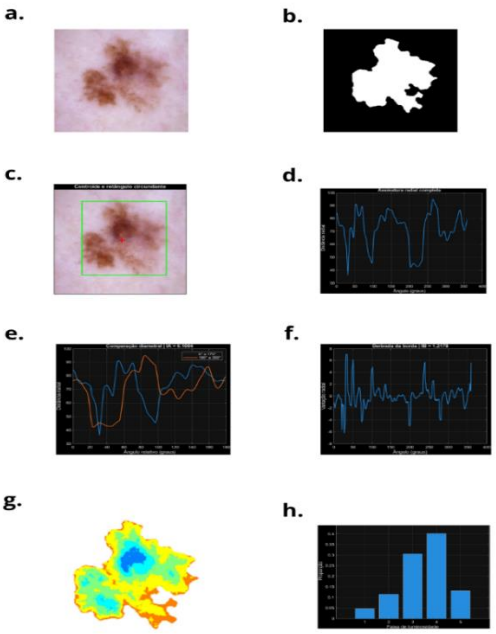

Fig. 2. Example of the execution of the proposed methodology for a melanoma image

Segmentation performed in the CIELAB color space using the k-means algorithm, complemented by morphological operations, showed satisfactory performance in most of the evaluated images. The resulting mask adequately preserved the lesion's contour, removing most of the artifacts present in the adjacent skin and allowing for the reliable extraction of geometric and pigmentation descriptors. For Image 5, an area of 16,346 pixels, a perimeter of 778.96 pixels, a circularity of 0.3385, a major axis of 164.77 pixels, a minor axis of 145.19 pixels, an eccentricity of 0.4728, and an orientation of 51.59° were obtained, indicating a lesion with significantly irregular geometry.

B. Evaluation of Computational Descriptors

B1. Asymmetry

The radial signature obtained for Image 5, shown in Fig. 2(d), showed significant oscillations throughout the 360°, reflecting geometric differences between opposite regions of the lesion. The comparison between diametrically opposite rays (Fig. 2(e)) resulted in an Asymmetry Index equal to IA = 0.1004, a value higher than those observed for images classified as non-melanoma. This behavior demonstrates the ability of the descriptor to objectively quantify the loss of symmetry of the lesion [9].

B2. Border Irregularity

The derivative of the radial signature, shown in Fig. 2(f), showed several abrupt oscillations along the contour of the lesion, indicating the presence of indentations and protrusions characteristic of melanomas. $IB_1 = 1.2178$, $IB_2 = 1.8963$, nine significant peaks, a mean amplitude of 5.46 pixels, and a maximum amplitude of 7.10 pixels were obtained. These results demonstrate that the combination of global and local descriptors provides a consistent quantitative representation of the geometric complexity of the border.

B3. Pigmentation

The analysis of the luminosity distribution was performed using the pigmentation map (Fig. 2(g)) and the luminosity histogram (Fig. 2(h)). Four pigmentation levels were identified, with a luminosity standard deviation of 10.45 and a luminosity amplitude of 54.80, indicating high heterogeneity in lesion pigmentation. Although these descriptors contributed to its characterization, they showed less discriminatory capacity when compared to geometric descriptors.

C. Comparison between Melanoma and Non-Melanoma

To illustrate the behavior of the proposed methodology, a comparison was made between Image 5 (melanoma) and Image 15 (non-melanoma), both subjected to the same processing pipeline. Fig. 3 shows the complete set of processing steps obtained for the non-melanoma lesion, allowing a visual comparison of the algorithm's behavior in the two classes.

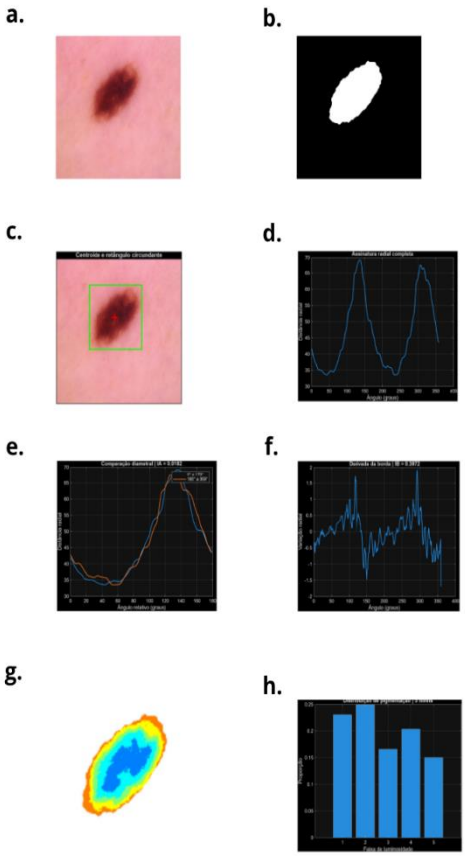

Fig. 3: Example of Operational Results for Non-Melanoma

Visual comparison between the original images (Fig. 4) reveals important morphological differences between the two lesions. While melanoma presents an irregular shape, asymmetrical contours, and heterogeneous pigmentation distribution, the non-melanoma lesion presents a more regular geometry, smooth borders, and greater structural uniformity.

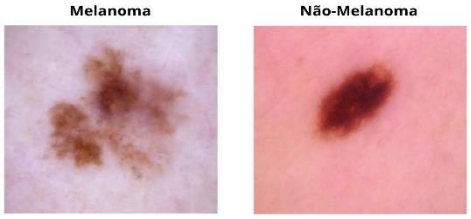

Fig. 4: Melanoma and Non-Melanoma (original images)

The observed differences are also evident in the radial signature (Fig. 5) and in the comparison between diametrically opposed rays (Fig. 6). Melanoma presented IA = 0.1004, while the non-melanoma lesion presented IA = 0.0179, a value approximately 5.6 times lower, indicating greater geometric symmetry of the benign lesion.

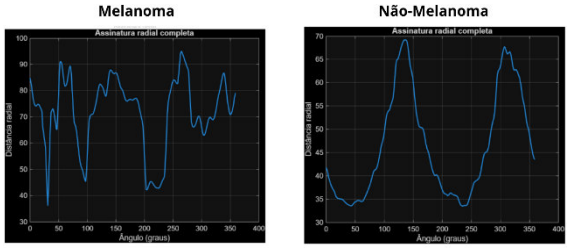

Fig. 5: Melanoma and Non-Melanoma (Signature)

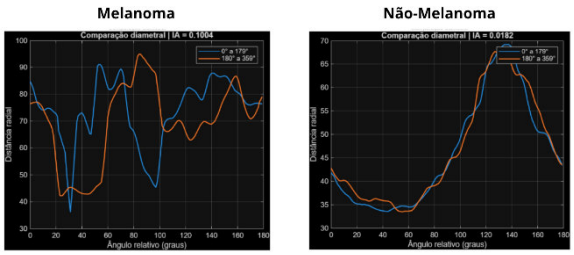

Fig. 6: Melanoma and Non-Melanoma (IA)

Similar differences were observed in border irregularity. Fig. 7 presents a comparison between the radial signature derivatives for the two lesions. The melanoma showed higher IB_1 and IB_2 values, mean amplitude, and maximum amplitude of the peaks, indicating greater geometric complexity of the contour. In contrast, the non-melanoma lesion showed less intense oscillations and a more regular contour.

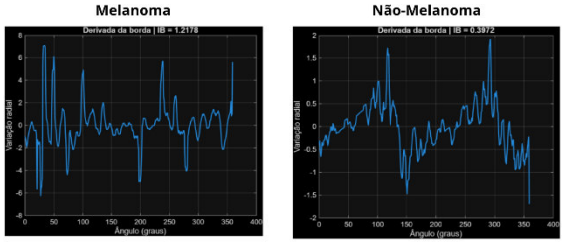

Fig. 7: Melanoma and Non-Melanoma (IN)

D. Performance of the Proposed Descriptors

Table I presents the individual performance of the computational descriptors under Leave-One-Out Validation (LOOCV), considering accuracy, sensitivity, specificity, precision, F1-score, and area under the ROC curve (AUC). The Skewness Index (SI) showed the best overall performance, with accuracy, sensitivity, specificity, and precision of 90%, an F1-score of 0.900, and an AUC of 0.990, demonstrating greater discriminatory capacity among the evaluated descriptors.

TABLE I. PERFORMANCE OF COMPUTATIONAL DESCRIPTORS EXTRACTED FROM ABC CRITERIA

Descritor	***Ac. (%)***	***Sen. (%)***	***Esp. (%)***	***Prec. (%)***	***F1***	***AUC***
A – IA	90	90	90	90	0,900	0,990
B – IB1	70	60	80	75	0,667	0,870
B – IB2	75	60	90	87,5	0,706	0,870
B – Nº picos	65	80	50	61,5	0,696	0,715
B – Average amplitude	60	30	90	75	0,429	0,890
B – Maximum amplitude	70	50	90	83,3	0,625	0,890
C – number of levels	80	90	70	75	0,818	0,800
C – Standard deviation	15	10	20	11,1	0,105	0,330
C – Amplitude	70	70	70	70	0,700	0,810

Among the border-related descriptors, the greatest variation in performance metrics was observed. Accuracies ranged from 60% to 75%, while AUC values ranged from 0.715 to 0.890. Some descriptors showed high specificity associated with lower sensitivity, such as Average Amplitude and Maximum Amplitude of Peaks, indicating a greater ability to recognize non-melanoma samples than melanoma samples. The Number of Peaks showed distinct behavior, with a sensitivity of 80% and a specificity of 50%, demonstrating greater identification of the melanoma class, but with a higher occurrence of false positives.

For the pigmentation criterion, the Number of Levels showed the best performance, achieving an accuracy of 80%, sensitivity of 90%, specificity of 70%, and an F1-score of 0.818. In contrast, the descriptor based on standard deviation showed the lowest performance among the metrics evaluated, with an accuracy of 15% and an AUC of 0.330. These results demonstrate that descriptors associated with the same ABC criterion can exhibit distinct behaviors in differentiating between classes, reinforcing the importance of their individual evaluation before combining them in a classification model.

Statistical comparison between melanoma and non-melanoma groups was performed using the Wilcoxon rank-sum test (Mann–Whitney U), with Bonferroni correction for the nine descriptors evaluated (adjusted $\alpha = 0.0056$). After correction, statistically significant differences were observed for Asymmetry ($p = 0.0002$), Mean Peak Amplitude ($p = 0.0036$), and Maximum Peak Amplitude ($p = 0.0036$). The other descriptors did not show statistically significant differences considering the adjusted significance level, although some showed relevant discriminatory performance in the classification metrics.

The superiority observed for the asymmetry descriptor may be related to the use of the radial signature, which allows quantifying differences between diametrically opposite regions of the lesion. The border descriptors, in turn, represent different aspects of contour irregularity, while the pigmentation descriptors characterize variations in the distribution of intensity levels. The results suggest, therefore, that these characteristics make distinct contributions to the differentiation between melanomas and non-melanomas in the evaluated sample.

Additionally, the combination of one descriptor from each ABC criterion—Asymmetry, Maximum Amplitude of Peaks, and Number of Pigmentation Levels—was evaluated using logistic regression with LOOCV validation. The combined model showed 90% accuracy, 90% sensitivity, 90% specificity, and an F1-score of 0.900, with nine true positives, nine true negatives, one false positive, and one false negative. However, the AUC obtained by the combined model was 0.930, lower than that presented by the Asymmetry descriptor alone (AUC = 0.990). Thus, the combination of the three criteria did not provide a performance gain compared to the best individual descriptor in this sample.

This behavior may be related to the existence of partially redundant information among the selected attributes. Asymmetry showed a strong correlation with the Maximum Peak Amplitude ($r = 0.843$) and a moderate inverse correlation with the Number of Pigmentation Levels ($r = -0.567$), indicating overlap between some of the information represented by the descriptors. Thus, the inclusion of multiple attributes does not necessarily result in increased discriminatory power when they have a high correlation.

In general, the results demonstrate that the proposed methodology made it possible to computationally quantify characteristics related to the evaluated ABC criteria, especially the Asymmetry Index. However, considering the small number of images used, the results should be interpreted as preliminary and restricted to the analyzed sample, and evaluation in larger and independent sets is necessary before inferring the generalizability of the method or its clinical applicability.

IV. Conclusion

This study presented a methodology based on Digital Image Processing for the computational quantification of criteria A (asymmetry), B (border), and C (color) of the ABCD rule, employing geometric and pigmentation descriptors automatically extracted from dermatoscopic images. The methodology integrated lesion segmentation techniques, radial signature extraction, and calculation of quantitative metrics, allowing the computational representation of characteristics related to the ABC criteria through interpretable descriptors with low computational cost.

The results indicated differences in the discriminatory power of the evaluated descriptors. The Asymmetry Index (AI) showed the best individual performance, with 90% accuracy and an AUC of 0.990, in addition to a statistically significant difference between the melanoma and non-melanoma groups after Bonferroni correction. Among the other attributes, the Mean Amplitude and Maximum Amplitude of the Peaks also showed statistically significant differences between the groups. These findings highlight, in the analyzed sample, the contribution of the descriptors associated with asymmetry and border irregularity to the differentiation between the classes.

The combination of descriptors from criteria A, B, and C through logistic regression showed 90% accuracy, 90% sensitivity, 90% specificity, and an AUC of 0.930. Although the overall performance was satisfactory in the evaluated sample, the combination did not provide discriminatory gain compared to the Asymmetry Index alone, which showed a higher AUC. The correlation observed between some of the attributes suggests the presence of partially redundant information, which may have limited the benefit resulting from the integration of the descriptors.

As a main limitation, the reduced number of images used in the evaluation (n = 20) stands out, which restricts the generalization of the results and the robustness of the statistical analyses. Therefore, the findings should be considered preliminary and restricted to the investigated sample, not allowing us to establish, at this stage, the clinical applicability of the methodology.

As future work, it is proposed to evaluate the approach in a substantially larger and more diverse sample, with adequate separation between development and test sets. Considering the performance of the Asymmetry Index, a hierarchical classification strategy could be investigated, in which this descriptor is used as an initial criterion and the other attributes contribute to the classification of ambiguous cases. A multiparametric model based on the weighting of descriptors could also be evaluated, with coefficients estimated from a larger sample, allowing for a more robust investigation of the benefit of integrating criteria A, B, and C.

***Resumo*—A presença de displasia epitelial em desordens orais potencialmente malignas, como a leucoplasia, está associada a um risco aumentado de desenvolvimento do carcinoma epidermoide oral. Nesse contexto, o diagnóstico precoce dessas lesões é fundamental para o sucesso terapêutico e para a redução da mortalidade associada à doença. Neste trabalho, é desenvolvido um sistema automatizado para detecção de displasia oral em casos de leucoplasia que integra imagens histopatológicas e dados clínicos em duas etapas. Primeiramente, uma rede ResNet50 classifica as imagens quanto à presença de displasia, e então os resultados são combinados com dados clínicos por um classificador SVM, gerando a decisão final. O sistema obteve um F1-*score* médio de 0,946 no conjunto de teste. A partir desse classificador, foi desenvolvida uma ferramenta educacional com o objetivo de auxiliar estudantes de patologia bucal na visualização dos resultados e na compreensão das regiões relevantes nas imagens, promovendo um aprendizado mais interpretável e alinhado ao uso da inteligência artificial na saúde.**

***Abstract*—The presence of epithelial dysplasia in potentially malignant oral disorders, such as leukoplakia, is associated with an increased risk of progression to oral squamous cell carcinoma. Therefore, early diagnosis of these disorders is crucial for improving treatment outcomes and reducing disease-related mortality. In this work an automated system for the detection of oral dysplasia in leukoplakia cases is developed by integrating histopathological images and clinical data in two stages. First, a ResNet50 network classifies the images regarding the presence of dysplasia; subsequently, these results are combined with clinical data using an SVM classifier, generating the final decision. The system obtained an average F1-score of 0.946 on the test set. From this classifier, an educational tool was developed to assist oral pathology students in vizualizing outcomes and understanding relevant regions within the images, promoting a more interpretable learning process aligned with the use of artificial intelligence in healthcare.**

I. Introdução

O carcinoma epidermoide é a principal neoplasia maligna que ocorre na boca, sendo o tabagismo e o etilismo os principais fatores etiológicos para o seu desenvolvimento [1]. De modo geral, o câncer de boca é precedido por um conjunto de alterações da mucosa oral, que se apresentam clinicamente como desordens orais potencialmente malignas, tais como a leucoplasia e a eritroplasia [2]. Essas lesões podem apresentar diferentes características histopatológicas, tais como hiperceratose, acantose e displasia epitelial, sendo a presença de displasia usualmente associada a um maior potencial de malignização [3].

Nos últimos anos, diversos estudos têm investigado a aplicação de técnicas de inteligência artificial na detecção e classificação da displasia epitelial oral [4]. Apesar dos avanços alcançados, a ausência de mecanismos de explicabilidade — sobretudo em modelos baseados em aprendizado profundo — permanece como uma limitação significativa e um campo em aberto para investigações. Nesse cenário, [5] destaca-se ao empregar o algoritmo Grad-CAM [6] como ferramenta de interpretação dos modelos preditivos, permitindo a visualização das regiões mais relevantes das imagens histopatológicas para a detecção do carcinoma epidermoide; um tipo de câncer frequentemente precedido por displasia epitelial e que apresenta alterações morfológicas importantes. Além disso, a maior parte dos estudos com inteligência artificial (IA) em patologia bucal está centrada no suporte ao diagnóstico clínico, sendo pouco explorado seu potencial no contexto educacional [7]. Observa-se, assim, uma lacuna importante no aproveitamento dessas tecnologias como instrumentos pedagógicos. Transformar soluções desenvolvidas inicialmente para diagnóstico em ambientes de aprendizado pode facilitar a compreensão de conceitos complexos e aumentar o interesse dos estudantes por disciplinas fundamentais como a patologia bucal. A construção de plataformas educacionais baseadas

em IA também pode democratizar o acesso a conteúdos de alta qualidade, especialmente em contextos com escassez de profissionais especializados ou infraestrutura laboratorial limitada.

O objetivo deste trabalho é viabilizar o desenvolvimento de uma ferramenta educacional voltada à formação de estudantes de patologia bucal. Nesse contexto, resultados promissores em termos de desempenho acadêmico e engajamento discente têm sido observados [8] [9]. As principais contribuições deste trabalho são: (i) desenvolvimento de um sistema de aprendizado de máquina para detecção de displasia epitelial oral a partir de imagens histológicas de casos de leucoplasia e dados complementares dos pacientes; (ii) utilização de técnica visual de explicabilidade do processo de decisão do modelo de aprendizado profundo; (iii) comparação dos mapas de explicabilidade gerados pelo modelo com a interpretação de patologistas especialistas e (iv) desenvolvimento de uma ferramenta educacional *online* que utiliza o sistema proposto neste trabalho.

A seção II apresenta uma fundamentação teórica a respeito de conceitos de patologia bucal, patologia digital e trabalhos relacionados à utilização de inteligência artificial nessas áreas. Na seção III são detalhados os materiais e métodos utilizados no desenvolvimento deste trabalho. A seção IV apresenta os resultados obtidos. Por fim, as seções V e VI apresentam a discussão e a conclusão do trabalho.

II. Fundamentação teórica

A leucoplasia oral é definida como uma lesão potencialmente maligna que se apresenta clinicamente como uma placa branca e que não pode ser caracterizada clinicamente como qualquer outra condição conhecida. Trata-se, portanto, de um diagnóstico exclusivamente clínico, baseado na exclusão de outras condições bucais, com características semelhantes, na mucosa oral [10]. O procedimento padrão para a avaliação da leucoplasia consiste na realização de biópsia da região afetada, seguida de análise histopatológica. A Figura 1 fornece um exemplo de uma fotografia de uma lâmina histológica; em que "A" representa a camada de ceratina, "B" o tecido epitelial e "C" o tecido conjuntivo. Com base na análise da imagem, a lesão pode ser classificada como com ou sem displasia epitelial.

A displasia epitelial oral (DEO) refere-se a um conjunto de alterações arquiteturais e citológicas do epitélio. A gravidade da displasia epitelial pode ser classificada, de acordo com os critérios da Organização Mundial da Saúde [11], com base na extensão das alterações no epitélio, em: (i) leve, quando as alterações estão restritas ao terço inferior; (ii) moderada, quando as alterações estão presentes até o terço médio; e (iii) severa, quando essas alterações ultrapassam os dois terços do epitélio. Entretanto, este procedimento de detecção de displasia e classificação em níveis (leve, moderada e severa) é altamente subjetivo, apresentando elevada variabilidade interobservador [4] [12] [13].

O estudo mais recente relacionado ao tema de uso da inteligência artificial para detecção de DEO é o de [14], que apresentou desempenho superior na detecção de displasia ao incorporar dados clínicos adicionais dos pacientes após uma etapa inicial de análise baseada em imagens histológicas. Embora proponha um sistema robusto e com baixo custo computacional, sua principal limitação reside na necessidade de segmentação manual das regiões do tecido epitelial para a obtenção dos resultados. Ademais, o trabalho não fornece informações visuais que evidenciem as regiões das imagens associadas à presença de displasia, o que limita a interpretabilidade do modelo proposto.

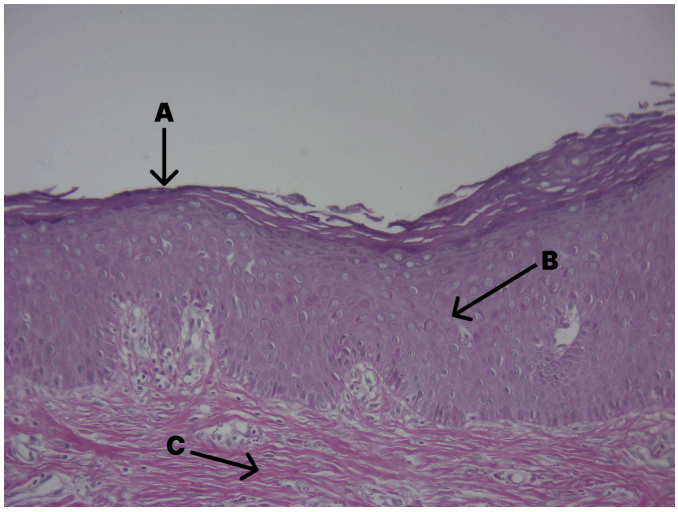

Fig. 1. Exemplo de uma fotografia com ampliação de 200 vezes de uma lâmina histológica corada com hematoxilina e eosina referente a uma lesão bucal; em que "A" indica a camada de ceratina, "B" o tecido epitelial e "C" o tecido conjuntivo.

III. Materiais e métodos

Esta seção apresenta o banco de dados e os métodos utilizados no desenvolvimento do modelo de detecção de displasia epitelial oral.

A. Banco de dados

O presente trabalho foi aprovado pelo Comitê de Ética em Pesquisa com Seres Humanos da UFSC (Plataforma Brasil, CAAE 15025319.3. 0000.0121). O banco de dados utilizado consiste em imagens histopatológicas e dados complementares de casos de leucoplasia cadastrados no Biobanco do Laboratório de Patologia Bucal da UFSC (CONEP B-051; Processo Nº. 25000.237810/2014-54).

O banco de dados utilizado neste estudo é composto por 114 casos clínicos de pacientes diagnosticados com leucoplasia, totalizando 406 imagens histopatológicas com resolução de 2584×1936 *pixels*. As imagens foram obtidas a partir de uma ampliação de 200 vezes de lâminas coradas com hematoxilina e eosina, cujas seções representativas foram digitalizadas por meio de um microscópio biológico trinocular da marca Novel BM2000 com câmera para captura de imagens marca Tucsen ISH500 de 5.0 MP acoplada; constituindo as imagens do banco de dados. Entre os casos de leucoplasia oral, 59 apresentam DEO, correspondendo a 193 imagens, enquanto os 55 casos

restantes não apresentam displasia, totalizando 213 imagens. Os casos que não apresentam displasia foram diagnosticados como hiperceratose e acantose. Como o objetivo do trabalho é a detecção de displasia, as classes utilizadas foram: displásico e não displásico.

O estudo em [14] demonstrou que a incorporação de dados complementares dos pacientes pode aumentar significativamente o desempenho de modelos de aprendizado de máquina e de aprendizado profundo na detecção de displasia epitelial. Com base nesse resultado, o banco de dados utilizado neste trabalho inclui, além das imagens histopatológicas, informações clínicas complementares dos pacientes, a saber: característica clínica da lesão, localização anatômica da lesão, idade, histórico de tabagismo e de etilismo. Esses atributos foram selecionados por dois patologistas orais com base em sua relevância diagnóstica, sendo apontados como os fatores de risco com maior influência na progressão do carcinoma epidermoide de boca [14]. Para viabilizar a integração desses dados ao modelo, os atributos foram convertidos em variáveis binárias, indicando a presença ou ausência de fatores de risco associados. A transformação foi realizada conforme a metodologia proposta por [14], descrita a seguir:

- Característica clínica da lesão: valor "1" atribuído para lesões heterogêneas; "0" para as demais;
- Localização da lesão: valor "1" para lesões localizadas na borda lateral da língua, ventre da língua ou assoalho bucal; "0" para outras localizações;
- Idade do paciente: valor "1" para pacientes com idade superior a 40 anos; "0" caso contrário;
- Histórico de tabagismo: valor "1" para pacientes fumantes ou ex-fumantes; "0" para não fumantes;
- Histórico de etilismo: valor "1" para pacientes alcoolistas ou ex-alcoolistas; "0" para não alcoolistas.

B. Metodologia

Este trabalho propõe um modelo para a detecção de displasia epitelial oral que integra informações em dois níveis: imagens histopatológicas e dados complementares dos pacientes. A Figura 2 ilustra o sistema proposto.

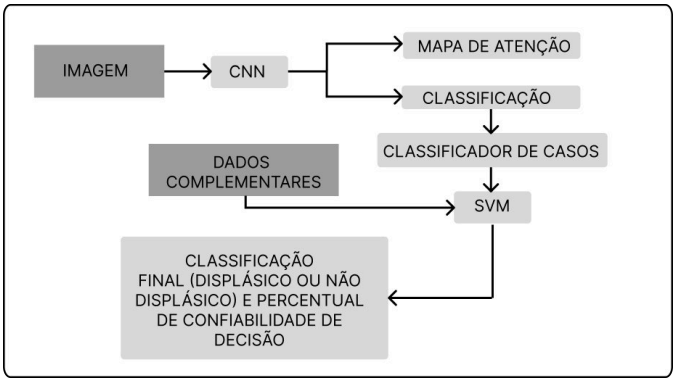

Fig. 2. Diagrama em blocos do sistema proposto.

Inicialmente, as imagens foram redimensionadas devido a limitações computacionais. A nova resolução adotada foi de 700 × 524 *pixels*, mantendo-se a mesma razão da dimensão original. Em sequência, o conjunto de dados foi particionado em subconjuntos de treinamento e teste (70% e 30%, respectivamente), assegurando que imagens pertencentes a um mesmo paciente fossem alocadas exclusivamente a um único subconjunto, evitando vazamento de informação. Para a etapa de validação, adotou-se a técnica de validação cruzada estratificada do tipo *K-Fold*, com $K = 5$.

Uma ResNet50 pré-treinada foi utilizada para ajuste fino na estratégia de aprendizado por transferência, utilizando as imagens do conjunto de treinamento. Os parâmetros de treinamento foram: 30 *epochs*, *batch size* de 16, *learning rate* de 10^{-5} e otimizador Adam. Adicionalmente, foi aplicada rotação das imagens como técnica de *data augmentation*. A partir da rede treinada, mapas de atenção foram obtidos por meio do algoritmo Grad-CAM [6]. A classificação dos casos foi realizada com base na mediana das probabilidades de predição individual de cada imagem (presença ou não de displasia) associada a um mesmo paciente. Ou seja, dado um paciente com *N* imagens, realiza-se a predição da presença de displasia em cada uma delas. Em seguida, calcula-se a mediana das probabilidades atribuídas. Essa probabilidade agregada foi então combinada com os dados clínicos complementares dos pacientes. Por fim, um classificador SVM foi empregado para a decisão final, com os seguintes parâmetros: $C = 100$, *kernel* RBF e *gamma* $= 10^{-1}$.

O procedimento de anotação das regiões de interesse (ROI) se deu através do *software Roboflow* [15]. Para as imagens de displasia, foram consideradas duas regiões: região displásica e restante da imagem (tecido epitelial não displásico, tecido conjuntivo e fundo da lâmina). Como mencionado previamente, a região displásica sempre estará contida na região do tecido epitelial. Após a demarcação das regiões, as anotações foram exportadas para um arquivo de texto contendo as coordenadas e classes das regiões anotadas. Os mapas de atenção foram gerados a partir dessas informações alocadas pelo patologista, de modo que regiões displásicas recebessem valor 1 e o restante das regiões recebesse valor 0. Dessa forma, os mapas de atenção foram gerados como máscaras binárias.

C. Métricas de desempenho

A partir da matriz de confusão, foram calculadas as métricas acurácia, sensibilidade, especificidade e F1-*score* [16]. Para a estimação dos intervalos de confiança de 95%, empregou-se a técnica de *bootstrapping*, que consiste em realizar amostragem com reposição a partir do conjunto de teste. Foram realizadas 5000 reamostragens para obter as estimativas dos intervalos de confiança associados às métricas de desempenho. A curva ROC, juntamente com a métrica AUC, também foram obtidas.

A análise comparativa dos mapas de atenção se deu apenas para as imagens do conjunto de teste diagnosticadas como displásicas, uma vez que a região de interesse (displasia) está presente apenas nessas imagens. Para essa etapa, utilizaram-se as máscaras binárias geradas a partir das anotações dos especialistas. A comparação entre os mapas de atenção gerados pelo modelo e as máscaras binárias de referência foi

realizada utilizando a métrica *Pointing Game* [17], que avalia a capacidade do mapa de atenção em destacar corretamente as regiões relevantes da imagem. Primeiro, identifica-se o ponto de maior ativação no mapa de atenção. Em seguida, verifica-se se esse ponto está localizado dentro da região anotada como relevante pelos especialistas. Se estiver, conta-se como um acerto; caso contrário, conta-se como um erro. A acurácia do *Pointing Game* é então calculada como a razão entre o número de acertos e o número de imagens avaliadas.

D. Mapas de atenção

O algoritmo Grad-CAM (do inglês – *Gradient-weighted Class Activation Mapping*) é uma técnica de visualização que permite interpretar o funcionamento interno de redes neurais convolucionais [6]. Ele gera mapas de ativação, a partir da última camada convolucional, que destacam as regiões da imagem que mais contribuíram para a decisão do modelo. Sendo assim, é possível produzir um mapa de calor que evidencia as áreas mais relevantes para a predição de determinada tarefa. O mapa de atenção gerado possui dimensão 17×22. De maneira a comparar os mapas gerados com as anotações dos especialistas, foi necessário redimensioná-los para o tamanho original da imagem utilizando interpolação. Neste trabalho, o algoritmo Grad-CAM foi utilizado como ferramenta de suporte à decisão, contribuindo para a explicabilidade do modelo de aprendizado profundo.

Devido à baixa resolução do mapa de atenção e o posterior redimensionamento para a mesma dimensão original das imagens, o método utilizado para obtenção dos mapas muitas vezes destaca regiões relativamente menores e incompletas de um objeto na imagem, podendo, também, falhar em detectar múltiplas ocorrências do mesmo objeto [18]. De maneira a avaliar a possível falha na identificação das regiões de interesse devido às limitações mencionadas, foram adotadas duas abordagens distintas para a comparação com as anotações dos especialistas. A primeira abordagem consiste em comparar o mapa de atenção redimensionado diretamente com as anotações, enquanto a segunda abordagem envolve a aplicação de uma dilatação morfológica nas anotações antes da comparação. A dilatação morfológica é uma operação que expande as regiões anotadas, possibilitando avaliar a vizinhança das regiões de interesse. Essa técnica é especialmente útil para compensar possíveis imprecisões no mapa de atenção devido à baixa resolução e ao redimensionamento. Para esse procedimento, foi utilizado um elemento estruturante quadrado de 7×7 *pixels*, buscando um equilíbrio entre a expansão das regiões anotadas e a preservação da forma original, de maneira que o incremento médio da área anotada ficasse em torno de 20%.

E. Ferramenta Educacional

Para viabilizar o uso educacional do modelo treinado, foi desenvolvida uma aplicação *web* interativa utilizando a biblioteca Gradio [19]. Essa ferramenta permite que estudantes e profissionais da área da saúde façam o *upload* de imagens histopatológicas e recebam uma predição quanto à presença de displasia epitelial, percentual de confiabilidade da decisão e mapas de atenção que destacam as regiões mais relevantes para a decisão do modelo. A aplicação foi disponibilizada na plataforma *Hugging Face Spaces* [20], o que garante fácil acesso sem necessidade de instalação local ou configuração técnica, tornando-a adequada tanto para uso em sala de aula quanto em ambientes de ensino a distância.

O fluxo geral de utilização da aplicação é simples e intuitivo: inicialmente, o usuário acessa a plataforma por meio de um navegador *web*; em seguida, realiza o carregamento da imagem histopatológica e fornece as informações complementares solicitadas. Após a submissão dos dados, o sistema executa automaticamente o pré-processamento da imagem, seguido da inferência utilizando o modelo previamente treinado. Como resultado, são exibidos simultaneamente a classificação predita, a estimativa de confiabilidade associada à decisão e os mapas de atenção gerados pela rede, permitindo ao usuário visualizar as regiões da imagem que mais contribuíram para a predição.

Do ponto de vista metodológico, a aplicação integra um modelo de aprendizado profundo previamente treinado e congelado, garantindo estabilidade durante o uso educacional. Todo o processamento é realizado de forma síncrona, possibilitando uma interação fluida com o usuário. A geração dos mapas de atenção é realizada sob demanda, sendo apresentada de maneira integrada à interface gráfica da aplicação, reforçando o caráter interpretável da ferramenta.

IV. Resultados

Os resultados do modelo proposto foram avaliados utilizando os dados dos pacientes pertencentes ao conjunto de teste. A Tabela I apresenta os resultados obtidos do modelo proposto, enquanto a Figura 3 ilustra a distribuição das métricas de desempenho em gráficos de violino. A Figura 4 ilustra a matriz de confusão e a Figura 5 a curva ROC juntamente com a medida AUC. A Figura 6 apresenta alguns exemplos de casos com a indicação do mapa de atenção da rede neural utilizada e a Figura 7 apresenta uma captura de tela da ferramenta educacional desenvolvida.

TABELA I
VALORES MÉDIOS DAS MÉTRICAS DE DESEMPENHO E INTERVALO DE CONFIANÇA 95%.

Métrica	Valor médio	Intervalo de confiança 95%
Acurácia	0,942	0,9 - 1
F1-*score*	0,946	0,889 - 1
Sensibilidade	0,899	0,8 - 1
Especificidade	1	1 - 1
AUC	0,990	0,96 - 1

A Figura 8 apresenta a métrica *Pointing Game*, responsável pela comparação entre os mapas de atenção gerados pelo modelo em relação às regiões de interesse anotadas pelos especialistas.

V. Discussão

A limitação de dados constitui um desafio recorrente no contexto da pesquisa em saúde [14]. Ademais, o processo de anotação de imagens histopatológicas demanda a atuação

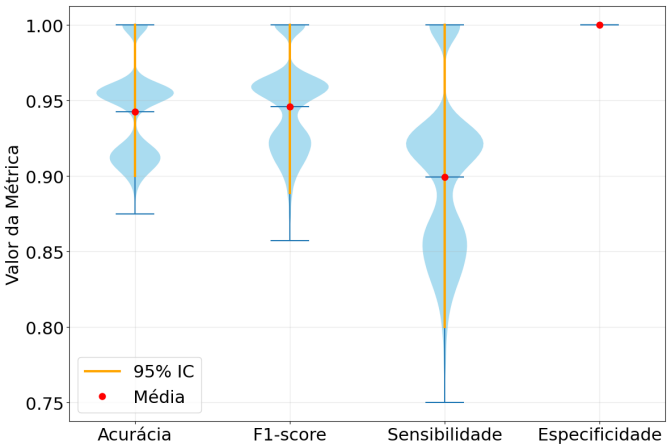

Fig. 3. Distribuição das métricas de desempenho em gráficos de violino.

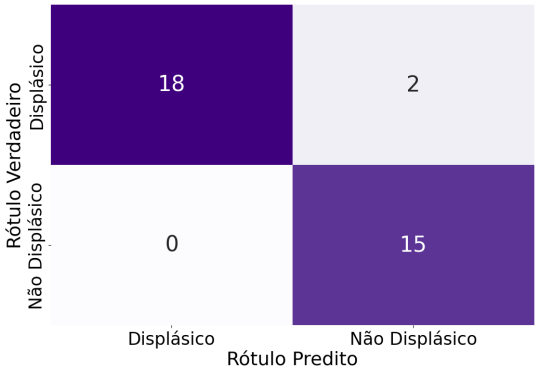

Fig. 4. Matriz de confusão.

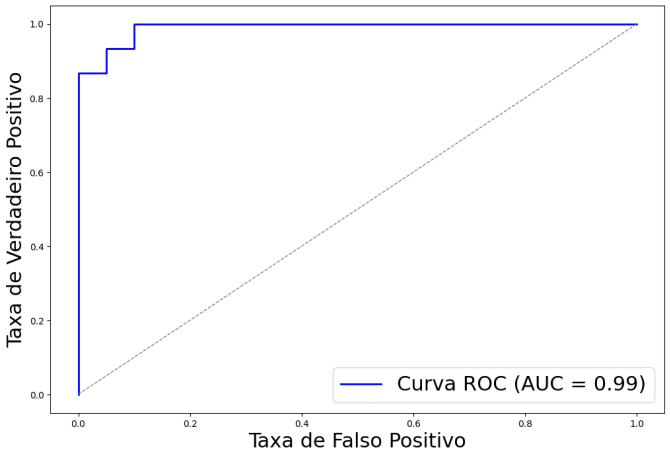

Fig. 5. Curva ROC e medida AUC.

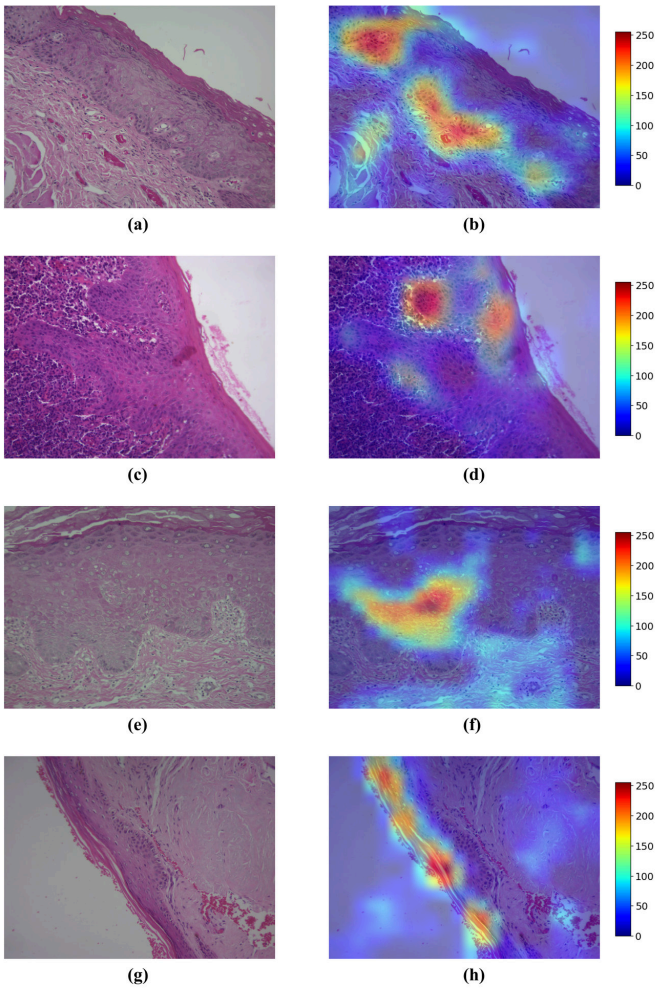

Fig. 6. Exemplos de imagem histológica e mapa de atenção provenientes do modelo pertencentes a casos: (a-b) corretamente classificado como displásico com percentual de confiabilidade de 100%; (c-d) corretamente classificado como displásico com percentual de confiabilidade de 99%; (e-f) erroneamente classificado como não displásico com percentual de confiabilidade de 67%; (g-h) erroneamente classificado como displásico com percentual de confiabilidade de 52%.

de patologistas qualificados, recurso frequentemente limitado. Esses fatores combinados dificultam a construção de conjuntos de dados extensos e diversificados. Nesse contexto, o banco de dados empregado neste estudo, embora apresente limitações quantitativas, representa uma contribuição relevante para o avanço da pesquisa na área. Tal afirmação fundamenta-se no fato de que o conjunto compilado de imagens e casos supera em dimensão outros bancos de dados utilizados em investigações recentes similares [14], os quais já se destacavam por ampliar substancialmente o volume de imagens em relação a trabalhos anteriores.

Este trabalho, embasado nos resultados de [14], diferencia-se ao endereçar a ausência de explicabilidade dos modelos, além de eliminar a necessidade de segmentação manual de recortes de imagem e também embarcar a solução proposta em uma aplicação didática.

Conforme apresentado na Tabela I, o modelo alcançou ele-

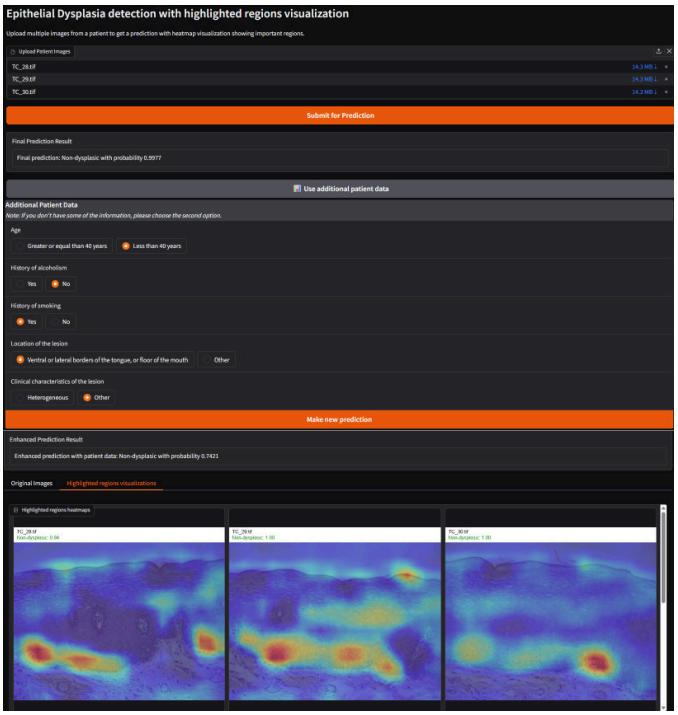

Fig. 7. Ferramenta educacional desenvolvida para auxílio na detecção de displasia epitelial oral (para melhor visualização utilize a ferramenta de lupa do *portable document format*).

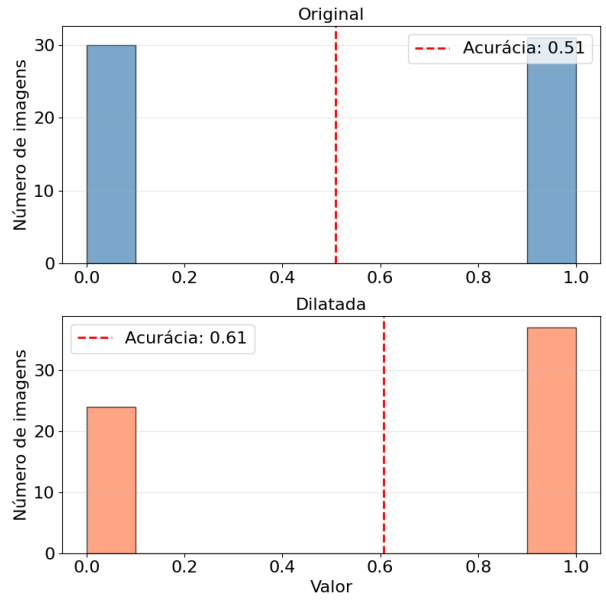

Fig. 8. Resultados da métrica *Pointing Game* para a ROI original e com dilatação.

vadas métricas de desempenho no conjunto de teste, com um F1-*score* médio de 0,946. Esse resultado supera o obtido em [14], cujo F1-*score* de 0,91 foi alcançado com uma ResNet50 treinada em recortes manuais das imagens. A solução aqui proposta, portanto, supera esse resultado sem a necessidade de segmentação prévia de regiões do tecido epitelial — o que pode introduzir maior erro humano no processo —, porém a um custo computacional maior. Vale destacar que o ganho de desempenho é resultado da combinação entre ResNet50 e SVM: quando avaliados isoladamente, ambos os classificadores apresentam desempenho inferior, com F1-*score* de 0,89 e 0,86, respectivamente. A robustez do modelo foi avaliada por meio de um conjunto abrangente de métricas complementares; como acurácia, AUC, precisão, sensibilidade e especificidade, todas acompanhadas de intervalos de confiança de 95%, em consonância com as métricas predominantemente adotadas na literatura da área. Essa combinação permite caracterizar o desempenho do modelo tanto sob perspectivas de equilíbrio entre classes quanto de capacidade discriminativa, oferecendo uma análise abrangente.

A Figura 6 ilustra os mapas de atenção gerados pela arquitetura ResNet50 no primeiro nível do processo de detecção de displasia epitelial. Nos dois primeiros exemplos, observa-se que as regiões com maior ativação (em tons mais avermelhados) concentram-se na região limítrofe do epitélio com conjuntivo, local onde tipicamente se manifestam os primeiros sinais de displasia. No terceiro exemplo, embora o modelo não tenha identificado a displasia corretamente, a atenção foi direcionada à região epitelial, o que indica uma ativação coerente na região de interesse. Em contraste, no quarto exemplo, o modelo cometeu tanto um erro de classificação quanto de localização, concentrando-se inadequadamente na camada de ceratina em vez do tecido epitelial.

A Figura 8 apresenta os resultados da métrica *Pointing Game*. No cenário original, a acurácia do *Pointing Game* é de aproximadamente 0,51, indicando que 51% dos picos de ativação do mapa de atenção coincidem com as regiões de interesse anotadas pelos especialistas. Após a dilatação das máscaras, essa acurácia aumenta para 0,61. Esse comportamento evidencia uma limitação do algoritmo Grad-CAM mencionada previamente, em que as regiões de ativação tendem a ser mais difusas e a cobrir áreas ligeiramente adjacentes às regiões de interesse. Os resultados obtidos — tanto em relação às anotações originais quanto às anotações dilatadas — são modestos, indicando a existência de espaço para aprimoramentos na geração dos mapas de atenção, seja por meio da aplicação de técnicas mais avançadas ou do refinamento do modelo de classificação.

Uma limitação deste trabalho, a ser mitigada futuramente, é a falta de validação da utilidade das informações de apoio (sugestão de diagnóstico, percentual de confiança e mapas de atenção) e da ferramenta por parte de estudantes de patologia. Entretanto, acredita-se que do ponto de vista educacional, as informações de apoio representam uma ferramenta de grande potencial para o ensino de patologia bucal. Ao visualizar simultaneamente as informações de apoio geradas pelo modelo,

o estudante é convidado a um exercício ativo de comparação crítica entre as informações fornecidas pela ferramenta e o conhecimento de patologia. Casos em que o modelo acerta tanto a classificação quanto a localização; isto é, concentrando a ativação em regiões displásicas ou na junção de tecido epitelial e conjuntivo — região reconhecidamente crítica para os primeiros sinais de displasia — reforçam conceitos histopatológicos ao tornar visível a lógica do diagnóstico. Por outro lado, os casos de erro, especialmente aqueles em que a atenção recai sobre estruturas irrelevantes como a camada de ceratina, oferecem oportunidades de discussão. O estudante é provocado a identificar por que o modelo falhou e quais características foram negligenciadas. Essa abordagem potencializa o desenvolvimento do pensamento diagnóstico crítico, tornando o aprendizado mais contextualizado e próximo da prática clínica e laboratorial.

Apesar do elevado desempenho de classificação obtido, uma limitação recorrente em estudos com imagens médicas é a possibilidade de variações no preparo das imagens, o que pode comprometer a generalização do modelo. Técnicas de pré-processamento envolvendo normalização de coloração não são a melhor prática recomendada [21], mas a literatura indica que técnicas de aumento de representatividade de coloração através de perturbações de tom e saturação nas imagens podem mitigar esse problema. Entretanto, trabalhos que se beneficiam dessa estratégia utilizam porções menores das imagens — denominadas *patches* —, aumentando consideravelmente o conjunto de imagens. O presente trabalho, ao utilizar as imagens completas de maneira a preservar as características arquiteturais [22], não se beneficia dessa estratégia. Vale destacar novamente que o banco de dados empregado neste estudo supera em dimensão outros bancos de dados utilizados em investigações recentes similares [14]. Entretanto, estudos complementares com imagens provenientes de diferentes laboratórios são necessários para incrementar a validação da solução proposta; além de possivelmente servir como aumento de representatividade de casos ao possibilitar variações de coloração.

VI. Conclusão

Neste trabalho, o modelo proposto para detecção de DEO — que integra imagens histopatológicas e dados clínicos dos pacientes —, alcançou um F1-*score* médio de 0,946. Além disso, a incorporação de uma técnica de explicabilidade baseada em Grad-CAM, capaz de destacar nas imagens as regiões mais relevantes para a predição realizada pelo modelo de aprendizado profundo, aumentou a transparência do processo de decisão. As métricas de comparação dos mapas de atenção gerados pelo modelo com as demarcações feitas por patologistas são modestas, porém promissoras. Ademais, o desenvolvimento da ferramenta educacional tem o potencial de tornar o uso da solução mais interativo, com potencial de aplicação didática.

A integração entre aprendizado profundo, técnicas de explicabilidade e aplicações educacionais interativas pode contribuir significativamente tanto para o avanço da pesquisa em patologia digital quanto para a formação de futuros profissionais da área. Entretanto, um estudo com estudantes de patologia oral é necessário para comprovar a utilidade das informações de apoio e da ferramenta. Além disso, a avaliação com conjuntos de imagens provenientes de diferentes laboratórios é recomendada.

***Abstract*—Congestive Heart Failure (CHF) is a progressive cardiovascular condition whose early identification can benefit from automated analysis of electrocardiogram (ECG) signals. This work investigates few-shot CHF classification using a frozen, pre-trained GPT-2 backbone adapted to process raw ECG recordings alongside age and gender information. The model employs a lightweight convolutional embedding layer, six frozen transformer blocks, and a binary classification head, without signal filtering or handcrafted feature extraction. Experiments were conducted on a dataset containing 840 three-second ECG samples from 28 subjects, including 14 patients with severe CHF and 14 matched healthy controls. Performance was evaluated across multiple training set sizes, learning rates, random seeds, checkpoint selection strategies, and data augmentation settings. The best configuration achieved a multi-seed mean F1-score of 0.8846 ± 0.1298 using 300 shots per class. In the more restrictive 15-shot setting, augmentation combined with validation-based checkpoint selection achieved a best F1-score of 0.8845 and a mean of 0.789 ± 0.092. These results indicate that a language-pretrained frozen transformer is a feasible approach for CHF classification with limited task-specific adaptation and substantially reduced training data.**

***Index Terms*—digital health, congestive heart failure, electrocardiogram, few-shot learning, frozen backbone, GPT-2, large language model**

I. Introduction

The increasing availability of digital health data has created new opportunities for automated clinical decision support, particularly in cardiology. Among the conditions that most burden healthcare systems globally, Congestive Heart Failure (CHF) stands out for its high prevalence, progressive nature, and significant impact on quality of life — affecting millions of patients with symptoms such as dyspnea, fatigue, and peripheral oedema [1].

The electrocardiogram (ECG) remains one of the most accessible tools for cardiac assessment, yet interpreting CHF-related patterns — such as QRS prolongation, T-wave inversions, and ST segment alterations — demands clinical expertise that is not uniformly available across healthcare settings. This gap motivates the development of automated, AI-driven classification systems that support diagnosis across diverse clinical environments.

Early approaches to ECG-based CHF detection relied heavily on handcrafted feature extraction and classical machine learning [2]. The advent of deep learning shifted the paradigm, with CNN and LSTM architectures achieving competitive accuracy on raw ECG signals [3]. However, these task-specific models are tailored to each application and dataset, limiting their broader adoption for other diseases, for example.

To overcome this condition, the applicability of foundation models emerges as a promising alternative, as they have recently demonstrated strong generalization capabilities across domains. Notably, LLM-based architectures, originally designed for sequential language modeling, have proven effective for time series analysis, as demonstrated by the One-Fits-All framework [4], which adapts a single pre-trained transformer backbone to diverse time series tasks without task-specific redesign.

This work originally proposes the application of such an LLM-based foundation model to the automated detection of CHF from raw ECG signals, focusing on exploring how many samples are necessary to use in the training to achieve the same (or better) results as dedicated deep learning models. Using a dataset constructed from the BIDMC Congestive Heart Failure and PTB Diagnostic ECG databases (PhysioNet). The remainder of this paper is structured as follows: Section 2 reviews related work, Section 3 details the methodology, Section 4 presents and discusses the results, and Section 5 draws the conclusions.

II. Related Work

Deep learning methods have been widely applied to detect pathology in diverse biosignals. LSTM networks have been used to classify chronic laryngitis [5] and cardiac arrhythmia [6], while ANN-based approaches have addressed EEG classification [7] and arrhythmia detection [8]. CNNs and hybrid architectures have also been explored for ECG component analysis [9], synthetic data generation via GANs [10], and atrial fibrillation detection through MLP-based feature extraction [11]. Although often regarded as a mature technology, these methods remain highly relevant — particularly for CHF detection in ECG signals.

Regarding CHF specifically, we can highlight our previous work [3], which reports 98.21% accuracy for the CNN model and 92.26% for the LSTM model in CHF detection. Furthermore, [12] presents an LSTM-based approach applied to wavelet-filtered signals, achieving an accuracy of 99.86%. In [13], a 1D CNN applied to single heartbeat segments was able to reach 97.8% accuracy in detecting CHF. [14] employed a 1D CNN combined with a Gabor filter to address multi-class ECG classification with CHF among the target classes, attaining

an accuracy of 98.74%. Finally, [15] proposes a CNN-LSTM architecture that uses RR intervals as network input, achieving 99.52% accuracy and a 98.94% F1-score.

The emergence of transformer-based architectures, specially LLM's, has opened new directions for ECG. By treating cardiac signals as sequential data, self-attention mechanisms can capture temporal dependencies, with their temporal embeddings serving as inputs to pre-trained LLMs.

Transformer-based models (without the use of LLMs) have shown competitive results in arrhythmia classification [16], arrhythmia detection [17], and multi-disease ECG diagnosis [18]. In the latter work, the model was pre-trained using masked image modeling on more than 8.5 million ECGs from 2.1 million patients. Despite their effectiveness, these architectures are still trained from scratch on ECG-specific data, limiting their ability to transfer sequential knowledge across domains.

Large language models are naturally associated with textual inputs and outputs. However, the architecture itself is essentially a transformer-based network. With this in mind, many foundation models have been conceived using pre-trained large-scale models as backbones, repurposing the LLMs to accept time series as inputs and perform classification, forecasting, and related tasks — offering a fundamentally different paradigm.

The most prominent example of this paradigm is the One-Fits-All framework [4], which uses a frozen GPT-2 backbone to process patched time series without task-specific architectural changes, achieving competitive performance across classification, forecasting, and anomaly detection. Among works that process ECG signals with LLM backbones, MedualTime [19] applied a frozen GPT-2 with lightweight adapters to medical ECG signals, and InstructTime [20] recast time-series classification (including ECG) as a language-generation task. In the heart failure domain, [21] leveraged ClinicalBERT to enhance ECG-based heart failure risk prediction through text-ECG embedding alignment. In this case, the LLM was used only for textual alignment, not as the main backbone.

Despite the growing body of work applying LLMs to ECG analysis, existing approaches either use the language model exclusively on the text side [21], or evaluate on benchmark datasets that lack a CHF label altogether, such as PTB-XL and MIT-BIH [19], [20]. CHF-specific studies, on the other hand, have relied on convolutional and recurrent architectures trained from scratch [3], [12], [13], [15], or at most on transformer encoders built without pre-trained language priors [22]. This work addresses this intersection directly: we propose using a frozen pre-trained GPT-2 backbone to process raw ECG signals for CHF detection, extending the One-Fits-All paradigm to a clinically relevant and underexplored pathology. To our knowledge, this represents the first application of a pre-trained language model backbone to CHF classification from ECG signals.

III. Methodology

This section provides an overview of the approach and model used to detect CHF from ECG signals. The methodology covers the dataset construction, the LLM-based architecture, the training and evaluation process.

A. Datasets

Two publicly available PhysioNet repositories [23] were used as data sources: the BIDMC Congestive Heart Failure Database [24], which contains ECG recordings from CHF patients, and the PTB Diagnostic ECG Database [25], which provided the healthy control signals. Since the BIDMC database lacks control recordings and the two repositories use different sampling rates, a custom dataset was constructed to ensure consistency across all samples.

The resulting dataset contains 840 samples from 28 subjects, with 30 samples extracted per individual. Half of the subjects (14) present severe CHF classified by the New York Heart Association (NYHA) functional classes 3 and 4, while the remaining 14 are healthy individuals taken from the PTB database.

Gender and age were used as matching criteria when pairing pathological and control subjects, so that each CHF patient is associated with a healthy match of the same gender and similar age. This pairing strategy reduces the risk of demographic bias during training and is detailed in Table I. Representative ECG samples from both groups are illustrated in Figure 1.

All recordings were resampled to 250 Hz, and no noise filtering was applied. Each sample lasts 3 seconds, corresponding to 750 time steps. No handcrafted feature extraction was performed; instead, Min-Max scaling was applied per class for normalization purposes. To avoid data leakage, the scaler was fitted exclusively on the training partition of each seed and subsequently applied to the corresponding validation and test partitions using the fitted parameters.

To prevent data leakage, for each seed, 2 individuals were randomly selected for validation and 2 different individuals for testing, with the remaining individuals used for training. This subject-wise split was varied across seeds, ensuring that no individual appearing in the validation or test sets was ever seen during training.

B. LLM-Based Architecture

The proposed model adapts the GPT4TS framework [4] to classify CHF from raw ECG signals, using a pre-trained GPT-2 as a frozen backbone (Figure 2). Rather than designing a task-specific architecture, the approach repurposes the language model's sequential pattern recognition capabilities, applying them directly to physiological time series.

1) Input Representation: Each raw ECG sample of 750 timesteps is first decomposed into overlapping sub-windows via a sliding window of length 250 and stride 125 (50% overlap), yielding 5 sub-windows per recording and expanding the working dataset from 840 to 4,200 samples. Each sub-window inherits the label, age, and gender of its parent

TABLE I
PAIRS FORMED BASED ON GENDER AND AGE. DATASET FIRST INTRODUCED IN [3].

Pair	Gender *(CHF)*	Gender *(Control)*	Age *(CHF)*	Age *(Control)*
1	Male	Male	71	68
2	Female	Female	61	67
3	Male	Male	63	64
4	Male	Male	54	54
5	Female	Female	59	57
6	Male	Male	48	37
7	Male	Male	51	50
8	Female	Female	63	69
9	Male	Male	22	26
10	Female	Female	54	54
11	Male	Male	61	59
12	Male	Male	63	68
13	Female	Female	61	52
14	Male	Male	53	55

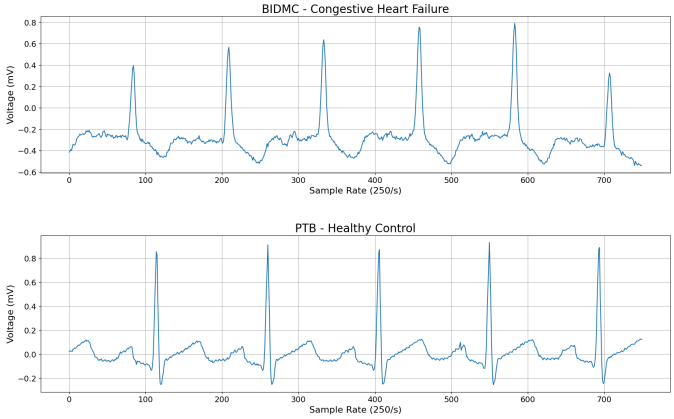

Fig. 1. Representative ECG samples from both groups: CHF (top) and healthy control (bottom). Reproduced from [3].

recording, and the few-shot split is enforced at the recording level to prevent data leakage between partitions.

Each sub-window is then passed through a token embedding layer implemented as a 1D convolutional layer (Conv1d, kernel size 3, circular padding), which projects each scalar timestep into a 768-dimensional vector matching GPT-2's hidden size while capturing local context between consecutive timesteps. A fixed sinusoidal positional encoding is added to the resulting sequence before it is fed into the backbone.

2) Frozen GPT-2 Backbone: The embedded sequence is passed directly to the first six transformer blocks of a pre-trained GPT-2 (124M parameters), bypassing its internal token embedding table entirely. Within this truncated stack, all attention and feed-forward weights remain frozen at their text-pretrained values. Only the internal LayerNorm parameters and the learned positional embedding table (`wpe`) of GPT-2 are kept trainable, alongside the token embedding layer and the classification head. This design follows the one-fits-all rationale [4]: the frozen attention heads are treated as a general-purpose sequence processor whose representations transfer across domains, while the lightweight trainable parameters adapt the interface between the ECG signal and the frozen backbone. Notably, GPT-2's internal positional embedding (`wpe`) is summed with the external sinusoidal encoding inside the first transformer block, so both positional signals are active during inference.

3) Classification Head: The output of the GPT-2 stack is passed through a GELU activation and an additional LayerNorm, then mean-pooled across the temporal dimension to produce a single 768-dimensional representation. Age and gender metadata are concatenated to this vector, expanding it to 770 dimensions, and a linear layer projects it to a single logit. The model is trained with binary cross-entropy loss, and predictions are obtained by applying a sigmoid function with a decision threshold of 0.5.

C. Training Procedure

All trials use the RAdam optimizer with batch size 32 (operating over sub-windows), and a fixed epoch budget per configuration with no early stopping — except in Experiment 2, where the best-validation-loss checkpoint is evaluated as an alternative to the final-epoch weights. Validation metrics are computed every epoch. A learning rate step-decay schedule is present in the implementation but configured with decay epochs that exceed every budget swept in this study, so it never triggers in practice.

D. Evaluation Protocol

Performance is reported as F_1 score, accuracy, precision, and recall, computed on the test split at a fixed 0.5 decision threshold. The base train/validation/test split is formed at the subject level: 2 subjects per class are held out for testing and 2 per class for validation, fixed via a `subject_split_seed` that is tied to the `few_shot_seed` used for the corresponding trial. This guarantees zero subject, recording, or sub-window overlap between partitions (verified empirically) and an identical test-subject composition across every shot level within a given seed. The few-shot constraint is then applied within the remaining training-pool subjects: N raw recordings per class are drawn at random from the training pool, and all 5 sub-windows from each selected recording are added to the effective training set. Because test-subject membership does not depend on N, the test set is fixed across shot levels for a given seed, avoiding a shrinking/growing test set as a confound in cross-shot-level comparisons.

IV. RESULTS AND DISCUSSIONS

This section presents the results of two experiments evaluating our proposed LLM method for detecting CHF in ECG signals. We then compare our method to earlier methods on the same dataset and to other current state-of-the-art solutions.

A. Experiment 1: Few-Shot Performance Across Shot Levels

The first experiment consists of training the model with different numbers of samples per class, referred to as shots in Table II. This table also reports F_1 scores, accuracies and precisions for each shot level and learning rate combination. The results show a clear overall improvement in classification

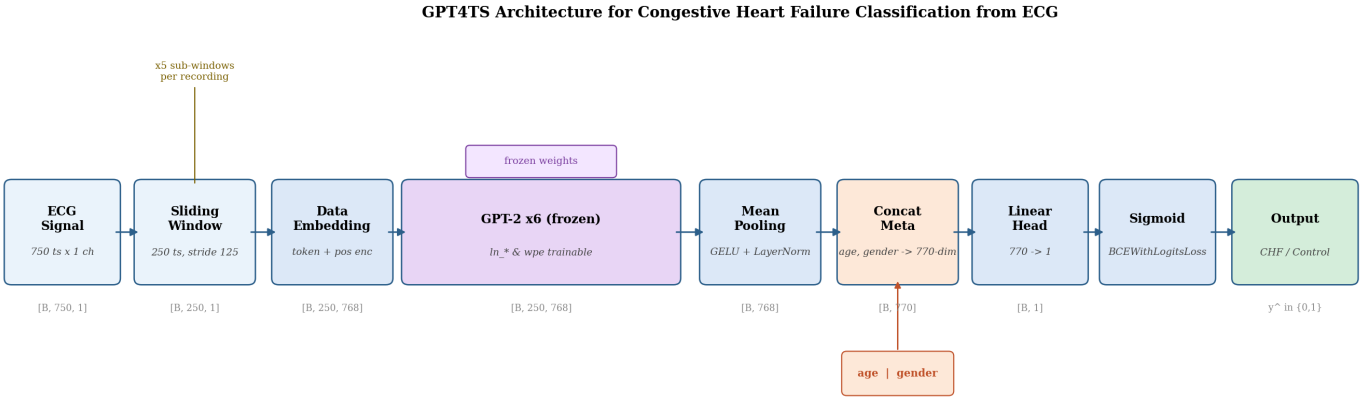

Fig. 2. GPT4TS architecture adapted for CHF classification from ECG signals. The raw ECG signal is decomposed into overlapping sub-windows, embedded via a Conv1d layer, and processed by a frozen six-block GPT-2 backbone. Age and gender metadata are concatenated after mean pooling before the final classification head.

performance as the number of training samples increases. The F1-score std rises from 0.4465 ± 0.3769 with one shot per class to 0.8846 ± 0.1298 with 300 shots, with the most pronounced gains occurring on early shots and performance approaching saturation from 30 shots.

TABLE II
BEST TEST-SET RESULT AT EACH SHOT LEVEL (480 TRIALS TOTAL; 30 TRIALS PER ROW).

Shots	LR	F_1 (std)	Accuracy (std)	Precision (std)
1	0.001	0.4465 (0.3769)	0.5498 (0.2446)	0.4163 (0.3814)
2	0.001	0.6233 (0.2222)	0.6338 (0.1269)	0.6324 (0.2950)
3	0.01	0.7024 (0.2803)	0.7617 (0.1789)	0.7771 (0.3113)

In Table III, to better visualize the results at each shot level, we report the mean F_1 across 10 training runs with different seed combinations and three learning rates. The best combination points to 300 samples per class with a learning rate of 0.0003. The multi-seed results provide a more conservative assessment of model robustness. Variability is high in the lowest-shot settings, particularly with one shot per class, but decreases substantially as more training samples are included, indicating that larger training sets improve both average performance and reproducibility. The learning rate also affects performance differently across shot levels, with 0.01 and 0.001 generally performing better in low- and intermediate-shot regimes and 0.0003 becoming competitive at higher shot counts. Since the best-case values represent the upper performance envelope across multiple trials, the reported means and standard deviations should be considered more representative of the model's expected behavior.

TABLE III
TEST F_1 MEAN (STD) OVER 10 SEEDS, PER CONFIGURATION

Shots	lr=0.001, e30	lr=0.01, e30	lr=0.0003, e50

B. *Experiment 2 - Boosting the few-shot classification*

To improve model performance in the few-shot regime (up to 20 shots per class), a second experiment was conducted, building on the first. The following strategies were introduced:

- **Checkpoint selection:** instead of always using the final-epoch weights, we compared two policies — the last-epoch checkpoint (*last*) versus the checkpoint with the lowest validation loss (*best*);
- **Data augmentation:** a lightweight augmentation scheme was applied during training, combining additive noise, amplitude scaling, and temporal shift, and compared against the no-augmentation baseline.

Both factors were crossed at three shot levels, $N \in \{1, 5, 15\}$, with 3 random seeds per combination, for a total of 36 trials. Table IV shows the full results of the experiment.

The effects of checkpoint selection and data augmentation vary across shot levels and are especially unstable at $N{=}1$, where mean F_1 ranges from 0.222 (best checkpoint, no

TABLE IV
CHECKPOINT SELECTION × AUGMENTATION, 3 SHOT LEVELS, 3 SEEDS EACH (36 TRIALS TOTAL)

Shots	Ckpt	Aug	Best F_1	Mean F_1 (std)
1	last	off	0.6667	0.222 (0.314)
1	last	on	0.9983	0.714 (0.216)
1	best	off	0.6667	0.389 (0.283)
1	best	on	0.9772	0.492 (0.399)
5	last	off	0.8119	0.713 (0.070)
5	last	on	0.9917	0.806 (0.144)
5	best	off	0.6667	0.644 (0.026)
5	best	on	0.9917	0.837 (0.114)
15	last	off	0.8186	0.714 (0.074)
15	last	on	0.8108	0.712 (0.070)
15	best	off	0.8848	**0.789 (0.092)**
15	best	on	0.8086	0.712 (0.068)

augmentation) to 0.714 (last checkpoint, with augmentation) across only 3 seeds. Augmentation improves the mean F_1 at every shot level and checkpoint policy tested here except one: at N=5, mean F_1 rises from 0.644/0.713 (best/last, off) to 0.837/0.806 (best/last, on); at N=15, the best-performing combination is instead the *best*-checkpoint without augmentation (mean $F_1 = 0.789$), the only cell in this experiment where augmentation does not help. Given the small seed count (3) and narrow shot-level coverage of this experiment, we treat these results as a directional signal about checkpoint/augmentation effects at very low shot counts, not a definitive characterization

C. Comparative Analysis - Same dataset

As shown, the proposed approach's mean result across seeds falls below both conventional deep learning models from our previous work, despite using less than the full dataset (the training pool at N=300 corresponds to roughly 71% of all 840 recordings, with the remainder held out for validation/testing at the subject level). We report this as evidence of the feasibility of a frozen, language-pretrained backbone on this task under a leakage-safe evaluation, not of superiority over the previous, purpose-built models.

TABLE V
COMPARISON WITH OUR PREVIOUS WORK [3] (MEAN F_1 ACROSS SEEDS).

Model	F_1 *(std)*	*Shots/class*	*Dataset (%)*
Proposed LLM-Based (Exp. 1)	0.8846 (0.1298)	300	≈71%
CNN [3]	0.9801	336	80%
Proposed LLM-Based (Exp. 2)	0.789 (0.092)	15	≈3.6%
LSTM [3]	0.9161	336	80%

The results provide strong evidence of data efficiency and competitive performance, although superiority over previous models is not consistently observed across all random seeds. An additional distinction is that the CNN and LSTM models were developed specifically for ECG classification and trained from scratch, whereas most of the proposed GPT-2 backbone's parameters remain frozen. The results, therefore, suggest that representations learned from a non-medical sequential domain can support ECG classification with only limited adaptation.

D. Comparisons with other State-of-the-Art Methods

Table V provides a reference for the performance of related works. Since these works differ substantially in their data sources and preprocessing pipelines, a direct comparison is not meaningful; nonetheless, the table offers a useful reference point for positioning the proposed approach relative to the state of the art. This result is particularly relevant given that the proposed model processes normalized ECG amplitudes directly, without wavelet filtering, handcrafted descriptors, or an ECG-specific backbone.

However, Table V should be interpreted as a contextual rather than a direct ranking. The studies differ in terms of database composition, number of subjects, signal duration, preprocessing, segmentation procedure, class balance, validation strategy, and whether the partitions are subject-independent. Some methods also classify individual heartbeats or RR intervals, whereas the proposed approach processes fixed-duration ECG windows. A direct benchmark using identical subject-level partitions and evaluation metrics would be required to establish superiority over the state of the art.

TABLE VI
COMPARISON OF RESULTS WITH STATE-OF-THE-ART METHODS FOR CHF CLASSIFICATION

Method	*Acc. (%)*	*Sens. (%)*	*Prec. (%)*	*F1*
[12] (LSTM)	99.86	99.85	99.87	0.9986
[15] (CNN+LSTM)	99.52	99.31	–	0.9894
LLM-Based (Exp. 1)	90.68	–	97.65	0.8846
[14] (CNN)	98.74	–	–	–
[3] CNN	98.21	96.10	100.00	0.9801
[13] (CNN)	97.80	–	–	–
LLM-Based (Exp. 2)	–	–	–	0.789 (0.092)
[3] LSTM	92.26	92.21	91.03	0.9161

V. LIMITATIONS AND FUTURE WORK

A limitation of this study is that each class was captured using a different acquisition setup, which may impact classification performance. It is important to note that every CHF sample originates from BIDMC (natively 250 Hz), while every control sample originates from PTB (natively 1 kHz, downsampled 4×). This means that differences in the acquisition system could potentially confound the classification process.

Another limitation is related to the data collection method. Although Min-Max scaling was fitted separately per class using only the training partition of each seed, avoiding leakage from validation or test data, the two sources employ different acquisition methods, so the resulting amplitude levels may not be directly comparable between classes. Ideally, both classes would be acquired using the same protocol and equipment.

As future work, we intend to include three simple ablation studies: (i) a frozen GPT-2 backbone versus random initialization of the same architecture, (ii) with and without age and gender covariates, and (iii) with and without dual positional encoding. These ablations are motivated by the fact that it is not yet established whether the observed gains stem from the knowledge transferred by GPT-2 or from the remaining components of the pipeline. Conducting these experiments

would make the computational contribution more verifiable without requiring extensive architectural changes.

VI. Conclusion

This work explored the application of a frozen pre-trained GPT-2 backbone to the detection of Congestive Heart Failure from raw ECG signals, following the One-Fits-All framework. Unlike the deep learning methods previously applied to this task, which were purpose-built and trained from scratch on domain-specific data, the proposed approach requires no task-specific architectural design, no signal filtering, and no hand-crafted feature extraction. The frozen backbone processes the raw ECG amplitude directly, with age and gender as the only additional inputs.

The results are modest relative to the full-data baselines. Using a subject-disjoint evaluation protocol designed to avoid patient-identity leakage, the mean result over 10 seeds is $F_1 = 0.8846 \pm 0.1298$ (accuracy $90.68\% \pm 9.67\%$) at the best shot level (300), below both full-data baselines from our previous work (CNN 98.21%, LSTM 92.26%).

The broader implication is architectural. A single frozen backbone, pre-trained exclusively with natural language data, can be repurposed for ECG classification with minimal adaptation. Just a lightweight embedding layer, a classification head, and a handful of trainable normalization parameters. This contrasts sharply with prior CHF detection methods, which require retraining from scratch whenever the dataset, lead configuration, or target pathology changes. Whether this reflects the backbone's pretrained linguistic knowledge or simply the architectural inductive bias of a frozen transformer of this size and depth remains an open question after future study's ablation results, and should be resolved before extending the approach to other cardiac conditions or physiological signals.

***Abstract*—Different mechanical and acoustic parameters of gas vesicles (GVs) must be analyzed for their application as contrast agent for ultrasound imaging, such as the modulus of elasticity and topogrphic information. Images acquired through Atomic Force Microscopy (AFM) are employed to analyze the GVs elasticity. Those images are affected by noise and other interferences. Hence, different filtering methods were proposed, such as median filtering applied conventionally to the RGB color representation of the image. However, this color representation is not adequate for evaluating useful image representation such as brightness and gray scale. This paper defines a new filtering method based on the application of median filter but applied in the HSV color representation. HSV (hue-saturation-value) gives information about brightness and saturation (related to grayscale) which are useful to identify images problems. Tests performed in experimental images of GVs acquired through AFM prove that the proposed filtering method is an useful alternative in the denoising of images acquired by AFM.**

***Index Terms*—Gas vesicles, Atomic Force Microscopy, HSV color representation, image enhancement, median filter, RGB color representation.**

I. Introduction

Biomedical imaging examinations are widely used in clinical practice for the assessment of organs and tissues. Among the most commonly used imaging modalities is ultrasound (US), a noninvasive and cost-effective technique that uses nonionizing radiation [1]. US enables the acquisition of real-time images of organs and tissues with high spatial and temporal resolution. Contrast-enhanced ultrasound (CEUS) can be applied to enhance the visualization of specific regions of interest. In CEUS, contrast agents increase the intensity of the echoes generated by the incident US beam within the target region relative to the surrounding tissue, thereby improving the contrast between the region of interest [2]–[4].

Gas vesicles (GVs) have been investigated as a promising alternative to conventional contrast agents used in CEUS. They are easy to produce in laboratory, and they have both structural stability and the capability (due to their nanoscale size) to access extravascular and extratumoral spaces that are inaccessible to conventional microbubble-based contrast agents. Hence, GVs can overcome some limitations of current CEUS techniques based on conventional microbubbles [3], [5].

GVs are subjected to hydrostatic pressure from the surrounding aqueous medium, as well as to internal turgor pressure generated by osmotic forces. GVs collapse occurs when the external pressure exceeds their critical collapse pressure. [5]. Understanding the mechanical properties of GVs is essential for characterizing and controlling their behavior under incident ultrasound. The resulting compression and rarefaction cycles impose mechanical stresses on the GVs that can induce their collapse, thereby limiting their stability and effectiveness as contrast agents.

Analyzing the mechanical properties of complex micro- and nanostructures is possible using Atomic Force Microscopy (AFM) [6]. This technique employs an intermolecular force sensor —consisting of a probe attached to a lever known as a cantilever—to scan the sample pixel by pixel, providing high-resolution qualitative and quantitative data on topography, adhesion, deformation, and sample stiffness.

The scanning process generates images that allow for the correlation of specific topographic regions with their corresponding mechanical responses. However, image quality can be compromised by noise and artifacts that hinder this correlation [7]. Hence, image processing is an essential step, involving tilt correction, line removal, and the application of filters to reduce noise and enhance the reliability of the results.

A image is composed by units called pixels. The color in each pixel can be expressed through different models. The RGB model is the most used representation approach, where the color is expressed as a combination of three basic colors red, green and blue. However, this representation has some limitations such as concepts such a brightness are difficult to interpret in this model. On the other hand, HSV color model gives a representation more similar to the human perception of the color. This color model defines a color using three characteristics: hue (V, the pure color), saturation (S, purity of the color, from gray tone to a lively color) and value (V, brightness concerning the saturation of the color). HSV model is used in many image processing techniques [8]–[11].

There are different kind of filters used in image processing. The median filter allows filtering preserving edges. The pixel in an square region (neighborhood) is substituted by the median of the valued associated to the pixels of the region [12], [13]. The median filter is usually applied into the three component of the RGB color representation of the image.

This paper proposes an image filtering procedure for atomic force microscopy (AFM) images used in the analysis of the mechanical properties of GVs, based on the application of median filtering in the HSV color space. The proposed approach allows analyzing and filtering, independently, the hue, saturation and value properties of each pixel of the image, enabling the attenuation of image imperfections, including noise and pixels with excessively high or low brightness within localized image regions, while preserving the remaining color information. Tests using actual photos about GVs shows that the proposed image filtering method allows improving the quality of images used in the elasticity analysis of GVs.

II. Theoretical Foundations

A. Gas Vesicles

Gas vesicles (GVs) are structures synthesized by microorganisms in the Archaea and Bacteria domains, such as the cyanobacterial strain *Anabaena flos-aquae*, which can be used as contrast agent in contrast-enhanced ultrasound (CEUS) imaging systems. They consist of a hollow, rigid, all-protein envelope composed primarily of the GvpA and GvpC proteins (which give to the GV its shape and structural rigidity, respectively). Their morphology ranges from fusiform to cylindrical, and the interior of GVs is filled with atmospheric air that circulates freely between the internal and external environments [14]–[16].

GVs can collapse under the influence of specific pressures [5]. These pressures result from evolutionary environment adaptations in which microorganisms develop and depend primarily on the cylindrical radius of their structure [17]. Collapse pressure is directly related to the mechanical rigidity of GVs. Hence, determining properties such as the modulus of elasticity, that is, the measure of resistance relative to the degree of deformation, allows a better understanding of the behavior of GVs when exposed to ultrasound waves.

B. Atomic Force Microscopy (AFM)

Mechanical characteristics of the sample—such as maximum contact force, adhesion, deformation, dissipation, and stiffness (e.g., the elastic modulus)—can be obtained using Atomic Force Microscopy (AFM) in PeakForce Tapping Quantitative NanoMechanics (QNM) mode. This mode performs quantitative nanomechanical mapping—specifically, pixel-by-pixel indentation of the sample by the probe—generating force-displacement curves at each pixel. Cantilever deflection determines the force the sample exerts on the probe relative to its deformation (whether reversible or not), following mass-spring dynamics [18].

AFM enables morphological analysis of GVs through topographic imaging. Topography and mechanical properties can be spatially correlated, allowing for the identification of specific structures—such as the cylindrical shape and capsid proteins—which can be examined in detail [19]. The reliability of the results depends on the quality of the images obtained during the scan [7]; excessive noise, artifacts, and other instabilities can hinder this correlation.

AFM image acquisition can involve artifacts stemming primarily from the probe, the piezoelectric scanner, or the feedback system, as well as issues related to surface contamination and electronic noise [20]. Common examples include probe wear and contamination, piezo nonlinearity, improper feedback system gain settings, acoustic noise, and electrical interference. These factors can cause topographic distortions, errors in determining the contact area between the probe and the sample, and alterations to the force-distance curves used to calculate mechanical properties. Consequently, results may be overestimated or underestimated, compromising the correlation between the observed morphology and the sample's mechanical response [21].

Raw data obtained during AFM scanning are rarely evaluated without further data processing. Mechanical and morphological characteristics can be better defined through image processing. Generally, basic leveling routines are applied to remove tilt errors between the microscope axis and the sample plane [22], alongside line subtraction and matrix filtering. These steps minimize distortions and improve the correlation between topography and mechanical maps.

Image processing can be performed using software integrated to the equipment, as well as commercial or free AFM software featuring user-friendly interfaces such as Gwyddion (a modular, cross-platform software for AFM data analysis) [22]. The software performs quantitative processing of the acquired physical data by operating on the original numerical matrix. Key tools include sample tilt removal, median and Gaussian filtering, frequency-domain analysis, and statistical parameter analysis, among others [22].

C. RGB and HSV Color Models

Different models were created to represent the colors that compose an image. The RGB model represents a color as the combination of the three primary colors red (R), green (G) and blue (B), where the intensity of each color goes from 0 to 255 (or from 0 to 1). Thus, a pixel color (C) can be expressed as a vector composed by the intensities of its primary colors:

$$C = [R,\ G,\ B]. \tag{1}$$

However, human sight does not understand some color characteristics such as luminance through these primary colors. HSV model is a better representation of how the human sight perceives colors. This model defines a color in terms of hue (H), saturation (S) and value (V):

- Hue (H): it indicates the true color (red, yellow, green, etc.), represented as an angle between 0^o too 360^o, or equivalently in the range $[0,\ 1]$ or $[0\%,\ 100\%]$.
- Saturation (S): it indicates the amount of gray. A saturation of 0% means pure gray color, while a saturation of 100% means complete pure vibrant color.
- Value (V): it represents the brightness respect of the saturation. The value 0% means black (independently of the Hue), while 100% means a full brightness.

Fig. 1 shows the HSV color representation. One advantage of using HSV color representation is that the luminance can be analyzed independently from chromatic information. Similarly to (1), the HSV representation can be expressed as a vector:

$$C = [H,\ S,\ V]. \tag{2}$$

Let R, G, and B be the intensity of red, green and blue of a pixel, expressed in the range $[0,\ 1]$. The conversion from RGB model to HSV model is performed as follows [24]:

$$C_{max} = max(R, G, B), \tag{3}$$
$$C_{min} = min(R, G, B), \tag{4}$$
$$\delta = C_{max} - C_{min}, \tag{5}$$

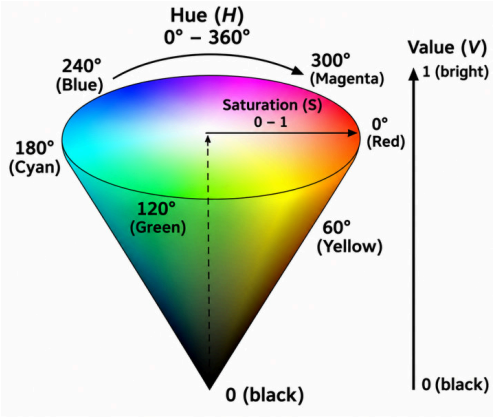

Fig. 1. HSV color map.

$$H = \begin{cases} 0, & \delta = 0; \\ (G-B)/(6\delta), & C_{max} = R \text{ and } C_{min} = B \\ 1 + (R-B)/(6\delta), & C_{max} = G \text{ and } C_{min} = B \\ 2 + (B-R)/(6\delta), & C_{max} = G \text{ and } C_{min} = R \\ 3 + (G-R)/(6\delta), & C_{max} = B \text{ and } C_{min} = R \\ 4 + (R-R)/(6\delta), & C_{max} = B \text{ and } C_{min} = G \\ 5 + (B-G)/(6\delta), & C_{max} = R \text{ and } C_{min} = G, \end{cases} \tag{6}$$

$$S = \begin{cases} 0, & \delta = 0 \\ \delta/C_{max}, & \delta \neq 0, \end{cases} \tag{7}$$

$$V = C_{max}. \tag{8}$$

The results of H, S and V from (6), (7) and (8) are scaled in the range $[0,\ 1]$. The conversion from HSV to RBG representation is done as follows [24]:

$$I = \begin{cases} 0, & 0 \leq 360H < 60 \\ 1, & 60 \leq 360H < 120 \\ 2, & 120 \leq 360H < 180 \\ 3, & 180 \leq 360H < 240 \\ 4, & 240 \leq 360H < 300 \\ 5, & 300 \leq 360H < 360. \end{cases} \tag{9}$$

$$F = 6H - I, \tag{10}$$
$$M = V(1 - S), \tag{11}$$
$$N = V(1 - SF), \tag{12}$$
$$K = V(1 - S(1 - F)), \tag{13}$$

$$[R,\ G,\ B] = \begin{cases} [V,\ V,\ V], & S = 0 \\ [V,\ K,\ M], & I = 0 \\ [N,\ V,\ M], & I = 1 \\ [M,\ V,\ K], & I = 2 \\ [M,\ N,\ V], & I = 3 \\ [K,\ M,\ V], & I = 4 \\ [V,\ M,\ N], & I = 5. \end{cases} \tag{14}$$

D. Median Filter for Images

The median of a dataset is the middle value of the group composed when all the values of the aforementioned dataset are sorted in ascending order.

Let define the $L \times L$ neighborhood of a pixel $P(x, y)$ as the square region with a side length of L pixels, where L is a positive odd number greater than one, and $P(x, y)$ is the center of that region. A median filter for imaging denoising is a non-linear process to suppress impulsive noise while preserving the edges, where the value of the pixel $P(x, y)$ is substituted by the median of the pixels values within its $L \times L$ neighborhood, as illustrated in Fig. 2 [12], [13].

III. Methodology

A. Gas Vesicles

For the cultivation of *Anabaena flos-aquae* (ANA), ASM-1 culture medium is used, and its pH is adjusted to 8.0 after preparation, as described by Gorham et al. [23]. The medium was then autoclaved for subsequent use in the growth of cyanobacteria. The culture was conducted in a room with controlled temperature, aeration, and light conditions, maintained at 24 °C, a 12-hour photoperiod, and a light intensity of 100 μmol photons m^{-2} s^{-1}, for a period of 20 days.

After this period, the culture was transferred to a previously sterilized separation funnel lined on the sides with aluminum foil, allowing light to enter only through the top of the funnel. The system remained in a natural environment for 1 to 3 days, or until a ring of cells formed on the surface. The floating cells were collected in 50 mL Falcon tubes and treated with a lysis solution in a 1:1 (v/v) ratio, consisting of 0.5% Tween 20, 500 mM sorbitol, and 10 mM Tris (pH 7.5), diluted in PBS.

Gas vesicles (GVs) were isolated through three centrifugation steps in Falcon tubes at 400 × g for 24 hours at 4 °C. After centrifugation, the GVs were pooled into a single Falcon tube and stored at 4 °C until use.

B. AFM Image Acquisition

The GVs were initially isolated from the cyanobacterial ANA, following the protocol established by Gorham et al. [23]. Samples with an optical density (OD) of 1.0, as measured by a spectrophotometer (NanoDrop One Microvolume UV-Vis; Thermo Fisher Scientific, Massachusetts, USA) operating at a wavelength of 500 nm, were used.

Purified GVs were diluted 1:10 in distilled water, deposited (150 µL volume) onto a freshly cleaved muscovite mica substrate, and allowed to dry for 24 hours.

Images were acquired using a Bruker Dimension FastScan-Icon Atomic Force Microscope located at the Centro Nacional de Biologia Estrutural e Bioimagem (CENABIO) at the Federal University of Rio de Janeiro. Scanning was performed in air using the PeakForce Quantitative NanoMechanics Mapping mode across four main channels: topography, error, DMT modulus, and adhesion.

During scanning, key parameters were set to a maximum peak force of 300 pN and a scan rate corresponding to a frequency of 0,977 Hz.

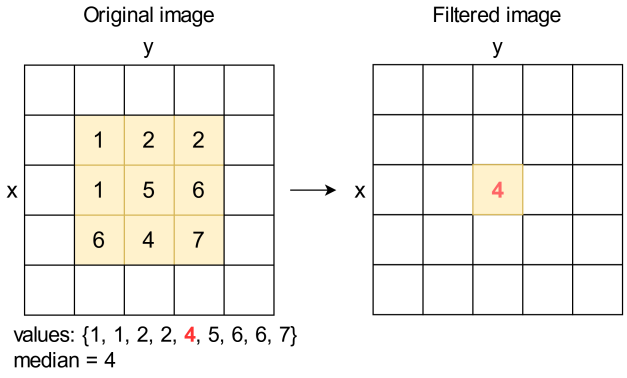

Fig. 2. Median filter for an 3×3 neighborhood.

C. Proposed Filtering Method

An image can be represented as a $M_I \times N_I \times 3$ matrix of pixels, where I_M is the is the number of rows (image height) and N_I is the is the number of columns (image width). Moreover, the number 3 represents the three parameters used to represent the color (R, G, B in RGB system; or H, S, V in HSV system).

The proposed filtering method consists in the application of median filter, with different neighborhood sizes, applied into the HSV representation. Let I the $M_I \times N_I \times 3$ be the matrix that contains the information about hue, saturation and value of each image pixel, obtained by applying the formulas given in (3)–(8) into the RGB color representation of the pixels. Following the matrix notation used in numerical software such as MATLAB and OCTAVE, three $M_I \times N_I$ matrices, denoted as I_H, I_S and I_V, can be defined, as follows:

$$\text{Matrix with Hue information: } I_H = I(:, :, 1), \quad (15)$$

$$\text{Matrix with Saturation information: } I_S = I(:, :, 2), \quad (16)$$

$$\text{Matrix with Value information: } I_V = I(:, :, 3), \quad (17)$$

where $I(:, :, k)$, is a $M_I \times N_I$ matrix composed by the values of the k-th color characteristic of the pixels in all rows and columns of I, where $k = 1$, $k = 2$ and $k = 3$ mean hue, saturation or value, respectively. In the proposed approach, median filters with independent neighborhoods are applied to the matrices $I(:, :, k)$, $k = 1, 2, 3$.

- Hue: $I(:, :, 1)$ gives information about color changes (e.g., edges).
- Saturation: $I(:, :, 2)$ gives information about grayscale in an image.
- Value: $I(:, :, 3)$ gives information about brightness (useful to analyze darker or lighter image artifacts).

Finally, (9)–(14) are used to obtain the RGB color-based image from the filtered hue, saturation, and value information.

IV. Results

The proposed approach was implemented in MATLAB. Two different tests were performed to evaluate the performance of the proposed HSV-based filter.

A. *Test 1*

Fig 3 shows a image of GVs obtained during the process to analyze their elasticity. This image is distorted by horizontal lines and bright points. Figs. 4 and 5 present the RGB and HSV representations of the image used in Test 1. Figs. 4.(b), 4.(c) and 4.(d) show the intensity of the red, green and blue components of the pixels in Fig. 3. Similarly, Figs. 5.(b), 5.(c) and 5.(d) represent the matrices I_H, I_S and I_V that contains the intensities of hue, saturation and value of each pixel in Fig 3, respectively. The noise is more readily identified in the HSV representation than in the RGB representation. Moreover, the hue and saturation representations are noisy, while the value plane is more homogeneous (less noisy).

According to the proposed approach, the following median filters were applied to the matrices I_H, I_S and I_V:

- I_H (hue): median filter with neighborhood $L = 15$.
- I_S (saturation): median filter with neighborhood $L = 31$.
- I_V (value): median filter with neighborhood $L = 9$.

Figs. 6 and 7 show the results obtained by applying a median filter in the the RGB and HSV color representations, respectively. A median filter with $L = 21$ was used in the red, blue and green matrices that compose the RGB image representation. The proposed HSV-based median filtering allows a better noise reduction. Fig. 8 shows the filtered image using the proposed approach, where the horizontal lines and the bright points were significant attenuated.

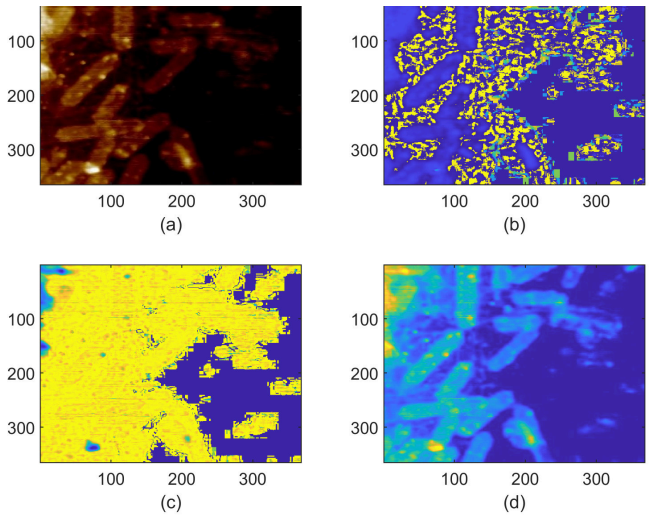

Fig. 5. HSV representation of the noisy image for test 1. a) Original image. b) Hue, c) Saturation, d) Value.

B. *Test 2*

A second test was performed, using the image shown in Fig. 9, obtained through AFM. The color scale in Fig. 9 represents the topography, or height, of the structure. Lighter colors indicate greater height, as this is a topographic image. Thus, the GV is located at a higher elevation relative to the background plane. Consequently, filtering colored noise and other image artifacts is important for accurate topographic analysis of GVs.

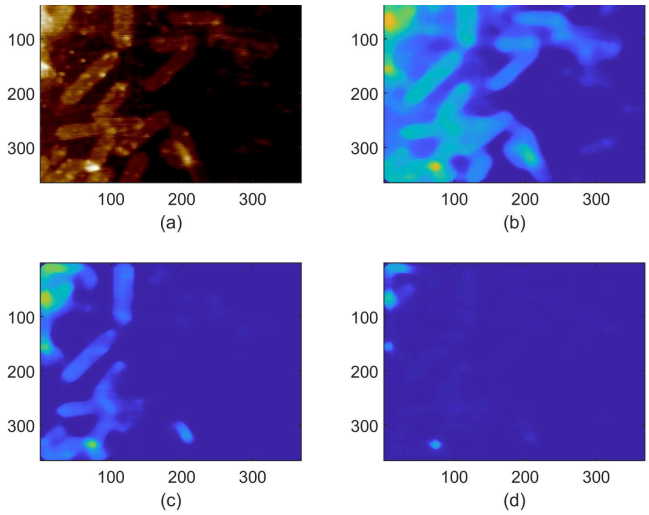

Fig. 6. Image obtained by applying the median filter in the RGB representation. a) Filtered image. b) Red, c) Green, d) Blue.

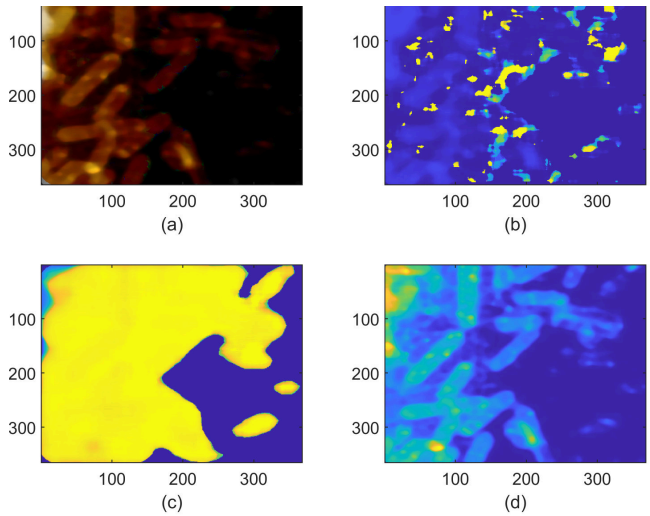

Fig. 7. Image obtained by applying the median filter in the HSV representation. a) Filtered image. b) Hue, c) Saturation, d) Value.

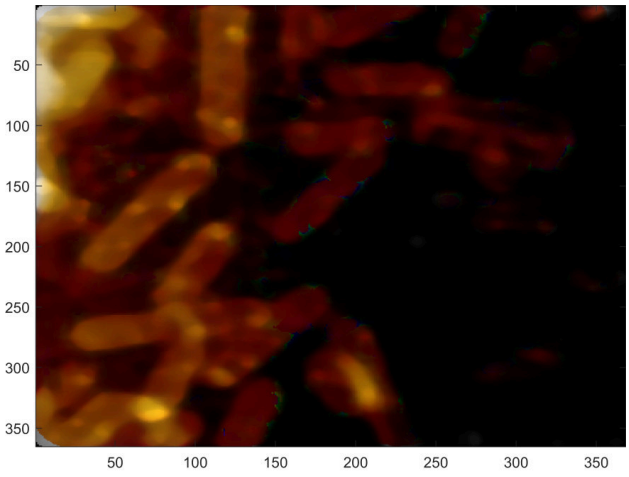

Fig. 8. Filtered image using the proposed approach.

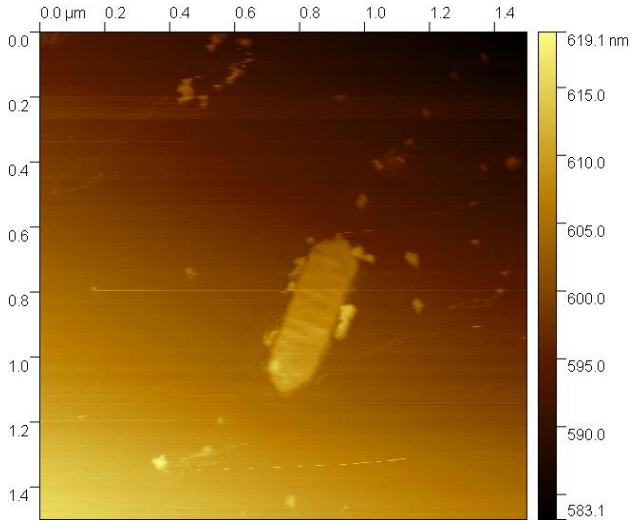

Fig. 9. Original image used in Test 2.

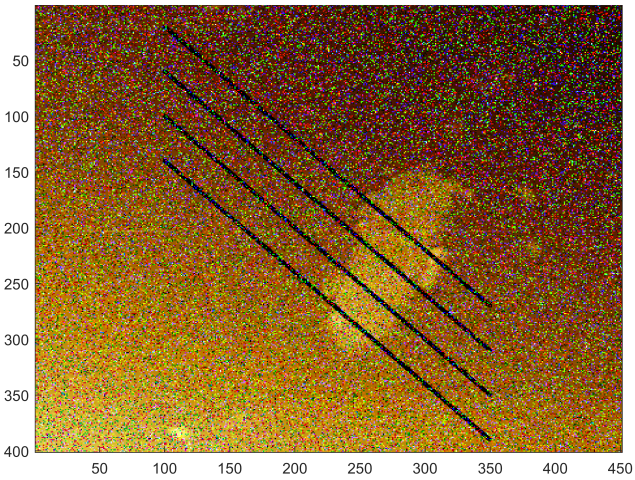

Fig. 10. Distorted image used in Test 2.

To test the proposed filtering process, black diagonal bars and salt-and-pepper noise with a noise density of 0.2 (using the command *imnoise(I2,'salt & pepper', 0.2)*), being *I2* the matrix with the pixels of the image) where added to the image, as shown in Fig. 10.

The structural similarity index (SSIM) was used to measure the similarity between the original image in Fig. 9 with a filtered image. SSIM can be used to compare visual quality based on three components: mean, variance, and cross-correlation [26]. The command *'ssim(Ifiltered, Ioriginal)'* of MATLAB was used to get the SSIM value, between the filtered and the original images (represented by the matrices *Ifiltered* and *Ioriginal*, respectively. Table I shows the SSIM values for different values of L_h, L_s and L_v. The best result was $SSIM = 0.9955$ for $L_h = 11$, $L_s = 11$ and $L_v = 9$.

Fig 11 shows the filtered images obtained through the proposed filter process with the best configuration in Table I ($L_h = 11$, $L_s = 11$ and $L_v = 9$), and using a median filter applied to the RGB representation (with $L = 11$ for the three sets of primary colors). The filtered image using RGB color representation has a $SSIM = 0.98785$. Therefore, the proposed filter method (with $SSIM = 0.9955$) provides a filtered image more similar to the original image, allowing a more accurate topographic analysis of GVs. Moreover, the SSIM values for the proposed HSV-based filtering process in Table I are greater than the SSIM value for the RGB-based filter.

On the other hand, Table I also indicates that increasing the neighborhood size (L) of the median filter will not necessarily improve the image quality. For example, the SSIM value for $L_h = 13$, $L_s = 11$ and $L_v = 15$ is 0.99319, which is less than the the result obtained for $L_h = 11$, $L_s = 11$ and $L_v = 9$ ($SSIM = 0.9955$). Optimization techniques, such as a genetic algorithm, can be used to get the optimal values for the median filter neighborhoods. A genetic algorithm is an optimization method inspired by the principles of biological evolution and natural selection. [27].

TABLE I
$SSIM$ FOR DIFFERENT VALUES OF L_h, L_s AND L_v

L_h	L_s	L_v	SSIM
11	11	15	0.9935
13	11	15	0.99319
11	13	15	0.99292
11	11	17	0.99259
9	11	15	0.99325
7	11	15	0.99062
15	11	15	0.99314
13	9	15	0.99317
11	9	15	0.99358
11	7	15	0.99196
11	9	13	0.99433
11	9	11	0.99532
11	9	9	0.99547
11	9	7	0.99312
11	11	13	0.99403

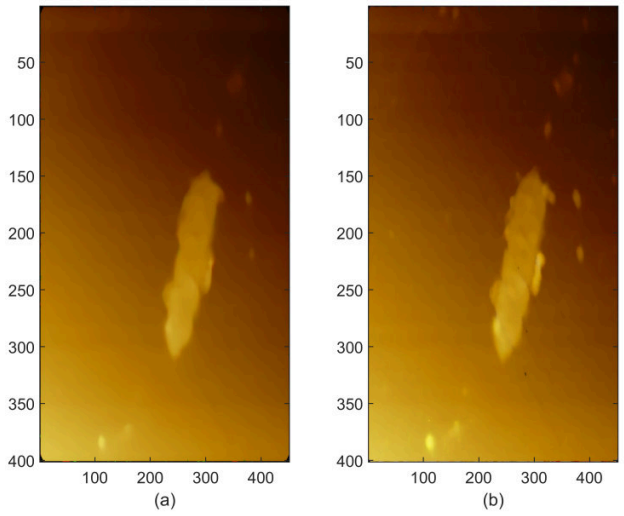

Fig. 11. Filtered images using median filters applied into RGB and HSV color representation: a) Using RGB representation ($SSIM = 0.98785$). b) Using HSV representation ($SSIM = 0.9955$).

V. CONCLUSION

This paper proposed a new image filtering technique for GV analysis based on median filtering applied to the HSV representation of the image. The use of HSV color representation allowed the identification and attenuation of noise and other artifacts in hue, saturation and brightness, which is more intuitive and simple to understand than working with primary colors. The proposed filter has simple mathematical structure, being simple to implement in software (or in embedded processors if necessary). Therefore, the proposed approach could be part of more complex image enhancement software used in the analysis of GVs. The results in Table I demonstrated that the proposed filtering method can provide better results than using a median filter applied to the RGB color representation. As future work, a genetic algorithm (GA) will be used to obtain optimal values of the median filter neighborhoods required in the proposed approach.

***Abstract*—Exposure to light and solar radiation can cause cumulative damage to ocular structures, making sunglasses an essential means of protection. However, their effectiveness depends not only on the optical properties of the lenses, but also on the ability of the frame to limit peripheral light entry through gaps between the accessory and the user's face. Current scientific literature predominantly focuses on lens transmittance, with limited quantitative evaluation of frame coverage and facial morphology. To address this gap, this study proposes an experimental methodology based on Digital Image Processing to evaluate the face–frame interface. Frame segmentation employs the YOLO11 model, trained with annotations generated by SAM3. Frontal analysis delineates facial regions using MediaPipe and HSV filtering, while profile analysis employs the YuNet detector with adaptive geometry in the lateral view, isolating exposed skin via bitwise boolean AND operations with the frame mask. The results demonstrate promising frame detection and anatomical mapping. Frontal facial landmarks isolate exposed skin, whereas profile analysis delineates the topology of the unshielded area, revealing spatial variations associated with individual anatomy. The methodology demonstrates potential to identify and quantify the gap dimensions between the frame and the face, establishing the structural baseline to enable future metric conversion to millimeters and subsequent normative comparison with the standardized size-M headform specified in ISO 18526-4:2022.**

I. Introduction

Exposure to Ultraviolet Radiation (UVR) constitutes a significant biological hazard to ocular health. The incident levels of UVR are contingent upon environmental variables, specifically altitude, latitude, and ground reflection [1] [2]. These radiation levels are capable of inducing both photochemical and thermogenic damage to various ocular structures. Furthermore, prolonged exposure leads to a cumulative effect, which subsequently manifests as severe pathologies, including but not limited to pterygium, macular degeneration, photokeratitis, and photoretinitis [3] [4].

Biological tissue damage is intrinsically linked to the selective absorption of UVA and UVB radiation, with the cornea and the crystalline lens functioning as natural protective filters [5]. Although the human organism employs physiological defense mechanisms, such as pupillary contraction (known as Miosis) and the squint reflex, these inherent processes are insufficient to confer total ocular protection [6]. Consequently, human intervention, specifically through the implementation of sunglasses, becomes essential.

This intervention serves as a necessary complementary barrier to effectively reduce the overall UVR dose received by the eyes [7].

Despite the established importance of wearing sunglasses, the existing literature presents a limited number of experimental analyses concerning the influence of facial geometry on the efficacy of this form of ocular protection. This gap is relevant because individual facial characteristics and cephalic morphological differences may inherently determine variations in the manner and extent to which solar radiation reaches the human eye [8].

Consequently, given the scarcity of studies investigating radiation penetration through the gaps between sunglass frames and the face under realistic usage conditions, this study proposes an integrated experimental methodology to evaluate and inform users about the true shielding capability of eyewear. In this context, visible light serves as a geometric proxy to map peripheral penetration pathways. Because ultraviolet radiation and visible light share identical spatial propagation trajectories, mapping the gaps through which visible light penetrates provides a direct indicator of anatomical regions

Supported by FAPESP and CNPq

vulnerable to peripheral radiation influx.

To achieve this objective, the proposed framework leverages Digital Image Processing (DIP) techniques for the automated characterization of facial anatomy and frame geometry using synchronized frontal and profile images. The system integrates a controlled-illumination acquisition setup with automated Region of Interest (ROI) detection and image segmentation, enabling individualized characterization of both facial structures and sunglass frames.

A. UVR Exposure Limits

The effective radiant exposure to the unprotected eye within the ultraviolet spectrum (180–400 nm) is restricted to a maximum threshold of 30 J/m² over an eight-hour period. Standard guidelines categorize ultraviolet radiation (UVR) into three distinct bands: UV-C (180–280 nm), UV-B (280–315 nm), and UV-A (315–400 nm). Wavelengths below 180 nm are excluded from hazard assessments, as atmospheric absorption renders their ground-level biological impact negligible. Consequently, while UV-C radiation is almost entirely absorbed by the stratospheric ozone layer, UV-B and UV-A reach the Earth's surface with sufficient intensity to penetrate ocular tissues [9].

Quantitatively, International Commission on Non-Ionizing Radiation Protection (ICNIRP) specifies that the daily effective radiant exposure (H_{eff}), spectrally weighted by the biological hazard function $S(\lambda)$, must not exceed 30 J/m^2 (3.0 mJ/cm^2) for actinic UV radiation (180–400 nm) over an 8-hour period [10]. Furthermore, for the UV-A spectrum (315–400 nm), the unweighted cumulative radiant exposure is capped at 10^4 J/m^2 (1.0 J/cm^2) to mitigate long-term lenticular damage [9]. These quantitative parameters serve as essential safety baselines for evaluating ocular exposure risks and defining sunglass shielding requirements.

In addition to ICNIRP recommendations, other studies provide further insight into UVR exposure thresholds. This is illustrated by the research conducted by [10], which translates normative metrics into practical measurements of radiation doses capable of causing harm. The authors evaluated the effectiveness of various types of protective wear, including sunglasses, caps, and hats, by comparing the exposure of protected and unprotected eyes.

The investigation revealed substantial variation in the efficacy of these devices, demonstrating that diffuse and effective radiation remains a persistent risk. The results indicated that increasing the distance between sunglasses and the forehead by only 6 mm altered the percentage of UVR reaching the eyes, producing values ranging from 3.7% to 44.8%. Consequently, such findings suggest that, in addition to the protective capability of the lenses, geometric factors and frame design also influence the level of protection [10].

B. Ocular UVR Exposure and Attenuation

The primary purpose of sunglasses is to provide visual comfort by attenuating the flux of visible light and acting as filters against ultraviolet radiation (UVR). Ocular protection has traditionally focused on the attenuation of the direct UVR component, largely because most research in the field concentrates on lens transmittance. Consequently, it is equally important to evaluate the impacts of diffuse and reflected radiation. [11].

Effective protection, however, requires attention beyond the filtering capacity of the lenses. The UVR that reaches the eye includes significant indirect components produced by atmospheric scattering and by reflection from surfaces such as the ground, snow, and water [12]. This diffuse and reflected radiation strikes the peripheral regions of the eye and creates penetration pathways that are not attenuated by the lenses.

When the geometric contribution and the design of the frames are considered, the frame can be understood as an additional protective barrier. The main challenge arises from the lateral and superior gaps between the frame and the face. These openings allow peripheral rays to reach the crystalline lens, establishing connections between cortical cataracts and the limbal focus of peripheral radiation, a phenomenon known as the Coroneo Effect [13].

For this reason, sunglasses that lack adequate lateral and superior barriers may pose a risk to ocular health. This demonstrates that, beyond the filtering capacity of the lenses, the design and positioning of the frame are essential for effective protection.

II. MATERIALS AND METHODS

A. Experimental Acquisition System and Setup

For a metrological evaluation, an image acquisition system was developed in a controlled lighting environment, whose physical configuration and experimental setup are illustrated in Fig. 1. The primary light source consisted of a cold white light panel featuring 240 SMD 2835 LEDs, with a color temperature of 6000K, powered by a stabilized power supply to prevent luminosity fluctuations. This 12V LED array was uniformly distributed under a polycarbonate panel. To ensure homogeneous illumination and minimize specular reflections and localized saturation on the lenses of the sunglasses, a high-transmittance white diffuser fabric was positioned over the panel, providing uniform light diffusion throughout the capture area.

(a) subject positioning on the ophthalmic chin rest (lateral view).

(b) orthogonal dual-camera configuration on the optical bench (perspective view).

Fig. 1: Experimental image acquisition setup.

The image acquisition system employed two webcam-type cameras (model WC577), rigidly mounted on an optical bench at a fixed distance of 40 cm from the subject's facial plane. These cameras operated at an effective resolution of 2560 x 1440 pixels and a field of view (FOV) of 110 degrees, with captures performed using the cameras' native operating settings. The optical axes of both cameras were geometrically aligned to ensure acquisition repeatability across different users from standardized viewpoints. Specifically, the frontal camera was positioned at the level of the nasal region, whereas the lateral camera was oriented perpendicularly to the zygomatic region, enabling precise recording of the lateral profile.

To ensure measurement repeatability and minimize the positioning variability inherent to the subject, an adjustable ophthalmic chin rest, originally designed for clinical ophthalmic diagnostic instruments and adapted for the present experimental setup, was incorporated into the optical bench. This device restricts involuntary head movements and maintains a constant position relative to the calibrated focal plane throughout the acquisition.

The images used in this study were acquired with the voluntary participation of members of the Ophthalmic Instrumentation Laboratory research group, where the proposed project was developed. All participants were previously informed about the objectives of the study and provided authorization for the use of their images exclusively for scientific purposes, including the development, validation, and dissemination of the results presented in this paper.

B. Sunglasses Segmentation

Geometric characterization of sunglass frames constitutes a fundamental step in the proposed methodology, as it enables the isolation of the accessory from the remainder of the image and provides an accurate representation of its shape and contours. This information is essential for subsequent stages involving the extraction of geometric parameters and for the analysis of the spatial relationship between the frame and facial anatomy, which will serve as the basis for ultraviolet radiation blocking studies. To automate this process, the SAM3 and YOLO11 tools were employed, whose functions are complementary throughout the construction and application of the segmentation model.

The Segment Anything Model 3 (SAM3) is an instance segmentation architecture developed to perform pixel-level segmentation from various types of prompts, including bounding boxes, points, textual descriptions, and visual examples. Compared with conventional segmentation approaches, the model produces binary masks that describe the contours of the objects of interest with high precision, preserving their geometric representation [14].

In this project, SAM3 was employed in the automatic annotation stage of the dataset. Images containing sunglass frames were processed to generate binary masks separating the frame from the background. These masks were then used to extract frame contours and automatically convert them into the annotation format required by YOLO11, establishing a direct geometric correspondence for supervised training while significantly reducing manual labeling effort.

The YOLO (You Only Look Once) architecture constitutes an approach to real-time object detection in the context of computer vision. Its primary objective is to identify and simultaneously localize multiple objects present in images or video sequences, reconciling high detection accuracy with low inference time. YOLO possesses capabilities beyond object detection, offering native support for instance segmentation, image classification, pose estimation, and oriented bounding box detection [15].

The dataset for training and evaluating the model consisted of 4 voluntary participants, all members of the Ophthalmic Instrumentation Laboratory (LIO) where this research was developed, utilizing 80 distinct sunglass models. This procedure yielded a total of 249 images captured under controlled lighting conditions. To assess the model's generalization capability, the images were divided into proportions of 80% for training (199 images) and 20% for validation (50 images), ensuring the representativeness of facial variations and the wide diversity of frame geometries.

During training, the model receives the images and their respective annotations, learning to automatically localize and segment the sunglass frames from the provided examples. At the end of each epoch, its performance was evaluated using the validation set and the set of weights corresponding to the best result obtained was automatically stored. The final model was saved as the best.pt file, which was subsequently used in the inference stage to perform automatic detection and segmentation of the frames in new images.

Fig. 2 presents the methodological flow employed in the construction of the segmentation model, from the automatic generation of annotations by SAM3 to the obtainment of the trained model (best.pt).

To quantitatively evaluate the segmentation accuracy of the trained YOLO11 model against reference annotations, standard overlap metrics, specifically Intersection over Union (IoU) and the Dice Similarity Coefficient (Dice), were computed on an independent test subset. These widely established metrics quantify spatial agreement and boundary fidelity by evaluating pixel-level overlap between binarized predicted frame masks and ground truth representations.

C. Frontal Facial Segmentation

Segmentation of facial structures constitutes a complementary step to sunglass frame segmentation, enabling the delineation of anatomical regions of interest used in characterizing the interface between the face and the accessory. Such regions can provide geometric information that allows analyzing the proximity between the frame and the facial anatomy, serving as a basis for identifying areas potentially susceptible to ultraviolet radiation incidence.

Automatic facial landmark estimation is a widely employed technique in computer vision for geometrically representing the human face, enabling the localization of characteristic points used in facial analysis applications [16]. In this project,

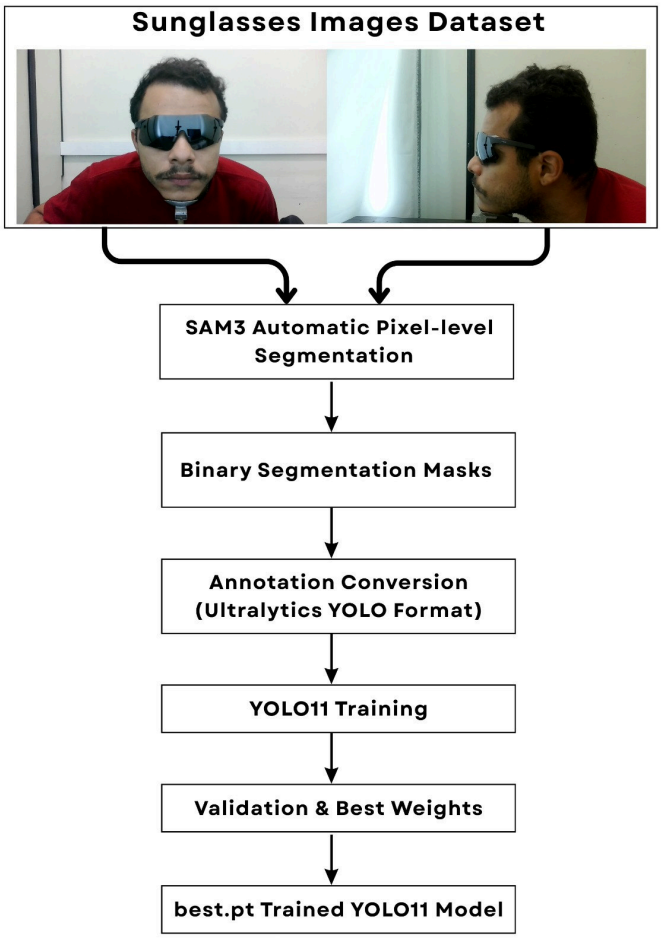

Fig. 2: Proposed SAM3 and YOLO11 segmentation pipeline workflow.

this step was implemented using the MediaPipe Face Landmarker library, which performs automatic detection of these anatomical landmarks and generates the facial mesh employed in defining the regions of interest.

From the selected landmarks, an initial geometric representation of the anatomical regions is constructed using the Convex Hull algorithm, which generates a polygon enclosing the points belonging to each facial structure. For the zygomatic regions, this initial representation is refined through a hybrid strategy based on subtracting the sunglass frame mask, automatically removing the areas covered by the accessory and preserving only the effectively visible facial regions.

Subsequently, the contours of the resulting regions are extracted, and a filter based on the minimum area of the objects is applied to eliminate small spurious regions arising from processing. The final contours and the facial landmarks are then overlaid onto the original image, producing the geometric representation employed in the analyses presented in the results section.

Fig. 3 presents the block diagram of the methodology employed for frontal facial segmentation, from facial landmark detection to the obtainment of the regions of interest used in the geometric characterization.

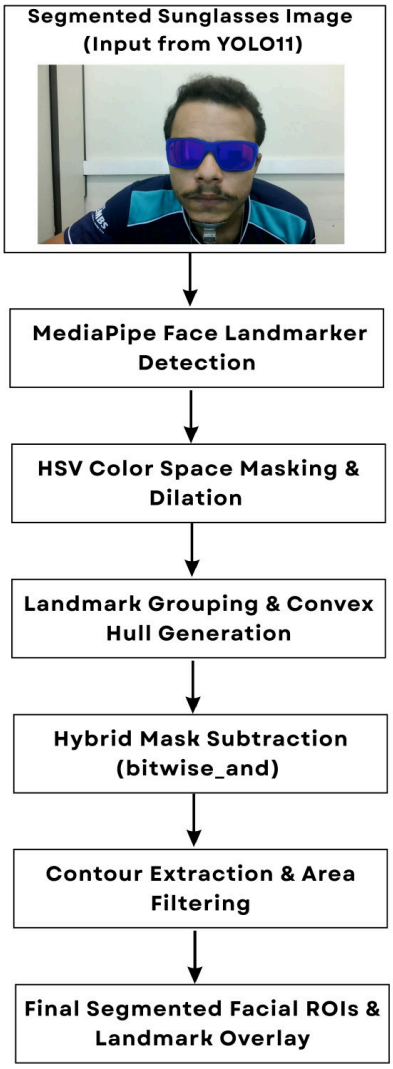

Fig. 3: Block diagram of the proposed frontal facial segmentation pipeline

D. Profile Exposed Facial ROI Segmentation

Although frontal facial segmentation enables the delimitation of different anatomical structures through a dense facial mesh, this approach presents limitations when applied to profile images, in which part of the anatomical landmarks becomes invisible due to facial self-occlusion. Given this limitation, a specific methodology was developed for the profile view, based on the combination of automatically detected anatomical points and adaptive relationships for defining the region of interest.

Face detection was performed using the YuNet Face Detector, which locates the face and estimates the main visible anatomical points, including the eye, nose, and mouth.

From the face bounding box and the coordinates of the detected anatomical points, proportional geometric relationships are calculated and used in constructing the region of

interest. These relationships enable the automatic definition of an adaptive polygon corresponding to the zygomatic region, adjusting its position and dimensions to the individual characteristics observed in each profile image. Subsequently, the image is converted to the HSV color space to retrieve the mask corresponding to the previously segmented sunglass frame, which is then dilated to create a safety margin during processing.

After constructing the initial geometry, the frame mask is subtracted from the region of interest, preserving only the effectively visible facial areas. Subsequently, morphological closing and opening operations are applied using an elliptical structuring element, promoting contour smoothing and reducing irregularities introduced by polygon discretization. Finally, the final contours of the segmented region are extracted, and the region of interest and the detected anatomical points are overlaid onto the original image.

It is worth noting that this profile processing stage specifically targets the delineation of the exposed zygomatic skin area (ROI) directly susceptible to peripheral radiation influx. Rather than directly measuring a single linear gap, the adaptive polygon isolates the unoccluded tissue boundary formed between the lower edge of the frame temple and the cheek contour. This segmented exposed mask acts as a spatial foundation that enables subsequent quantitative extraction of the lateral gap distance.

III. RESULTS

A. Sunglasses Detection and Segmentation Results

The presented results demonstrate that the developed pipeline is not restricted to a single frame shape or to a specific set of facial characteristics. The correct identification of the regions of interest constitutes a fundamental requirement for the subsequent stages of the methodology, since the extraction of geometric information depends directly on the precision with which the frame is segmented relative to the remainder of the image.

The segmentation pipeline was evaluated across the complete independent test set ($n = 50$), achieving a global mean IoU of 0.9044 and a Dice score of 0.9488. Table I highlights a representative subset of 10 evaluation cases to illustrate boundary fidelity across distinct viewing angles and frame geometries, confirming strong spatial accuracy across diverse user poses. Spatial distribution of segmentation fidelity is illustrated in Fig. 4. The pixel classification map shows that true positives, represented by green pixels, dominate the target region. Discrepancies such as false positives (red) and false negatives (blue) are strictly confined to boundary transition zones.

Angle-specific evaluation indicates higher mean IoU values in frontal views (exceeding 0.93) compared to profile acquisitions, where lower values were recorded (such as 0.8031 for sample 8). Across all evaluated perspectives, IoU values remained above 0.80, establishing the segmentation baseline for subsequent facial ROI extraction.

TABLE I: Quantitative evaluation of the YOLO segmentation model on unseen data.

Sample	View	IoU	Dice Score
1	Frontal	0.9509	0.9749
2	Lateral	0.8096	0.8948
3	Lateral	0.8966	0.9455
4	Lateral	0.9189	0.9578
5	Frontal	0.9547	0.9768
6	Frontal	0.9644	0.9819
7	Frontal	0.9444	0.9714
8	Lateral	0.8031	0.8908
9	Frontal	0.9544	0.9767
10	Lateral	0.8472	0.9173
Mean		**0.9044**	**0.9488**

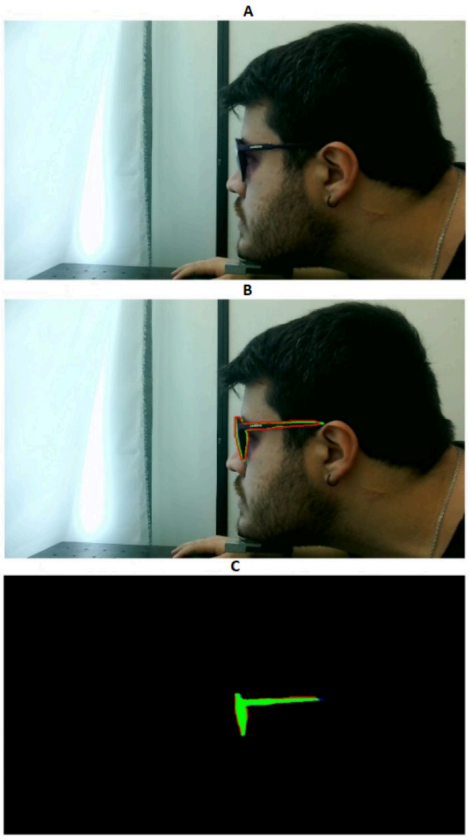

Fig. 4: Qualitative spatial evaluation of segmentation accuracy: (A) original profile acquisition, (B) ground truth (green) and predicted YOLO11 (red) boundary overlay, and (C) pixel classification map highlighting true positives (green), false positives (red), and false negatives (blue).

Although the previous results demonstrate the model capability to detect different frames, an important issue consists of evaluating the behavior of the same frame model when used by different individuals. For this analysis, a round-frame model was selected, characterized by circular and flat lenses with reduced dimensions, which naturally leave uncovered the lateral regions near the eyes.

As observed in Fig. 5, even when using the same frame, differences are verified in the distribution of the spaces existing

between the face and the sunglasses. Such variations may be associated with the facial characteristics of each user, as well as with minor differences in frame positioning during use. Consequently, lateral regions remain more or less exposed depending on the combination between the frame geometry and the facial anatomy.

Fig. 5: Frame-to-face spatial variation assessment using identical round sunglasses across multiple users.

The results presented in Fig. 5 evidence that the geometric characterization of the interface between the frame and the face must be performed for each condition of use. Assuming that the same frame model presents the same fit for all users may lead to inaccurate interpretations, since the distribution of the gaps depends both on the facial anatomy and on the manner in which the accessory is worn. In this way, it becomes possible to individually analyze the regions potentially more susceptible to radiation incidence through the openings existing between the frame and the face.

B. Frontal Facial ROI Segmentation Results

The MediaPipe Face Landmarker detected the anatomical landmarks in the volunteers analyzed. The facial mesh remained stable under different lighting conditions and in the presence of facial hair. From these points, the Convex Hull applied to the nasal region delineated the nose structure using red polygons, without encroaching upon adjacent areas.

The integration of HSV chromatic filtering with a bitwise AND operation cropped the upper cheek boundaries flush with the lower edge of the blue frame (derived from SAM3-YOLO segmentation). As illustrated in Fig. 6, the zygomatic region was effectively restricted to visible skin. However, the lower cheek boundary varied according to individual mandibular anatomy and peripheral landmark distribution. Because the lower ROI contour relies on linear connections between landmarks, minor alignment discrepancies occur relative to the natural curvature of the jawline. Refining this mandibular contouring via non-linear boundary fitting represents an opportunity for future algorithmic improvement.

This approach eliminates accessory overlap over the skin surface, establishing a precise geometric delimitation of the non-occluded skin. Consequently, the extracted topological data provide a promising basis for calculating the area exposed to ultraviolet radiation in subsequent stages.

Fig. 6: Frontal view region of interest (ROI) segmentation results.

C. Profile Facial ROI Segmentation Results

For the profile view analysis, detection of reference points (eye, nose tip, and mouth corner) by the YuNet detector served as anchoring to delimit the lateral zygomatic region, overcoming the self-occlusion limitation inherent to this viewing angle. Delimitation of this area is based on the hypothesis that the cheek constitutes a zone susceptible to peripheral solar radiation incidence. The adaptive polygon adjusted its dimensions to the craniofacial characteristics of each photographed face, maintaining algorithmic stability.

Integration of the sunglass mask via the bitwise AND operation prevented the demarcation from extending over the accessory. As presented in Fig. 7, the upper red boundary precisely follows the lower contour of the blue frame. Although all volunteers wore the same frame model, the results evidence subtle variations in the peripheral gaps between the frame and the anatomy of each face.

The profile segmentation results depicted in Fig. 7 highlight the exposed zygomatic skin area remaining unshielded by the eyewear geometry. The upper boundary of the red polygon strictly conforms to the lower contour of the blue frame mask, while the lower and posterior edges correspond to the adaptive face bounding box proportions.

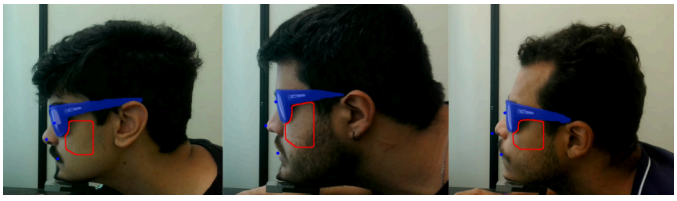

Fig. 7: Profile Facial Segmentation Results Across Multiple Faces

Although this output represents the topological region of exposed skin rather than a direct linear distance measurement, isolating this specific boundary provides the required input for gap quantification. By computing the distance profile across

the top edge of this exposed skin mask and the adjacent frame border, future iterations of the algorithm will extract the physical gap width (in millimeters) along the lateral axis.

IV. Conclusions

This research presented an experimental strategy focused on the geometric analysis of the interface between the user's face and sunglasses. The integration of the SAM3 and YOLO11 models demonstrated promising accuracy in the automated detection and segmentation of frames across distinct poses, supported by IoU metrics that remained consistently above 0.80 even in lateral views. In the frontal view, the methodology enabled the demarcation of critical facial regions, such as the nose and cheeks.

In profile acquisitions, the use of the YuNet detector enabled anchoring and delimitation of the lateral zygomatic region, overcoming the self-occlusion limitations inherent to this viewing angle. The application of a logical bitwise AND operation with the frame mask ensured precise isolation of the exposed skin area without overlap with the accessory, establishing the topological baseline required to quantify the lateral gap width in millimeters in future work.

In continuation of this work, the research progresses toward a methodology designed to spatially map and quantify regions lacking geometric coverage, thereby evaluating the actual blocking capacity of sunglasses. For the experimental evaluation, a single frame model will be analyzed across a sample of approximately five to ten participants exhibiting diverse facial morphological characteristics, alongside a parallel measurement using an ISO 18526-4 standardized headform (size M). This approach will enable the investigation of coverage variability associated with individual anatomical features and establish a direct comparison between standardized normative conditions and actual usage scenarios.

To achieve comprehensive mapping of exposure areas, the experimental apparatus will be expanded with the addition of three cameras positioned to capture the superior and inferior facial regions.

Currently configured as a benchtop platform for metrological research and laboratory validation, the system is projected to evolve into a practical tool suitable for deployment in commercial optical centers, industry trade fairs, public exhibitions, and scientific outreach initiatives as the research matures.

***Abstract*—Synthesizing non-acquired projections in digital breast tomosynthesis (DBT) could support acquisition protocols with fewer exposures, potentially reducing radiation dose and acquisition time. This work presents a preliminary, projection-domain evaluation of a geometry-guided deep learning architecture for intermediate-projection synthesis. The architecture combines a U-Net that estimates a per-pixel depth map, deterministic differentiable warping based on known acquisition angles and a parallax approximation, and a residual refinement U-Net. Training combines reconstruction, structural similarity, depth regularization, geometric consistency, and gradient-preservation losses. Experiments used 100 OpenVCT breast phantoms, divided into 80 for training, 10 for validation, and 10 for testing. Evaluation included comparison with linear blending and an ablation of the geometric consistency loss at two angular gaps. The original implementation yielded higher mean PSNR and SSIM than linear blending; however, its PSNR was not reproduced with a separately implemented pipeline, preventing a firm conclusion about the consistency of this advantage. In the reported ablation experiments, removing the geometric consistency loss yielded higher mean PSNR and SSIM at both gaps, providing no evidence of a benefit from this loss under the tested conditions. Estimated depth maps lacked physical validation, and mean geometric displacements remained subpixel. These preliminary results motivate further investigation of the architecture as an alternative for DBT projection synthesis, while its specific geometric contribution remains unresolved. Further evaluation should establish reproducibility and assess the impact on tomographic reconstruction before drawing conclusions about potential reductions in radiation dose or acquisition time.**

I. Introduction

Breast cancer remains one of the most frequently diagnosed cancers worldwide, motivating continuous improvements in screening and diagnostic imaging technologies [1]. Digital breast tomosynthesis (DBT) acquires multiple low-dose projections from different angular positions to reconstruct sectional planes of the breast, significantly reducing the anatomical superimposition inherent to conventional two-dimensional mammography [2], [3]. Clinical studies have demonstrated improvements in lesion detection rates and reductions in recall rates compared to standard digital mammography [4].

However, acquiring more projections involves a trade-off among image quality, angular range, and cumulative radiation dose [5]. One strategy to address this consists of acquiring a reduced subset of real projections, computationally synthesizing the intermediate views that were not acquired, and completing the set with these synthetic projections before tomographic reconstruction, thereby preserving angular sampling. Depending on how this protocol is implemented, it could in principle allow a reduction not only in radiation dose but also in acquisition time.

The present work, however, evaluates only the projection synthesis step of this proposal: it does not yet assess the effect of the synthesized projections on tomographic reconstruction, nor does it demonstrate an actual reduction in radiation dose or acquisition time. The application outlined above motivates this line of work, but should be distinguished from what is effectively evaluated in this article, which is restricted to the projection domain; extending the evaluation to reconstruction is left for future work (Section IV-A).

Costa et al. [6] explored this approach by adapting a residual refinement interpolation network (RRIN) [7]—originally de-

veloped for video frame interpolation and trained with a VGG-based perceptual loss—to generate a single intermediate DBT projection from two real neighboring projections. Two usage strategies were investigated: inserting synthetic projections between existing ones to increase angular sampling without additional exposure, and replacing part of the acquired set with synthetic projections to reduce dose and acquisition time—for instance, reconstructing from eight acquired and seven synthesized projections instead of acquiring all 15. Both the synthesized projections and the resulting reconstructions were evaluated on virtual phantoms, a physical anthropomorphic phantom, and clinical cases; the inclusion of synthetic projections improved the contrast-to-noise ratio (CNR) relative to the corresponding reduced sets and helped suppress reconstruction artifacts. However, the synthesized projections also exhibited blurring and a measurable increase in systematic bias relative to the real acquisitions, indicating that the interpolation network did not fully preserve fine structural detail.

The idea of completing a reduced projection set with synthetic projections before reconstruction has therefore already been investigated by Costa et al. [6]. The contribution of the present work lies in studying a different architecture to perform this synthesis step, motivated specifically by the blurring and systematic signal alterations described above.

The RRIN, like other video frame interpolation networks, infers displacement between frames without any explicit notion of acquisition geometry: an optical-flow-based interpolation network estimates the displacement directly from the two input images. In DBT, however, the detector and breast remain stationary while the X-ray source moves along a known trajectory, and internal structures at different depths are displaced by different amounts as the source position changes, following a relationship fully constrained by the known acquisition geometry [9]. This raises the question of whether explicitly incorporating this geometric information can better guide the synthesis process and help preserve such depth-dependent structures, compared to a video-oriented network with no access to it. Rather than conditioning on the angle implicitly, the proposed approach incorporates the acquisition geometry *explicitly* and *differentiably*: a U-Net estimates a per-pixel depth map, the displacements are computed from this depth map and the known acquisition angles via a deterministic geometric deformation, and a second U-Net performs residual refinement, analogous to geometry-integrated novel-view synthesis methods [10]. The formal parallax equation is introduced in Section II.

This work presents a preliminary, projection-domain evaluation of this alternative architecture. We cannot yet claim that it surpasses the RRIN or reduces blurring, as this would require a direct, matched-protocol comparison that was not performed here, since the two studies differ in data, training objective, and evaluation protocol; nor does this work yet assess the resulting effect on tomographic reconstruction, which Costa et al. [6] already investigated for their approach.

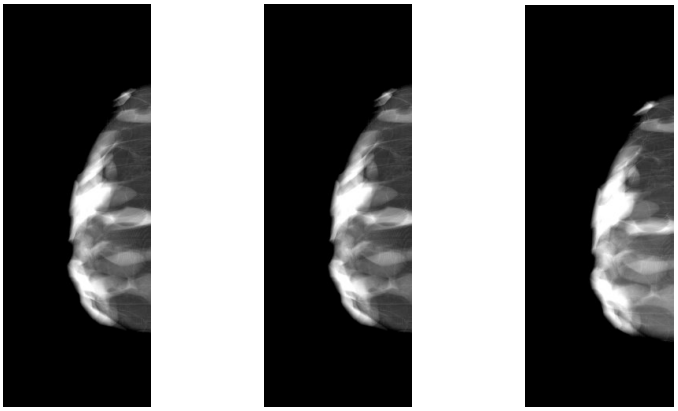
II. Materials and Methods

A. Dataset and Acquisition Geometry



One hundred virtual breast phantoms were generated using OpenVCT [11], simulating the acquisition protocol of the Hologic Selenia Dimensions® system. A virtual clinical trial platform was chosen over a physical DBT system because the acquisition geometry of physical equipment cannot be freely modified, whereas OpenVCT allows generating projections under any specified geometry. This makes it possible to know the exact acquisition angle of every projection and, in turn, to verify directly whether the proposed model is indeed making use of that geometric information, rather than relying on it being approximately recoverable from clinical metadata. Realistic quantum and electronic noise, characteristic of clinical DBT acquisitions, was added to each projection using the noise-insertion model provided by OpenVCT [11]. Each phantom comprises 15 DBT projections in DICOM format with dimensions of 4096×3328 pixels, 14-bit depth, and a pixel spacing of $p = 0.07$ mm (full detector resolution, without binning). Projections are distributed symmetrically over an arc of $\pm 7.49^\circ$ in uniform steps of 1.07°.

The exact acquisition angle θ_i for each projection i was computed from the known X-ray focal spot position (FS_x, FS_z) extracted from simulator metadata as:

$$\theta_i = \operatorname{atan2}(FS_x, FS_z). \tag{1}$$

Angles are reported in degrees for interpretation and converted to radians for trigonometric operations during geometric warping. It was empirically confirmed that parallax displacement occurs predominantly along the vertical axis (rows), consistent with the angular trajectory of the X-ray tube, as illustrated in Fig. 1. The dataset was partitioned into training, validation, and test sets (80/10/10) at the complete phantom level, preventing information leakage.

Fig. 2 shows three DBT projections from the same virtual breast phantom at different angular positions. The visible

spatial shifts across views are directly related to the depth-dependent parallax expressed in Eq. (2), motivating the explicit use of acquisition geometry during intermediate projection synthesis.

B. Preprocessing, Triplet Formation, and Patch Extraction

Each full-resolution projection was normalized from 16-bit unsigned integer to float32 in $[0, 1]$ using percentile-based intensity scaling (1st–99th percentiles), computed independently from each projection's own pixel values. During training, this includes the target projection P_{target}, which is available in the simulated dataset for supervision. In a real deployment scenario, however, P_{target} is by definition not acquired, so its own percentiles would not be available; in that case, the normalization scale would instead need to be derived from the two acquired neighboring projections (for instance, their average or interpolated percentiles). This practical aspect of the pipeline was not evaluated in the present work. Breast tissue was segmented from the background using Otsu thresholding.

Training samples were organized as ordered triplets $(P_{\text{before}}, P_{\text{target}}, P_{\text{after}})$, where P_{target} is the projection to be synthesized and P_{before}, P_{after} are its two neighboring projections at angular distance gap $\times\, 1.07^\circ$ from the target. For gap = 2, each neighboring projection is located 2.14° from the target,yielding an angular separation of 4.28° between the two input projections. For each phantom with 15 projections and gap = 2, valid target indices range from 2 to 12, resulting in 11 possible triplets per phantom.

Patches of 256×256 pixels were randomly sampled within the segmented breast region, requiring at least 90% tissue coverage. Three valid patches were extracted per triplet, yielding 2,640 training samples, 330 validation samples, and 330 test samples. Quantitative evaluation was performed on 328 test samples because the batch-wise evaluation procedure used batches of eight and discarded the final incomplete batch. As data augmentation, a random vertical flip was applied with probability 0.5, with simultaneous sign inversion of the associated angles—geometrically valid given the vertical direction of parallax.

Fig. 3 illustrates one training triplet with its associated acquisition angles.

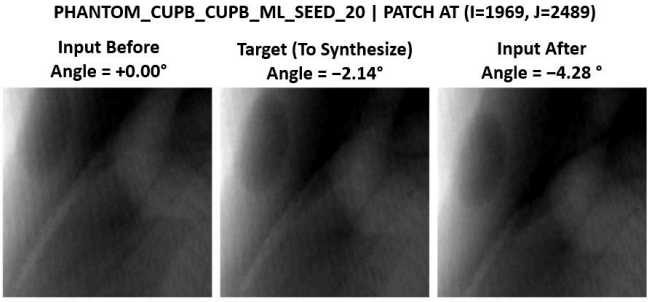

Fig. 3. Training triplet: neighboring input projections ("Input Before" and "Input After") and intermediate target projection ("Target"), with exact acquisition angles incorporated as geometric information. Source: Author's own elaboration from virtual phantoms simulated in OpenVCT.

C. Geometric Formulation

In DBT, the parallax displacement of a structure at depth z above the detector, when transitioning from angle θ_a to angle θ_b, is approximated by [9]:

$$\Delta_{\text{row}} \approx \frac{z}{p} \left(\tan \theta_b - \tan \theta_a \right), \tag{2}$$

where $p = 0.07\,\text{mm}$ is the pixel spacing. This relationship is analogous to the classical shift-and-add DBT reconstruction principle, repurposed here for projection synthesis. The displacement is purely vertical, consistent with the empirically confirmed direction of parallax.

D. Proposed Architecture

The model receives the two neighboring projections and the three acquisition angles associated with the before, after, and target views (θ_{before}, θ_{after}, θ_{target}), with spatial patch dimensions of 256×256 pixels. Stage 1 receives the two neighboring projection images, whereas Stage 3 receives the two warped views and their blend. The acquisition angles are not supplied as additional image channels to either U-Net; they are used in Stage 2 to compute the geometric shift via Eq. (2). The architecture operates in three sequential stages, illustrated in Fig. 4.

Stage 1 — Depth Network (learned): A U-Net [12] with a ResNet-18 encoder [13], randomly initialized (X-ray projections differ substantially from natural ImageNet images), estimates a per-pixel depth map bounded to $[0, 60]$ mm via scaled sigmoid activation, compatible with the simulated compressed breast thickness.

Stage 2 — Geometric Deformation (not learned): The estimated depth map and the exact acquisition angles are combined in (2) to compute a per-pixel vertical shift for each neighboring projection toward the target view. The deformation is implemented as differentiable bilinear sampling,

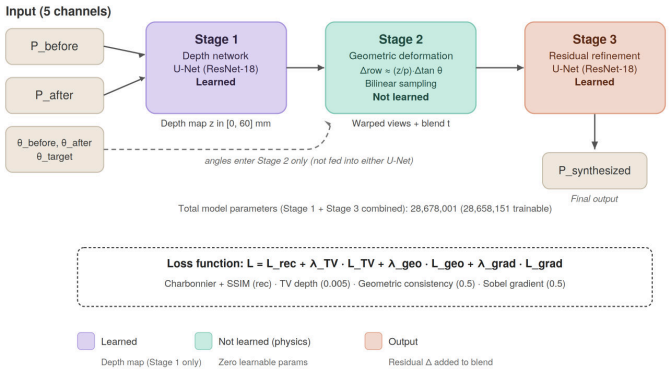

Fig. 4. Proposed three-stage architecture for DBT projection synthesis. Stage 1 (learned): U-Net depth estimator producing a per-pixel depth map. Stage 2 (not learned): deterministic geometric deformation using the DBT parallax equation and differentiable bilinear sampling. Stage 3 (learned): residual refinement U-Net producing the final synthesized projection. Source: Author's own elaboration.

allowing gradients to flow back to the depth network during training. The two warped views are blended by the relative angular position:

$$t = \frac{\theta_{\text{target}} - \theta_{\text{before}}}{\theta_{\text{after}} - \theta_{\text{before}}}. \tag{3}$$

This stage contains *no learnable parameters*.

Stage 3 — Residual Refinement (learned): A second U-Net with a ResNet-18 encoder receives the blended result and both warped views, predicting a residual correction added to the blend to produce the final synthesized projection. The model output includes the synthesized projection, the estimated depth map, and an auxiliary geometric consistency view used only during training. The complete model contains 28,678,001 parameters (28,658,151 trainable).

E. Loss Function

The total loss function is defined as:

$$\mathcal{L} = \mathcal{L}_{\text{rec}} + \lambda_{\text{TV}}\,\mathcal{L}_{\text{TV}} + \lambda_{\text{geo}}\,\mathcal{L}_{\text{geo}} + \lambda_{\text{grad}}\,\mathcal{L}_{\text{grad}}, \tag{4}$$

where weights were determined empirically through preliminary experiments on the validation set, evaluating PSNR over configurations in $[0.001,\ 0.1]$ for λ_{TV} and $[0.1,\ 1.0]$ for λ_{geo} and λ_{grad}.

$\mathcal{L}_{\text{rec}}$ combines Charbonnier loss—a smooth, pixel-wise L1 approximation robust to outliers, widely adopted in video frame interpolation networks [7], here averaged over all pixels—with structural similarity (SSIM) [8]:

$$\mathcal{L}_{\text{rec}} = \frac{1}{N}\sum_{i=1}^{N}\sqrt{(\hat{y}_i - y_i)^2 + \varepsilon^2} + 0.2\,(1 - \text{SSIM}(\hat{y},\, y)), \tag{5}$$

where i indexes the N pixels of the patch and $\varepsilon = 10^{-3}$.

$\mathcal{L}_{\text{TV}}$ penalizes high-frequency spatial noise in the depth map, computed as the mean of the absolute horizontal and vertical first-order differences of the estimated depth map, preventing warping artifacts ($\lambda_{\text{TV}} = 0.005$, chosen to regularize without suppressing spatial variation).

$\mathcal{L}_{\text{geo}}$ is the geometric consistency loss ($\lambda_{\text{geo}} = 0.5$): the "before" projection warped toward the "after" view is compared against the real "after" projection using the mean absolute error (L1), providing a spatially meaningful training signal intended to anchor the depth network's output to the acquisition geometry. Since the vertical warp (Section II-D, Stage 2) can require sampling positions outside the 256×256 patch near its top and bottom borders, the sampling row index is clamped to the valid range before bilinear interpolation, which effectively extends the nearest valid row rather than introducing padding or discarding those regions. The individual contribution of the $\mathcal{L}_{\text{geo}}$ term is quantified through an ablation study in Section III-A.

$\mathcal{L}_{\text{grad}}$ is a Sobel-based gradient loss ($\lambda_{\text{grad}} = 0.5$), computed as the mean absolute difference between the Sobel horizontal and vertical edge-magnitude maps of the real and synthesized projections, penalizing blurriness without requiring an external feature extractor network.

No additional normalization (e.g., rescaling each term to a common numerical range) is applied to the four terms in Eq. (4) beyond computing each of them as a mean over its respective per-pixel quantity, as detailed above; the λ weights were tuned empirically at this scale (Section II-E) to balance their relative contributions during training.

F. Experimental Design

The primary experiments were conducted with gap = 2, as defined in Section II-B; the study was later extended to gap = 3 and an additional quality metric (QILV) as part of the ablation study (Section III-A). A separate model was trained independently for each configuration analyzed in this work—one training run per combination of gap (2 or 3) and loss configuration (full loss, or with $\lambda_{\text{geo}} = 0$)—rather than a single shared network applied across gaps. The proposed model (gap = 2, full loss) was compared against a linear blending baseline—a weighted average of the two neighboring projections according to t in (3)—containing no learned components. Evaluation metrics were PSNR and SSIM [8], reported as mean ± standard deviation over 328 test samples, computed from 328 of the 330 available test patches; the batch-wise evaluation procedure discarded the final, incomplete batch of two patches, which was not necessary given that the metrics could equally be computed one patch at a time. Every training run used the Adam optimizer with an initial learning rate of 10^{-4}, batch size of 4, and a maximum of 60 epochs, with ReduceLROnPlateau (patience = 2, factor = 0.5) and EarlyStopping (patience = 5, best weights restored). The model reported in Table I converged at epoch 28; the independently trained instances used in the ablation study (Section III-A) were each trained under the same protocol but converged at their own, generally different, epochs, consistent with each being a separate training run rather than a continuation or reuse of the same weights.

III. Results

Table I presents the quantitative results for gap = 2 over 328 evaluated test samples. The proposed model achieved PSNR = 55.18 ± 7.01 dB and SSIM = 0.9939 ± 0.0052, surpassing the linear blending baseline by $+3.80$ dB in PSNR and $+0.0094$ in SSIM. Only methods evaluated under the same experimental protocol are reported.

TABLE I
IMAGE QUALITY METRICS ON THE TEST SET FOR GAP = 2 (2.14° PER NEIGHBORING PROJECTION RELATIVE TO THE TARGET AND A TOTAL ANGULAR SPAN OF 4.28°). RESULTS ARE REPORTED AS MEAN $\pm$ STANDARD DEVIATION OVER 328 EVALUATED SAMPLES.

Method	PSNR (dB)	SSIM
Linear blending baseline	51.38 ± 9.01	0.9845 ± 0.0135
Proposed model	$\mathbf{55.18 \pm 7.01}$	$\mathbf{0.9939 \pm 0.0052}$
Δ: $+3.80$ dB PSNR and $+0.0094$ SSIM.		

In addition to improving the mean PSNR and SSIM, the proposed model reduced the dispersion of the results. The PSNR standard deviation decreased from ± 9.01 dB for the linear blending baseline to ± 7.01 dB for the proposed model. This reduction indicates more consistent performance across the evaluated test samples, particularly in cases for which direct linear interpolation was less effective.

Fig. 5 presents two representative qualitative examples. The columns show the preceding neighboring projection, the corresponding real target, and the synthesized projection. The synthesized images reproduce the main global intensity distributions and tissue patterns observed in their corresponding target projections. Nevertheless, local differences, residual smoothing, and small spatial deviations remain visible.

For the model reported in Table I, the estimated depth values are concentrated within a narrow range of approximately 0–0.1 mm, several orders of magnitude below the physically expected 0–60 mm corresponding to the compressed breast thickness. Visual inspection of these maps, including contrast-enhanced renderings, did not reveal an interpretable anatomical or structural pattern; for this reason, depth map visualizations are not included in this work. The predicted values are therefore considered an internal, non-calibrated geometric representation generated by the depth branch to guide the deformation stage, rather than a physically interpretable depth estimate. This 0–0.1 mm range applies specifically to the model reported in Table I (gap = 2, full loss). The depth range was not consistent across the other training instances analyzed in the ablation study below (Section III-A): for gap = 2, the independently retrained full model exhibited a wider range of approximately 0–0.2 mm, while the ablated (no-$\mathcal{L}_{\text{geo}}$) model exhibited a substantially wider and more variable range, with per-batch minima and maxima observed between approximately 0 and 1.0 mm. The corresponding depth ranges for the two gap = 3 configurations were not systematically recorded. Given this variability, the resulting per-pixel vertical shift (Section III-A), rather than the raw depth magnitude, is used there as the more direct and comparable quantitative characterization of the geometric deformation actually applied in each case.

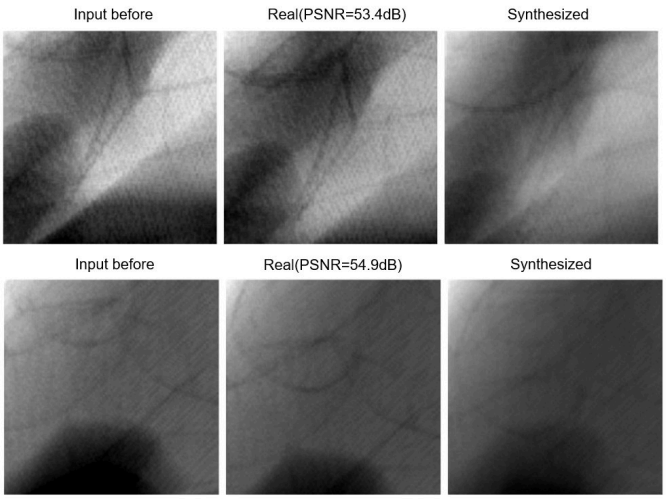

Fig. 5. Qualitative evaluation of intermediate DBT projection synthesis for two representative test cases. From left to right: preceding neighboring projection (Input before), corresponding real target, with the PSNR between the synthesized projection and the real target indicated in the panel header, and the synthesized projection. The synthesized images reproduce the main global intensity distributions and tissue patterns observed in their corresponding target projections; local differences and residual smoothing remain visible. Source: Author's own elaboration.

A. Ablation Study: Contribution of the Geometric Consistency Loss

To directly quantify the contribution of $\mathcal{L}_{\text{geo}}$, a second model was trained under identical conditions but with $\lambda_{\text{geo}} = 0$. This experiment was repeated for gap = 2 and gap = 3 (angular separation of 3.21° per neighboring projection, 6.42° total) to assess whether the contribution of this term scales with the expected parallax magnitude. Results are summarized in Table II. The full-model results for $\text{gap} = 2$ in Tables I and II were obtained using different code implementations. The original PSNR of 55.18 dB was not reproduced in the reconstructed pipeline, which yielded 49.63 dB for the full model reported in Table II. The cause of this discrepancy was not established. Therefore, the two tables should not be interpreted as directly comparable evaluations, and the advantage over linear blending reported in Table I remains specific to the original experiment. The ablation results are reported descriptively, without establishing robustness across implementations or training runs.

Contrary to the initial hypothesis, removing $\mathcal{L}_{\text{geo}}$ did not degrade PSNR or SSIM at either angular separation; the ablated model showed higher mean PSNR and SSIM than the full model at both angular separations tested (gap = 2: -0.74 dB in mean PSNR; gap = 3: -1.56 dB in mean PSNR; see Table II for the corresponding SSIM means). As the 328/264 evaluated patches are drawn from only 10 test phantoms and are therefore not fully independent observations (Section IV-A), these mean differences are reported descrip-

TABLE II

ABLATION OF THE GEOMETRIC CONSISTENCY LOSS ($\mathcal{L}_{\text{GEO}}$) ACROSS TWO ANGULAR SEPARATIONS. "SHIFT" DENOTES THE MEAN ABSOLUTE PER-PIXEL VERTICAL DISPLACEMENT APPLIED BY STAGE 2 (SECTION II-D) WHEN WARPING THE "BEFORE" NEIGHBORING PROJECTION TOWARD THE TARGET VIEW; THE DISPLACEMENT APPLIED TO THE "AFTER" NEIGHBOR IS OF COMPARABLE MAGNITUDE, BY SYMMETRY OF THE GAP-BASED SAMPLING, AND IS NOT REPORTED SEPARATELY.

Gap	Method	PSNR (dB)	SSIM	Shift (px)
2 (n=328)	Full ($\mathcal{L}_{\text{geo}}$)	49.63 ± 4.41	0.9921 ± 0.0039	0.06
2 (n=328)	No $\mathcal{L}_{\text{geo}}$	50.37 ± 2.48	0.9924 ± 0.0036	0.41
3 (n=264)	Full ($\mathcal{L}_{\text{geo}}$)	47.19 ± 5.18	0.9885 ± 0.0070	0.31
3 (n=264)	No $\mathcal{L}_{\text{geo}}$	48.75 ± 2.37	0.9899 ± 0.0048	0.37

tively, without a formal significance test. An analysis of the per-pixel vertical displacement actually applied by Stage 2 (Section II-D) showed that, although this displacement grew with gap as expected from Eq. (2) (mean shift increasing from 0.06 to 0.31 px for the full model), its mean remained sub-pixel in every configuration tested. This mean does not imply that every individual displacement was sub-pixel: for gap = 2, the 95th-percentile and maximum displacement were 0.08 px and 0.09 px for the full model, and 0.43 px and 0.53 px for the ablated model (the corresponding percentiles were not computed for gap = 3). Under such small typical displacements, the warped views fed into Stage 3 are nearly identical to the unwarped inputs (mean absolute difference < 0.0004 on the $[0, 1]$ intensity scale), which is consistent with, but does not by itself establish, the hypothesis that the residual refinement stage accounts for most of the reconstruction quality observed independently of $\mathcal{L}_{\text{geo}}$.

As a consistency check on the units and degree-to-radian and depth-to-pixel conversions used in Eq. (2), a depth of $z = 0.1$ mm at gap = 2 ($\Delta\theta = 2.14°$ between a neighboring projection and the target) yields a predicted shift of $(z/p)\tan(\Delta\theta) \approx (0.1/0.07) \times \tan(2.14°) \approx 0.053$ px. This is consistent, to within the same order of magnitude, with the 0.06 px mean shift observed for the full model at gap = 2 given its ∼0–0.2 mm depth range noted above. Applying the same relation in reverse, the ablated model's larger 0.41 px mean shift at gap = 2 implies a mean depth on the order of 0.4–0.8 mm, consistent with the wider, higher depth range (∼0–1.0 mm) separately observed for that model. This agreement supports that the degree-to-radian conversion and the depth-to-pixel scaling by $1/p$ in the sampling coordinates are implemented correctly. This ablation isolates only the contribution of the $\mathcal{L}_{\text{geo}}$ loss term to training; the geometric deformation module (Stage 2) remains active with or without this loss, since the depth network continues to estimate depth and drive the warp in both configurations. Whether removing the deformation module itself—rather than only the loss term that partly shapes it—would change the results, and whether Stage 3 alone would perform comparably given only the unwarped neighboring projections, were not tested here and are identified as open questions for future work (Section IV-A). As an additional, loss-independent quality metric, the Quality Index based on Local Variance (QILV) [14] was computed for gap = 2, yielding 0.9994 ± 0.0024 for the full model and 0.9997 ± 0.0012 for the ablated model. Both values are close to the maximum of 1, and the small difference between them is in the same direction as the PSNR/SSIM trend above; however, given how close both values already are to 1, this difference should not be interpreted as evidence that either configuration better preserves fine structures, only as being broadly consistent with the direction of the PSNR/SSIM comparison.

IV. DISCUSSION

The proposed model surpassed the linear-blending baseline for gap = 2 (Table I), consistent with the motivating hypothesis that incorporating the acquisition geometry could better guide the synthesis process (Section I) — through a learned depth map, a deterministic parallax-based deformation, and a residual refinement stage. This contrasts with the limitations reported by Costa et al. [6]: their RRIN-based approach, trained without explicit access to the acquisition geometry, exhibited blurring and a measurable increase in systematic bias relative to the real acquisitions (Section I). However, this comparison to the baseline does not by itself establish that the geometric mechanism specifically, as opposed to the additional network capacity introduced by the depth and refinement U-Nets, is responsible for the observed gain; the ablation study in Section III-A showed no measurable benefit from the geometric consistency loss $\mathcal{L}_{\text{geo}}$ specifically, for either gap = 2 or gap = 3. This indicates that this specific loss term does not account for the observed advantage over linear blending; whether that advantage instead reflects the architecture's overall capacity (the depth-driven warping and residual refinement stages acting together), the residual refinement stage alone irrespective of the geometric warp, or some combination of these, was not isolated in this work and remains an open question (Section IV-A).

For reference, Costa et al. [6] reported PSNR = 57.28 dB and SSIM = 0.9981 for RRIN-interpolated projections in their virtual-phantom evaluation. These values are not directly comparable to those in Table I: beyond the noise-free synthetic reference used in that evaluation—versus the simulated projections with realistic quantum and electronic noise used as reference here, generated by OpenVCT and not acquired from patients—the two studies also differ in network architecture, training objective (a VGG-based perceptual loss versus the geometry-aware loss in Eq. (4)), dataset, and patch/evaluation protocol. Consequently, no single factor, including the noise characteristics of the reference, should be assumed to fully account for the numerical gap between the two results.

Regarding the estimated depth values, the raw predicted magnitudes remain far below the physically expected 0–60 mm range corresponding to the compressed breast thickness. Since the estimated depth enters Eq. (2) multiplicatively, a predicted depth close to zero necessarily yields a correspondingly small geometric deformation. Describing these values as an internal,

non-calibrated representation does not fully resolve this discrepancy, since they are not merely an abstract intermediate feature: they are substituted directly into Eq. (2), which interprets them as a physical depth in millimeters to compute the warp. Part of the difficulty may also lie in the depth representation itself, rather than only in training: each pixel of an X-ray projection integrates contributions from structures located at multiple depths along the beam path, so representing this with a single scalar depth per pixel is an approximation that may not admit an unambiguous physical value even for a well-trained network. Visual inspection, including contrast-enhanced renderings, did not reveal a physically interpretable or visually coherent pattern, indicating that the depth branch does not yet learn a calibrated anatomical representation, whether due to insufficient training signal, this representational limitation, or both. The ablation study (Section III-A) further showed that, at these magnitudes, the resulting geometric warp is sub-pixel on average regardless of whether $\mathcal{L}_{\text{geo}}$ is used, consistent with, though not sufficient on its own to establish, the interpretation that Stage 2 contributes only a minor perturbation relative to the original inputs and most of the reconstruction quality is attributable to the residual refinement stage (Stage 3). Stronger depth supervision, for instance using the inter-projection parallax displacement as pseudo-ground-truth, remains a direction worth exploring to anchor the depth branch's output closer to physically meaningful magnitudes; however, given the multi-depth integration described above, it is not guaranteed that such supervision alone would yield anatomically accurate, per-pixel depth estimates, and this should be verified rather than assumed.

The two qualitative examples in Fig. 5 (PSNR of 53.4 dB and 54.9 dB) fall close to the overall test-set mean (55.18 ± 7.01 dB), suggesting these particular cases are not unusually favorable; however, two examples close to the mean do not by themselves characterize the full range of behaviors observed across the test set—in particular, they do not illustrate the higher-dispersion tail reflected in the ± 7.01 dB standard deviation, nor a direct qualitative comparison against the linear-blending baseline at the same locations. In both examples shown, the synthesized projection reproduces the coarse tissue structure and global contrast of the real target; the visible residual smoothing is concentrated around fine, high-frequency structures (thin fibroglandular strands and tissue boundaries), consistent with, though not conclusively demonstrating, the sub-pixel geometric displacement discussed above and the reconstruction burden falling mainly on the residual refinement stage.

A. Limitations

The following limitations should be kept in mind when interpreting the results above:

- **Simulated data only.** All projections come from virtual breast phantoms generated with OpenVCT [11]; no clinical or physical phantom images were used.
- **Evaluation restricted to the 2D projection domain.** The clinically most relevant validation requires assessing the impact on 3D reconstruction quality (e.g., CNR on reconstructed slices), following the methodology of Costa et al. [6]; this was not performed here.
- **Evaluation performed on patches, not full projections.** Quantitative evaluation was carried out on randomly sampled 256×256 patches (Section II-B) rather than on full-resolution (4096×3328) projections; whether the model performs consistently across an entire projection, including larger-scale artifacts or inconsistencies at patch boundaries when patches are reassembled, was not evaluated.
- **Test set limited to 10 phantoms.** The 328 (gap = 2) and 264 (gap = 3) evaluated patches are drawn from only 10 held-out phantoms, so patches sharing a phantom are not statistically independent observations. For this reason, the ablation comparison (Section III-A) is reported descriptively, as mean and standard deviation over patches, without a formal significance test; a phantom-level analysis—computing the mean difference between methods for each of the 10 phantoms individually, then testing at that level—should be performed before drawing stronger conclusions from these averages. Furthermore, comparing many patches produced by two trained networks characterizes the difference between those two specific training runs, but does not by itself substitute for assessing run-to-run variability (e.g., across repeated trainings with different random initializations), which was not evaluated here.
- **Depth map without physical validation.** The estimated depth values, while bounded to the $[0, 60]$ mm range by construction (Section II-D), are concentrated implausibly close to zero rather than spanning the physically expected range for the compressed breast thickness (Section III), and have not been validated against any physical ground truth. It remains unclear whether this stems from insufficient training signal, from representing a multi-depth beam path with a single scalar per pixel, or both.
- **Contribution of the deformation module not yet isolated.** The ablation study (Section III-A) removed only the geometric consistency loss $\mathcal{L}_{\text{geo}}$; the deformation module (Stage 2) remained active in both configurations. Whether removing Stage 2 entirely would change the results was not tested.

V. Conclusions

This work presented a preliminary, projection-domain evaluation of a geometry-guided architecture for DBT intermediate-projection synthesis. As an alternative to the RRIN-based approach investigated by Costa et al. [6], the proposed method combines a learned depth map with known acquisition angles to perform deterministic, differentiable warping, followed by residual refinement. No direct comparison with RRIN was performed.

The original implementation yielded higher mean PSNR and SSIM than linear blending (Table I). However, the full-model results in that comparison and in the ablation study were

obtained using different code implementations, and the original PSNR was not reproduced in the reconstructed pipeline. Consequently, the reported advantage over linear blending should be interpreted as an observation from the original experiment, rather than an established, reproducible gain. The discrepancy cannot be attributed to training variability alone on the available evidence.

In the reported ablation experiments, removing the geometric consistency loss ($\mathcal{L}_{\text{geo}}$) yielded higher mean PSNR and SSIM at both tested angular gaps, and higher mean QILV at $\text{gap} = 2$ (Section III-A). These descriptive results did not establish a benefit from this loss term under the tested conditions. Because the geometric warping module remained active in both configurations, its contribution was not isolated. The lack of physically validated depth estimates and the small mean geometric displacements further limit conclusions about the role of geometric guidance.

Future work should first establish a unified, reproducible implementation and evaluation protocol. Subsequent experiments will assess the contribution of the warping module, investigate depth supervision and calibration, and compare the architecture with RRIN under matched conditions. Evaluation will also extend to clinical images and tomographic reconstructions, comparing reduced acquisition sets, reduced sets completed with synthetic projections, and full reference sets.

These preliminary, projection-domain findings motivate further investigation of the proposed architecture as an alternative for DBT projection synthesis. Its impact on tomographic reconstruction and its potential to support reductions in radiation dose and acquisition time remain to be established.

***Abstract*—Radiomics extracts quantitative data from medical images and can be used to identify habitats inside tumours, but the lack of reproducibility and of standardisation is still a frequent problem in these studies, which often lack the support needed to reproduce their results. This work implements a habitat clustering algorithm and documents how the sigma of the Gaussian filter, the window size, the radius of the closing structuring element and the step of the sliding window affect the results. The *pipeline* resamples the images to isotropic voxels, selects blocks of voxels through a regular *grid*, extracts 17 first-order and 11 texture (GLCM) features from each block and groups the blocks by K-means into three *clusters*. Thirteen configurations, varying one parameter at a time, were applied to four rectal cancer cases (T2-weighted MRI) and compared with the reference configuration through the adjusted Rand index, the habitat proportions, the visual appearance and the execution time. Larger sigma values produced more homogeneous regions with less detail; larger windows reduced detail and coverage, and one of the cases had no valid supervoxels with the largest window; larger radii favoured the most abundant habitats; and a step larger than the window produced gaps in coverage, although varying the step was what most reduced the execution time. The parameter values are not generalisable, but the qualitative behaviour tends to hold, as it is a geometric effect of the method. The code is publicly available, and the stability and robustness of the features still need to be verified.**

***Index Terms*—habitat imaging, habitat analysis, tumour subregions, radiomics, intratumoral heterogeneity**

Ethics statement: the images used were previously acquired and the study was approved by the Research Ethics Committee of ICESP, under opinion CEP No. 1736/20, approved in June 2020.

I. Introduction

Rectal cancer is a malignant tumour that develops in the rectum, the final portion of the gastrointestinal tract responsible for storing faeces and for evacuation. After acquisition and segmentation, the images must be processed so that the data they carry are turned into information.

Segmentation separates distinct regions of the image, delimiting regions or volumes of interest (ROI and VOI) that help define therapeutic strategies [1], [4], [5]. It can be manual, semi-automatic or automatic, and the latter two reduce the intra- and inter-observer biases inherent to the manual method [1]–[3]. In modalities that produce volumetric data, such as CT, MRI and PET-CT, segmentation can be three-dimensional. This article focuses on magnetic resonance images of rectal cancer, with manual segmentation of the tumour.

After segmentation, filtering prepares the image for the application of other algorithms and is widely used in computer vision to reduce noise [6]. Magnetic resonance images contain Rician noise [7], which tends towards a Gaussian distribution as the signal-to-noise ratio increases; for this reason, Gaussian filters are widely used in this modality, including optimised versions such as the bilateral filter [8]. Filtering also favours the extraction of radiomic features [9], [10]. Another preprocessing stage is the application of structuring elements, for example, to masks, reducing the gaps or holes that hinder the extraction of radiomic features; to this end, the closing

operation is applied, which combines a dilation followed by an erosion [12].

Tumours are heterogeneous and present sub-regions, called habitats, which differ from one another in ways that are not visible to the naked eye [1], [16] and whose identification relies on radiomics [9], [13], [14]. Radiomics is a set of computational methods for extracting quantitative data from medical images, and habitat radiomics identifies these sub-regions of lesions by means of radiomic and clustering methods [15], revealing heterogeneous regions within the segmented area. One of the most widely used algorithms for forming the *clusters* is K-means, an unsupervised clustering method.

However, reproducibility, standardisation and validation are still reported as problems in radiomics studies [9], [14], [17], which also face difficulties in being applied in daily clinical practice. Moreover, the habitat results depend on the parameters and on the pre-processing operations applied to the images.

II. Methodology

A. Materials and Tools

The code was run locally in Python, in VS Code, on a Samsung Galaxy Book 4 notebook. The images were provided by ICESP (Instituto do Câncer de São Paulo). Gemini and Claude assisted in the organisation, the writing and the coding, in a strictly supportive role, with the critical reading of the articles and the final writing remaining the responsibility of the authors. Table I details the tools, the execution environment and the versions of the libraries.

TABLE I
TOOLS AND *software* ENVIRONMENT USED FOR THE DEVELOPMENT OF THE WORK.

Tool / Material	**Description**
Samsung Galaxy Book 4	Intel Core i7-1355U (13$^{\text{th}}$ generation). 512 GB SSD. 16 GB of RAM. Intel Iris Xe graphics.
Operating system	Windows 11, *build* 10.0.26200 (SP0)
VS Code	Version 1.117.0
ITK-SNAP	Version 4.0.2
Python	3.14.3 (MSC v.1944 64 bit / AMD64). Libraries: NumPy 2.4.6; SciPy 1.17.1; scikit-learn 1.9.0; matplotlib 3.10.9; pandas 3.0.3; SimpleITK 2.5.5.

B. Objective

The objective is to evaluate how changes in the window size, in the step, in the size of the closing sphere and in the sigma of the Gaussian filter affect the habitat formation algorithm, making explicit how much the results depend on the pre-processing stages and providing implementation details that frequently do not accompany radiomics studies.

C. Procedures

1) Image acquisition: After approval by the ethics committee, four sets of magnetic resonance images of rectal cancer were selected, all previously segmented and obtained with the same equipment model, the Signa HDx 1.5T (GE Healthcare, Chicago, IL, USA), and the same acquisition protocols. The sequences were T2-weighted (T2WI), with 3 mm thick slices. Further details are given in Table II.

2) Method for the Identification of Tumour Habitats: The method combines the extraction of radiomic features and K-means clustering, which uses these quantitative values to group the voxels. The number of clusters was fixed at $k = 3$ after clustering tests with the `calinski_harabasz` and `davies_bouldin` metrics [18]; all the calculated values for the metrics are given in Table III. This value was also adopted by another study to evaluate tumour sub-regions [1].

TABLE III
CLUSTER EVALUATION METRICS FOR THE DEFINITION OF THE NUMBER OF CLUSTERS. VALUES IN BOLD INDICATE THE BEST RESULT OF EACH METRIC. FOR `DAVIES_BOULDIN`, THE LOWER THE VALUE, THE BETTER THE SEPARATION OF THE GROUPS; FOR `CALINSKI_HARABASZ`, THE HIGHER THE VALUE, THE BETTER THE SEPARATION.

Metric	$k = 2$	$k = 3$	$k = 4$	$k = 5$
`davies_bouldin`	1.84	**1.45**	1.49	1.62
`calinski_harabasz`	131,937	**154,654**	125,050	115,253

The algorithm was organised into a *pipeline* (Fig. 1) with the stages of pre-processing, supervoxel selection, feature extraction, clustering and visualisation.

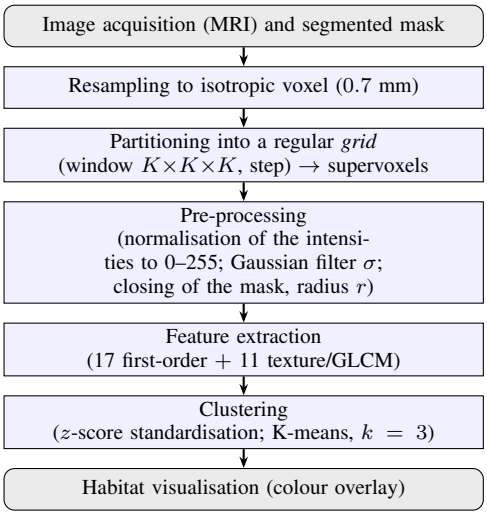

Fig. 1. Stages of the implemented regular-*grid* habitat formation *pipeline*.

In the pre-processing, the image is smoothed by a Gaussian filter (`sigma`) and the mask undergoes morphological closing with a spherical structuring element, being then applied to the image before the feature extraction. Isotropic resampling is also performed, which can be of $1 \times 1 \times 1$ mm [20]–[22]; however, $0.7 \times 0.7 \times 0.7$ mm was chosen so as not to impair the quality of the images, which, being of high resolution, took on a pixelated appearance.

In the supervoxel selection, a cubic $K\times K\times K$ window traverses the volume with a defined step; each block entirely

CHARACTERISTICS OF THE IMAGE SETS, MAGNETIC RESONANCE ACQUISITION PARAMETERS AND PRE-PROCESSING APPLIED.

Item	**Sagittal projection**	**Axial projection**
Acquisition		
Tumour type (histology/ staging)	Rectal cancer; no histological data; locoregional staging.	
Equipment and magnetic field	Signa HDx 1.5 T (GE Healthcare, Chicago, IL, USA).	
Weighting	T2-weighted (T2WI)	
Sequence	FRFSE	FRFSE
TR (ms)	3317	3184
TE (ms)	120	105
Slice thickness (mm)	3	3
Gap	0	0
Matrix	256×256	256×256
Number of signals acquired	6	8
FOV (cm^2)	20–24	16
Bandwidth (kHz)	50	31.25
In-plane spacing	0.3 mm.	
Scanner across cases	Same model and same manufacturer.	
Segmentation and pre-processing		
Origin of the manual mask	Manual delineation in ITK-SNAP, version 4.0.2	
Registration between sequences	Not applied.	
Normalisation of intensities and of the *features*	The intensities are rescaled to the range of 0 to 255 gray levels and the z-score is applied to the extracted features, before the clustering	
Resampling	Resampling to an isotropic spacing of 0.7 mm (SimpleITK), with linear interpolation for the image and nearest neighbour for the mask, on the same grid.	
Lesion volume	Case 1 (32.07 cm³), Case 2 (19.97 cm³), Case 3 (6.23 cm³), Case 4 (4.60 cm³).	

contained within the mask and without null values is considered valid, and the coordinates of its voxels are stored. Only the voxels in the interior of the volume (with a complete $3\times3\times3$ neighbourhood) are considered in the computation of the features, with the border voxels being discarded, as well as the blocks that do not gather at least K^3 non-null voxels.

For each supervoxel, 17 first-order features and 11 texture features derived from the gray-level co-occurrence matrix (GLCM) are computed, detailed in Table IV [9], [19]; the GLCM is obtained in a $3\times3\times3$ neighbourhood around each voxel, with local quantisation into 8 levels and 13 directions. The functions were implemented manually based on the PyRadiomics documentation [11], without the use of the library owing to its lack of maintenance, and part of the construction of the GLCM was based on [19].

In the clustering, the features of the four cases are concatenated, standardised (z-score) and grouped together by K-means with $k = 3$; since the concatenation takes place before the grouping, there is habitat correspondence within the same run, and each label receives a colour. Table V gathers the parameters and the configuration used in the code.

The division of the image into regular *grids* is only a precursor of supervoxels, and many articles do not use this term for these blocks; nevertheless, since they play the same role (in the sense of *oversegmentation*), they will be referred to, for simplicity, as supervoxels throughout the work.

TABLE IV
FIRST- AND SECOND-ORDER FEATURES EXTRACTED FROM EACH SUPERVOXEL.

# First Order	**# Second Order (GLCM)**
1 `mean`	18 `asm`
2 `std_dev`	19 `glcm_entropy`
3 `median`	20 `contrast`

3) Varied parameters: The extraction of the *features* and the formation of the habitats were performed 13 times, each with a distinct set of parameters, and one slice

TABLE V
PARAMETERS AND CONFIGURATIONS USED IN THE CODE.

Parameter / Item	Value	Description
Partitioning and pre-processing		
`kernel_size`	3	Supervoxel size ($3 \times 3 \times 3 = 27$ voxels).
`step`	1	Step of the sliding window in the block partitioning (step $<$ *kernel* produces overlap).
`sigma`	0.4	Sigma of the Gaussian filter applied to the image before the extraction.
`closing_radius`	1	Radius of the sphere of the morphological closing of the mask.
`iterations`	1	Number of iterations of the morphological closing.
`novo_spacing`	0.7 mm	Isotropic spacing ($x = y = z$) of the resampling.
`normalizar`	`True`	Rescaling of the intensities to the range of 0 to 255 gray levels.
Feature extraction		
Families extracted	17 + 11	First order (17 features) and GLCM texture (11 features)
`n_levels` (GLCM)	8	Gray levels in the local quantisation of the GLCM.
Clustering		
normalisation	*z-score*	Applied to the features before the clustering (mean = 0, standard deviation = 1).
`n_clusters` (k)	3	Number of habitats.
initialisation	`k-means++`	Default of `scikit-learn`.
`n_init`	10	Number of initialisations (restarts) of K-means.
`max_iter`	300	Maximum number of iterations per K-means initialisation.
`random_state`	42	Seed for reproducibility.

was chosen for the visualisation of each configuration. The reference configuration uses `sigma=0.4`, `kernel=3`, `closing_radius=1` and `step=1`, and only one parameter was varied at a time. Table VI summarises, for each set, the varied parameter, its description and the values used.

TABLE VI
TEST SETS: VARIED PARAMETER. IN EACH SET ONLY ONE PARAMETER IS VARIED; THE OTHERS REMAIN AT THE REFERENCE CONFIGURATION (`SIGMA=0.4`, `KERNEL=3`, `CLOSING_RADIUS=1`, `STEP=1`).

Set	Parameter	Brief description	Values
1	Filtering	Gaussian filter.	sigma = 0.2; 0.4; 0.8; 1
2	Window	Size of the $K \times K \times K$ block in the voxel selection.	3x3x3; 5x5x5; 7x7x7; 9x9x9
3	Structuring element	Radius of the spherical closing element.	radius = 1; 2; 3; 4
4	Step	Displacement of the window.	step = 1; 2; 3; 4

4) Metrics applied: The comparison with the reference configuration was performed with the adjusted Rand index and the variation of volume and proportions and the visual appearance of the habitats were also evaluated.

III. RESULTS

All 13 runs can be seen in Fig. 2. The colours in the images correspond within the same run, because the cases were clustered together, but different runs do not present this correspondence among themselves. In this figure, the visual effect of the parameter variation and its impact on the habitats were evaluated.

Increasing the sigma resulted in more homogeneous areas within each habitat, which captured less detail, and this affected the adjusted Rand index values (Fig. 3). The highest values were obtained for sigma = 0.2 (0.74–0.87) and the lowest for sigma = 1 (0.35–0.61). Varying the window size reduced the detail of the images, but cases 1 and 2 were less affected than the others, probably because they have more voxels. The highest values were obtained for the $5\times5\times5$ window (0.15–0.55) and the lowest for $9\times9\times9$ (0.11–0.32), and case 4 did not present valid supervoxels with this size. Increasing the radius of the closing element prioritised the most abundant habitats, as shown in Fig. 4: as the radius increases, the bars tend to present only two habitats. The highest values were obtained for radius = 2 (0.36–0.58) and the lowest for radius = 4 (0.32–0.54), but the indices were close among the three radii tested, not counting the reference one. In the step variation, the results were good for step = 2 and step = 3, despite the variations in the adjusted Rand index. The drop was more pronounced for step = 4, which, being larger than the default $3\times3\times3$ window, produced gaps in the images, as shown in Fig. 2.

Table VII shows the execution time of the 13 configurations. Varying the step was what most reduced the execution time, and varying the radius of the structuring element was what least affected it. In the window variation, the time peaks at $5\times5\times5$ (1219.3 s) and falls at $7\times7\times7$ and $9\times9\times9$, since larger windows accept fewer blocks.

IV. DISCUSSION

This work presented a tumour habitat formation algorithm based on a regular *grid* of voxels, on the extraction of first-order and texture radiomic features and on K-means clustering, evaluating the effect of four parameters: the sigma of the

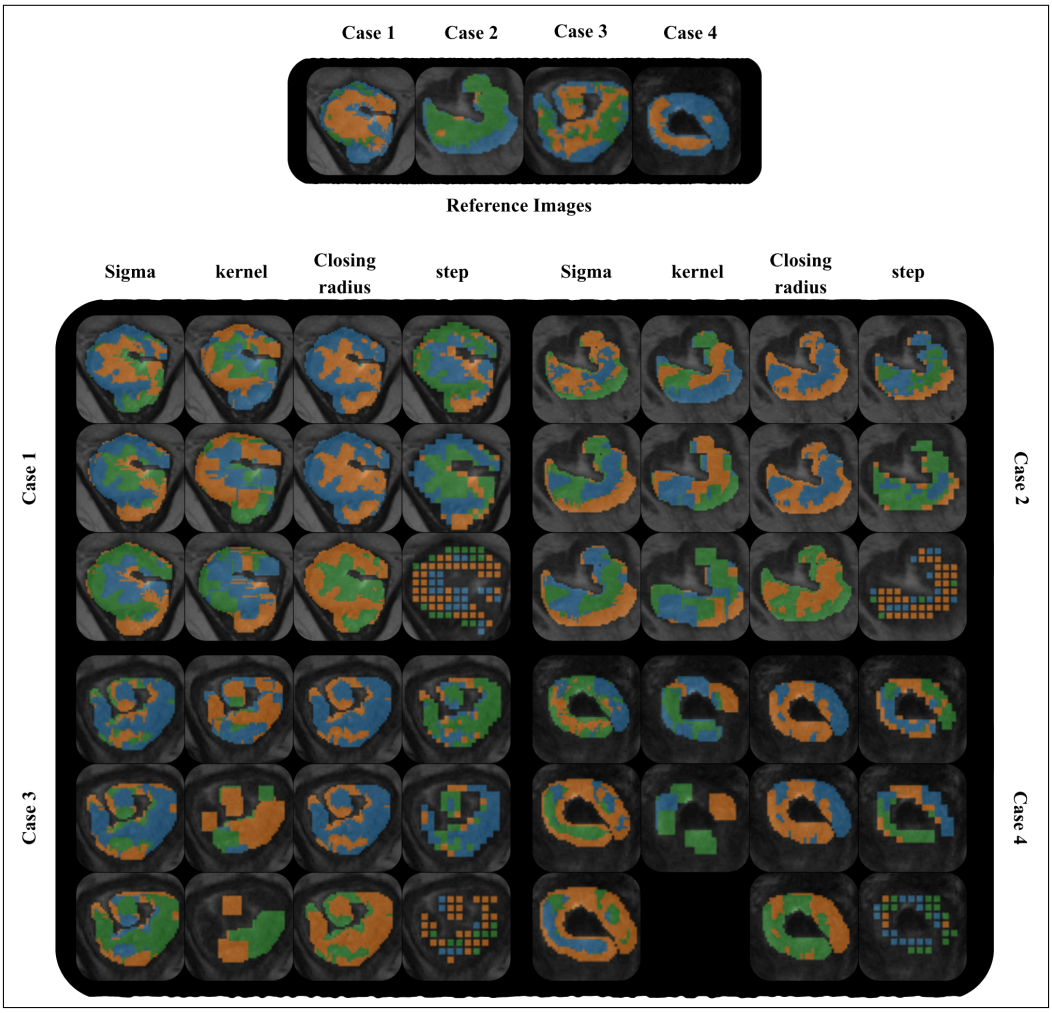

Fig. 2. Visual habitat results for the variations of the sigma, the window, the structuring element radius and the step. The cases are separated into four blocks, and the images at the top correspond to the reference configuration of each case. In each block, the first column shows the variations of the sigma (0.2, 0.4, 0.8 and 1); the second, the window dimensions (5×5×5, 7×7×7 and 9×9×9); the third, the closing radius (2, 3 and 4); and the fourth, the step (2, 3 and 4).

TABLE VII
EXECUTION TIME OF EACH CONFIGURATION. IN EACH SET ONLY ONE PARAMETER IS VARIED RELATIVE TO THE REFERENCE CONFIGURATION (`SIGMA=0.4`, `KERNEL=3`, `CLOSING_RADIUS=1`, `STEP=1`); THE OTHERS REMAIN AT THE REFERENCE VALUES.

Varied parameter	**Value (time in s)**		
Reference	531.6		
Sigma	0.2 (717.4)	0.8 (1286.4)	1 (1707.3)
Window	5 (1219.3)	7 (1013.6)	9 (800.7)
Radius	2 (613.9)	3 (581.8)	4 (667.4)
Step	2 (333.4)	3 (313.0)	4 (243.6)

Gaussian filter, the window size, the radius of the closing structuring element and the step of the sliding window. The tests were performed on four rectal MRI cases from a single institution, acquired with the protocol described in Table II. Since the features of the four cases are concatenated before the clustering, all the cases of a given run share the same centroids, so that no displacement of the centroids occurs from one case to another and the habitats are directly comparable within that run.

A. Filtering

Filtering is necessary to prevent the features from being computed over the noise of the image, but, in excess, it can reduce the information present. Thus, very noisy images may lose diagnostic potential if they cannot be filtered without a loss of relevant information. The results showed this effect, with a slight loss of detail as the sigma increased.

B. Window

The code requires all the values inside the window to be greater than zero (`np.all(current_mask > 0)`), that is, the whole block must lie inside the mask, which has already undergone the closing, in order to avoid gaps. Therefore, the number of accepted blocks decreases as the *kernel* grows, since requiring a large cube (7×7×7) to lie entirely inside the mask is more restrictive than accepting a small one (3×3×3). In very

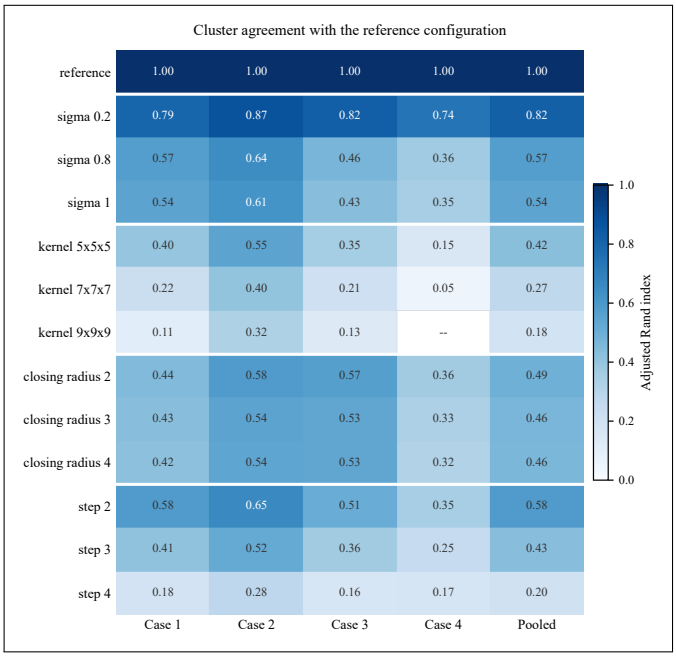

Fig. 3. Adjusted Rand index (ARI) between each configuration and the reference configuration ($\sigma = 0.4$; window $3\times3\times3$; radius 1; step 1). Each row is a configuration and each column is a case; the last column brings the pooled ARI, computed over the voxels of all the cases concatenated. The first row is the reference compared with itself. Cells without a value indicate configurations that did not generate any block in that case. The ARI is invariant to the permutation of the labels, so that the comparison does not depend on which colour was assigned to each habitat.

small masks, large windows may generate few or no blocks, as the images show: larger tumours had enough elements for windows of up to $7\times7\times7$ to return results, which did not occur in the smaller ones. The window size may also interfere with the computation of the features, which must be taken into account, since some slices presented regions that "changed" habitat, something that does not happen biologically.

C. Closing structuring element

The closing fills the holes formed in the mask by non-segmented regions along the volume, allowing more voxels to be processed and avoiding the discarding of groups owing to null values between one slice and its neighbours in the z direction. The images show that the shape of the tumour varies between the slices and, if the mask has many gaps or is very irregular, the operation may not be sufficient to include a good number of voxels in the analysis. In these cases, or if the mask was not well made, it may be worth redoing the segmentation in order to allow the use of smaller structuring elements.

D. Step

The choice of the step must be based mainly on the dimensions of the window *kernel*, in order to avoid gaps in the voxel coverage, and, indirectly, on the size of the tumour. Overlap may occur, since only the central voxels receive the K-means classification and, depending on the step, more than one voxel may receive the classification of the same block.

- Step $<$ *kernel* dimension $\rightarrow$ the blocks overlap, and the last block that passed over a voxel "wins" the overlap, assigning its K-means label to that voxel.
- Step $=$ *kernel* dimension $\rightarrow$ the blocks touch without overlap and without gaps, with perfect coverage in the *array* (each voxel belongs, or belonged, to only one block).
- Step $>$ *kernel* dimension $\rightarrow$ the blocks become separated and gaps appear. In order to use a step larger than K (the dimension of the sliding window), it may be necessary to apply an interpolation, such as *nearest neighbor* or linear [28].

The sigma and the radius preserve the number of voxels evaluated, and their main effect is the loss of information, that is, the reduction of the level of detail of the habitats. The window and the step, on the other hand, reduce the total number of voxels evaluated: increasing the window leaves many portions of the image without coverage, especially in the smaller cases, whereas increasing the step reasonably preserves the composition, although the subsampling may reduce the available information for large values.

E. Execution time

The execution times reported in Table VII are specific to this implementation, but what is interpretable is the relative behaviour between the configurations. The execution time is important because medical images are large and can be difficult to process, and slow algorithms would not be efficient in the medical routine. The parameter that most reduced the time, the step, does so by processing fewer blocks rather than by processing them faster, which is a trade-off between speed and information. The configurations that are cheapest to compute are also the ones that cover less of the tumour. It is not advantageous to sacrifice so much information for speed: some of these methods can be applied, but only up to a certain limit, and, for this reason, when the loss becomes large, it may be worth optimising and parallelising the code or improving the available processing resources.

F. Generalisability

The effects described are limited to these cases and are, initially, not generalisable to other modalities, scanners or sets of pre-processing tools. The performance of prognostic models is sensitive to the *pipeline* and dependent on the sequence used, and MRI intensities are acquired in arbitrary, scanner-dependent units, which prevents the direct comparison of the examinations, even with the same acquisition protocol [24]. Moreover, there are fewer reproducible *features* between different scanners, even with identical acquisition parameters [25], and, although normalisation can be applied in these cases, the normalisation of the features improves reproducibility more than the normalisation of the images [27].

Resampling to isotropic voxels can also improve robustness [26], but above all it corrects the anisotropy, making the parameters (window, step, sigma, radius) comparable in physical units. The variation of the *kernel* dimensions, in turn, may

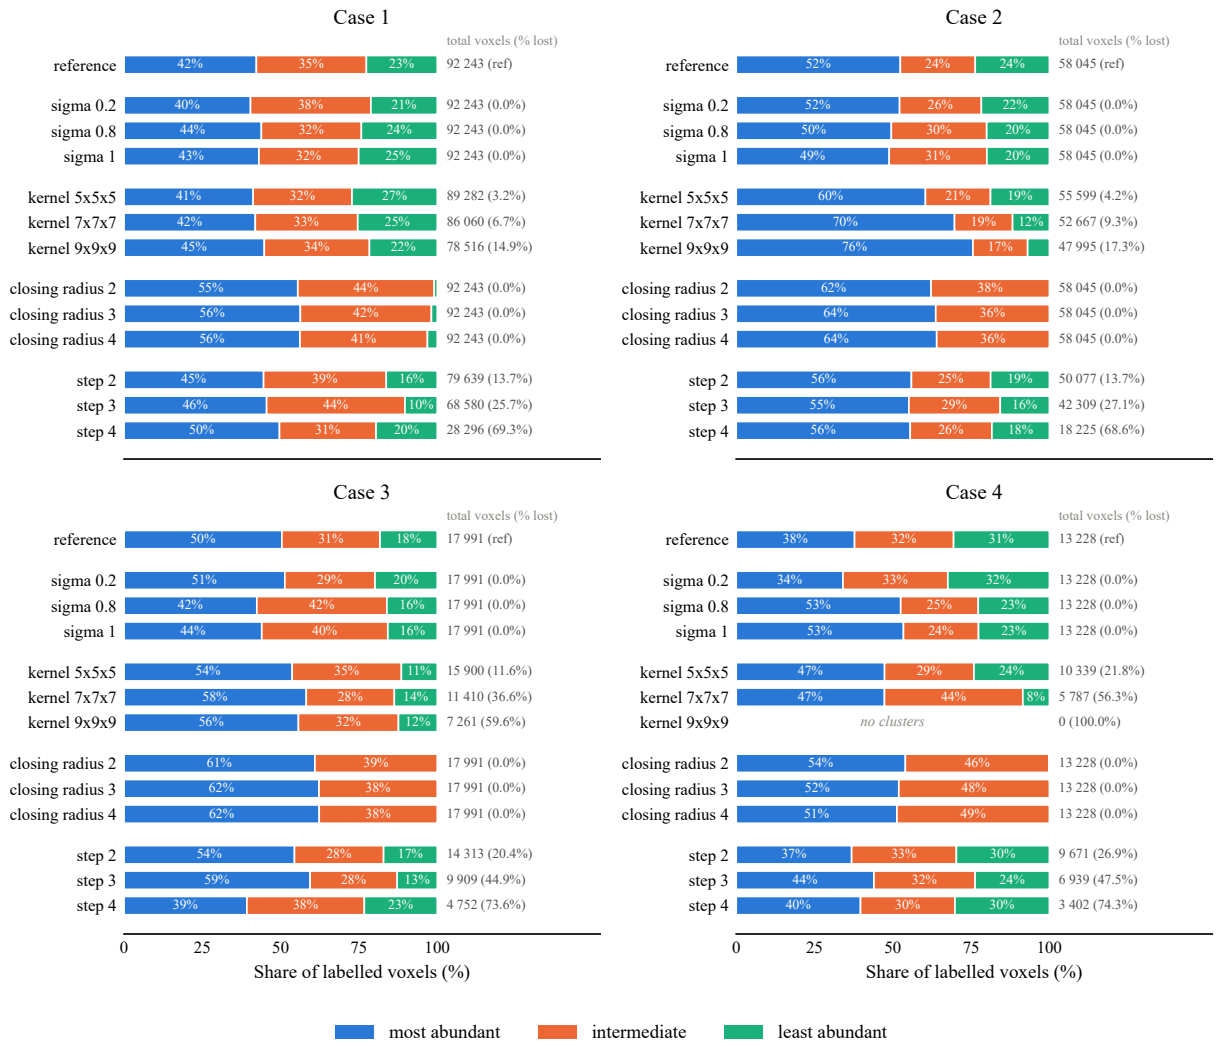

Fig. 4. Proportion of each habitat and total of labelled voxels, per configuration and per case. Each panel corresponds to a case and each bar to a configuration, with the reference at the top and the four parameter families separated by a blank line. Within each bar, the habitats are ordered from the most abundant to the least abundant, and not by label, because the clustering is fitted independently in each run and the labels are not comparable between runs. The number to the right of each bar is the total of labelled voxels in that configuration, followed in parentheses by the percentage of voxels lost relative to the reference configuration of the same case.

reduce the repeatability and the reproducibility of 3D radiomic features [23]. Thus, without testing which features vary in a given context, there is no way to state that they will remain stable in another.

This work can be understood as a basis for future studies and not as a set of recommended values. Although the parameter values are not generalisable, the qualitative behaviour (a larger sigma reduces detail; a larger window reduces coverage in small tumours) tends to hold, as it is a geometric effect of the method rather than a property of the data.

V. Conclusion

This article discussed, in four rectal MRI cases, the effect of the parameter choice on a habitat formation algorithm based on K-means and radiomic features, which employs filtering, a structuring element and a sliding window with a step. Other algorithms and clustering methods can be explored with the same objective: to make accessible the data that support the standardisation and the reproducibility of radiomics studies (a field in which many works present results without the support needed to reproduce them), to improve the method and to guide the choice of parameters by researchers in the same line of research.

The adjusted Rand index is computed over the intersection of the labelled voxels and does not report the portion of the tumour that was left out of the evaluation; the visualisations and the proportion plot complement it. In the variations of sigma and radius, the total of labelled voxels equals that of the reference in all four cases and the comparison covers the complete set; in those of window and step, this total varies, and the index describes the agreement within a subset that may

be small, so that a high value would not guarantee that the division of the tumour as a whole had been maintained. The proportions in Fig. 4, in turn, are ordered by abundance, and not by habitat identity: the habitats are equivalent within a run, but not between runs. Verifying the stability and the robustness of the *features* would be a proposal for future work capable of complementing the data needed to increase the reproducibility of the study.

CODE AVAILABILITY

The developed code and the installation and usage instructions are available at https://github.com/sarahsouza200054/CBEB_2026_Sarah. The MRI images are not part of the repository.

ACKNOWLEDGMENT

The authors thank the funding agencies CAPES and CNPq, as well as the institutions and collaborators who contributed to this work. The translation into English and the foreign-language revision of this manuscript were carried out with the aid of artificial intelligence tools, under the supervision of the authors and with a final revision by them.

***Abstract*—Valvular heart diseases contribute significantly to global morbidity, making phonocardiography (PCG) an essential non-invasive diagnostic tool. However, the detection of heart sounds (S1 and S2) is frequently hindered by the presence of pathological murmurs and instrumentation noise. This paper proposes an algorithm for the detection of S1 and S2 heart sounds. The method integrates the Discrete Wavelet Transform (DWT) as preprocessing for noise removal, 2nd-order Shannon energy envelope and a dynamic adaptive threshold based on local peaks, followed by postprocessing rules for artifact rejection and physiological segment junction. The algorithm was validated on the public CirCor database using an event-based metric. The results obtained from a total of 787 patients and 31,210 annotated heart sounds demonstrated consistent overall performance, achieving a Sensitivity of 93.48%, Precision of 87.29%, and an F1-Score of 90.28%, when compared against the same algorithm without the preprocessing stage, which yielded gains of 4.01pp in Sensitivity, 2.2pp in Precision and 3.05pp in F1-Score, thereby demonstrating an advantage in its utilization.**

***Index Terms*—Phonocardiogram, wavelet transform, Shannon energy, heart segmentation, heart sounds.**

I. Introduction

Cardiovascular diseases represent the leading cause of mortality worldwide, accounting for an estimated 17.9 million deaths annually according to the World Health Organization (WHO) [1]. Although coronary artery disease is the most common, valvular heart diseases also contribute to global morbidity and mortality. Heart sounds (HS) are vital for early detection and warning of these pathologies, as they contain physiological and pathological information that the electrocardiogram (ECG) often fails to capture, such as murmurs caused by mechanical valve problems [2]. Historically, cardiac auscultation has been the primary technique for this verification; however, its effectiveness is limited by the constraints of human auditory perception and physician subjectivity [2].

To overcome these limitations, digital phonocardiography (PCG) has been adopted as a non-invasive and easily acquired alternative, allowing the recording, graphical visualization, and objective processing of the acoustic signals of the cardiac cycle [2], [3]. However, event detection in PCG faces major challenges: the signals are relatively weak and highly susceptible to environmental noise and instrumentation interference, resulting in noisy data that reduces the accuracy of parameter extraction and increases diagnostic uncertainty [3]. Furthermore, the randomness and variability of cardiovascular diseases lead to enormous complexity and diversity in signal manifestation [3], often masking heart sounds with murmurs characteristic of the pathologies [4].

The cardiac cycle can produce up to four acoustic heart sounds (S1, S2, S3, and S4), which reflect the mechanical and hemodynamic dynamics of the heart [5], [6]. The two main ones, present in a normal cycle, are the first heart sound (S1), generated at the onset of ventricular systole by the closure of the mitral and tricuspid valves, and the second heart sound (S2), which marks the onset of diastole with the closure of the aortic and pulmonary valves. Occasionally, a third heart sound (S3) and a fourth heart sound (S4) can be recorded [5]. S3 occurs during the period of rapid passive ventricular filling in early diastole, being considered physiological in children and young adults, but frequently pathological in adults, associated with cardiac dilation or failure. S4, in turn, occurs in late diastole, immediately before ventricular systole, produced by vibrations in the ventricle when the atria contract; although inaudible S4 vibrations can be recorded by PCG in normal individuals, its audible prominence indicates abnormalities such as reduced ventricular distensibility (stiffness) [5], [6]. The accurate detection and segmentation of S1 and S2 sounds is a fundamental step in any phonocardiography system, as it establishes the temporal reference needed to diagnose and locate these murmurs and extra sounds.

To extract the true heart sounds among various types of murmurs and noise, the literature has adopted a wide range of advanced techniques. Machine learning-based approaches, Hidden Markov Models (HMM), and Deep Learning have been widely explored for PCG signal segmentation [3], [7]. Although they present high accuracy rates, these models often require high computational costs and extensive training databases, which hinders their deployment in portable devices [3] and the broad application of these techniques.

Concurrently, in signal processing methodologies, the wavelet transform has stood out for its ability to efficiently denoise the PCG signal, attenuating murmur energy without compromising the time-frequency characteristics of the S1 and S2 sounds [2], [4]. After this initial filtering, the use

of energy envelopes, such as Shannon energy, is applied to track and enhance heart sounds, isolating them from residual background noise [8], [9]. In this context, classical methods based on static thresholds frequently fail to accurately identify these HS because of the inherent non-stationarity of the signal, intrapatient variability and the presence of artifacts may cause amplitude fluctuations, causing the desired heart sounds to be attenuated or confused with murmurs [9].

Given this scenario, this work proposes a heart sound detection algorithm. The main points of the proposed algorithm are: (1) The use of the wavelet transform for murmur attenuation coupled with the Shannon energy envelope; (2) An adaptive thresholding method based on dynamic peak tracking; and (3) The proposition of an event-based evaluation focused on the midpoint of the heart sounds. The algorithm was validated on the public CirCor database [10].

II. Materials and methods

The detection algorithm proposed in this work was developed using MATLAB [11] and consists of six main stages: pre-processing via wavelet transform, Shannon energy envelope, normalization of the envelope, dynamic thresholding based on local peaks, artifact removal, and the junction of split heart sounds.

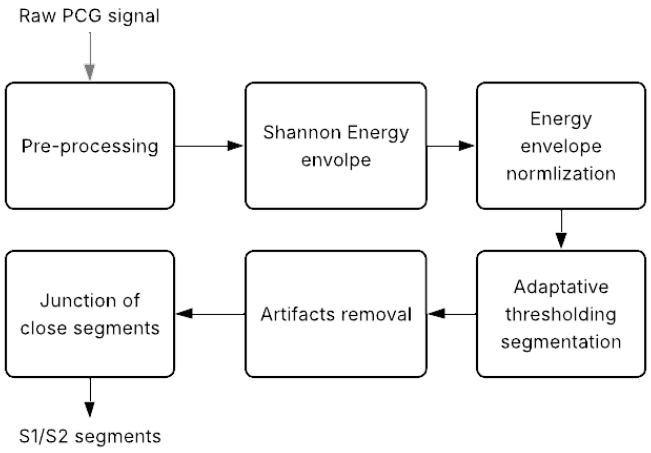

Fig. 1. Algorithm pipeline block diagram

A. Database

The phonocardiogram signals used for the development and validation of the algorithm were extracted from the public CirCor database, which was consolidated through a partnership between the Real Hospital Português de Beneficência and the Hospital Universitário Oswaldo Cruz (HUOC) [10]. This database contains records of patients categorized as "Normal" and "Abnormal", encompassing a great diversity of cases.

Given that the CirCor database focuses on the pediatric population, the age range was classified according to standardized clinical definitions: Neonatal (0 to 27 days), Infant (28 days to 1 year), Child (1 to 11 years), and Adolescent (12 to 18 years). Table I summarizes the characteristics of the database population, detailing weight, height, Body Mass Index, and the distribution between sex and age group.

The patients were designated a category (*Normal* or *Abnormal*) based the pediatric cardiologist's overall assessment of the patient's cardiac condition. This is a diagnosis based on clinical history, physical examination, analog auscultation, echocardiogram, etc. The cardiologists did not have access to the digital auscultations and the murmur gradings when making these diagnoses, and the indicated outcomes do not necessarily imply that the expert had identified a murmur during analog auscultation. The pediatric cardiologists were not the annotators of the digital auscultations.

For this study, we exclusively used records captured at the aortic valve auscultation site. The original sampling rate was maintained at 4000 Hz.

TABLE I
CirCor database patients characteristics

	Min	**Max**	$\mu \pm \sigma$
Weight (kg)	2.3	108.6	23.44 ± 14.7
Height (cm)	35	180	111.08 ± 29.15
BMI	6.18	36.97	17.79 ± 8.89
	Distribution (N and %)		
Sex			
Male	389 (49.43%)		
Female	398 (50.57%)		
Age group			
Neonatal	4 (0.51%)		
Infant	96 (12.2%)		
Child	579 (73.57%)		
Adolescent	60 (7.62%)		
Not informed	48 (6.1%)		
PCG category			
Normal	394 (50.06%)		
Abnormal	393 (49.94%)		

B. Pre-processing

PCG signals are inherently non-stationary and frequently contaminated by low-frequency noise, such as respiratory movements or stethoscope friction, and high-frequency noise, such as electronic interference or ambient noise. Before applying the detection algorithm, the records were submitted to a pre-processing stage to ensure data integrity.

First, each record was temporally segmented. The signal was truncated to maintain exclusively the intervals between the first and last annotations made by the HUOC specialists.

After cropping the validated intervals, the Discrete Wavelet Transform (DWT) was applied for noise suppression (denoising). The signal was decomposed into 8 resolution levels using the 8th-order wavelet of the Daubechies family (db8) [12]. In DWT, the signal is passed through a series of high-pass and low-pass filters, resulting in detail coefficients (D_j) and approximation coefficients (A_j), respectively, which provide a multi-resolution time-frequency analysis.

Given the original sampling rate of 4000 Hz, the Nyquist frequency is 2000 Hz. Through frequency partitioning, the detail coefficients D_5, D_6 and D_7 correspond to the frequency

bands of 15.625 to 125 Hz. Since the predominant components of S1 and S2 heart sounds are concentrated in the frequency range between approximately 30 Hz and 70 Hz [13], the filtered PCG signal was reconstructed exclusively from the sum of these three detail coefficients ($D_5 + D_6 + D_7$), the choice of using the seventh level of detail coefficient is to encompass some low frequency components that are present in some patients HS, it does not usually coincide with the frequency components of undisered noise or murmurs.

Thus, the DWT acts as a band-pass filter, trying to isolate the heart sounds and attenuate murmurs and noise without causing distortion or altering the position of the heart sounds. Finally, the resulting signal was normalized by its absolute maximum value. An example can be seen in Fig. 2.

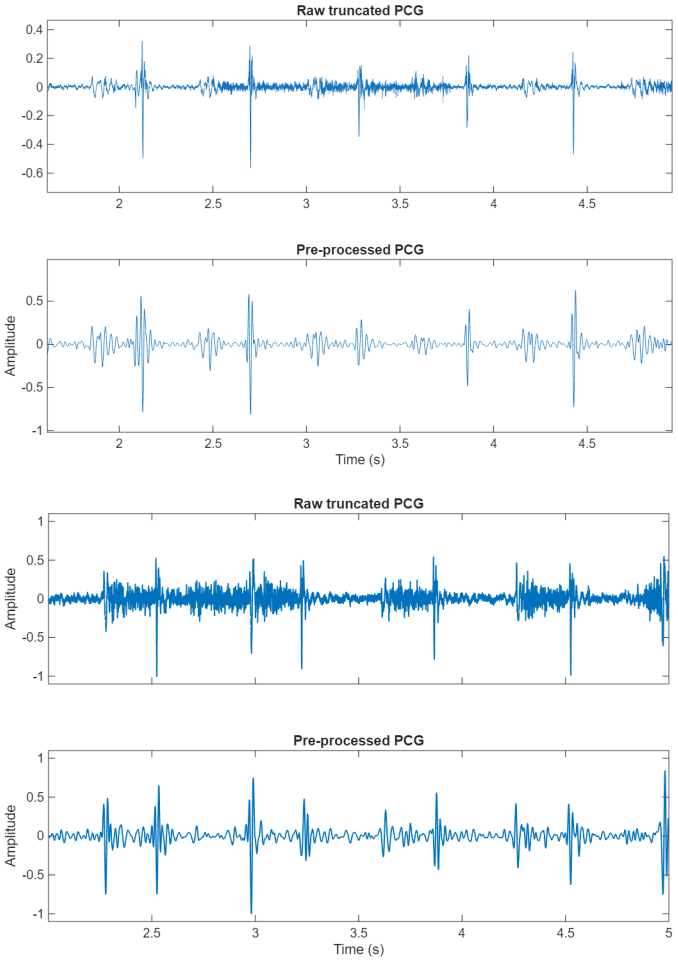

Fig. 2. Comparison of the DWT pre-processing stage. Top: Raw and pre-processed signals for a abnormal patient. Bottom: Raw and pre-processed signals for an abnormal patient with a strong murmur.

C. Shannon energy envelope extraction

Robust detection and segmentation of heart sounds require a representation that highlights short-duration events (S1 and S2) while suppressing background noise and undesired murmurs. For this purpose, the filtered and normalized signal x_i is processed through the 2nd-order Shannon energy envelope. This choice is based on the logarithmic function's ability to emphasize medium-intensity variations, which characterize heart sounds, disproportionately attenuating low-amplitude noise and high-energy murmur interference [9], [14].

The 2nd-order Shannon energy is calculated following Equation 1 [14], [15]:

$$E_s(i) = -\frac{1}{N}\sum_{k=1}^{N} x_k^2 \cdot \log(x_k^2) \tag{1}$$

Where N represents the analysis window size (defined as 80 samples, or 20 milliseconds) and x_k is the filtered PCG signal.

D. Energy envelope normalization

To obtain the final normalized envelope curve, statistical processing is applied to $E_s(i)$ aiming to mitigate the influence of remaining noise and baseline variations. The normalized envelope, $P_a(t)$, is obtained by standardizing the energy samples according to Equation 2 [14], [15]:

$$P_a(t) = \frac{E_s(t) - \mu(E_s(t))}{\sigma(E_s(t))} \tag{2}$$

Where $\mu(E_s(t))$ and $\sigma(E_s(t))$ represent, respectively, the mean and standard deviation of energy within a sliding window of half a second, ensuring the window encompasses only approximately one heart sound at a time. This adaptive normalization is fundamental for the algorithm to maintain detection sensitivity even in signals with temporal variations in gain or acoustic intensity. Figure 3 shows a result of the Shannon energy envelope.

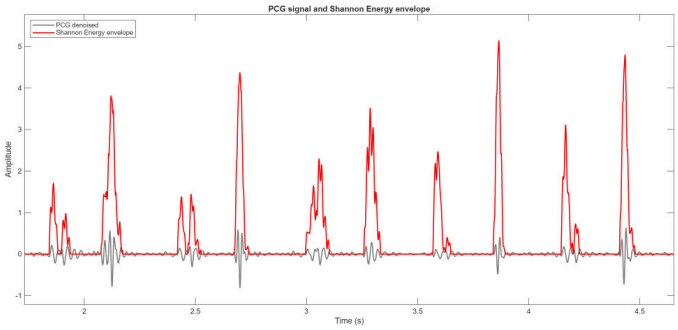

Fig. 3. Processing result after the extraction and normalization of the Shannon energy envelope

E. Adaptive Thresholding and Parameter Optimization

From the normalized envelope $P_a(t)$, the detection threshold must be calculated dynamically. To address limitations that classical methods based os statical thresholds present, the proposed algorithm employs an adaptive threshold based on the maximum energy peak within a 0.5-second sliding window, governed by a percentage factor (α).

To determine the optimal threshold factor and prevent empirical bias, a sweeping optimization was conducted across the training database. The parameter space was evaluated by

varying α from 0.1% to 100% while maintaining the fixed sliding window of 0.5 seconds. The performance trade-off was evaluated using a three-dimensional Precision-Sensitivity-F1 trajectory, which maps the algorithm's performance across the theoretical F1-Score surface, the equations on how Precision, Sensitivity and F1-score are calculated are presented ahead in subsection III-B.

The optimal operating point is visually represented, as illustrated in Fig. 4, by the peak of the trajectory scaling the F1-Score surface. This global maximum was achieved using an α of 10.6% of the local peak value ($Threshold = 0.106 \cdot P_{max,500ms}$). Envelope segments that exceed this dynamically calculated limit are considered initial candidates for S1 and S2 heart sounds. This optimal threshold factor was subsequently fixed for the global validation phase.

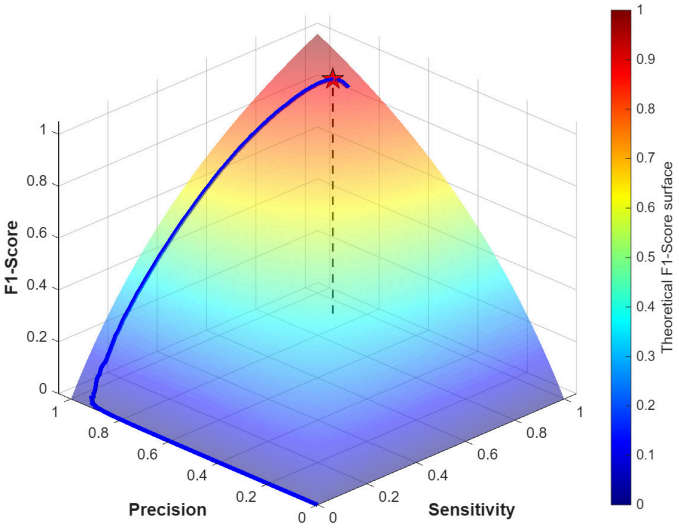

Fig. 4. Three-dimensional Precision-Sensitivity trajectory across the theoretical F1-Score surface for the adaptive threshold optimization. The red marker indicates the optimal threshold parameter ($\alpha = 10.6\%$) that maximizes the global F1-Score.

F. Artifact removal and segment junction

After initial candidates detection, two post-processing procedures are applied to refine the segmentation mask:

1) **Artifact removal:** Events with a duration shorter than 20 ms are classified as non-HS and discarded.
2) **Junction of close segments:** Due to the physiological phenomenon of heart sound splitting, a single heart sound can exhibit two distinct energy peaks separated by a brief interval of silence. According to the temporal stability criteria established by Liang et al. [15], the maximum normal splitting interval between the internal components of a healthy heart sound is approximately 50 ms. Therefore, if the silence interval between two consecutive detected energy peaks is less than 50 ms, they are classified as parts of the same split heart sound and are automatically merged into a single physiological segment.

Figure 5 presents the result of the detection, supression and junction of adjacent signals applied to a record.

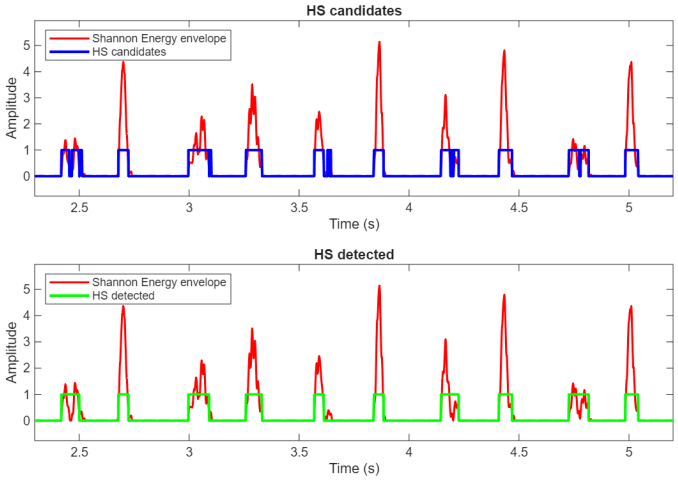

Fig. 5. Initial threshold detection (top) and after HS post-processing procedures (bottom)

III. Results

A. Evaluation criteria

To quantitatively evaluate the performance of the proposed algorithm, an event-based methodology was adopted. Thus, the decision criterion was based on the geometric midpoint of each detected heart sound, which represents the temporal center of the detected segment. This midpoint (n_{mid}) is calculated as the arithmetic mean of the starting (n_{start}) and ending (n_{end}) sample indices of the detected event. Consequently, the classification of each event is established as follows:

- **True positive (TP):** A detected event is classified as TP when its geometric midpoint is contained within the time window of the ground truth annotation (reference annotations by HUOC specialists).
- **False positive (FP):** Occurs when the algorithm identifies an event whose temporal location (midpoint) does not coincide with any reference annotation.
- **False negative (FN):** Occurs when a reference annotation provided by the specialist does not contain any detected heart sound midpoint from the algorithm.

.

B. Algorithm performance

The proposed algorithm was validated using a total sample of 787 patients (394 classified as "Normal" and 393 as "Abnormal") extracted from the public CirCor database [10].

The results of the processing with DWT as preprocessing and with no preprocessing at all are presented in Table II.

It is also possible, using these results, to extract algorithm evaluation metrics such as Sensitivity (Se), Precision (P), and F1-Score ($F1$)

Sensitivity measures the algorithm's ability to correctly detect heart sounds annotated by specialists (minimizing false negatives) and is defined by Equation 3:

TABLE II
HEART SOUNDS DETECTION RESULTS (TP, FN, FP) WITH AND WITHOUT DWT

	TP		FN		FP		Total	
Category	**DWT**	**No DWT**	**DWT**	**No DWT**	**DWT**	**No DWT**	**DWT**	**No DWT**
Clinical condition								
Normal	12564	12137	609	1047	1746	1955	14919	15139
Abnormal	12055	11425	1109	1725	1840	2173	15004	15323
Age group								
Neonate	75	60	1	16	2	15	78	91
Infant	1906	1721	351	532	333	390	2590	2643
Child	18697	17920	1080	1866	2416	2867	22193	22653
Adolescent	2011	1970	157	187	420	432	2588	2589
Not inf.	1930	1891	129	171	415	424	2474	2486

$$Se = \frac{TP}{TP + FN} \tag{3}$$

Precision quantifies the reliability of the detections performed, evaluating the proportion of identified heart sounds that were indeed true (minimizing false positives). Its mathematical formulation is presented in Equation 4:

$$P = \frac{TP}{TP + FP} \tag{4}$$

The F1-Score represents the harmonic mean between sensitivity and precision, providing a single, balanced metric for the global performance of the detection system, as expressed in Equation 5:

$$F1 = 2 \cdot \frac{P \cdot Se}{P + Se} = \frac{2 \cdot TP}{2 \cdot TP + FP + FN} \tag{5}$$

These were calculated separately for each category, as well as for global results, and tested in a algorithm that had no DWT as pre-processing, and are presented in Table III

TABLE III
HEART SOUNDS DETECTION METRICS WITH AND WITHOUT DWT

	Sens (%)		Prec (%)		F1 (%)	
Category	**DWT**	**No DWT**	**DWT**	**No DWT**	**DWT**	**No DWT**
Clinical condition						
Normal	95.38	92.06	87.80	86.13	91.43	88.99
Abnormal	91.58	86.88	86.76	84.02	89.10	85.43
Age group						
Neonate	98.68	78.95	97.40	80.00	98.04	79.47
Infant	84.45	76.39	85.13	81.53	84.79	78.87
Child	94.54	90.57	88.56	86.21	91.45	88.33
Adolescent	92.76	91.33	82.72	82.01	87.45	86.42
Not inf.	93.73	91.71	82.30	81.68	87.65	86.41
Total	**93.48**	**89.47**	**87.29**	**85.09**	**90.28**	**87.23**

IV. DISCUSSION

The quantitative performance achieved by the proposed algorithm, evidenced by a global F1-Score of 90.28%, a sensitivity of 95.38% for the normal class, and 91.58% for the abnormal class, demonstrates the viability of the approach.

The slight reduction observed in the sensitivity of the abnormal class is an expected behavior from a clinical standpoint. In phonocardiographic records containing murmurs or noise, the amplitude of these acoustic abnormalities can, at specific moments of the cardiac cycle, compete directly with the energy of S1 and S2 heart sounds.

Even so, the algorithm's demonstration of high sensitivity in such a complex pediatric scenario reinforces the quality of the denoising performed by the DWT reconstruction, exclusively using details D_5, D_6 and D_7 of the db8 wavelet

A. Limitations and future works

Despite the good results, the current evaluation methodology and the system architecture present limitations that define clear guidelines for future investigations.

First, the evaluation was conducted using a midpoint event-based metric. While this is a standard approach for initial validation, merely detecting the temporal center of a sound is a relatively simple task for the algorithm and does not guarantee precise morphological boundaries. Second, the reliance on the CirCor database, which is inherently focused on murmur classification rather than temporal heart sound detection, imposes restrictions on validating the exact onset and offset of the S1 and S2 sounds. The improvement of the preprocessing stage, F1 going from 87.23% to 90.28%, could be higher, but the signals from the database had a good Signal-to-Noise-Ratio (SNR).

For future work, we propose expanding the evaluation metrics to strictly measure the temporal boundaries (onset and offset) of the events, rather than just the geometric midpoint. Additionally, future iterations of the algorithm will focus on distinguishing the first heart sound (S1) from the second heart sound (S2). To further optimize the pre-processing stage, rigorous comparative studies with other classes of digital filters will be conducted.

Finally, validating the algorithm demands acquiring or constructing a dedicated database focused exclusively on the precise temporal identification of heart sounds. Overcoming these limitations is essential for future analysis.

Despite the promising results, the current system presents limitations that define guidelines for future investigations.

The primary limitation is that the proposed algorithm can only detect the heart sound position; it is not yet capable of precisely segmenting the start and end of the sounds, nor of distinguishing the first from the second heart sound.

For future work, we propose the development of a more detailed algorithm for the precise segmentation of these heart sounds delimiting their onset and offset and labeling S1 and S2 accordingly, addind to the reliability and checking for the robustness of the proposed algorithm.

***Abstract*—Heart-evoked spectral disturbances (HESDs) summarize heartbeat-aligned EEG spectral dynamics and provide an exploratory measure of brain–heart interaction. We compared HESDs between nine participants with refractory epilepsy (RE) and seven neurotypical controls (CTRL). Participant-level inference was evaluated across 20 predefined region-by-band comparisons with Benjamini–Hochberg false-discovery-rate correction. Although substantial standardized effect sizes were observed in the RE group, most notably in theta (Hedges' $g = 1.27$–1.68), no region-by-band contrast retained statistical significance at the nominal threshold ($q_{\mathrm{FDR}} \geq 0.116$). Furthermore, none of these salient contrasts exceeded the null distribution obtained by circularly shifting R-peak trains relative to the continuous EEG (all surrogate-adjusted $q = 0.693$), and a dedicated 25–45 Hz sensitivity analysis yielded no FDR-significant regional effect. Quantitative artifact analysis indicated that ICA reduced mean 25–45 Hz ECG–EEG coherence by 57.9%, although residual coupling remained. Conventional time-domain heart-rate variability metrics (RMSSD, SDNN, and pNN50) did not differ significantly between groups. These results characterize peri-R spectral dynamics in refractory epilepsy while establishing an absence of statistical robustness to multiple-comparison correction and a lack of temporal specificity to true cardiac events.**

***Index Terms*—biomedical signal processing, brain–heart interaction, electroencephalography, heart-evoked spectral disturbance, refractory epilepsy**

I. Introduction

Cardiac signals interact continuously with neural activity through autonomic, visceral-afferent, and interoceptive pathways [1], [2]. Cortical responses aligned to individual heartbeats have traditionally been studied using heartbeat-evoked potentials and related time–frequency measures [3], [4]. These signals offer a means of investigating central processing of cardiovascular information, although their low amplitude and temporal proximity to cardiac electrical and mechanical events make artifact control particularly important [4], [5]. Here, we use the term heart-evoked spectral disturbance (HESD) for frequency-specific EEG changes quantified in peri-R segments.

In refractory epilepsy (RE), autonomic dysfunction and altered brain–heart communication have been reported using EEG, heart-rate variability (HRV), and directional coupling measures [6]–[8]. A previous study in refractory epilepsy, for example, identified altered information exchange between cortical and autonomic cardiac dynamics [6], while more recent work in focal epilepsy has demonstrated changes in directional brain–heart information flow surrounding seizures [7]. Nevertheless, the frequency-specific profile and cardiac specificity of peri-R cortical spectral differences remain insufficiently characterized.

The present study compares HESDs between participants with RE and healthy controls. Regional and frequency-specific effects are evaluated using participant-level inference, explicit correction for multiple comparisons, standardized effect sizes and confidence intervals. Because cardiac-field and myogenic artifacts can be particularly problematic in heartbeat-aligned and high-frequency EEG [5], [9], [10], we additionally quantify ECG–EEG contamination, examine the 25–45 Hz range separately, and test temporal specificity using surrogate R-peak trains.

II. Methods

A. Participants and Data Acquisition

EEG and ECG data were obtained from individuals with RE, whose clinical characteristics are summarized in Table I, and neurotypical controls (CTRL). The study was approved by the appropriate institutional research ethics committee (CAAE: 76518417.0.0000.001), and all participants provided written informed consent before data acquisition.

The dataset comprised seven healthy controls (age: 32.0 ± 10.7 years; range: 20–50 years; three female participants) and nine participants with RE (age: 32.8 ± 11.0 years; range: 17–49 years; five female participants). EEG was recorded at 256 Hz, with ECG obtained from a separate lead.

B. R-Peak Detection and HRV Feature Extraction

R-peaks were identified from the CA1+ ECG channel with a minimum interpeak distance of 0.4 s. Candidate event timing was subsequently refined within a ± 10 ms interval using the maximum absolute amplitude of the mean EEG signal. Because this local refinement can increase the temporal alignment of EEG transients, cardiac specificity was not inferred from R-peak alignment alone and was tested independently using circularly shifted event trains.

For the surrogate analysis, each participant's complete R-peak train was displaced relative to the EEG while preserving the number and temporal spacing of events. Standard time-domain HRV measures, including RMSSD, SDNN, and pNN50,

TABLE I
CLINICAL CHARACTERISTICS OF THE PATIENTS INCLUDED IN THE STUDY.

Patient	Age	Sex	Onset of crises (age)	Type of epilepsy / Etiology	Antiseizure medication / dose (mg/day)	Frequency of seizures (per month)	Type of crisis
1	33	M	7	TLE/L	CBZ/1200; PHB/120	12	F
2	45	M	22	TLE/L; Cavernoma	PHB/100; PHT/300	4	F
3	17	F	2	TLE/B; CFD	CBZ/1200; CLM/200; PHB/200	>100	G
4	24	F	12	TLE/L; DNET	PHB/200; PHT/100	5	F
5	45	M	24	TLE/R; Gliosis	CBZ/1200; SV/1500; TPM/200	8	F
6	31	F	14	FLE/B	CLM/20; PHT/300; SV/1500	12	G
7	49	M	45	Unknown	PHT/100	4	G
8	24	F	2	TLE	CBZ/900; PHB/100	12	F
9	27	F	4	TLE/R	SV/1500; CBZ/20	12	F

Notes: M = male; F = female. TLE = temporal lobe epilepsy; CFD = cortical frontal dysplasia; FLE = frontal lobe epilepsy; DNET = dysembryoplastic neuroepithelial tumor. R = right; L = left; B = bilateral. ASM = antiseizure medication. SV = sodium valproate; CBZ = carbamazepine; PHT = phenytoin; PHB = phenobarbital; TPM = topiramate; CLM = clobazam. G = generalized seizure; F = focal seizure.

were computed for each participant according to established HRV definitions [11], [12].

C. EEG Processing and HESD Estimation

Continuous EEG signals were preprocessed using a notch filter to attenuate 60 Hz power-line interference, followed by band-pass filtering from 1 to 40 Hz and average re-referencing. An R-locked cardiac template spanning ± 100 ms around each R-peak was estimated and subtracted prior to HESD estimation. For the bandwise analysis, fourth-order Butterworth filters and Hilbert transforms were applied to delta (1–4 Hz), theta (4–8 Hz), alpha (8–13 Hz), beta (13–30 Hz), and nominal gamma (31–45 Hz) bands. Because the continuous signal had undergone 40-Hz low-pass preprocessing, the upper portion of the nominal gamma band was attenuated and high-frequency results were interpreted conservatively.

For each heartbeat, HESD was defined as the difference between the standard deviation of the analytic-signal envelope during the 0 to 600 ms post-R interval and that during the -200 to 0 ms pre-R interval. Heartbeat-level values were averaged within participant and cortical region before group-level inference.

Peri-R time–frequency RE–CTRL difference maps were also calculated for the parietal, temporal, and central regions and are shown in Figs. 2–4. Because inferential testing was performed on participant-level regional summaries rather than on visually selected time–frequency bins, these maps are interpreted descriptively.

D. ECG–EEG Artifact Assessment

Heartbeat-aligned EEG is intrinsically vulnerable to the cardiac field artifact because electrical activity generated by the heart propagates to scalp electrodes [9]. Residual ECG contamination was therefore quantified independently using an ICA-based analysis. Independent component decomposition followed the FastICA framework [13]. ECG–EEG magnitude-squared coherence was calculated before and after ICA in the 25–45 Hz range.

Pre–post changes were summarized at the participant level, and residual post-ICA coherence was also compared between groups. These measurements were treated as quantitative artifact diagnostics rather than as evidence that cardiac or myogenic contamination had been completely removed. This distinction is particularly relevant for high-frequency scalp EEG, in which cranial and ocular muscle activity can substantially contaminate apparent gamma-band activity [10], [14].

E. Statistical Analysis

The participant was the inferential unit. Channels were averaged within participant and cortical region before group comparison. The primary inferential family comprised 20 predefined region-by-band comparisons formed by four regions (frontal, central, parietal, and occipital) and five canonical frequency bands. Benjamini–Hochberg false-discovery-rate correction was applied across all 20 tests [15].

The temporal T7/T8 region was analyzed separately as a five-test secondary family. For regional comparisons, we report raw RE–CTRL mean differences, Hedges' g, participant-level 95% bootstrap confidence intervals based on 10,000 resamples, Welch tests, and exact group-label permutation tests over all 11,440 allocations of 9 of 16 participants to RE.

A separate 25–45 Hz analysis evaluated the robustness of the visually prominent high-frequency regional patterns. Temporal specificity was assessed for the six primary contrasts displaying the largest effect sizes by recomputing the complete HESD extraction after 100 circular shifts of each participant's R-peak train. The same processing and regional summaries were applied to each shifted event train, and the six surrogate tests were corrected together using the Benjamini–Hochberg procedure. HRV measures were compared between groups as exploratory peripheral outcomes.

III. RESULTS

Participant-level analysis suggested observable elevations in HESD across canonical frequency bands in the RE group (Fig. 1-A,B). In the frontal region, the mean RE–CTRL difference in theta was 0.228 μV (95% CI 0.115–0.350 μV; Hedges' $g = 1.51$, 95% CI 1.00–2.64). Substantial point estimates and effect sizes in theta were also present across central ($g = 1.58$), parietal ($g = 1.57$), and occipital ($g = 1.68$) regions, alongside parietal delta ($g = 1.27$) and occipital gamma ($g = 1.38$). Across the complete 20-test primary inferential family, however, no region-by-band contrast retained statistical significance following Benjamini–Hochberg FDR correction at the nominal

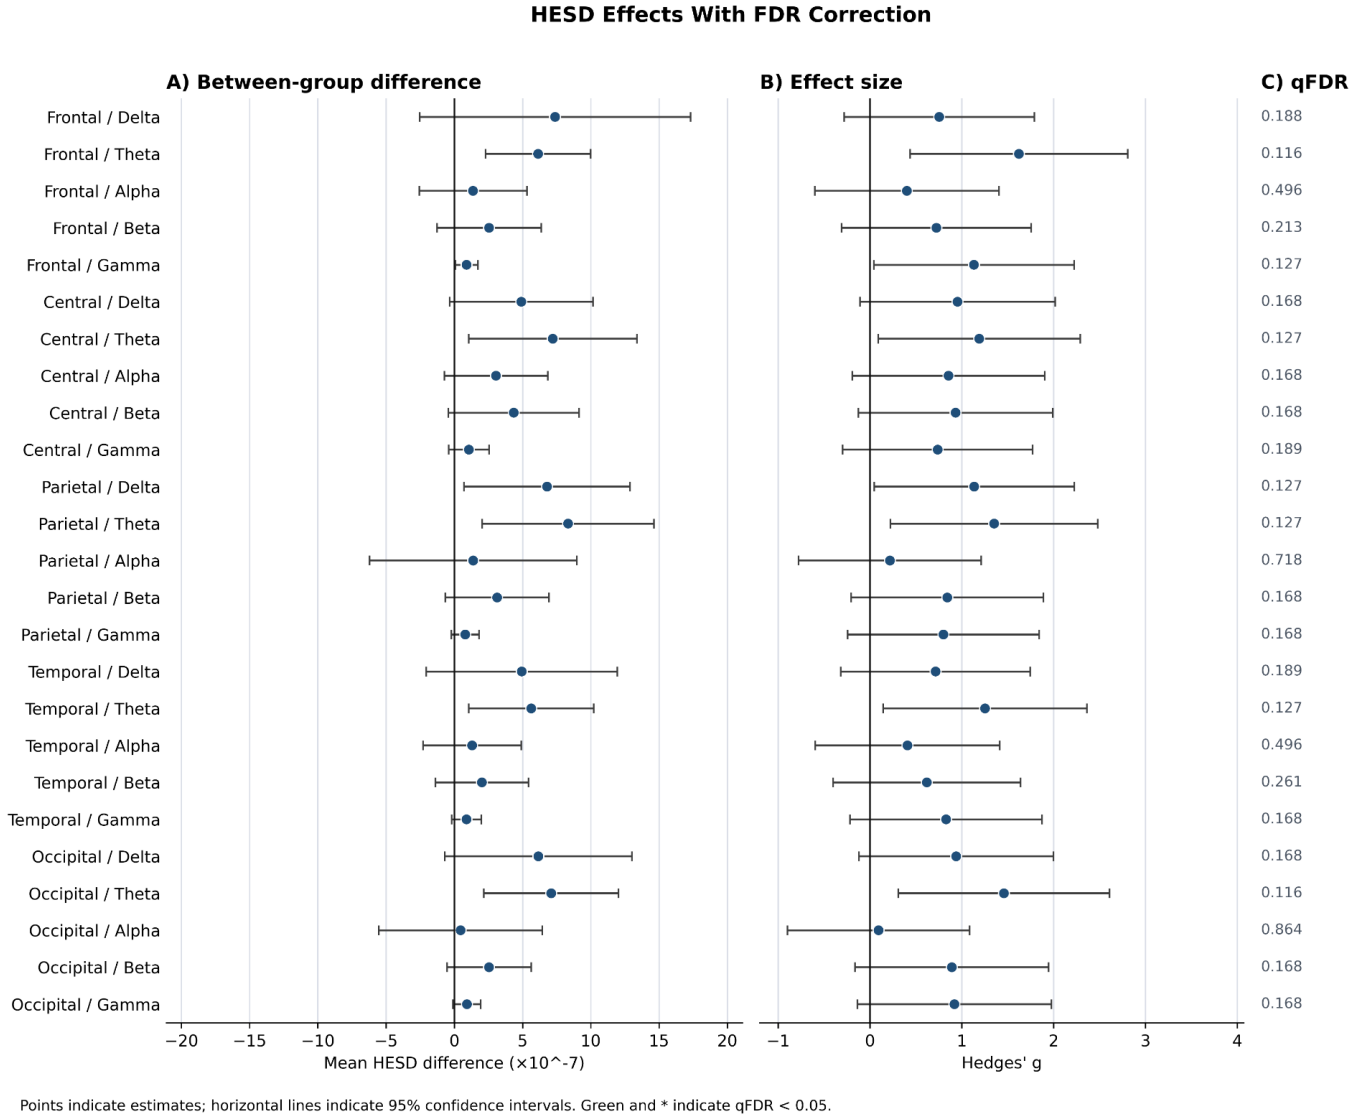

Fig. 1. Participant-level HESD effects with FDR correction. Panel A shows RE–CTRL mean HESD differences with 95% confidence intervals; Panel B shows standardized effect sizes (Hedges' g) with 95% confidence intervals; Panel C reports the corresponding q_{FDR} values.

threshold, yielding minimum values of $q_{\mathrm{FDR}} = 0.116$ for frontal and occipital theta, and $q_{\mathrm{FDR}} \geq 0.127$ across all remaining contrasts (Fig. 1-C). Within the secondary temporal-region family, no frequency band reached statistical significance (minimum $q = 0.127$).

The peri-R time–frequency difference maps showed broad positive RE–CTRL contrasts at approximately 25–45 Hz across parietal, temporal, and central regions (Figs. 2–4). Nevertheless, these descriptive patterns were not corroborated by participant-level high-frequency inference (parietal: $g = 0.80$, $q = 0.178$; temporal: $g = 0.12$, $q = 0.929$; central: $g = 0.19$, $q = 0.793$), and no comparison in the dedicated 25–45 Hz sensitivity analysis survived FDR correction (all $q \geq 0.145$).

Quantitative artifact diagnostics demonstrated that ICA reduced mean 25–45 Hz ECG–EEG coherence from 0.0178 to 0.0075 (a 57.9% reduction; 95% CI 0.0064–0.0146; exact paired $p = 0.00012$), while residual post-ICA coherence did not differ significantly between groups ($q = 0.249$). Notably, in the surrogate control analysis, none of the salient HESD contrasts exceeded the empirical null distribution generated by circular R-peak shifting (all surrogate-adjusted $q = 0.693$), indicating an absence of demonstrable temporal specificity to actual cardiac events under these testing conditions.

Finally, standard peripheral HRV parameters (RMSSD, SDNN, and pNN50) showed no statistically significant differences between RE and CTRL.

IV. Discussion

The participant-level analysis indicated observable exploratory elevations in the derived HESD metric, with the most notable effect sizes concentrated in the theta band across frontal, central, parietal, and occipital regions ($g = 1.27$–1.68) [1], [2].

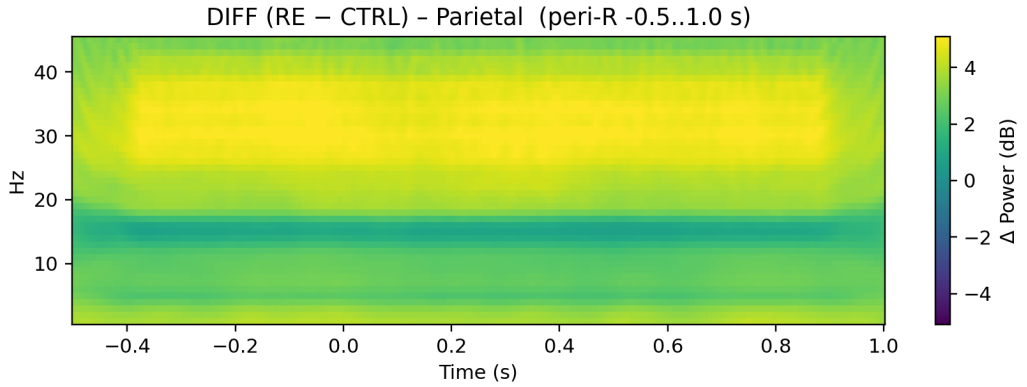

Fig. 2. Descriptive parietal peri-R time–frequency difference map (RE–CTRL). Positive values indicate higher power in RE. The broad high-frequency pattern did not correspond to an FDR-significant participant-level 25–45 Hz effect.

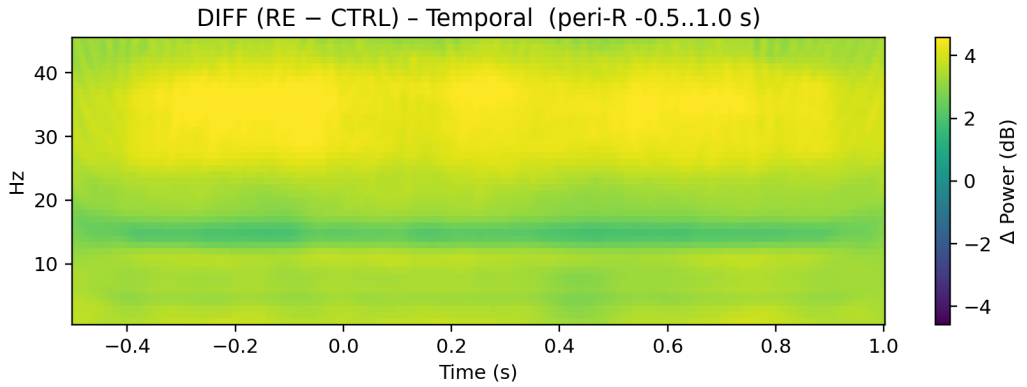

Fig. 3. Descriptive temporal peri-R time–frequency difference map (RE–CTRL). A visually sustained high-frequency group difference is present, but the corresponding participant-level high-frequency comparison did not survive multiple-comparison correction.

However, after strict false discovery rate correction across the 20-test primary inferential family, none of these comparisons maintained statistical significance at the nominal threshold ($q_{\mathrm{FDR}} \geq 0.116$). Similarly, the visually prominent high-frequency contrasts observed in parietal, temporal, and central time–frequency maps were not corroborated by participant-level inference, as no regional comparison survived multiple-comparison adjustment in the dedicated 25–45 Hz sensitivity analysis (all $q \geq 0.145$).

The circular-shift surrogate control analysis provides essential boundaries for interpreting these regional HESD patterns. None of the salient contrasts exceeded the empirical null distribution generated by circularly displacing R-peak event trains relative to the continuous EEG (all surrogate-adjusted $q = 0.693$). Consequently, while the present findings reflect group-level variations in spectral envelope dynamics within peri-R epochs, they do not establish that these perturbations are temporally specific to, or phase-locked with, individual cardiac cycles. In heartbeat-evoked electrophysiology, temporal co-occurrence alone cannot demonstrate a direct neural response to cardiac afference, particularly given the persistence of residual cardiac-field and biomechanical artifacts [3]–[5].

The high-frequency patterns require critical methodological caution. Although independent component analysis substantially attenuated 25–45 Hz ECG–EEG coherence by 57.9% on average, measurable residual coupling persisted across participants, and no regional high-frequency contrast achieved statistical significance. High-frequency scalp EEG is inherently susceptible to cranial and ocular electromyographic contamination as well as residual cardiac-field artifacts [9], [10]. Therefore, the descriptive peri-R time–frequency spectrograms should be considered exploratory representations rather than definitive evidence of cortical gamma-band synchronization or network hyperexcitability.

The low-frequency observations showed greater regional consistency in terms of effect magnitude, with theta-band elevations displaying standardized effect sizes exceeding $g = 1.50$. Cortical slowing and altered frontolimbic oscillatory dynamics are recognized electrophysiological features in focal epilepsy [6], [7]. However, given the lack of temporal specificity confirmed by the surrogate analysis, these observations should be viewed as broad alterations in oscillatory stability during recorded segments rather than genuine heartbeat-evoked interoceptive responses [3], [4].

Standard peripheral HRV metrics (RMSSD, SDNN, and pNN50) did not exhibit statistically significant group differ-

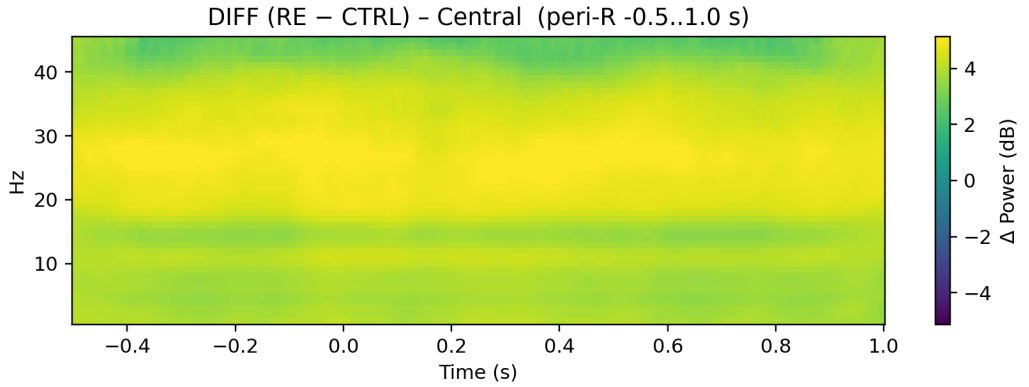

Fig. 4. Descriptive central peri-R time–frequency difference map (RE–CTRL). The visible high-frequency component was not supported by corrected participant-level high-frequency inference.

ences. While previous studies have suggested that central and autonomic interaction metrics may capture subtle regulatory disturbances not readily detected by isolated time-domain HRV parameters [6], [8], the absence of peripheral differences in this cohort must be interpreted with caution. In an exploratory sample, null findings in peripheral autonomic measures may reflect limited statistical power, inter-individual baseline variability, or recording constraints rather than preserved peripheral autonomic integrity [11], [12].

V. Limitations

The conclusions of this study are bounded by some constraints. While non-parametric bootstrap confidence intervals, exact permutation testing, and participant-level inference offer robust protection against inflated false-positive rates, these analytical safeguards cannot compensate for the statistical power constraints imposed by a small sample.

The absence of temporal specificity documented by the circular-shift control analysis constrains physiological interpretation. None of the salient regional HESD contrasts differed significantly from the surrogate null distribution, demonstrating that the observed spectral envelope alterations cannot be definitively resolved as phase-locked or causal cortical responses to discrete cardiac afferent volleys under the present experimental paradigm. Furthermore, the local temporal refinement employed during candidate event detection underscores the necessity of corroborating cardiac specificity through independent surrogate modeling rather than relying on alignment markers alone.

Regarding artifact attenuation, independent component analysis substantially reduced ECG-EEG coherence across the 25–45 Hz band by 57.9%, confirming the efficacy of ICA-based spatial filtering for suppressing volume-conducted cardiac activity in line with standard electrophysiological pipelines. While this filtering strategy effectively isolated neural components from cardiac artifacts, high-frequency scalp recordings remain sensitive to subtle myogenic contributions. Therefore, treating the peri-R time-frequency spectrograms as exploratory representations provides a conservative, methodologically sound framework that complements our participant-level inferential analysis.

Finally, unmodeled clinical heterogeneity presents a potential confounding influence. Key clinical variables documented in Table I, including antiseizure medication regimens, epileptogenic zone localization, duration of epilepsy, seizure burden, and neurobehavioral comorbidities, exert known modulatory effects on central oscillatory dynamics and autonomic tone. Given the cohort size, multivariable adjustment was not statistically tenable, leaving these factors as unmodeled contributors to inter-individual variance that require systematic stratification in larger prospective studies.

VI. Conclusion

In this exploratory investigation, participant-level analysis revealed substantial standardized effect sizes in peri-R spectral dynamics in refractory epilepsy, dominated by elevations in the theta band across frontal, central, parietal, and occipital regions ($g = 1.27$–1.68). However, following Benjamini–Hochberg FDR correction across the complete 20-test primary inferential family, no region-by-band comparison retained statistical significance at the nominal threshold ($q_{\mathrm{FDR}} \geq 0.116$), and conventional time-domain peripheral HRV parameters (RMSSD, SDNN, and pNN50) did not differ significantly between groups. Furthermore, circular-shift surrogate controls demonstrated that the observed spectral envelope perturbations were not temporally specific to true cardiac R-peak timings (all surrogate-adjusted $q = 0.693$).

Although these findings do not establish heartbeat-specific cortical modulation in this cohort, they characterize a distributed peri-R electroencephalographic profile in a well-defined clinical sample. Epilepsy affects approximately 1% of the global population, imposing a considerable burden on patient quality of life, particularly in pharmacoresistant cases where therapeutic options remain constrained. Advancing methodologically rigorous investigations into brain–heart coupling remains imperative to elucidate the neurovisceral mechanisms underlying severe clinical outcomes, such as sudden unexpected death in epilepsy (SUDEP). Ultimately, this work provides

an empirical baseline and underscores the critical need for prospective, large-scale cohorts incorporating surrogate controls and clinical stratification to evaluate the translational utility of central interoceptive metrics.

***Resumo*—Sistemas de decodificação da atenção auditiva (AAD) buscam identificar o locutor de interesse de um ouvinte na presença de múltiplas fontes sonoras, permitindo o direcionamento espacial de dispositivos de auxílio auditivo. Uma dificuldade existente no projeto e avaliação de sistemas AAD é a limitada disponibilidade de bancos de dados, devido às dificuldades técnicas e ao alto custo de implementação. A construção de um modelo generativo para as saídas de sistemas AAD permite gerar observações sintéticas que preservam as características estatísticas observadas em sujeitos reais, ampliando a disponibilidade de sinais para avaliação experimental. Para isso, este trabalho propõe um modelo estatístico baseado em Modelos Ocultos de Markov (HMM) com distribuições Beta para caracterizar as propriedades estatísticas e temporais dessas saídas. A qualidade dos dados sintéticos gerados pelo modelo é avaliada por meio de testes estatísticos, demonstrando que o modelo preserva as principais características distributivas dos dados originais. A avaliação de algoritmos de pós-processamento utilizando 100 ouvintes sintéticos apresentou menor variabilidade nas métricas de desempenho, como PESQ e STOI, em comparação com a avaliação baseada em apenas 16 participantes reais, indicando que o modelo proposto pode ser uma alternativa para ampliar a validação experimental de sistemas AAD.**

Palavras-chave—Decodificação de atenção auditiva, EEG, modelo oculto de Markov, pós-processamento.

I. Introdução

A capacidade de direcionar a atenção para uma fonte sonora específica em ambientes com múltiplos estímulos acústicos (*cocktail party effect*) é uma das principais características do sistema auditivo humano e desempenha papel fundamental na compreensão da fala em ambientes ruidosos. Entretanto, indivíduos com perda auditiva apresentam dificuldades significativas nessa tarefa, mesmo com o uso de aparelhos auditivos ou implantes cocleares. Isso porque esses dispositivos, embora incorporem algoritmos de amplificação, redução de ruído e separação de fontes, não dispõem de informações sobre qual locutor representa o foco de atenção do usuário [1]. Como consequência, a seleção e o realce do sinal de fala de interesse permanecem como um desafio em cenários com múltiplos falantes.

Nesse contexto, os sistemas de decodificação de atenção auditiva (*Auditory Attention Decoding* - AAD) têm recebido crescente atenção por utilizarem sinais neurais, especialmente o eletroencefalograma (EEG), para estimar o foco atencional do ouvinte e, dessa forma, fornecer informações que permitam o controle de dispositivos auditivos inteligentes. Essa abordagem viabiliza o desenvolvimento de próteses auditivas neurocontroladas (*neuro-steered hearing devices*), capazes de amplificar seletivamente a fala de interesse e atenuar fontes sonoras interferentes [2].

Os métodos de AAD baseados em EEG podem ser classificados em duas abordagens principais: reconstrução do estímulo e classificação direta dos sinais neurais. A primeira baseia-se na reconstrução de características do estímulo auditivo atendido, como o envelope da fala, a partir da atividade neural, seguida da comparação com os estímulos sonoros disponíveis. Embora essa abordagem apresente resultados consistentes, seu desempenho é fortemente dependente do cálculo de correlações com os sinais de áudio de interesse e tende a degradar significativamente em janelas curtas de decisão, limitando sua aplicação em sistemas de processamento em tempo real [2].

Em contrapartida, a classificação direta busca inferir o foco atencional exclusivamente a partir dos sinais neurais, dispensando o conhecimento prévio dos estímulos acústicos durante a inferência. Nos últimos anos, essa abordagem tem recebido crescente atenção devido à incorporação de técnicas de aprendizado profundo, especialmente redes neurais convolucionais (CNNs), recorrentes (RNNs) e, mais recentemente, arquiteturas baseadas em grafos, que exploram de forma mais eficiente as características espaciais e temporais dos sinais de EEG. Em particular, a decodificação da atenção auditiva espacial (*Spatial Auditory Attention Decoding* – SpAAD), que estima a direção da fonte sonora atendida sem utilizar informações do conteúdo da fala, destaca-se como uma alternativa para dispositivos auditivos neurocontrolados, por possibilitar decisões rápidas e reduzir a dependência de informações acústicas externas [3].

Embora os avanços recentes tenham melhorado o desempenho dos algoritmos de AAD, suas predições são normalmente realizadas em janelas temporais curtas de EEG, tornando-as suscetíveis a flutuações e classificações incorretas. Janelas reduzidas são desejáveis por permitirem uma resposta mais rápida às mudanças de atenção do usuário, porém, geralmente, resultam em menor confiabilidade das decisões. Nesse contexto, técnicas de pós-processamento têm sido empregadas para explorar a continuidade temporal do processo atencional, suavizando as predições e reduzindo a influência de erros esporádicos sem comprometer significativamente a capacidade de detectar mudanças reais de atenção. Além de aumentar a robustez das decisões, esses métodos favorecem a implementação de sistemas AAD em tempo real ao proporcionar transições mais estáveis entre estados atencionais e evitar alterações abruptas no ganho dos dispositivos auditivos [4].

Uma das principais limitações da área é a reduzida disponibilidade de bases de dados que reproduzam cenários

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

auditivos realistas com múltiplas fontes sonoras concorrentes e contenham registros neurais adequados para o desenvolvimento e a validação desses sistemas. Além disso, os conjuntos de dados mais amplamente utilizados na literatura contam com um número limitado de participantes, restringindo a diversidade interindividual e a capacidade de generalização dos modelos [5] [6]. Essa limitação afeta não apenas a comparação entre diferentes algoritmos de AAD, mas também a avaliação de técnicas de pós-processamento, cuja eficácia depende da análise de padrões temporais e da variabilidade das decisões produzidas pelos classificadores em um conjunto representativo de usuários.

Neste trabalho, propõe-se um modelo estatístico baseado em Modelos Ocultos de Markov (*Hidden Markov Models* – HMM) para caracterizar temporalmente a saída de sistemas de AAD. O modelo possui dois objetivos principais. O primeiro consiste em possibilitar uma avaliação mais robusta de algoritmos de pós-processamento por meio da geração de ouvintes sintéticos cujas sequências de decisões preservem as características estatísticas observadas em usuários reais, ampliando a variedade de sequências disponível para validação experimental. O segundo objetivo é fornecer uma representação compacta e interpretável do comportamento temporal dos sistemas AAD, permitindo descrever sua dinâmica por meio dos parâmetros estimados do HMM. Para validar a abordagem proposta, foram comparados os desempenhos de um algoritmo AAD com e sem pós-processamento utilizando tanto os participantes reais de uma base de dados quanto os ouvintes sintéticos gerados pelo modelo. A avaliação foi realizada considerando métricas objetivas de qualidade e inteligibilidade da fala, bem como métricas temporais relacionadas à dinâmica das decisões, permitindo analisar o impacto do pós-processamento tanto na qualidade da saída quanto na estabilidade temporal do sistema.

O trabalho foi organizado da seguinte forma: a Seção II apresenta o modelo estatístico que caracteriza a saída de sistemas AAD através de HMM com distribuições Beta. A Seção III detalha a metodologia utilizada, além do banco de dados empregado. A Seção IV apresenta os resultados obtidos e respectiva discussão. As conclusões sobre o trabalho estão na Seção V.

II. Modelo Estatístico da Saída de um Sistema AAD usando HMM com Distribuições Beta

Um modelo oculto de Markov é formalmente definido pelo conjunto de parâmetros $\lambda = \{\pi, A, B\}$, por um conjunto finito de N estados ocultos $S = \{s_1, s_2 \dots s_N\}$ e por uma sequência de T observações $O = \{o_1, o_2 \dots o_T\}$ [7]. A distribuição inicial dos estados é dada por $\pi = \{\pi_1, \pi_2 \dots \pi_N\}$, em que $\pi_i = P(q_1 = s_i)$, sendo q_1 a variável de estado inicial. A matriz de probabilidades de transição entre estados $A = [a_{ij}]$ é definida por

$$a_{ij} = P\left(q_{t+1} = s_j \middle| q_t = s_i\right), \tag{1}$$

descrevendo a probabilidade de transição do estado s_i para o estado s_j no instante t+1, em que q_t representa a variável de estado no instante t. As probabilidades de emissão (ou verossimilhanças das observações) são representadas por B, sendo definidas por

$$b_j(o_t) = P\left(o_t \middle| q_t = s_j\right), \tag{2}$$

que expressa a probabilidade de observar o_t dado que o sistema se encontra no estado s_j.

No contexto da AAD, os algoritmos produzem decisões probabilísticas sequenciais referentes à fonte sonora à qual o indivíduo está direcionando sua atenção em ambientes com múltiplos falantes. Um paradigma experimental amplamente empregado considera dois locutores concorrentes, por exemplo, posicionados à esquerda e à direita do ouvinte. Em cada instante de decisão, o algoritmo estima a probabilidade de que a atenção do usuário esteja direcionada a cada um desses locutores (Fig. 1).

Como os rótulos de referência da direção de atenção são conhecidos nos conjuntos de dados utilizados para treinamento e avaliação, a saída de um sistema AAD pode ser representada por uma matriz $P \in R^{T \times S}$, em que T representa o número de decisões temporais e S o número de participantes. Cada elemento $P_{t,s}$ corresponde à probabilidade de que a decisão no instante t, para o participante s, esteja correta, denotada por p_{correto}.

Nesse contexto, a utilização da probabilidade de classificação correta, p_{correto}, como variável de observação do HMM, mostra-se particularmente adequada, pois fornece uma medida contínua da confiança do decodificador em cada instante de tempo. Diferentemente de decisões binárias, que descartam informações relacionadas ao grau de confiança da classificação, as saídas probabilísticas preservam informações importantes sobre a confiabilidade de cada estimativa produzida pelo sistema AAD, permitindo que o HMM atribua maior ou menor peso às observações de acordo com seu nível de confiabilidade.

Como $p_{\text{correto}} \in [0,1]$, o espaço das observações é naturalmente limitado ao intervalo unitário, o que motiva a utilização da distribuição Beta para modelar as probabilidades de emissão, proporcionando uma forma estatisticamente consistente de incorporar as saídas probabilísticas do sistema AAD ao modelo HMM [8]. Diferentemente da mais empregada distribuição Gaussiana, cujo domínio compreende toda a reta real, a distribuição Beta respeita naturalmente os limites impostos por variáveis probabilísticas, dispensando procedimentos artificiais de truncamento. Essa característica permite interpretar cada estado oculto como um padrão distinto de confiança associado às decisões produzidas pelo sistema AAD.

Considerando essa formulação, a probabilidade de emissão $b_j(o_t)$ associada ao estado s_j é modelada pela função densidade de probabilidade (PDF) de uma distribuição Beta parametrizada pelos parâmetros positivos α_j e β_j. Dessa forma, a verossimilhança de uma observação o_t dado o estado s_j é expressa por

$$b_j(o_t) = f\left(o_t \middle| \alpha_j, \beta_j\right) = \frac{1}{B\left(\alpha_j, \beta_j\right)} o_t^{\alpha_j - 1} (1 - o_t)^{\beta_j - 1}, \tag{3}$$

em que

$$B(\alpha, \beta) = \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha + \beta)} \tag{4}$$

representa a função Beta e $\Gamma(\cdot)$ denota a função Gama.

Dada uma sequência de observações O e um conjunto de N estados ocultos, o objetivo consiste em estimar os parâmetros do HMM, incluindo a matriz de probabilidades de

transição A e as probabilidades de emissão B, determinadas pelos parâmetros α_j e β_j das distribuições Beta associadas a cada estado. A estimação desses parâmetros é realizada por meio de um procedimento iterativo de máxima verossimilhança conhecido como algoritmo *forward-backward*, ou algoritmo de Baum-Welch [7]. Esse algoritmo parte de uma estimativa inicial dos parâmetros do modelo e, de forma iterativa, alterna entre a estimação das probabilidades dos estados ocultos e a atualização dos parâmetros do modelo, aumentando progressivamente a verossimilhança da sequência de observações.

Após a estimação dos parâmetros do HMM $\hat{\lambda} = (\hat{\pi}, \hat{A}, \{\hat{\alpha}_j, \hat{\beta}_j\}_{j=1}^{N})$, o modelo pode ser utilizado para gerar sequências sintéticas de probabilidades, provenientes de sistemas AAD, que preservam as características estatísticas e temporais dos dados originais. Em particular, a distribuição inicial dos estados $\hat{\pi}$, a matriz de transição $\hat{A}$ e os parâmetros $(\hat{\alpha}_j, \hat{\beta}_j)$ das distribuições Beta associadas a cada estado definem completamente o processo gerador das observações.

Para construir um conjunto de dados sintético composto por L ouvintes artificiais, são inicialmente simuladas sequências de estados ocultos $\{q_t\}_{t=1}^{T}$. O estado inicial é amostrado de acordo com a distribuição $\hat{\pi}$ e, nos instantes subsequentes, as transições entre estados são geradas segundo as probabilidades definidas em $\hat{A}$. Em cada instante t, dado que o sistema se encontra no estado $q_t = s_j$, uma observação o_t é amostrada da distribuição Beta correspondente. Esse procedimento produz sequências de probabilidades $o_t \in [0,1]$ que reproduzem os níveis de confiança fornecidos pelo sistema AAD original.

Ao repetir esse processo de forma independente para L realizações, obtém-se um conjunto de dados sintético capaz de reproduzir tanto a dinâmica temporal das transições entre estados atencionais quanto as propriedades estatísticas da confiança do decodificador. Esses dados sintéticos são particularmente úteis para a avaliação da robustez de algoritmos, a realização de experimentos controlados e a ampliação de bases de dados experimentais de tamanho reduzido, preservando a estrutura probabilística e temporal aprendida a partir das observações reais produzidas por sistemas AAD.

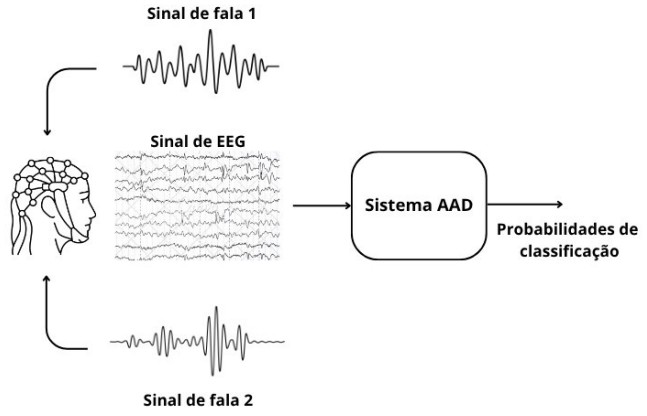

Fig. 1. Diagrama ilustrativo do paradigma experimental utilizado em problema de decodificação de atenção auditiva.

A. Seleção do número ótimo de estados

Para selecionar o número ótimo de estados, os dados de observação foram particionados em conjuntos de treinamento e teste. A seleção do modelo foi realizada utilizando o Critério de Informação Bayesiano (*Bayesian Information Criterion* – BIC) e o Critério Integrado da Verossimilhança Completa (*Integrated Completed Likelihood* – ICL), ambos avaliados sobre o conjunto de treinamento, enquanto a capacidade de generalização foi analisada por meio da log-verossimilhança no conjunto de teste independente [9].

O BIC estabelece um compromisso entre o ajuste do modelo aos dados e sua complexidade, sendo definido por

$$BIC = -2 \cdot \log P(O|\lambda) + p \cdot \log M, \tag{5}$$

em que $P(O|\lambda)$ representa a verossimilhança da sequência de observações do conjunto de treinamento dado o conjunto de parâmetros do HMM $\lambda = \left(\pi, A, \{\alpha_j, \beta_j\}_{j=1}^{N}\right)$, M corresponde ao número total de observações e p representa o número de parâmetros livres do modelo. Para o HMM considerado, com distribuições Beta modelando as probabilidades de emissão, o número de parâmetros é dado por

$$p = (N-1) + N(N-1) + 2N, \tag{6}$$

o qual contempla os parâmetros da distribuição inicial dos estados, da matriz de probabilidades de transição e das distribuições de emissão de cada estado. Valores menores de BIC indicam um melhor equilíbrio entre qualidade de ajuste e complexidade, penalizando modelos excessivamente complexos à medida que o número de estados aumenta.

Com o objetivo de considerar também a qualidade da separação entre os estados ocultos, foi empregado o critério ICL. Esse critério estende o BIC por meio da incorporação de um termo de penalização baseado na entropia da distribuição posterior dos estados:

$$ICL = BIC - 2 \sum_{t=1}^{T} \sum_{k=1}^{N} \gamma_t(k) \log \gamma_t(k), \tag{7}$$

em que $\gamma_t(k) = P(q_t = s_k | O, \lambda)$ representa a probabilidade posterior do sistema estar no estado s_k no instante t. O termo adicional penaliza modelos que apresentam atribuições de estados difusas ou com elevada sobreposição, favorecendo soluções cujos estados sejam bem separados e mais facilmente interpretáveis.

Além desses critérios, a capacidade de generalização de cada modelo candidato foi avaliada por meio do cálculo da log-verossimilhança, $\log P(O|\lambda)$, sobre o conjunto de teste independente. Essa etapa garante que o modelo selecionado não apenas apresente um adequado ajuste aos dados de treinamento, mas também seja capaz de capturar padrões subjacentes que se generalizem para observações não utilizadas durante o processo de estimação.

Por fim, realizou-se uma avaliação qualitativa do modelo aprendido, com o objetivo de verificar sua interpretabilidade e plausibilidade física. Em particular, os parâmetros das distribuições Beta associadas às probabilidades de emissão foram analisados por meio das médias e variâncias por elas induzidas, verificando-se se cada estado oculto representa um regime distinto de confiança do decodificador. Adicionalmente, a estrutura da matriz de probabilidades de transição foi examinada para confirmar a coerência da

dinâmica temporal do modelo, incluindo a presença de estados estáveis, padrões de transição consistentes e a ausência de fragmentação artificial em estados redundantes ou de curta duração.

III. Metodologia

Neste trabalho, é proposto um modelo estatístico baseado em HMM para caracterizar as propriedades estatísticas e temporais da saída de sistemas AAD. Nas subseções seguintes, são apresentados os detalhes do banco de dados e do modelo AAD utilizado, os procedimentos de implementação e treinamento do modelo proposto, bem como as métricas de avaliação e os algoritmos de pós-processamento empregados nos experimentos.

A. Banco de dados e modelo AAD

O modelo de AAD empregado neste trabalho é baseado na abordagem proposta em [3], a qual utiliza uma rede neural convolucional para decodificar a direção espacial da atenção auditiva a partir de sinais de EEG em um cenário com dois locutores. O modelo fornece, para cada janela temporal de decisão, a probabilidade de que o ouvinte esteja direcionando sua atenção ao locutor posicionado à esquerda ou à direita.

Os experimentos foram realizados utilizando uma base de dados pública disponibilizada pela KU Leuven [5]. Os sinais de EEG foram adquiridos de 16 indivíduos com audição normal por meio de um sistema BioSemi ActiveTwo, composto por 64 canais e frequência de amostragem de 8196 Hz. Os estímulos auditivos consistiram em quatro discursos em língua holandesa, narrados por três diferentes locutores do sexo masculino. Cada discurso possui aproximadamente 12 minutos de duração e foi dividido em dois segmentos de aproximadamente 6 minutos. Dessa forma, cada participante (ouvinte) realizou oito ensaios (*trials*) de aproximadamente 6 minutos cada, totalizando 48 minutos de gravação.

Durante cada ensaio, os participantes foram expostos simultaneamente a dois fluxos de fala apresentados com o mesmo nível sonoro, tendo sido instruídos a concentrar sua atenção em apenas um deles, ignorando o outro. Os estímulos foram apresentados de forma dicótica, com um locutor em cada ouvido, ou espacializados por meio de funções de transferência relacionadas à cabeça (*Head-Related Transfer Functions* – HRTFs), simulando fontes sonoras localizadas a ±90° em relação ao ouvinte.

Para evitar vazamento de informação entre os conjuntos de treinamento, validação e teste, neste trabalho tanto o conteúdo dos discursos quanto a identidade dos locutores foram mantidos distintos entre essas partições. Especificamente, a avaliação foi conduzida individualmente para cada participante (*leave-one-subject-out*). As narrativas 1 e 2 foram utilizadas para treinamento e validação, excluindo-se os dados do participante sob avaliação, enquanto as narrativas 3 e 4 desse mesmo participante foram reservadas para teste. Destaca-se que as narrativas 3 e 4 foram narradas pelo mesmo locutor, ao passo que as narrativas 1 e 2 envolvem locutores distintos.

Os sinais de EEG foram segmentados em janelas temporais sobrepostas utilizando uma estratégia de janela deslizante com sobreposição de 50%. Foi considerada a duração da janela de decisão de 1 s.

A saída do modelo AAD consiste em uma sequência de probabilidades que representa, para cada janela de decisão, a probabilidade de que a atenção do ouvinte esteja voltada para o locutor à esquerda ou à direita. Para os 16 participantes, essas probabilidades são organizadas em uma matriz $P \in R^{T\times 16}$, em que T representa o número de janelas temporais e 16 corresponde ao número total de participantes da base de dados. Como o conjunto de teste é composto apenas pelas narrativas 3 e 4, as saídas do sistema AAD correspondem aos ensaios 3, 4, 7 e 8. Essas sequências probabilísticas constituem as observações utilizadas como entrada para o modelo HMM descrito nas seções anteriores. Informações adicionais sobre a arquitetura da CNN, o procedimento de treinamento e a implementação do sistema AAD podem ser encontradas em [10].

B. Inicialização dos parâmetros do HMM

Embora o algoritmo de Baum–Welch possibilite a estimação não supervisionada dos parâmetros de um HMM, seu desempenho depende fortemente da inicialização desses parâmetros [9]. Devido à natureza não convexa da função de verossimilhança, o algoritmo converge garantidamente apenas para um ótimo local. Consequentemente, uma inicialização inadequada pode conduzir a soluções subótimas, convergência lenta ou casos degenerados, como estados com probabilidade de ocupação desprezível ou distribuições de emissão pouco distintas.

Seja o conjunto de parâmetros do HMM denotado por $\lambda = \{\pi, A, B\}$,em que $B = \left\{\alpha_j, \beta_j\right\}_{j=1}^{N}$ representa os parâmetros das distribuições Beta associadas às probabilidades de emissão. A distribuição inicial dos estados, $\pi^{(0)}$, é definida como uniforme, de modo que

$$\pi_j^{(0)} = \frac{1}{N},\ j = 1,\ldots,N, \tag{8}$$

refletindo a ausência de conhecimento prévio que favoreça qualquer estado oculto.

A matriz inicial de probabilidades de transição, $A^{(0)} \in R^{N\times N}$, é construída de forma que cada linha represente uma distribuição de probabilidades válida. Para isso, seus elementos $a_{ij}^{(0)}$ são inicialmente gerados como valores aleatórios positivos e, em seguida, normalizados de forma que

$$\sum_{j=1}^{N} a_{ij}^{(0)} = 1\ ,\ \forall i, \tag{9}$$

garantindo que a soma dos elementos de cada linha seja igual à unidade. Essa estratégia de inicialização confere flexibilidade ao modelo para capturar diferentes dinâmicas temporais, evitando padrões de transição determinísticos ou enviesados.

Para as probabilidades de emissão, cada estado oculto s_j é modelado por uma distribuição Beta parametrizada por (α_j, β_j). A inicialização desses parâmetros é realizada de maneira orientada pelos dados, com o objetivo de promover uma separação significativa entre os estados desde o início do processo de estimação. Especificamente, o conjunto de observações O é particionado em N grupos utilizando N-1 quantis, de forma que cada grupo contenha aproximadamente o mesmo número de amostras. Para cada grupo j, são calculadas a média e a variância amostrais, as quais são

empregadas na estimação inicial dos parâmetros $\alpha_j^{(0)}$ e $\beta_j^{(0)}$ por meio do método dos momentos.

Essa estratégia de inicialização apresenta diversas vantagens. Primeiramente, garante que as distribuições de emissão estejam distribuídas ao longo de todo o intervalo (0,1), reduzindo a sobreposição inicial entre os estados ocultos. Além disso, favorece uma convergência mais rápida do algoritmo de Baum–Welch ao fornecer uma aproximação inicial estruturada da distribuição dos dados. Por fim, reduz a probabilidade de ocorrência de soluções degeneradas, como estados que convergem para distribuições praticamente idênticas ou que passam a representar apenas uma parcela insignificante das observações.

C. Procedimento de treinamento e estabilidade numérica

O treinamento do modelo por meio do algoritmo de Baum–Welch foi realizado com um limite máximo de 50 iterações e um critério de parada antecipada baseado na variação da log-verossimilhança total. Especificamente, o processo iterativo foi encerrado quando o ganho relativo da log-verossimilhança entre duas iterações consecutivas tornou-se inferior a 10^{-4}, assegurando a convergência do algoritmo e evitando iterações desnecessárias.

Cuidados adicionais foram adotados para garantir a estabilidade numérica durante a estimação dos parâmetros de emissão. Como a distribuição Beta é definida no intervalo (0,1), ela não admite observações exatamente iguais a 0 ou 1. Essa limitação decorre da forma de sua função densidade de probabilidade, que pode tornar-se indefinida ou divergir nos extremos do intervalo, dependendo dos valores de seus parâmetros.

Para contornar esse problema, todos os valores das observações foram limitados ao intervalo $[10^{-6}, 1\text{-}10^{-6}]$ por meio de truncamento. De forma análoga, as probabilidades produzidas pelo sistema AAD foram restringidas ao intervalo $[10^{-4}, 1\text{-}10^{-4}]$, evitando valores extremos que poderiam comprometer a estabilidade numérica ou resultar em avaliações degeneradas da função de verossimilhança durante o processo de treinamento.

D. Critérios objetivos de qualidade e inteligibilidade da fala

A qualidade e a inteligibilidade da fala foram avaliadas por meio das métricas de banda larga PESQ (*Perceptual Evaluation of Speech Quality*) [11] e STOI (*Short-Time Objective Intelligibility*) [12], respectivamente.

Devido à longa duração de cada ensaio, os índices PESQ e STOI foram calculados em segmentos de aproximadamente 4 s [13]. Como a saída do sistema AAD consiste em uma estimativa probabilística da direção da atenção auditiva do ouvinte, indicando a probabilidade de atenção direcionada ao locutor à direita ou à esquerda, essas probabilidades foram utilizadas para controlar linearmente o ganho aplicado a cada fluxo de fala. Dessa forma, os valores de PESQ e STOI foram calculados considerando uma combinação ponderada das fontes sonoras, na qual o ganho atribuído a cada locutor é proporcional à probabilidade estimada pelo sistema AAD. Essa abordagem permite avaliar o impacto da incerteza das decisões do AAD na qualidade e inteligibilidade da fala, em vez de considerar apenas decisões binárias de seleção do locutor atendido.

E. Algoritmos de pós-processamento

Foram avaliados dois algoritmos de pós-processamento: o método de controle de ganho (*Gain Control* - GC) proposto em [4] e o rastreador de estados (*State Tracker* - ST) proposto em [14]. O objetivo dessa análise é comparar o desempenho desses métodos em relação à saída direta do sistema AAD e, principalmente, investigar a influência da variabilidade proporcionada pelos ouvintes sintéticos gerados pelo modelo proposto. Para isso, os algoritmos de pós-processamento foram avaliados considerando tanto as saídas originais do AAD obtidas a partir dos participantes reais da base de dados quanto as sequências probabilísticas geradas pelo modelo estatístico proposto.

Além das métricas objetivas de qualidade e inteligibilidade da fala, PESQ e STOI, o desempenho dos métodos também foi analisado por meio de métricas associadas à dinâmica temporal das decisões do classificador, incluindo acurácia, *switch rate*, *false-switch burst* e *dwell time* [10]. Essas métricas permitem avaliar não apenas o desempenho global do sistema, mas também sua estabilidade e capacidade de acompanhar corretamente as mudanças no estado de atenção do usuário. O *switch rate* quantifica a frequência de mudanças incorretas de decisão ao longo do tempo. O *false-switch burst* caracteriza a duração de períodos consecutivos em que o algoritmo permanece em uma decisão incorreta após uma troca indevida, enquanto o *dwell time* representa o tempo durante o qual o sistema permanece corretamente no estado correspondente à atenção verdadeira antes de ocorrer uma transição incorreta.

IV. Resultados e Discussão

Esta seção apresenta os resultados obtidos a partir dos métodos descritos na seção anterior, além da discussão sobre os mesmos.

A. Determinação do número ótimo de estados

O número ótimo de estados ocultos foi determinado por meio de uma análise conjunta do BIC, do ICL e da log-verossimilhança obtida para dados não utilizados no treinamento. O conjunto de observações foi dividido em um conjunto de treinamento e um conjunto de teste, sendo que o conjunto de treinamento compreendeu os ensaios 3, 4 e 7, enquanto o conjunto de teste correspondeu ao ensaio 8. Os critérios BIC e ICL foram calculados utilizando os dados de treinamento, enquanto a capacidade de generalização de cada modelo foi avaliada por meio da log-verossimilhança obtida no conjunto de teste independente.

Foram avaliados diferentes modelos candidatos com número crescente de estados ocultos N, iniciando em $N = 2$. A análise foi conduzida até que não fossem observadas melhorias significativas, caracterizadas por um comportamento de platô ou aumento nos valores de BIC e/ou ICL, juntamente com a saturação da log-verossimilhança calculada no conjunto de teste.

Conforme ilustrado na Fig. 2, observa-se que o ICL apresenta um aumento gradual a partir de $N = 7$, indicando uma redução na separação entre os estados para modelos mais complexos. Simultaneamente, a log-verossimilhança avaliada no conjunto de teste apresenta um comportamento de saturação, indicando que a inclusão de estados adicionais não proporciona melhorias significativas na capacidade de generalização do modelo. Embora o BIC continue apresentando redução para valores maiores de N, a taxa de

diminuição torna-se marginal, indicando um ganho limitado no ajuste do modelo em relação ao aumento da complexidade.

Com base na análise conjunta desses três critérios, o número ótimo de estados foi definido como $N = 8$, proporcionando um equilíbrio adequado entre complexidade do modelo, capacidade de generalização e interpretabilidade, evitando a criação de estados redundantes e o *overfitting*.

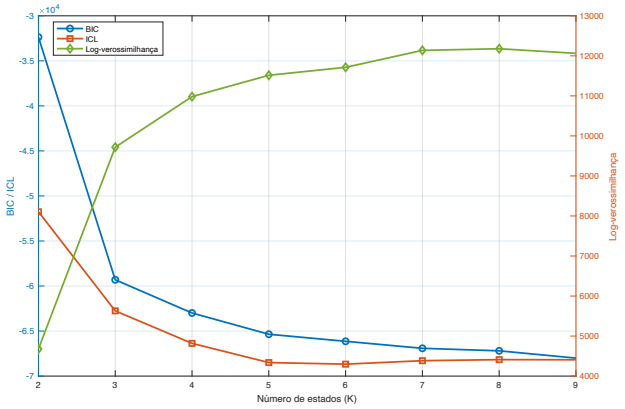

Fig. 2. Determinação do número ótimo de estados ocultos utilizando BIC, ICL e log-verossimilhança.

B. *Validação estatística do modelo*

Foram realizados dois testes estatísticos para avaliar a similaridade entre as distribuições das saídas do sistema AAD obtidas para os 16 participantes da base de dados e para os 100 ouvintes sintéticos gerados pelo modelo proposto: o teste de Kolmogorov–Smirnov para duas amostras (KS) [15] e a distância de Wasserstein de primeira ordem [16].

Em ambos os testes estatísticos, os dados sintéticos foram gerados utilizando o procedimento *leave-one-subject-out*. Para cada um dos 16 ouvintes reais, o modelo HMM foi treinado utilizando os dados dos outros 15 ouvintes. A partir dos parâmetros estimados pelo modelo, foram então gerados os dados sintéticos, que foram comparados, por meio dos testes estatísticos, com os dados do ouvinte real excluído do processo de treinamento. Esse procedimento foi repetido individualmente para cada um dos 16 ouvintes, garantindo que, em cada avaliação, o ouvinte utilizado como referência permanecesse fora do conjunto de dados empregado no treinamento do modelo.

O teste KS quantifica a máxima diferença entre as funções de distribuição acumulada empíricas de duas amostras, enquanto a distância de Wasserstein fornece uma medida da discrepância global entre suas distribuições. Em ambas as análises, foi empregado um procedimento de *bootstrap*, no qual cada participante real foi comparado, em 100 iterações, com ouvintes sintéticos selecionados aleatoriamente.

Os resultados do teste KS, apresentados na Fig. 3, apresentaram estatísticas predominantemente entre 0,13 e 0,27. Como valores menores da estatística KS indicam menores diferenças entre as distribuições acumuladas [15], esses resultados sugerem que as sequências sintéticas apresentam comportamento estatístico semelhante ao observado nos participantes reais, embora algumas diferenças específicas entre indivíduos sejam identificadas.

A distância de Wasserstein de primeira ordem, apresentada na Fig. 4, apresentou valores predominantemente inferiores a 0,15, com média aproximada de 0,11. Considerando que valores menores dessa métrica representam maior proximidade entre as distribuições [16], os resultados indicam que o modelo preserva as características globais das distribuições originais.

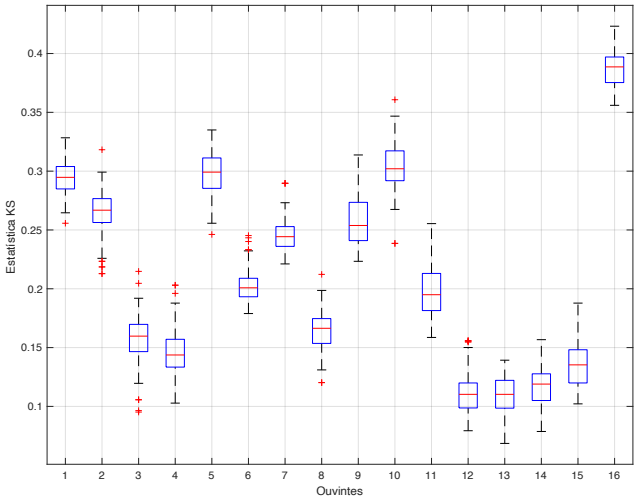

Fig. 3. Distribuição da estatística KS para cada participante real, obtida por *bootstrap* ao comparar as saídas do AAD dos 16 sujeitos da base de dados com os 100 ouvintes sintéticos.

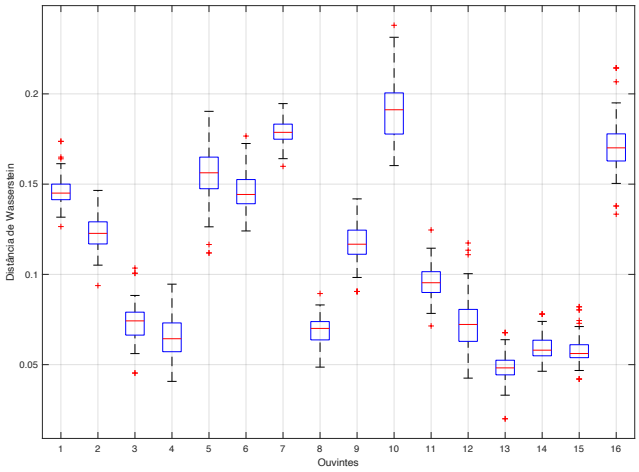

Fig. 4. Distribuição da distância de Wasserstein para cada participante real, obtida por *bootstrap* ao comparar as saídas do AAD dos 16 sujeitos da base de dados com os 100 ouvintes sintéticos.

C. *Comparação das distribuições de PESQ e STOI entre ouvintes reais e sintéticos*

Foram comparados os valores de PESQ e STOI obtidos a partir das saídas do sistema AAD para os 16 ouvintes reais da base de dados e para 100 ouvintes sintéticos gerados pelo modelo proposto, conforme descrito na Seção III-D. As Fig. 5 e Fig. 6 apresentam a comparação global das distribuições dos valores de PESQ e STOI, respectivamente, considerando ambos os grupos de ouvintes. A Fig. 7 apresenta a evolução temporal dessas métricas, mostrando a média e o desvio padrão calculados para cada segmento, permitindo comparar a variabilidade dos resultados entre os ouvintes reais e sintéticos ao longo dos ensaios.

Observa-se que, de forma geral, as distribuições das métricas de qualidade e inteligibilidade da fala são preservadas pelo modelo proposto, indicando que as características estatísticas dos dados reais são adequadamente

reproduzidas pelos ouvintes sintéticos. A análise da evolução temporal das métricas também demonstra comportamento semelhante entre os dois grupos, com valores médios de PESQ e STOI acompanhando a mesma tendência ao longo dos ensaios.

Além disso, nota-se que os ouvintes sintéticos apresentam menor dispersão ao longo dos ensaios, resultando em valores de PESQ e STOI mais estáveis quando comparados aos participantes reais. Por outro lado, os dados reais apresentam maiores oscilações, principalmente nos dois últimos ensaios de teste analisados. Essas variações podem estar associadas a características individuais dos participantes, como diferenças no comportamento de atenção ou na dificuldade de manutenção do foco atencional durante os experimentos.

Apesar dessas diferenças pontuais, os resultados indicam que o modelo proposto é capaz de reproduzir não apenas as distribuições globais de desempenho, mas também o comportamento temporal médio das métricas de qualidade e inteligibilidade obtidas a partir das saídas do sistema AAD.

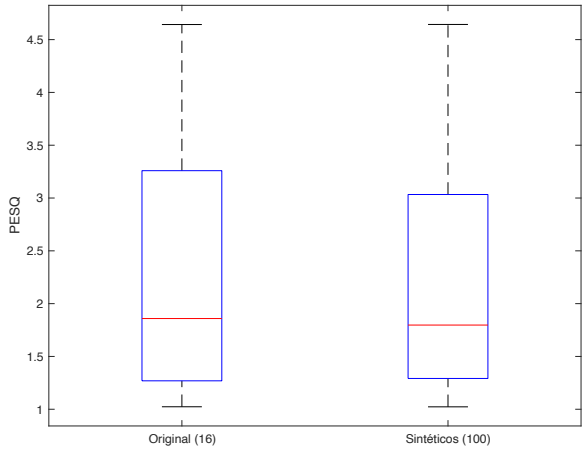

Fig. 5. Diagramas de caixas dos valores de PESQ obtidos para os 16 ouvintes reais e para os 100 ouvintes sintéticos.

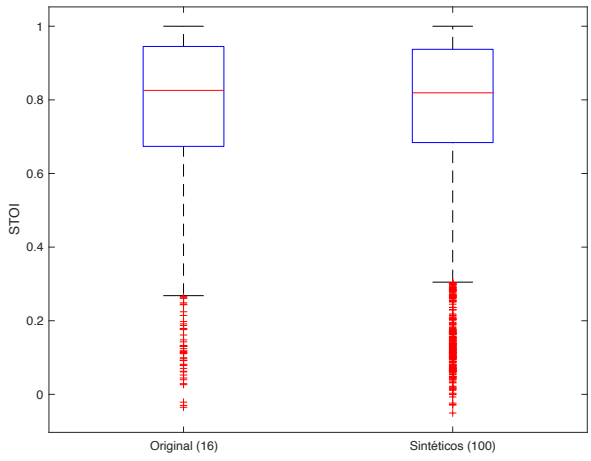

Fig. 6. Diagramas de caixas dos valores de STOI obtidos para os 16 ouvintes reais e para os 100 ouvintes sintéticos.

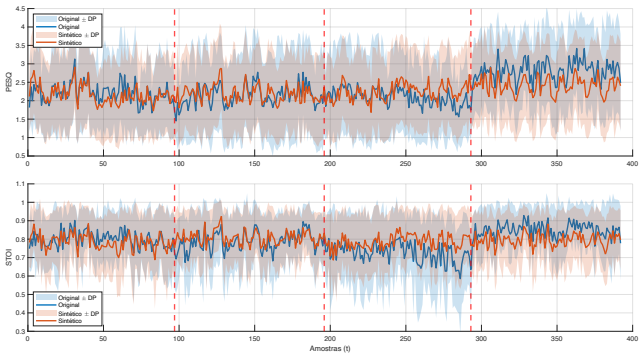

Fig. 7. Evolução temporal dos valores médios de PESQ e STOI para os ouvintes reais e sintéticos. As regiões sombreadas indicam um desvio padrão em torno da média. As linhas tracejadas vermelhas delimitam os quatro ensaios de teste.

D. Avaliação de algoritmos de pós-processamento para AAD utilizando ouvintes reais e sintéticos

Como descrito na Seção III-E, foram avaliados dois algoritmos de pós-processamento propostos na literatura em relação às métricas objetivas e temporais, utilizando como entrada as probabilidades de saída do sistema AAD obtidas tanto para os 16 ouvintes reais da base de dados quanto para os 100 ouvintes sintéticos gerados pelo modelo proposto. Ambos os algoritmos possuem hiperparâmetros responsáveis por controlar a estabilidade temporal das decisões e a velocidade das transições entre estados de atenção. Para cada método, foi realizada uma busca em grade considerando cinco valores para os respectivos hiperparâmetros, sendo apresentados os resultados correspondentes às configurações com melhor desempenho.

Os resultados apresentados nas Tabelas I e II mostram que o algoritmo GC proporciona melhorias consistentes em relação à saída direta do AAD sem pós-processamento, principalmente nas métricas PESQ, STOI, acurácia, *switch rate* e *dwell time*. A redução observada no *false-switch burst* está relacionada ao comportamento esperado dos algoritmos de suavização, uma vez que a maior estabilidade temporal das decisões pode prolongar a permanência em uma classificação incorreta após uma troca equivocada. O algoritmo ST, por sua vez, apresenta ganhos mais limitados, com principalmente nas métricas PESQ, *switch rate* e *dwell time*.

A principal contribuição do modelo proposto é evidenciada pela comparação entre os resultados obtidos com os ouvintes reais e sintéticos. As Tabelas I e II mostram que os valores médios das métricas obtidos com os 100 ouvintes sintéticos permanecem dentro da faixa de variação observada para os 16 ouvintes reais, indicando que o modelo preserva o comportamento estatístico das avaliações de desempenho do sistema AAD e dos algoritmos de pós-processamento.

Além disso, os resultados obtidos com os ouvintes sintéticos apresentam uma redução na variabilidade das métricas, com desvios padrão menores em comparação aos observados para os ouvintes reais. Essa característica representa uma vantagem para a avaliação de algoritmos de AAD e técnicas de pós-processamento, pois permite análises com maior consistência estatística e menor influência de variações individuais presentes em bases de dados com número reduzido de participantes. Dessa forma, o modelo proposto possibilita ampliar a avaliação experimental desses sistemas, mantendo as características estatísticas dos dados originais.

V. CONCLUSÃO

Este trabalho apresentou um modelo estatístico baseado em HMM com distribuições Beta para caracterizar as propriedades estatísticas e temporais das saídas probabilísticas de sistemas de AAD. Ao modelar simultaneamente a evolução temporal dos estados de atenção e a incerteza associada às decisões do AAD, o modelo proposto possibilitou a geração de sinais de observações sintéticas que preservam as principais características observadas nos sujeitos reais.

A similaridade entre as saídas do AAD obtidas para sujeitos reais e sintéticos foi avaliada por meio do teste de Kolmogorov–Smirnov e da distância de Wasserstein, demonstrando que o modelo é capaz de reproduzir a estrutura estatística dos dados originais. Além disso, a avaliação de algoritmos de pós-processamento utilizando ouvintes sintéticos mostrou que os dados gerados mantêm o comportamento observado nos participantes reais, ao mesmo tempo em que reduzem a variabilidade das métricas de desempenho, incluindo PESQ e STOI. No entanto, é importante deixar claro que os dados sintéticos complementam a avaliação dos algoritmos, não substituindo a validação com dados de participantes humanos.

Trabalhos futuros deverão investigar o uso de bases de dados incluindo participantes com deficiência auditiva, bem como avaliar a generalização dos dados sintéticos em dados de saída de diferentes arquiteturas de AAD. Além disso, será importante comparar a abordagem proposta com modelos generativos como *autoencoders* e modelos difusos.

O modelo proposto apresenta-se como uma alternativa para ampliar a avaliação experimental de sistemas AAD em bases de dados com número limitado de participantes. A geração de sinais estatisticamente consistentes de ouvintes sintéticos permite análises mais robustas de algoritmos de pós-processamento e da dinâmica temporal das decisões do AAD.

***Abstract*—Horse height measurement is important for the contexts of morphometric evaluation, management, selection, and competition. Although conventional measurement with a measuring stick, hippometer, or measuring tape is well established, it depends on direct physical measurement and correct positioning of both the animal and the measuring instrument. This study proposes an image-based methodology for estimating horse height from a single lateral photograph using anatomical landmark detection and pixel-to-centimeter calibration. A You Only Look Once (YOLO) pose model based on the yolo11s-pose architecture was trained to detect two landmarks: the withers and the contact point of the hoof with the ground. The vertical distance between these keypoints was used to estimate height in pixels and then converted into centimeters using simple linear regression. The pose model was trained and validated using 116 lateral horse images, while calibration used 15 images acquired under a standardized protocol with reference heights measured by a leveling hippometer. The evaluation was organized into three stages: YOLO pose validation using 17 images, pixel-to-centimeter calibration using 15 images, and a preliminary complete-pipeline demonstration using two independent images. In validation, the model detected all horses and showed strong agreement between the predicted and reference pixel heights, with an R^2 of 0.9905 and an MAE of 19.61 px. Pixel-to-centimeter calibration achieved an MAE of 2.56 cm and RMSE of 2.96 cm using leave-one-out cross-validation based on reference keypoint annotations, and therefore this error reflects the calibration stage rather than the complete automatic pipeline. In the preliminary complete-pipeline demonstration, height was estimated for two independent images, resulting in a mean absolute error of 2.86 cm and a mean percentage error of 1.74%. The results indicate that the proposed method is a promising single-image alternative for horse height estimation, without the need for depth sensors, multiple viewpoints, or specialized acquisition devices.**

***Index Terms*—Computer vision, equine morphometry, horse height estimation, image-based measurement, pose estimation, YOLO.**

I. Introduction

Measuring the height of a horse may appear to be a simple procedure, but it remains a fundamental part of equine evaluation. Height at the withers is routinely used in morphometric assessment, breed characterization, management, selection, and competition contexts. It also contributes to the description of body proportions and general conformation, supporting decisions related to animal classification, functional aptitude, and breeding programs [1]. For this reason, obtaining reliable height measurements is still an important task in both scientific and practical equine evaluation.

The conventional procedure is based on direct manual measurement using a measuring stick, hippometer, or measuring tape. In formal contexts, the measurement is taken at the highest point of the withers, which is the anatomical reference adopted in official veterinary regulations [2]. Although manual measurement is well established, it requires the evaluator to remain close to the animal and depends on the correct positioning of both the horse and the measuring instrument. In practice, these requirements can make the procedure slower or more difficult when animals are reactive, unfamiliar with the equipment, or evaluated outside controlled facilities.

These practical limitations have motivated the development of image-based and non-contact approaches for animal morphometry. In horses, digital image analysis has been investigated as a tool for estimating body measurements and evaluating conformation from standardized photographs [3]–[5]. Other studies have explored three-dimensional sensing, Light Detection and Ranging (LiDAR), and machine vision systems to obtain equine body measurements with reduced physical interaction between the evaluator and the animal [6], [7]. Together, these works indicate a clear movement toward more objective, repeatable, and less invasive methods for morphometric assessment.

Recent advances in computer vision have further expanded this possibility. Deep learning models can detect animals, localize anatomical landmarks, and support automatic measurement pipelines. In equine applications, target detection and keypoint-based approaches have been proposed for automated body measurement, while horse pose estimation has also emerged as a relevant task for anatomical landmark localization [8], [9]. However, many available approaches are designed for multiple body traits or rely on more complex acquisition setups, such as depth sensors, three-dimensional point clouds, multiple landmarks, or specialized imaging devices.

In this context, a simplified image-based approach focused specifically on height estimation may provide a practical alternative. Since horse height is represented by the vertical relationship between the withers and the ground, this measurement can be adapted to a keypoint-based image analysis problem. By detecting the upper and lower anatomical references in a standardized lateral photograph and applying a calibration strategy, the pixel measurement can be converted into a real-world height estimate. Therefore, this study proposes and eval-

uates an image-based methodology for estimating horse height from a single lateral photograph. The proposed approach uses a You Only Look Once (YOLO) pose model to detect two anatomical landmarks, the withers and the hoof contact point with the ground, calculates the corresponding height in pixels, and applies a linear regression model to convert this measurement into centimeters. By combining anatomical landmark detection, standardized image acquisition, and pixel-to-centimeter calibration, this work aims to provide a practical alternative for estimating horse height from a single lateral image.

II. Materials and Methods

A. Proposed System

This study proposes a methodology for estimating horse height from a single lateral image. Conceptually, the system was structured into two main stages: the automatic detection of anatomical landmarks using a YOLO pose model, and the conversion of the image-based measurement into centimeters. The complete operational pipeline is illustrated in Fig. 1, comprising image acquisition, YOLO-based landmark detection, pixel-height estimation, and regression-based conversion to centimeters.

Initially, the model identifies two points of interest on the animal's body: the withers and the contact point between the most visible front hoof and the ground. The difference between the vertical coordinates of these points provides the horse height in pixels. This measurement is then converted into centimeters using a linear regression model calibrated with images acquired under a standardized protocol and real heights obtained using a leveling hippometer. The following subsections describe each stage in more detail.

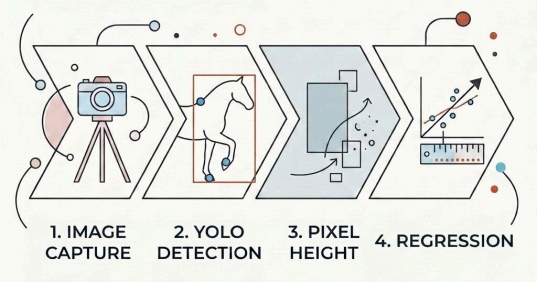

Fig. 1. Overview of the proposed pipeline for horse height estimation, including image acquisition, YOLO-based landmark detection, pixel-height estimation, and regression-based conversion to centimeters.

B. Dataset Description

The images used in this study were organized according to their role in the proposed pipeline. One subset was used for training and validating the YOLO pose model, a second subset was used for calibrating the relationship between pixel-based measurements and real height in centimeters, and two additional images were reserved for a preliminary demonstration of the complete system.

The first subset consisted of 116 lateral-view horse images used for anatomical landmark detection. These images were obtained from a personal catalog and from publicly available online sources licensed under Creative Commons Attribution 4.0 International (CC BY 4.0), selected through a directed search according to visual criteria compatible with the objective of this study. Only images containing a single horse were included, with the animal positioned laterally, visually aligned, and with visible withers and identifiable hooves. This subset was used only for training and validating the landmark detection model, since images obtained from online sources do not necessarily follow a controlled acquisition protocol for metric calibration.

The pose estimation subset was divided into training and validation sets, totaling 99 images for training and 17 images for validation. The split was performed randomly and reproducibly using a fixed seed of 42, with approximately 85% of the images assigned to training and 15% assigned to validation.

The second subset consisted of 15 images acquired specifically for the calibration stage during a classical equestrian competition. These images were obtained under a standardized capture protocol, with the camera positioned 3 m from the horse, in landscape orientation, without digital zoom, with the device positioned at an average height of 1.20 m from the ground and aligned with the lateral plane of the animal. The device used for image acquisition was an iPhone 17 Pro Max.

During the acquisition of the calibration subset, the horses were kept on flat ground and in a quadrupedal standing position, that is, standing still and supported by all four limbs. The real height of each animal was obtained using a leveling hippometer, and this measurement was considered the experimental reference. The images acquired by the authors involved privately owned animals and were obtained with permission from the responsible owners or handlers. Since the procedure was non-invasive and consisted only of photographic recording and reference height measurement, no experimental animal intervention was performed. The use of image-based measurements in this study was supported by previous works that explored digital morphometric measurement, machine vision, and pose estimation approaches for horses and livestock, reinforcing the potential of computer vision as a non-contact alternative for extracting body measurements from images [4], [8], [9].

Finally, two additional images were acquired under the same standardized capture protocol and used only for the preliminary complete-pipeline demonstration. These images were not used for YOLO training, validation, or pixel-to-centimeter calibration.

C. Image Annotation Protocol

All images in the pose estimation subset were manually annotated using the Computer Vision Annotation Tool (CVAT). The annotations were performed by a single annotator to avoid inter-annotator variability. As illustrated in Fig. 2, each image was annotated with a bounding box surrounding the entire horse and two anatomical keypoints: the withers and

the contact point between the most visible front hoof and the ground.

Fig. 2. Manual annotation of the horse bounding box and anatomical keypoints used for height estimation.

The bounding box was included to guide the model in identifying the horse within the image, limiting the region of interest and reducing background interference during keypoint detection. However, it was not directly used to calculate the height in pixels. The height estimation was based only on the anatomical keypoints, which were selected to represent the upper and lower references of the vertical measurement.

The withers were selected as the upper reference point because they correspond to the conventional anatomical landmark used for horse height measurement. According to the veterinary regulations of the Fédération Equestre Internationale (FEI), the measurement is taken at the highest point of the withers, immediately above the spinous process, usually associated with the fifth thoracic vertebra. The same regulations also indicate that the animal should be in a normal standing position, weight-bearing on all four limbs, before measurement [2].

Since the proposed methodology is based on two-dimensional lateral images, the lower reference point was operationally defined as the contact point between the most visible front hoof and the ground. This point represents the lower vertical reference required to estimate the animal's height in the image, aligning the computational measurement with the conventional procedure while adapting it to the visual information available in a lateral photograph. Additionally, the 15 calibration images were annotated following the same criteria to provide reference keypoint coordinates for fitting the pixel-to-centimeter regression model, as described in Section F.

D. YOLO Pose Model Training

For automatic anatomical landmark detection, a YOLO pose estimation model based on the yolo11s-pose architecture was used. This architecture was selected for its ability to simultaneously perform object detection and keypoint localization within the same structure [10], [11]. This characteristic is suitable for the objective of this study, since the estimated height depends on the accurate localization of the withers and the hoof contact point with the ground.

Training was performed using transfer learning from pre-trained weights. The images were processed with an input size of 960 pixels, a batch size of 8, and 150 training epochs. The AdamW optimizer was used, with an initial learning rate of 0.005, a weight decay of 0.0005, and a patience of 50 epochs.

Considering the limited size of the dataset, data augmentation techniques available in the YOLO training framework were applied during training, including variations in scale, translation, rotation, shear, hue, saturation, and brightness, as well as mosaic and mixup in controlled proportions. These strategies were adopted to increase the visual variability presented to the model and reduce the risk of overfitting.

E. Pixel-Based Height Estimation

After training, the model was used to automatically detect the withers and the hoof contact point in lateral horse images. Since the animal's height is represented by a vertical measurement, the initial estimate was calculated using only the y-axis coordinates of the two detected keypoints. The height in pixels was obtained as the absolute difference between the vertical coordinate of the hoof and the vertical coordinate of the withers, as follows:

$$H_{px} = |y_{hoof} - y_{withers}| \tag{1}$$

where H_{px} represents the estimated height in pixels, y_{hoof} corresponds to the vertical coordinate of the hoof contact point with the ground, and $y_{withers}$ corresponds to the vertical coordinate of the withers.

This pixel-based measurement corresponds to an intermediate stage of the system. Although it does not directly represent the unit of interest for the final user, it preserves the logic of conventional height measurement, which also considers the vertical distance between the withers and the ground.

F. Pixel-to-Centimeter Calibration

To convert the estimated height in pixels into centimeters, simple linear regression was used. The calibration was performed using the calibration subset described in Section B, which included images acquired under a standardized capture protocol and associated with real height measurements obtained using a leveling hippometer. For each calibration image, the pixel height was calculated from the reference keypoint annotations, following the same anatomical criteria described in Section C.

This measurement was obtained as the absolute difference between the vertical coordinates of the hoof contact point and the withers, as defined in Section E. The use of reference annotations in this stage allowed the regression model to be fitted from consistent image measurements before being applied to automatically predicted keypoints. The relationship between the image-based measurement and the real height was modeled as:

$$H_{cm} = a \cdot H_{px} + b \tag{2}$$

where H_{cm} represents the estimated height in centimeters, H_{px} corresponds to the height in pixels obtained from the reference keypoint annotations, and a and b are the coefficients fitted by the linear regression model.

G. Evaluation Metrics

The evaluation was organized into three complementary analyses: validation of the YOLO pose model, evaluation of the pixel-to-centimeter calibration, and a preliminary complete-pipeline demonstration. The YOLO pose model was evaluated on the validation set, composed of 17 images not used during weight updating. For each image, the predicted horse instance was matched to the reference annotation using the highest Intersection over Union (IoU) between predicted and annotated bounding boxes, with a minimum IoU threshold of 0.3. This criterion was used only to select the corresponding detected instance before evaluating the anatomical keypoints. The minimum confidence threshold used during validation was 0.05.

Keypoint accuracy was assessed by the Euclidean pixel error between predicted and reference points, calculated separately for the withers and hoof contact point. Pixel-based height was evaluated by comparing the height obtained from predicted keypoints with that obtained from reference annotations, using mean absolute error (MAE), root mean squared error (RMSE), and coefficient of determination R^2.

The calibration analysis was performed using 15 images acquired under the standardized capture protocol. Pixel heights were obtained from CVAT reference annotations and related to the corresponding hippometer measurements using simple linear regression. Calibration performance was evaluated using leave-one-out cross-validation (LOOCV), with 14 samples used for fitting and one for testing at each iteration. The resulting estimates were compared with the real heights using MAE and RMSE, while R^2 was reported for the regression fitted to the complete calibration subset. This analysis was based on reference keypoint annotations and therefore characterized the pixel-to-centimeter conversion stage.

Finally, the complete system was demonstrated on two additional images not included in the training, validation, or calibration subsets. In this stage, the predicted instance was selected by the highest detection confidence, simulating real use of the system. The pixel height obtained from the YOLO-predicted keypoints was converted into centimeters using the calibrated regression model and compared with the reference height measured using the leveling hippometer.

III. RESULTS AND DISCUSSION

The experimental results are organized according to the main stages of the proposed pipeline: anatomical landmark detection, pixel-to-centimeter calibration, and preliminary complete-pipeline demonstration.

A. YOLO Pose Validation

The YOLO pose model was evaluated on the validation set composed of 17 images that were not used during weight updating. The model detected the horse in all validation images, resulting in a detection rate of 100%. For the pixel-based height estimation, the comparison between the values obtained from the predicted keypoints and those obtained from the reference annotations resulted in an R^2 of 0.9905, RMSE of 24.78 px, and MAE of 19.61 px. When normalized by the reference pixel-height measurements, the mean absolute error corresponded to 3.10%. These results indicate a strong agreement between predicted and reference pixel heights, suggesting that the model was able to preserve the vertical measurement required for subsequent height estimation.

The anatomical landmarks showed different levels of localization error. The MAE was 16.65 px for the withers and 46.72 px for the hoof contact point. The higher error observed for the hoof is consistent with the greater visual variability of the distal limb region, where ground contact, limb overlap, shadow, and background texture may affect point localization. Despite this difference between keypoints, the overall pixel-height error remained moderate relative to the reference pixel-height scale, which is the most relevant factor for the proposed height estimation pipeline.

The mean bounding box IoU was 0.873, indicating that the detected horse instances were well aligned with the reference annotations. However, the bounding box was used only as an auxiliary criterion to match the predicted instance to the annotated animal during validation, and it was not used to calculate height. As shown in Fig. 3, the model localized the withers and hoof contact point and generated a predicted pixel-height measurement close to the reference annotation, illustrating the agreement observed in the quantitative validation results.

Fig. 3. Representative example of YOLO pose prediction and reference annotation, illustrating the procedure used for pixel-height validation.

B. Pixel-to-Centimeter Calibration

After validating the pixel-based measurement, a linear regression model was used to convert height in pixels into

centimeters. The calibration analysis was performed using 15 images acquired under the standardized capture protocol. The reference heights of the animals used for calibration ranged from 151 to 175 cm, with a mean height of 165.53 cm. The fitted regression model was represented by:

$$H_{cm} = 0.0575 \cdot H_{px} + 35.7890, \tag{3}$$

where H_{cm} is the estimated height in centimeters and H_{px} is the height in pixels obtained from the reference anatomical landmarks. In the complete fit, the model achieved an MAE of 2.20 cm, RMSE of 2.55 cm, and R^2 of 0.8195. These results indicate that the pixel-height measurement was able to explain a substantial part of the variation in real height, even though the calibration subset was limited in size.

Leave-one-out cross-validation was used to obtain a more conservative estimate of calibration performance. In this evaluation, the model achieved an MAE of 2.56 cm and RMSE of 2.96 cm. Since this analysis was based on reference keypoint annotations, these values characterize the pixel-to-centimeter calibration stage. The increase in error compared with the complete fit was expected, since each prediction was made using a model trained without the tested sample. Even so, the LOOCV error remained close to the fitting error, suggesting that the relationship between pixel height and real height was reasonably stable under the standardized acquisition protocol. The calibration curve is shown in Fig. 4.

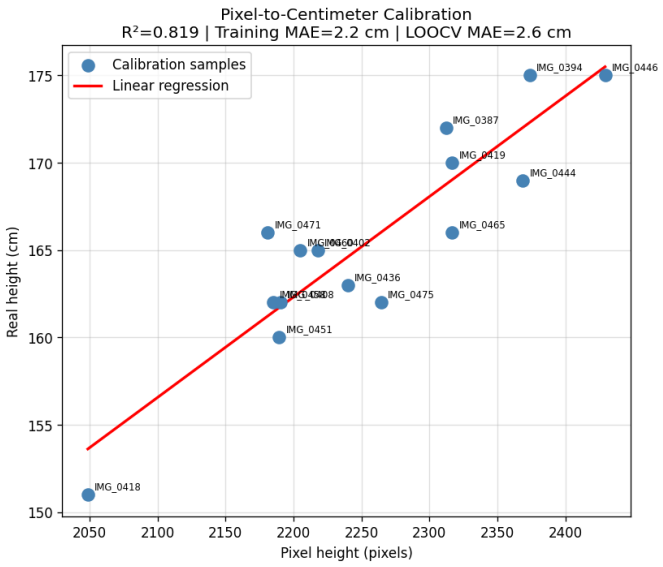

Fig. 4. Linear regression between pixel height and real height in centimeters.

Since the calibration subset included animals between 151 and 175 cm, estimates for horses substantially outside this interval should be interpreted with caution, as they would involve extrapolation beyond the fitted range. Additionally, the fitted regression is specific to the acquisition geometry used in this study, including camera distance, device height, image orientation, and lateral alignment. Changes in these conditions may require a new calibration procedure.

C. Complete Pipeline Demonstration

The complete system was demonstrated using two additional images ($n = 2$) that were not included in the training, validation, or calibration subsets. In this stage, the full automatic pipeline was applied: the YOLO pose model detected the anatomical keypoints, the pixel height was calculated from the predicted coordinates, and the calibrated regression model converted the measurement into centimeters. The results obtained for each image are presented in Table I.

TABLE I
COMPARISON BETWEEN REFERENCE AND ESTIMATED HORSE HEIGHT.

Image	Reference height (cm)	Estimated height (cm)	Absolute error (cm)	Percentage error (%)
IMG_0514	167.00	170.96	3.96	2.37
IMG_0523	160.00	161.76	1.76	1.10

The mean absolute error in this preliminary complete-pipeline demonstration was 2.86 cm, with a mean percentage error of 1.74% and RMSE of 3.06 cm. These values were close to the LOOCV calibration error, indicating that the complete system behaved consistently with the expected performance of the regression model in the two tested cases. However, because this stage was limited to two independent images, these results should be interpreted as an initial demonstration of feasibility rather than a conclusive estimate of system performance. These results suggest that the proposed pipeline can provide useful height estimates when the acquisition protocol is followed, although further testing with a larger number of images is still required.

D. Further Discussion

The results obtained in this study support the feasibility of estimating horse height from a single lateral image using anatomical landmark detection and regression-based calibration. This outcome is aligned with previous studies that have explored image-based morphometric assessment, computer vision, and keypoint detection for equine body measurement [4], [8], [9]. Although these studies differ in acquisition protocols, measured traits, and computational strategies, they reinforce the potential of digital imaging methods as alternatives or complements to traditional morphometric measurement.

When compared with related image-based approaches, the proposed method presented results within a similar order of magnitude, while adopting a simplified height-specific pipeline. Freitag et al. used standardized photographs and ImageJ-based analysis to estimate equine body measurements, reporting strong agreement between image-derived and conventional measurements [3]. More automated approaches based on deep learning and machine vision have reported mean relative errors of 2.98% for withers height and 4.01% for shoulder height in Mongolian horses [7]. Similarly, a method combining target detection and keypoint detection reported mean relative errors of 3.86% for shoulder height,

3.98% for body height, and 2.89% for croup height [8]. In the present study, the YOLO validation resulted in a normalized pixel-height MAE of 3.10%, while the preliminary complete-pipeline demonstration resulted in a mean percentage error of 1.74% in two independent images. These results suggest that the proposed approach is compatible with the performance range reported by related image-based methods, although the complete-pipeline result should be interpreted cautiously due to the limited number of final test images.

A central contribution of the proposed approach is its simplified and height-specific design. Unlike broader morphometric systems, which may require multiple body points, depth information, or more elaborate acquisition setups, the present method estimates height using only two anatomical landmarks: the withers and the hoof contact point. This allows the complete estimation process to be performed from a single lateral RGB image, positioning the method as an intermediate alternative between direct manual measurement and more complex computer vision systems. Compared with approaches that require a physical scale reference in each image, the proposed strategy relies on a fixed acquisition geometry combined with linear calibration. Since fixed distances and spatial references are commonly used in handling, training, and competition settings, the proposed acquisition protocol may be simple to understand and apply in practical equine environments.

The standardized capture protocol was essential for the performance of the calibration model. Since a monocular image does not inherently provide metric scale, controlling distance, camera orientation, zoom, and animal posture helped reduce variation not related to the animal's real height. Therefore, the fitted regression model should be interpreted as specific to the acquisition geometry used in this study, including camera distance, device height, image orientation, and lateral alignment. For this reason, estimates for horses substantially outside the calibration range of 151 to 175 cm should be interpreted with caution, since they would involve extrapolation beyond the fitted data.

Future work should expand both the annotated image dataset used to train the YOLO pose model and the standardized image set used for pixel-to-centimeter calibration. A larger and more diverse dataset may improve landmark detection and calibration robustness across different animal sizes, conformations, coat colors, backgrounds, and acquisition conditions. Additional experiments should also evaluate the influence of camera distance, camera height, lateral alignment, image resolution, lighting conditions, and animal posture on the final height estimate. These experiments may help determine whether a single calibration model is sufficient or whether device-specific or protocol-specific calibration models are required under different acquisition conditions.

Despite these limitations, the results indicate that the proposed method is a promising initial step toward a practical single-image alternative for horse height estimation.

IV. Conclusion

This study presented an image-based methodology for estimating horse height from a single lateral photograph by combining YOLO pose detection, pixel-height calculation from two anatomical landmarks, and linear regression calibration. The results support the feasibility of the proposed approach as an initial proof-of-concept, showing that the pipeline can estimate horse height under a standardized acquisition protocol. The method has potential as a practical single-image alternative that does not require depth sensors, multiple viewpoints, or specialized acquisition devices. However, the complete automatic pipeline was demonstrated on a limited number of independent images, and the reported final estimates should therefore be interpreted as preliminary evidence of feasibility rather than a conclusive measure of system performance.

Future work should expand the annotated dataset used for YOLO training and the calibration set used for pixel-to-centimeter conversion. Additional tests under different acquisition conditions and with a larger number of horses are also required to improve robustness and support broader practical application.

ACKNOWLEDGMENT

The authors would like to thank all those who assisted during image acquisition and reference height measurement.

***Abstract*—Open-loop Functional Electrical Stimulation (FES) output stages require a characterized relationship between the digital-to-analog converter (DAC) command and output current. This bench study evaluates a Howland current-source stage based on the STIMGRASP architecture. Four separate acquisitions were recorded for each of three nominal resistive loads (1, 2, and 4.7 kΩ), each comprising one ascending DAC sweep. For each load, the first acquisition was used for calibration and model development; the three subsequent acquisitions were held out. Across the nine held-out acquisitions (1683 DAC-bin means; 10 mV bin width), the frozen model gave a pooled bias of 0.200 mA, MAE of 0.529 mA, RMSE of 0.707 mA, and maximum absolute error of 1.815 mA. Mean per-acquisition RMSE was 0.855, 0.389, and 0.514 mA for the 1, 2, and 4.7 kΩ loads, respectively. The repeated acquisitions support acquisition-to-acquisition validation under the same bench setup, while persistent load-dependent bias shows that the single line does not capture all systematic behavior. The nominal 5%-tolerance shunt and loads were measured as 10.2, 984, 1975, and 4592 Ω; these values were used in the analysis. The model remains limited to the evaluated hardware, resistive loads, and frozen load-specific ranges, and embedded use requires explicit command-range checks.**

***Index Terms*—Functional Electrical Stimulation, Howland current source, linearity analysis, open-loop control.**

I. Introduction

Functional Electrical Stimulation (FES) systems electrically activate peripheral nerves in order to assist or restore motor functions in rehabilitation and assistive applications [1], [2]. FES uses electrical pulses to evoke muscle contractions for functional assistance or rehabilitation. Stimulation systems typically allow the configuration of pulse amplitude, width, frequency, and waveform shape. Among these variables, amplitude control is particularly important because it is associated with the recruited neuromuscular response and user comfort [3]. Before any application-level inference, the relationship between the embedded command variable and the output current must be characterized on the bench.

This work is related to the STIMGRASP FES master's thesis developed at Centro Universitário FEI by Barelli, which proposed a portable neuromuscular electrical stimulator for grasp restoration [4]. The original work describes a digitally controlled stimulation architecture based on a modified Howland current source and discusses linear stimulation sweeps and current-controlled stimulation behavior. In that investigation, predictable current control behavior is assumed as part of the stimulation architecture. However, detailed DAC-versus-current characterization curves under different load conditions are not presented, and the behavior implied by the architecture is not quantitatively characterized through correlation, regression, compliance, or load-consistency analyses.

The present work extends the original investigation by experimentally evaluating the output-stage transfer characteristic of the FES circuit. The purpose is not to redesign the STIMGRASP hardware or to provide a clinical validation of the stimulator. Instead, this study focuses on output-stage characterization: the relationship between DAC control voltage and delivered current, the effect of different resistive loads, the identification of a valid compliance region, and the derivation of an embedded DAC estimation model for open-loop operation.

The STIMGRASP circuit does not include current feedback to the microcontroller unit (MCU). Consequently, the output stage operates as an open-loop stimulation system, where the delivered current is not directly monitored during operation. A bench-derived DAC-to-current relation can provide a candidate command mapping only inside its characterized domain. If the load changes substantially, the output stage may reach voltage compliance and the delivered current may be lower than the modeled current. Without current feedback, this condition cannot be detected by the MCU in real time.

The main contributions of this paper are: (i) quantitative bench characterization of the DAC-voltage-to-output-current relationship; (ii) empirical compliance-region analysis based on inferred load voltage; (iii) load-specific and pooled calibration errors; (iv) held-out acquisition validation of the frozen global model; (v) investigation of its structured residuals; and (vi) explicit limits and range-check requirements for any prospective open-loop implementation.

II. Background

A. Howland Current Source and Compliance Voltage

The Howland current source is commonly used when a voltage command must be converted into a load current [5]. Ideally, the output current is determined by the input control voltage and resistor network, and it remains independent of the load impedance. In practice, load-independent behavior is maintained only while the amplifier output can provide the voltage required by the load. This constraint is described by the compliance voltage [6].

For a resistive load, the load voltage can be reconstructed from the measured current as

$$V_{\text{load}} = I_{\text{out}} R_{\text{load}}, \tag{1}$$

where I_{out} is expressed in amperes and R_{load} in ohms. Current-source operation is expected to remain valid inside signed negative and positive compliance boundaries,

$$V_{\text{comp},-} < V_{\text{load}} < V_{\text{comp},+}. \tag{2}$$

Samples near or beyond the available output-voltage range may exhibit compliance-limited behavior, particularly for higher load resistances.

B. Open-Loop DAC Estimation

Because the evaluated FES circuit does not provide real-time current feedback to the MCU, the embedded controller cannot directly regulate the delivered current during stimulation. Instead, current configuration must rely on an experimentally identified DAC-to-current relationship to estimate the DAC voltage required for a desired stimulation current. The experimentally identified direct model is

$$I_{\text{out}} = a V_{\text{DAC}} + b, \tag{3}$$

where V_{DAC} is the DAC control voltage and a and b are regression coefficients.

The embedded DAC estimation equation is obtained by rearranging Equation 3:

$$V_{\text{DAC}} = \frac{I_{\text{target}} - b}{a}. \tag{4}$$

Equation 4 is valid only within the experimentally characterized range. Outside this range, the output current is constrained by the available output voltage and load resistance, and the model may predict a current that cannot be physically delivered once the output stage reaches its compliance limit. Because the present open-loop implementation provides no current or output-voltage feedback to the microcontroller, the firmware cannot detect this condition during operation. It should therefore reject current requests outside the validated range and verify that the resulting DAC command remains within the corresponding characterized interval. These range checks prevent model extrapolation but cannot detect compliance caused by an unknown or time-varying load. Future implementations should incorporate current feedback or compliance monitoring, together with an independent hardware current limit.

III. Materials and Methods

A. Experimental Setup

The evaluated output stage was an FES circuit based on a Howland current source. Dedicated experimental firmware generated an ascending DAC sweep bracketed by initial and final resting intervals; it was not the conventional stimulation firmware and did not generate a therapeutic pulse train. The nominal resting point was approximately 1.65 V, corresponding to approximately zero output current. The DAC was swept from approximately 0 to 3.3 V.

Figure 1 shows the evaluated DAC and Howland-current-source output stage as extracted from the STIMGRASP documentation. It also defines the measurement convention: CH1 is the DAC node, and CH2 is the voltage at the load–shunt junction relative to ground. Thus, $I_{\text{out}} = V_{\text{CH2}}/R_{\text{shunt}}$.

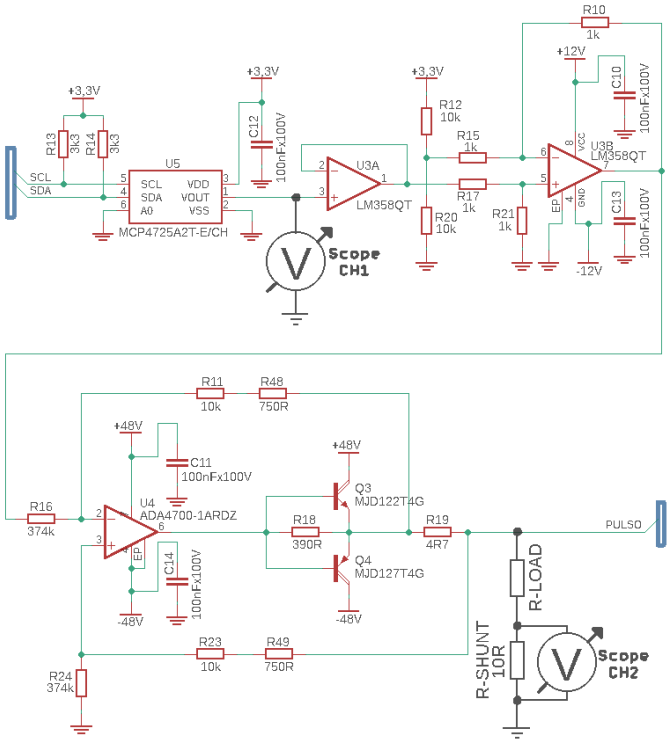

Fig. 1. Evaluated DAC and Howland-current-source output stage.

The 0–3.3 V DAC command is buffered by U3A, centered by U3B about the nominal $V_{\text{ref}} = 1.65$ V, and inverted by the Howland stage, so $I_{\text{out}} \propto -(V_{\text{DAC}} - V_{\text{ref}})$ and a negative slope is expected. The bipolar supplies let commands below and above the midpoint produce positive and negative current, respectively. The former is defined as flow through the load and shunt to ground; the sign of V_{load} therefore denotes current direction.

The nominal 10 Ω shunt and 1, 2, and 4.7 kΩ loads all had a stated tolerance of ±5%. They were measured with a UNIT-T UT89XD multimeter as 10.2, 984, 1975, and 4592 Ω, respectively; all readings were within the stated component tolerance. The measured 10.2 Ω shunt was used to convert

CH2 voltage to current, and the measured load values were used to infer V_{load}. The resistive loads provide controlled bench conditions but are not models of the nonlinear, time-varying, and electrode-dependent skin–electrode interface [7].

B. Data Acquisition

Raw data were recorded with a Tektronix MSO46B oscilloscope in 12 CSV files, corresponding to four separate acquisitions for each of the three loads. Each acquisition contained one complete ascending DAC sweep bracketed by initial and final resting intervals. For each load, the first acquisition was used for calibration and model development, whereas the three subsequent acquisitions were reserved exclusively for held-out testing. No held-out acquisition was used to determine the compliance bounds, select the model form, or estimate the regression coefficients. CH1 measured the DAC voltage and CH2 measured the shunt voltage, as shown in Figure 1. Both channels used DC coupling and 1× probes. The acquisition configuration is summarized in Table I.

TABLE I
MEASUREMENT AND ACQUISITION CONFIGURATION

Parameter	Value
Oscilloscope model	MSO46B
Channels	CH1: DAC; CH2: shunt voltage
Time base	2 s/div
Sampling rate	12.5 kS/s
Configured record length	250 kpoints
Acquisition mode/resolution	Sample, 12 bits
Channel coupling	DC (CH1 and CH2)
Probe attenuation	1× (CH1 and CH2)
Resistance meter	UNIT-T UT89XD
Shunt (nom./meas.)	10/10.2 Ω
Loads (nom./meas.)	1000/984; 2000/1975; 4700/4592 Ω

Figure 2 shows a representative raw recording for the 1 kΩ load. The DAC remains near the nominal zero-current command during the initial and final resting intervals and performs one complete ascending sweep between them. The abrupt DAC transitions delimit the portion subsequently processed as the active sweep segment.

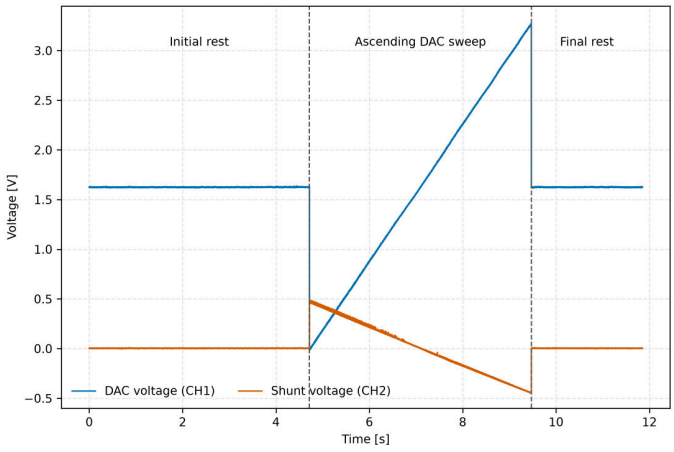

Fig. 2. Representative raw DAC and shunt voltages for the 1 kΩ load.

C. Data Processing

The active sweep segment in each acquisition was delimited by the first and last DAC discontinuities larger than 0.5 V, with a 512-sample (40.96 ms) guard removed at each boundary. The active segments of the calibration acquisitions for 1, 2, and 4.7 kΩ contained 58,386, 58,386, and 58,389 time samples, respectively; those of the nine held-out acquisitions contained 58,395–58,423 samples. Files were processed separately without sample-count equalization. Shunt voltage was converted to output current as $I_{\mathrm{out}} = V_{\mathrm{CH2}}/R_{\mathrm{shunt}}$ using the measured 10.2 Ω value; because the load and shunt were in series, this was also the load current. Output voltage was not measured directly; V_{load} was inferred from Equation 1 using the corresponding measured load resistance.

The DAC axis was rounded to 10 mV bins. For each load and acquisition, the analysis value at a bin was the arithmetic mean of all time-sample currents in that bin. Figure 3 shows these binned output-current values versus DAC voltage for the complete calibration acquisition of each load. A bin was not treated as an independent experimental replicate. The calibration set contained 325 bin means per load before compliance selection. The flattened portions for the larger loads identify output-voltage compliance. Regression used only the selected calibration-bin means; test metrics were first calculated within each complete held-out acquisition and then summarized across the three acquisitions per load.

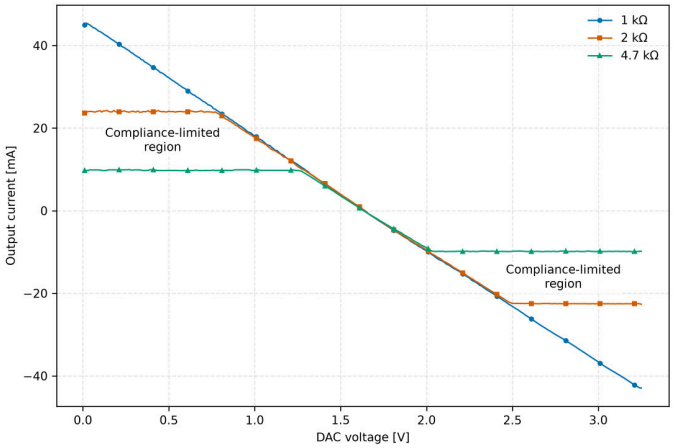

Fig. 3. Binned output current versus DAC voltage.

D. Compliance-Limited Region Selection

For each load, the minimum and maximum binned currents were converted to load-voltage bounds using the measured resistance. The shared empirical selection interval was defined as

$$V_{\mathrm{min,limit}} = \max(V_{\mathrm{min},1k}, V_{\mathrm{min},2k}, V_{\mathrm{min},4.7k}), \qquad (5)$$

and

$$V_{\mathrm{max,limit}} = \min(V_{\mathrm{max},1k}, V_{\mathrm{max},2k}, V_{\mathrm{max},4.7k}). \qquad (6)$$

This produced $-42.257 < V_{\mathrm{load}} < 44.695$ V. These are data-derived selection bounds, not independently measured amplifier compliance ratings. Because plateau noise can place isolated saturated bins just inside a strict voltage boundary, the largest contiguous 10 mV DAC run inside the interval was retained for each load; disconnected bins were rejected. This rule was applied exclusively to the calibration acquisitions, and the resulting load-specific DAC-bin sets were frozen before being applied unchanged to the nine held-out acquisitions. The complete binned calibration data remain available to describe the observed full-range behavior.

After this selection, the retained current-versus-DAC curves were similar but did not have the same DAC support: the larger loads reached compliance earlier.

E. Statistical Analysis and Model Identification

Ordinary least-squares lines were fitted separately to each load and to all retained calibration bin means pooled across loads. For each fit, the slope, intercept, R^2, mean absolute error (MAE), root mean square error (RMSE), and maximum absolute residual were calculated on the fitting data and labeled as calibration metrics. The primary predictive model was the pooled line fitted to the three calibration acquisitions; its coefficients, preprocessing, compliance bounds, and exact load-specific DAC-bin sets were frozen before evaluating the nine held-out acquisitions.

No correlation p-values or point-wise cross-validation were used as evidence of repeatability. Adjacent 10 mV bins from a monotonic DAC sweep are not independent experimental replicates, and a random split would place neighboring bins from the same acquisition in both training and test sets. Instead, each complete acquisition was kept intact. For every held-out acquisition, bias, MAE, RMSE, and maximum absolute error were calculated without refitting; per-load summaries report the mean and sample standard deviation across the three acquisitions. Pooled held-out errors are also given descriptively but reflect the unequal number of valid bins among loads.

For the pooled linear calibration, residual was defined as $e = I_{\mathrm{measured}} - I_{\mathrm{predicted}}$. Bias, MAE, RMSE, maximum absolute error, and lag-1 autocorrelation between residuals in consecutive 10 mV DAC bins were computed separately by load. The pooled line was also compared descriptively with a centered quadratic model and a continuous two-segment linear model with a breakpoint (knot) at 1.65 V. These alternatives were introduced after inspecting the calibration residuals and were not used for the primary held-out claim; choosing among them using the nine tests would require another untouched validation set.

Finally, a calibration sensitivity fit was restricted to the DAC bins represented by all three loads. This exposes the effect of the unequal pooled domains: 1 kΩ contributes 322 bins, whereas 4.7 kΩ contributes only 75. This sensitivity fit was not substituted for the frozen primary equation.

IV. Results

A. Linear Operating Region

The empirical compliance selection retained 322, 164, and 75 bin means for the calibration acquisitions at 1, 2, and 4.7 kΩ, respectively. Table II places the load-specific domains, coefficients, and error measures in one implementation-oriented summary. Each N_{bins} counts 10 mV means from one acquisition, not independent time samples or repeat acquisitions.

B. Linear Regression and Global Model

The frozen pooled calibration had the negative slope expected from the inverting topology shown in Figure 1. Its experimentally identified zero crossing, $-b/a \approx 1.653$ V, was consistent with the nominal 1.65 V reference:

$$I_{\mathrm{out,mA}} = -27.489872 V_{\mathrm{DAC}} + 45.442251. \tag{7}$$

The in-sample $R^2 = 0.999662$ reported in Table II quantifies explained calibration variance; predictive performance was assessed on the held-out acquisitions.

C. Held-Out Acquisition Validation

Table III reports the primary validation of Equation 7. The 1 kΩ tests covered 322 of 322 frozen calibration bins (100.0%), from 0.03 to 3.24 V; all 164 and 75 bins were available for the 2 and 4.7 kΩ tests, respectively. No test coefficient or compliance bound was re-estimated. Across all 1683 held-out bin means, the frozen line gave a bias of 0.2001 mA, MAE of 0.5289 mA, RMSE of 0.7070 mA, and maximum absolute error of 1.8148 mA. Because the pooled result is weighted toward the wider 1 kΩ domain, the per-load and per-acquisition results are the more informative repeatability summary.

Between-acquisition dispersion was small for 1 and 2 kΩ and larger for 4.7 kΩ. More importantly, the repeated-acquisition biases retained the load-dependent signs seen in calibration: positive for 1 kΩ and negative for the larger loads. The held-out RMSE was also higher than the 0.3810 mA pooled calibration RMSE. Thus, the additional data demonstrate stable acquisition-to-acquisition behavior under this setup but confirm systematic model-form/load effects rather than random residual scatter.

Only 75 DAC bins, from 1.26 to 2.00 V, were represented by all three loads. Restricting the sensitivity fit to this common support changed the line to $I_{\mathrm{out,mA}} = -27.0241 V_{\mathrm{DAC}} + 44.3638$ and gave an in-sample RMSE of 0.2444 mA. The coefficient change demonstrates that the pooled result depends on its unequal load composition; the wider pooled range must not be interpreted as support from all loads.

A model-form diagnostic on the same 561 calibration bins reinforced the residual finding. The global linear MAE, RMSE, and maximum error were 0.3241, 0.3810, and 1.1281 mA; corresponding values were 0.1835, 0.2359, and 0.9429 mA for a centered quadratic and 0.1552, 0.2117, and 0.9698 mA for a segmented linear model with a breakpoint at 1.65 V. These alternatives were formulated from the calibration residuals

TABLE II
OPERATING DOMAINS AND IN-SAMPLE LINEAR CALIBRATION METRICS

Load/model	Acq.	N_{bins}	V_{DAC} (V)	I_{out} (mA)	V_{load} (V)	a (mA/V)	b (mA)	R^2	MAE (mA)	RMSE (mA)	Max. (mA)
1 kΩ	1	322	0.03–3.24	−42.882–45.218	−42.196–44.494	−27.5664	45.7041	0.999818	0.2815	0.3461	0.7291
2 kΩ	1	164	0.82–2.45	−21.330–22.610	−42.127–44.655	−27.0874	44.6812	0.999799	0.1505	0.1819	0.4123

[a]One calibration source file for each load; all nine held-out files were excluded. [b]The pooled row is the union of the load-specific domains; it is not a domain supported by every load. [c]Empirical signed selection bounds inferred with measured resistances. All errors in this table are evaluated on the calibration bins used to fit the corresponding row.

TABLE III
HELD-OUT ERROR OF THE FROZEN GLOBAL LINEAR MODEL

Load	Test acquisition	N_{bins}	V_{DAC} (V)	Bias (mA)	MAE (mA)	RMSE (mA)	Max. (mA)
1 kΩ	1	322	0.03–3.24	0.5160	0.6311	0.8477	1.7481
1 kΩ	2	322	0.03–3.24	0.4596	0.6305	0.8512	1.7969
1 kΩ	3	322	0.03–3.24	0.4748	0.6459	0.8653	1.8148
1 kΩ	Mean ± SD	3 acquisitions	—	0.483 ± 0.029	0.636 ± 0.009	0.855 ± 0.009	1.8148[a]
2 kΩ	1	164	0.82–2.45	−0.0746	0.3380	0.3756	0.6952
2 kΩ	2	164	0.82–2.45	−0.1368	0.3676	0.3987	0.6710
2 kΩ	3	164	0.82–2.45	−0.1265	0.3670	0.3932	0.6217
2 kΩ	Mean ± SD	3 acquisitions	—	-0.113 ± 0.033	0.358 ± 0.017	0.389 ± 0.012	0.6952[a]
4.7 kΩ	1	75	1.26–2.00	−0.2654	0.3745	0.4359	1.1570
4.7 kΩ	2	75	1.26–2.00	−0.3005	0.4178	0.4814	1.1790
4.7 kΩ	3	75	1.26–2.00	−0.4313	0.5409	0.6239	1.1211
4.7 kΩ	Mean ± SD	3 acquisitions	—	-0.332 ± 0.087	0.444 ± 0.086	0.514 ± 0.098	1.1790[a]
All loads	Pooled bins	1683	Load specific	0.2001	0.5289	0.7070	1.8148

Residual is measured minus predicted current. Per-load bias, MAE, and RMSE summaries are mean ± sample SD across three complete acquisitions; [a] The Max. entry is the worst absolute error among the three acquisitions, not a mean. Pooled metrics use all eligible bin means and therefore inherit unequal load support.

and were not substituted for the prespecified linear model in Table III; selecting one after viewing the held-out results would make those acquisitions a model-selection set rather than an untouched validation set.

D. Residuals and Load Consistency

The pooled model has different calibration error profiles by load. For 1 kΩ, bias was 0.1367 mA, RMSE 0.3788 mA, and maximum error 0.7430 mA. Corresponding values were -0.1030, 0.2828, and 0.5777 mA for 2 kΩ, and -0.3617, 0.5430, and 1.1281 mA for 4.7 kΩ. Adjacent-bin residual autocorrelations were 0.981, 0.981, and 0.996, showing strong persistence along each calibration sweep. These are descriptive diagnostics; no inferential p-values are assigned to adjacent bins.

Figure 4 resolves the previously pooled calibration residuals by load and overlays the three held-out traces for each load. The smooth calibration guides reveal curvature and distinct load-dependent tracks rather than random scatter around zero, while the held-out traces show that the structure persists across acquisitions. In particular, the individual calibration slopes differ from the pooled slope by -0.077, 0.402, and 1.809 mA/V for 1, 2, and 4.7 kΩ, respectively.

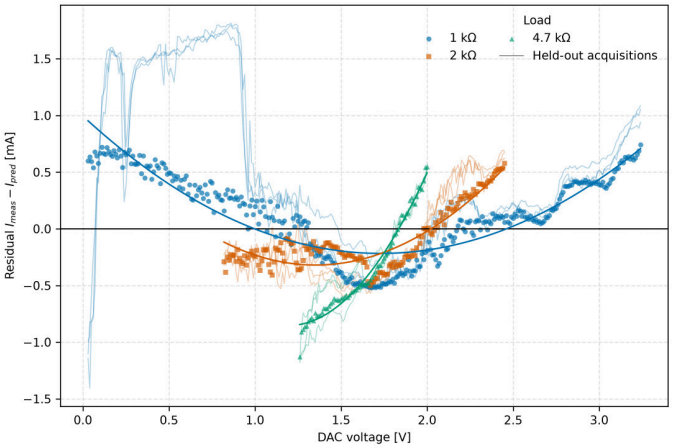

Fig. 4. Residuals of the frozen pooled linear model. Markers and solid guides show calibration residuals; thin light-colored traces show the three held-out acquisitions for each load. Guides are descriptive, not alternative prediction models.

V. DISCUSSION

The DAC-to-current response is nearly linear in a variance-explained sense after empirical compliance selection, but R^2 alone is not an accuracy or repeatability metric for a dense monotonic DAC sweep. The complete held-out acquisitions provide the relevant test: pooled RMSE increased from 0.3810 mA in calibration to 0.707 mA in testing, and the held-out maximum deviation was 1.815 mA. The small within-load SD across three held-out acquisitions supports repeatability under the same setup, but the load-dependent mean errors limit the accuracy of one global line.

The residual structure qualifies the original single-line interpretation. Strong serial persistence, load-dependent bias, visibly curved calibration tracks, and persistence of the bias signs in the repeated acquisitions show that the remaining deviations are systematic. The diagnostic segmented model reduces in-sample RMSE, but it was derived after inspecting the calibration residuals. The present tests therefore validate

the frozen linear model only; using them to promote an alternative would require another untouched dataset for an unbiased final assessment.

The pooled dataset is also unbalanced in DAC support. At the outer voltages, only the 1 kΩ load remains inside the selected interval; all three loads are represented together only from 1.26 to 2.00 V. Consequently, Equation 7 is a candidate calibration for the three observed load-specific domains, not evidence of load invariance over 0–3.3 V. The empirical signed load-voltage bounds are similarly a calibration-set selection rule rather than independently measured compliance specifications.

The nine held-out acquisitions provide acquisition-level validation under the same hardware and measurement chain. Future work should repeat the characterization under varied supply, temperature, and load conditions to quantify the model's robustness beyond the evaluated bench setup.

The resistors characterize the output stage under simple bench conditions; they do not establish performance for stimulation pulses or the electrode–skin interface. A low-cost next experiment should add a documented RC or published electrode–skin equivalent circuit, including topology, measured component values, tolerances, initial capacitor state, and repeated acquisitions using DAC sweeps or stimulation pulses. Until such a load is tested, no inference about clinical current repeatability or outcomes is supported.

Any embedded use of Equation 4 requires finite-value and range checks, rejection to a safe state outside the validated current/DAC domain, and an independent hardware current limit. These checks prevent numerical extrapolation but cannot reveal compliance under an unknown load. Current feedback or compliance monitoring would still be required to detect that condition during operation.

VI. Conclusion

This study provides a reproducible bench calibration and held-out acquisition assessment of the STIMGRASP-related Howland output stage. The first acquisition at each of three nominal resistive loads defined the frozen pooled line; three subsequent acquisitions per load were excluded from fitting. On those nine tests, pooled MAE, RMSE, and maximum absolute error were 0.529, 0.707, and 1.815 mA, respectively. The low within-load dispersion supports repeatability under this bench setup, while the persistent load-dependent residuals show that the global line is not a complete error model.

The evidence validates the frozen equation only for this hardware, the three resistive loads, and their frozen load-specific DAC/current ranges. The tests do not represent the electrode–skin interface, therapeutic pulses, or clinical outcomes; a documented RC/electrode model remains required. Conservative range rejection, compliance awareness, and hardware current limits remain necessary in any embedded implementation.

***Abstract*—Dementia represents a major global health challenge, with increasing prevalence driven by population aging and a growing demand for accessible tools for early diagnosis. Electroencephalography (EEG) has emerged as a promising low-cost and non-invasive alternative for cognitive assessment, particularly when combined with machine learning techniques. This study investigates the classification of Healthy Controls (HC), Mild Cognitive Impairment (MCI), Alzheimer's Disease (AD), and Frontotemporal Dementia (FTD) using EEG signals from the Brazilian GeronGnosis database. EEG recordings from 50 older adults were segmented into 2-second windows and transformed into time-frequency representations through Fast Wavelet Transform (FWT) using Daubechies-8 filters. Feature extraction was performed using transfer learning with EfficientNet-B0, generating 1,281-dimensional embeddings (Base 1). Feature selection based on Particle Swarm Optimization (PSO) reduced the dimensionality to 324 attributes (Base 2). Multiple machine learning classifiers, including Random Forest (RF), Support Vector Machine (SVM), Multilayer Perceptron (MLP), Naive Bayes, and Bayes Network, were evaluated using 10-fold cross-validation with 30 repetitions. In the training phase, RF with 500 trees achieved the highest accuracy on Base 1 (83.43%), while MLP reached 83.57% on Base 2. Independent test-set evaluation showed that MLP achieved the highest accuracy (73.75%) after PSO-based feature selection, whereas RF-500 achieved 68.19% accuracy with substantially lower computational cost, providing a favorable trade-off between predictive performance and efficiency. The proposed approach successfully discriminated among the four cognitive conditions and demonstrated the potential of combining EEG, wavelet-based representations, deep feature extraction, and machine learning for supporting dementia screening in clinical settings. These findings contribute to the development of accessible and scalable decision-support tools tailored to the Brazilian healthcare context.**

***Index Terms*—Electroencephalography, Dementia, Machine Learning, Wavelet Transform**

I. Introduction

Population aging has emerged as one of the most significant demographic phenomena of the 21st century, directly contributing to the increasing prevalence of neurodegenerative diseases. In this context, dementia represents a major public health challenge, currently affecting tens of millions of individuals worldwide, with projections indicating a continuous increase in prevalence by 2050 [1]. In Brazil, millions of people are estimated to be living with dementia, with Alzheimer's disease (AD) accounting for approximately 60–70% of diagnosed cases [2]. Beyond its high prevalence, dementia is associated with progressive loss of functional independence, increased

healthcare costs, and substantial social and economic burdens on patients, families, and healthcare systems.

One of the main clinical challenges associated with dementia syndromes is the early identification and accurate differentiation between healthy aging, Mild Cognitive Impairment (MCI), Alzheimer's disease (AD), and Frontotemporal Dementia (FTD) [3]. MCI represents a critical transitional stage within the continuum of cognitive decline and is associated with an elevated risk of progression to dementia [3], [4]. However, the symptomatic overlap among these conditions often hinders diagnosis based solely on clinical assessment. Although gold-standard diagnostic methods, such as Positron Emission Tomography (PET), Magnetic Resonance Imaging (MRI), and cerebrospinal fluid (CSF) biomarker analysis, provide high diagnostic sensitivity, their widespread implementation is limited by high costs, invasiveness, and restricted availability in specialized healthcare centers [5], [6].

In response to these limitations, Electroencephalography (EEG) has emerged as a promising alternative for screening and diagnostic support due to its low cost, non-invasive nature, portability, and high temporal resolution [7]. Neurodegenerative processes are reflected in brain electrical activity, producing characteristic spectral alterations associated with signal slowing and reduced complexity of cortical oscillations [8]. Previous studies have demonstrated that abnormal increases in Delta and Theta activity, together with reductions in Alpha power and disruptions in higher-frequency bands, may serve as relevant neurophysiological biomarkers for identifying different stages of cognitive impairment and distinguishing dementia subtypes [9].

The growing availability of Artificial Intelligence (AI) and Machine Learning techniques has significantly expanded the diagnostic potential of EEG. Computational approaches combined with advanced signal processing methods, such as the Wavelet Transform, enable the extraction of time-frequency representations capable of revealing neurophysiological patterns that are difficult to identify through conventional visual inspection [10]. Recent studies have reported promising results in the classification of healthy controls, MCI patients, and individuals with different forms of dementia, achieving high levels of accuracy through the integration of EEG and supervised learning algorithms [4], [11], [12]. Despite these advances, the literature still lacks studies conducted using datasets representative of the Brazilian population, limiting the direct applicability of existing models within the national healthcare context.

In this context, the present study aims to evaluate the performance of supervised machine learning algorithms for the multiclass classification of EEG signals represented in the time-frequency domain using the Wavelet Transform, based on data from the Brazilian GeronGnosis database [9]. Specifically, the proposed framework employs a pre-trained EfficientNet architecture to automatically extract deep features from wavelet-based image representations of EEG signals. These features are then used to train and compare the performance of classical machine learning classifiers, including Random Forest, Support Vector Machine (SVM), and Multilayer Perceptron (MLP), among others. Furthermore, Particle Swarm Optimization (PSO) is investigated as a feature selection strategy to reduce dimensionality and identify the most informative feature subset. The proposed approach is evaluated for discriminating healthy controls, patients with Mild Cognitive Impairment, Alzheimer's disease, and Frontotemporal Dementia.

II. Methodology

A. Proposed Method

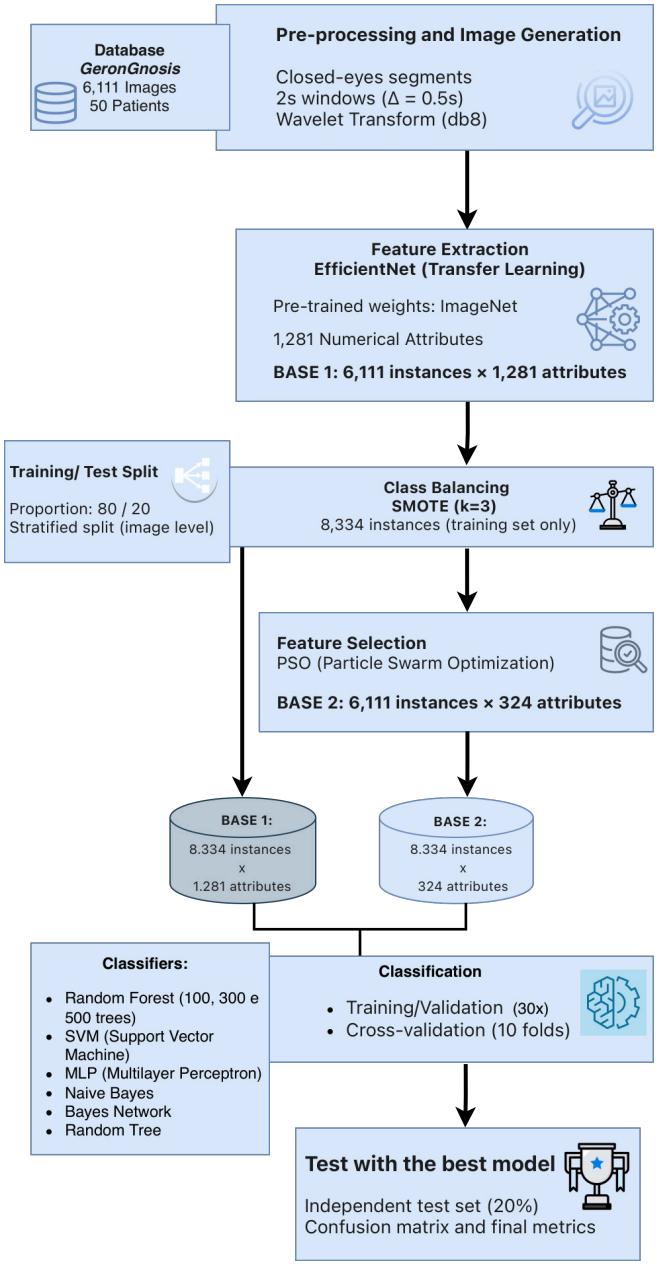

Fig. 1. Methodological workflow: from EEG acquisition to classifier evaluation.

This study proposes a deep learning and machine learning framework for the classification of EEG signals obtained

from the GeronGnosis database. The proposed methodology consists of converting EEG signals into image representations through the Wavelet Transform, followed by feature extraction using the EfficientNet convolutional neural network architecture. To address class imbalance, the Synthetic Minority Oversampling Technique (SMOTE) was applied, while Particle Swarm Optimization (PSO) was employed for feature selection and dimensionality reduction.

Several classification algorithms were evaluated, including Random Forest, Support Vector Machine (SVM), Multilayer Perceptron (MLP), Naive Bayes, Bayes Network, and Random Tree. The best-performing model was subsequently selected and assessed on an independent test set comprising 20% of the available data in order to obtain the final performance metrics.

The complete methodological workflow, illustrating the EEG signal processing and classification stages, is presented in Figure 1. The following subsections provide a detailed description of each methodological step adopted in this study.

B. GeronGnosis Database

The study used the GeronGnosis database [9], which comprises electroencephalography (EEG) recordings from 50 older adults recruited at the Cognitive Neurology outpatient clinic of the Hospital das Clínicas of the Federal University of Pernambuco (UFPE-EBSERH). The sample was distributed into four diagnostic groups: Alzheimer's Disease (n = 15), Frontotemporal Dementia (n = 5), Mild Cognitive Impairment (n = 10), and Healthy Controls (n = 20). Regarding sex distribution, the sample consisted of 40 women and 10 men, with a mean age of 69.92 ± 7.43 years. Cognitive assessment was performed using the Mini-Mental State Examination (MMSE), yielding an overall mean score of 18.48 ± 5.36 points. The mean scores for each group were: MCI (22.20 ± 4.20), AD (15.84 ± 5.30), FTD (19.50 ± 2.50), and HC (27.10 ± 2.90).

EEG signals were acquired using a Brain Wave III system (Neurovirtual), with 19 active electrodes positioned according to the International 10–20 System [13] (Fp1, Fp2, F7, F3, Fz, F4, F8, T3, C3, Cz, C4, T4, T5, P3, Pz, P4, T6, O1, and O2), in addition to auricular references (A1 and A2) and a frontal reference electrode. Electrode impedance was maintained below 5 kΩ, with a sampling frequency of 300 Hz and a resolution of 7 μV/mm. The acquisition protocol consisted of 2 minutes of baseline recording, followed by 5 minutes of resting-state EEG with eyes closed and 5 minutes with eyes open.

All procedures were approved by the Research Ethics Committee of UFPE (CAAE 71096223.3.0000.5208), and all participants or their legal representatives provided written informed consent prior to data acquisition.

C. Pre-processing and Image Generation

EEG signals from the GeronGnosis database were preprocessed using the open-source software GNU Octave [9]. Initially, the original recordings in .edf format were converted to .csv files, and only the eyes-closed segments were selected in order to minimize visual interference and standardize the resting-state condition. Temporal segmentation was then performed using 2-second windows with a 0.5-second overlap.

Subsequently, EEG signals were converted into image representations through the Fast Wavelet Transform (FWT), employing Mallat's algorithm with 10 filter banks from the Daubechies 8 (db8) wavelet family. The resulting wavelet coefficients were plotted to generate time-frequency images. Prior to transformation, all EEG channels were concatenated, allowing a single image to be generated for each signal window. This procedure produced image representations capable of capturing the time-frequency characteristics of brain activity [10]. Such an approach enables the application of convolutional neural network (CNN)-based architectures for automatic feature extraction [14].

After image generation, all samples were cataloged in an Attribute-Relation File Format (.arff) file containing the image paths and their corresponding diagnostic labels (Healthy Control, MCI, AD, and FTD). This file was subsequently used as input for the Weka platform, where the feature extraction stage was performed.

For feature extraction (Dataset 1), the EfficientNet-B0 convolutional neural network architecture was employed through the DI4jMlpFilter available in Weka, which enables deep learning-based feature extraction using the DL4J library. EfficientNet belongs to a family of CNN models known for their computational efficiency and scalability, relying on a compound scaling strategy that optimally balances network depth, width, and image resolution [15]. Transfer learning was adopted by utilizing weights pre-trained on the ImageNet dataset, one of the largest publicly available image repositories, containing more than 14 million images distributed across approximately 21,000 categories [16]. This strategy allows the model to leverage visual representations learned from large-scale datasets and adapt them to the specific domain of wavelet images derived from EEG signals.

Feature embeddings were extracted through a Dense Layer positioned after a Max Pooling operation, which preserves the most relevant patterns while reducing spatial dimensionality. This procedure resulted in Dataset 1, comprising 6,111 instances described by 1,281 numerical attributes.

Due to the high dimensionality of Dataset 1, a feature selection stage was performed using Particle Swarm Optimization, generating Dataset 2. PSO is an evolutionary optimization metaheuristic inspired by the collective behavior of bird flocks and fish schools [17]. The algorithm searches for an optimal subset of features by maximizing classifier performance while minimizing redundant and noisy information. As a result, dimensionality was reduced from 1,281 to 324 selected attributes while preserving all 6,111 instances, producing the dataset subsequently used for classification model development.

D. Training/Test Split and Class Balancing

The dataset was partitioned into training and testing subsets using the Resample method [18], following a stratified ratio of 80% for training and 20% for testing. The split was performed at the image level rather than at the subject

level. This approach represents a limitation of the present study, since different image windows derived from the same participant may be present in both the training and testing sets. Consequently, subject-specific patterns may be shared between the two subsets, potentially leading to information leakage and an overestimation of the model's generalization performance. Future studies should therefore adopt subject-level partitioning, ensuring that all image windows from a given participant are assigned exclusively to either the training or testing set.

As described in the previous section, Dataset 1 (features extracted using EfficientNet-B0) resulted in 4,888 instances for training and 1,223 instances for testing, while preserving the original dimensionality of 1,281 attributes. Similarly, Dataset 2 (after feature selection through PSO) contained 4,888 training instances and 1,223 testing instances, with the dimensionality reduced to 324 attributes.

Due to the natural imbalance among diagnostic classes, particularly the Frontotemporal Dementia group, which included the smallest number of participants, the SMOTE was applied exclusively to the training set [19]. Restricting oversampling to the training data prevents data leakage and ensures that model performance is evaluated on real, previously unseen samples during testing.

SMOTE generates synthetic examples for minority classes by interpolating between neighboring instances in the feature space [20]. In this study, a neighborhood size of (k = 3) was adopted for synthetic sample generation. After balancing, the training sets of both Dataset 1 and Dataset 2 reached a total of 8,334 instances, ensuring an approximately uniform representation of all diagnostic classes (Healthy Control, MCI, AD, and FTD) during classifier training.

E. Classifiers and Experimental Setup

To evaluate the performance of machine learning models for the multiclass discrimination of Healthy Controls, Mild Cognitive Impairment, Alzheimer's Disease, and Frontotemporal Dementia based on wavelet images derived from EEG signals, several classifiers implemented in Weka version 3.8.6 were investigated [21]. The evaluated algorithms comprised probabilistic methods (Naive Bayes and Bayes Network), tree-based approaches (Random Tree and Random Forest), artificial neural networks (Multilayer Perceptron), and SVM. For the Random Forest classifier, ensembles consisting of 100, 300, and 500 trees were evaluated. The Multilayer Perceptron employed a single hidden layer with 50 neurons, whereas the SVM classifier was assessed using linear, second-degree polynomial, and Radial Basis Function (RBF) kernels.

Experiments were conducted independently on both generated datasets (Dataset 1 and Dataset 2). Model training and selection were performed using 10-fold cross-validation with 30 repetitions on the balanced training set, providing a robust estimation of classifier performance while reducing the influence of random variations associated with a single data partition.

F. Evaluation Metrics

Upon completion of the training process for both datasets, the results were individually exported to .csv files for subsequent analysis. To assess the performance of each classifier across the two experimental datasets, the following evaluation metrics were considered: Accuracy, Cohen's Kappa coefficient, Sensitivity (Recall), Specificity, and the Area Under the Receiver Operating Characteristic Curve (AUC-ROC), as described in Table I. In the formulas presented in the Table I, TP denotes True Positives, TN True Negatives, FP False Positives, FN False Negatives, ρ_o the observed agreement, and ρ_e the agreement expected by chance.

TABLE I
PERFORMANCE EVALUATION METRICS OF THE CLASSIFIERS.

Metric	Description	Formula
Accuracy	Proportion of correctly classified instances relative to the total	$\frac{TP + TN}{TP + TN + FP + FN}$
Kappa Index	Agreement measure that accounts for the probability of chance agreement	$\frac{P_o - P_e}{1 - P_e}$
Sensitivity	Model's ability to correctly identify positive cases	$\frac{TP}{TP + FN}$
Specificity	Model's ability to correctly identify negative cases	$\frac{TN}{TN + FP}$
AUC-ROC	Discriminative ability across different thresholds (0 to 1; closer to 1 is excellent)	N/A

G. Best Classifier Selection and Final Testing

Following the evaluation of all classifiers during the training phase, the best-performing model was selected based on its mean Accuracy and Cohen's Kappa coefficient. These metrics were chosen to jointly assess predictive performance and the level of agreement beyond chance, particularly in the context of multiclass classification.

The selected classifier was subsequently applied to the independent test set, corresponding to 20% of the available data. Importantly, the test set retained the original class distribution and contained exclusively original samples; SMOTE was applied only to the training data, ensuring that no synthetic samples were introduced into the final evaluation. Model evaluation was performed using the Explorer interface of Weka, generating the confusion matrix as well as all performance metrics previously described. This final assessment enabled the evaluation of model performance on data not used during model training while preserving the naturally imbalanced class distribution.

III. Results

The experimental results are presented as the mean and standard deviation of the performance metrics described in the metrics section. Table II presents the performance results for the four-class scenario Control, MCI, AD, and FTD using the complete base (Dataset 1), composed of the features extracted directly by EfficientNet without feature selection. The decision-tree-based models, the SVM classifiers, and the MLP stood out, achieving accuracy values equal to or greater than 80% (with the exception of SVM-RBF, which reached 71.93% accuracy). Among all the evaluated models, Random Forest 500 (RF-500) obtained the best classification performance during training, reaching an accuracy of 83.43%, a result that was consistently reflected across all other metrics.

Figure 2 presents the boxplot of the accuracy values obtained by the classifiers evaluated on Dataset 1. In agreement with the results presented in Table II, the Random Forest and SVM with a degree-2 polynomial kernel classifiers presented the highest mean accuracies. Furthermore, both demonstrated low dispersion of results and the absence of outliers, indicating greater stability in performance. It is also observed that the variation ranges of these classifiers overlap, suggesting similar performances when considering the variability of the obtained results.

The RF-300 and RF-500 models were then applied to the independent test set, corresponding to 20% of the data, through the Weka Explorer interface, with the aim of validating the performance obtained in the training stage and supporting the choice of the final classifier. The results confirmed the superior performance of the RF-500 model, which reached an accuracy of 67.70% on the test set. The confusion matrix obtained for this model (Table III) allowed a detailed analysis of the classification patterns. It is observed that the healthy control group presented the highest number of correct classifications, with 416 samples correctly identified, although it showed confusion mainly with the AD (49 samples) and MCI (45 samples) groups. The MCI group also presented good identification capacity, with 161 correct classifications and a lower number of errors distributed among the other classes. For the AD class, 165 correct classifications were obtained; however, a high confusion with the healthy control group was observed, with 128 AD samples classified as control, representing the model's main error pattern. Finally, the FTD group presented high discrimination capacity, with 86 correct classifications and reduced confusion with the other classes (31 classified as control, 3 as MCI, and 7 as AD).

After feature selection via PSO (standard version with 20 iterations), the number of features was substantially reduced. In the multiclass classification (Control, MCI, AD, and FTD), the initial set of 1281 features was reduced to 324. From the analysis of the multiclass classification group's performance, after PSO-based feature selection, through the results in Table IV, it can be observed that the Multilayer Perceptron (MLP), SVM K2, followed by the Random Forest with 500 trees (RF-500) achieved the best training performances, reaching accuracies of 83.57%, 83.13%, and 82.78%, respectively, in addition to obtaining considerable values in most of the other evaluation metrics. Figure 3 displays the box plots of accuracy for all tested models. It is observed that the RF-300, RF-500, SMO K2, and MLP models presented the highest median accuracy values, all greater than approximately 80%, in addition to low dispersion of results across executions. Among them, RF-500 and MLP presented the highest medians, indicating superior performance. In contrast, classifiers such as Naive Bayes, BayesNet, and Random Tree presented lower accuracies, evidencing lower discriminative capacity for the analyzed database. In general, the low amplitude of the boxes and the absence of relevant outliers indicate good stability of the evaluated models.

During the test phase, the MLP continued to demonstrate

TABLE II
Classification result: control, MCI, AD, and FTD for Base 1 (EfficientNet).

AD	128	24	165	18
FTD	31	3	7	86

the best generalization performance, reaching an accuracy of 73.75% and an AUC-ROC of 0.62. Although the MLP presented the highest test accuracy (73.75%), its high computational cost considerably higher than that of RF-500 during the training phase compromises its viability in clinical applications with limited resources. RF-500, in turn, reached 68.19% accuracy with a significantly lower computational cost, being selected as the reference classifier for Dataset 2 for offering the best balance between predictive performance and computational efficiency. Using the selected classifier, the confusion matrix presented in Table V was obtained. The confusion matrix obtained for reduced dataset, composed of the features selected by PSO, evidences good classifier performance on the independent test set. The healthy control group presented the highest number of correct classifications (417 samples), followed by the MCI (163), AD (166), and FTD (88) groups. Despite the good overall performance, the main source of error was the confusion between individuals with AD and healthy controls, with 124 AD samples classified as control. On the other hand, the FTD class presented greater discrimination capacity, with low confusion relative to the other classes, indicating that the selected features were more effective in distinguishing this group.

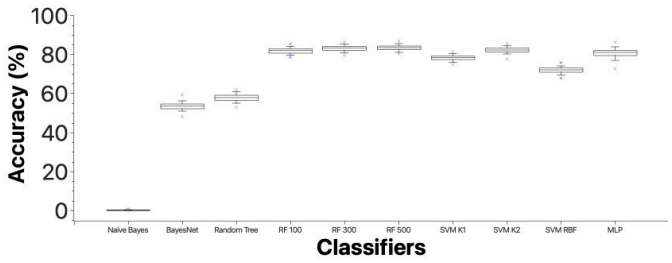

Fig. 3. Box Plot of the classification: control, MCI, AD, and FTD for Base 2 (EfficientNet with PSO).

IV. DISCUSSION

The results obtained demonstrate that the approach based on time-frequency representation of EEG signals, combined with

FTD	29	3	7	88

feature extraction by pre-trained deep convolutional neural networks (EfficientNet) and classification by classical machine learning, is capable of discriminating between four cognitive conditions: Healthy, MCI, AD, and FTD, with competitive performance compared to the literature [1], [3], [22]. RF-500 emerged as the reference classifier in both bases, achieving 67.70% accuracy in Base 1 and 68.19% in Base 2 on the independent test set, with Kappa indices of 0.53 and 0.54, respectively. These values indicate moderate agreement with the actual diagnoses, substantially outperforming simpler models such as Naive Bayes and BayesNet, and demonstrating consistent robustness across the 30 cross-validation repetitions [18]. The performance of Random Forest is consistent with

the findings of Oliveira et al. [1], who reported an accuracy of 98% with RF-500 on the same GeronGnosis database using explicitly extracted EEG signal features. The substantially higher accuracy reported in their study indicates that, for this dataset, explicit signal features provided a more effective representation of the discriminative EEG information than the image embeddings adopted in the present approach. This result also highlights a limitation of the Transfer Learning strategy based on EfficientNet-B0, which was originally pretrained on ImageNet [16]. Although such pretrained networks provide powerful generic feature extractors, the domain mismatch between natural images and EEG time-frequency representations may limit their ability to capture specific spectral and temporal patterns associated with cognitive impairment. These findings suggest that domain-specific EEG features or deep learning models specifically trained or fine-tuned for EEG representations should be further investigated.

In addition, the performance drop observed between the training phase (83.43% in Base 1; 82.78% in Base 2) and the test set (67.70% and 68.19%, respectively) suggests some degree of overfitting to the characteristics of the training data. Despite this reduction, test-set performance remained above the reference threshold for moderate agreement ($\kappa > 0.40$), indicating that the extracted features retained relevant discriminative information beyond the training set [18]. Nevertheless, these results reinforce the need to improve the generalization capability of the proposed approach, particularly through more domain-specific feature representations and validation strategies that better assess performance on previously unseen subjects.

The comparison between Base 1 (without PSO) and Base 2 (with PSO) reveals a positive, albeit modest, impact of feature selection. The reduction from 1,281 to 324 features promoted by the PSO algorithm [9] did not degrade training performance and resulted in a slight improvement in generalization to the test set (67.70% vs. 68.19%), in addition to a substantial reduction in computational cost. These results indicate that PSO was effective in preserving the most informative features, eliminating redundancies without sacrificing performance, which is particularly relevant for applications in systems with limited computational resources, such as the SUS [10].

The per-class analysis reveals that AD was consistently the condition with the highest error rate in both bases (128 and 124 instances misclassified as Healthy, respectively). This finding has direct clinical relevance: in the context of population screening, the incorrect classification of an AD patient as healthy represents a high-impact false negative, as it delays diagnosis and the start of treatment [11]. This limitation is consistent with the literature, which points to the overlap of electrophysiological patterns between AD and normal aging as one of the main diagnostic challenges [3], [12]. In this context, the spectral slowing characteristic of AD marked by the increase in delta and theta bands and the reduction of alpha activity in posterior regions [12] may overlap with normal aging patterns, hindering discrimination in the Wavelet representations.

MCI, by its transitional nature between healthy aging and established dementia [23], also presented confusions distributed with both adjacent classes in the two bases, which is neurologically coherent. It is estimated that 50% to 60% of individuals with MCI progress to AD [22], [23], which implies that part of the sample may already present electrophysiological signatures consistent with early neurodegeneration, while others retain cortical activity profiles closer to healthy aging [3].

FTD demonstrated the best relative performance in both bases, with the highest AUC-ROC values among the pathological classes. This result suggests that the Wavelet representations captured spectral and temporal patterns characteristic of this condition, possibly associated with the predominant impairment of the frontal and temporal regions. Studies indicate that disturbances in the beta and gamma bands provide topographic markers of cortical synchronization useful in discriminating FTD variants [1], which may have contributed to the better discriminative performance of this class. EEG-based FTD classification is also corroborated by Lal et al. [4], who achieved accuracies of 91% to 93% in discriminating between AD, FTD, and healthy controls using SVD entropy associated with the KNN classifier.

From the standpoint of clinical applicability, the proposed approach presents favorable characteristics for integration into diagnostic support systems. The use of EEG as an input modality is non-invasive, low-cost, and widely available in healthcare units, including the Brazilian public system [10], [22]. Furthermore, the use of the GeronGnosis base [9], composed of data from patients in Northeastern Brazil, represents an advance in the validation of computational tools for the national demographic and socioeconomic context, reducing exclusive dependence on international bases.

Among the limitations of the study, the reduced size of the GeronGnosis base stands out (50 participants, only 5 with FTD) [9], which imposes restrictions on the generalization of the models to broader clinical populations. Class imbalance, although mitigated by SMOTE [20] exclusively in the training set, may still influence performance on minority classes in the test set [2]. Additionally, the train-test split was performed at the image level, without separation by subject, which may allow windows from the same patient to simultaneously compose the training and test sets, possibly inflating the obtained metrics and limiting the real estimate of the model's generalization capacity.

In addition, the absence of interpretability analysis of the features extracted by EfficientNet prevents the direct association between regions of the Wavelet images and electrophysiological patterns specific to each condition, limiting the clinical transparency of the model. Future work should prioritize the expansion of the database and external validation in independent populations [1], [22].

V. Conclusion

This work proposed a non-invasive, low-cost computational tool to support the diagnosis of dementias, focusing

on the screening and early differentiation between healthy older adults, individuals with Mild Cognitive Impairment, Alzheimer's Disease, and Frontotemporal Dementia. The central motivation lay in the need to validate accessible and scalable solutions capable of capturing early neurophysiological alterations from the electroencephalogram, a modality compatible with the operational reality of the Brazilian Unified Health System.

To this end, an approach was adopted based on the conversion of EEG signals from the Brazilian GeronGnosis database into time-frequency image representations through the Wavelet Transform, followed by automatic feature extraction with the EfficientNet metwork, and feature selection by Particle Swarm Optimization. Different classical classifiers were compared in a multiclass scenario.

The results demonstrated that the Random Forest with 500 trees achieved accuracy of 67.70% on Dataset 1, while MLP achieved the highest accuracy observed in Dataset 2, reaching 73.75%. Feature selection reduced the dimensionality from 1,281 to 324 feature without degrading performance, with a slight gain in generalization and a reduction in computational cost. The FTD class presented the best relative discriminative performance, while the confusion between AD and healthy controls constituted the model's main predictive limitation.

As future perspectives, we intend to evaluate additional architectures and classifiers that may improve the discrimination between classes, especially between AD and controls. The incorporation of interpretability methods, such as SHAP analysis, is also recommended, in order to associate the extracted features with electrophysiological patterns specific to each condition, expanding the clinical transparency of the model. Finally, the adoption of a multimodal approach is suggested, integrating the clinical and sociodemographic data available in the database with the EEG signals, as well as expansion and external validation in independent populations, consolidating the potential of this tool as clinical decision support in the context of the SUS.

ACKNOWLEDGMENT

***Abstract*—Electrical impedance tomography is a portable and non-ionizing imaging modality with potential for bedside monitoring of hemorrhagic stroke. Its practical use is limited by the nonlinear, ill-posed inverse problem and by sensitivity to corrupted electrode measurements. This paper presents a finite-element reconstruction framework that combines the complete electrode model with hybrid robust data fidelity and prior regularization. All voltage data used in this study were numerically generated from a two-dimensional hemorrhagic-stroke conductivity phantom on a fine forward mesh and reconstructed using a separate, coarser inverse mesh. The data-fidelity term blends a robust L_1 component, which limits the influence of large residuals, with a quadratic L_2 component, which remains efficient for small approximately Gaussian errors. The prior term similarly balances smooth Tikhonov-type stabilization with sparsity-promoting edge preservation. The resulting nonlinear problem is solved using a Levenberg-Marquardt iteratively reweighted least-squares method. The simulations with a hemorrhagic inclusion and localized faulty-electrode corruption show that robust data weighting improves reconstruction stability, contrast recovery, and spatial overlap compared with purely quadratic fitting. The results indicate that robust data fidelity is the dominant factor for suppressing high-amplitude corrupted-channel residuals, while the prior term controls the trade-off between smoothness and edge preservation.**

***Index Terms*—Electrical impedance tomography, hemorrhagic stroke, faulty electrodes, hybrid regularization**

I. Introduction

Stroke remains a major global health burden and requires rapid, reliable, and accessible diagnostic and monitoring strategies [1]. Hemorrhagic stroke is particularly time sensitive because intracranial bleeding can progress rapidly and can alter the electrical properties of brain tissue. Electrical impedance tomography (EIT) is a promising modality for bedside monitoring in this setting because it is portable, low cost, non-ionizing, and suitable for repeated measurements. In EIT, low-amplitude alternating currents are injected through boundary electrodes, and the resulting boundary voltages are measured. The internal conductivity distribution is then estimated from these current voltage measurements. Previous studies have demonstrated the potential of EIT for brain data acquisition, stroke-oriented monitoring, and conductivity reconstruction [2]–[4]. Classical EIT studies further show that reconstruction quality depends strongly on the electrode model, tissue-property assumptions, measurement noise, and regularization strategy [5]–[7].

Despite these advantages, EIT reconstruction remains a challenging computational problem because the underlying inverse problem is highly nonlinear and ill-posed. Consequently, even small measurement errors in the boundary voltage data may produce large variations in the reconstructed conductivity distribution [6], [7]. A physically realistic forward model is usually obtained using the complete electrode model (CEM), which accounts for finite electrode size, contact impedance, injected currents, and measured electrode voltages [8], [9]. Although the CEM provides a physically realistic measurement model, the associated inverse problem remains sensitive to modeling errors, contact-impedance variations, electrode misplacement, and corrupted measurements. Achieving stable conductivity reconstructions therefore requires both reliable physical modeling and regularization strategies.

Many EIT reconstruction methods are formulated as least-squares data-fitting problems with quadratic Tikhonov regularization [10]–[12]. Such formulations are computationally efficient and generally yield stable reconstructions when the measurement errors are small and approximately Gaussian. However, the L_2 data-fidelity term grows quadratically with the residual magnitude. As a result, a small number of outliers caused by faulty electrodes, motion artifacts, impulsive noise, or contact-impedance changes can dominate the objective function, producing reconstruction artifacts and degrading image quality [13], [14]. Moreover, purely quadratic regularization tends to oversmooth conductivity distributions, which may blur sharp boundaries and reduce the detectability of localized anomalies.

Robust and sparsity-promoting penalties provide an effective alternative to purely quadratic reconstruction models. Unlike the quadratic growth of the L_2 norm, the L_1 norm increases linearly with the residual magnitude, thereby reducing the influence of large residuals and improving robustness when the measured data contain outliers or corrupted channels [15], [16]. When applied to spatial differences, L_1-type regularization can promote localized conductivity variations and help preserve sharp boundaries [17]. These properties are important in EIT because relevant abnormalities may manifest as spatially localized conductivity changes. Nevertheless, purely L_1 formulations are inherently nonsmooth and may lead to numerical

This work was financed by the São Paulo Research Foundation (FAPESP), process numbers 2023/13729-0, 2022/03243-0, 2013/07559-3, and 2021/11905-0.

difficulties during optimization. To address these challenges, hybrid L_1/L_2 formulations offer a practical compromise by combining the numerical stability of quadratic regularization with the robustness and edge-preserving properties of L_1-type penalties.

In this work, a hybrid L_1/L_2 reconstruction framework is developed for EIT in the presence of localized faulty-channel corruption. The proposed formulation combines robust data fidelity and stabilizing prior regularization in a unified nonlinear optimization problem, which is solved using a Levenberg-Marquardt iteratively reweighted least-squares (LM-IRLS) strategy [18], [19]. The LM component improves numerical stability through adaptive damping, whereas the IRLS component handles the L_1-type terms through adaptive weighted L_2 approximations. This study further investigates how different combinations of quadratic and robust penalty terms affect reconstruction accuracy, robustness to corrupted measurements, and preservation of localized conductivity variations.

The rest of this paper is organized as follows. Section II presents the complete electrode model and finite-element discretization. Section III describes the formulation of hybrid objective functions. Section IV derives the LM-IRLS reconstruction algorithm. Section V describes the simulation protocol. Section VI presents the reconstruction results. Section VII discusses the findings and limitations, and Section VIII concludes the paper.

II. Forward Model and Finite-Element Discretization

A. Complete Electrode Model

Let $\Omega \subset \mathbb{R}^2$ denote the imaging domain, and let $\partial\Omega$ represent its boundary. The boundary contains L electrodes, denoted by $E_1, E_2, \ldots, E_L$, through which electrical currents are injected and boundary voltages are measured. For a positive conductivity distribution $\sigma(\mathbf{x}) > 0$, the electric potential field $\Phi(\mathbf{x})$ inside the domain satisfies the conductivity equation

$$\nabla \cdot (\sigma \nabla \Phi) = 0, \qquad \mathbf{x} \in \Omega, \tag{1}$$

which follows from charge conservation under the quasi-static approximation. This forward problem provides a physically realistic representation of electrode-based measurements by accounting for finite electrode size and electrode-skin contact impedance [8], [9].

In the CEM, each electrode E_ℓ is associated with an electrode voltage Φ_ℓ and a contact impedance $z_\ell > 0$. On the electrode surfaces, the boundary conditions are given by

$$\Phi + z_\ell \sigma \frac{\partial \Phi}{\partial \mathbf{n}} = \Phi_\ell, \qquad \mathbf{x} \in E_\ell, \quad \ell = 1, \ldots, L, \tag{2}$$

$$\int_{E_\ell} \sigma \frac{\partial \Phi}{\partial \mathbf{n}} \, \mathrm{d}S = I_\ell, \qquad \ell = 1, \ldots, L, \tag{3}$$

where $\partial\Phi/\partial\mathbf{n}$ denotes the outward normal derivative of the electric potential, and I_ℓ is the current applied through the ℓth electrode. The first condition accounts for the voltage drop across the electrode-tissue contact impedance, whereas the second condition enforces conservation of the total current through each electrode.

On the insulating boundary gaps between electrodes, no current flow is imposed. This boundary condition is expressed as

$$\sigma \frac{\partial \Phi}{\partial \mathbf{n}} = 0, \qquad \mathbf{x} \in \partial\Omega \setminus \bigcup_{\ell=1}^{L} E_\ell. \tag{4}$$

The injected current vector $\mathbf{I} = [I_1, \ldots, I_L]^T$ satisfies the charge-conservation condition,

$$\sum_{\ell=1}^{L} I_\ell = 0. \tag{5}$$

Since the electric potential and electrode voltages are determined only up to an additive constant, a voltage reference condition is required to ensure uniqueness of the forward solution. In this work, the electrode closest to the origin is selected as the ground reference.

B. Nodal-Conductivity Finite-Element Discretization

The domain Ω is discretized with linear triangular finite elements. Let $\{\varphi_i(\mathbf{x})\}_{i=1}^{N_n}$ denote the nodal basis functions, where N_n is the number of mesh nodes. The electric potential and conductivity are approximated by nodal finite-element expansions as

$$\Phi(\mathbf{x}) \approx \Phi_h(\mathbf{x}) = \sum_{i=1}^{N_n} u_i \varphi_i(\mathbf{x}), \tag{6}$$

and

$$\sigma(\mathbf{x}) \approx \sigma_h(\mathbf{x}) = \sum_{a=1}^{N_n} \sigma_a \psi_a(\mathbf{x}). \tag{7}$$

respectively. Here, u_i and $\varphi_i(\mathbf{x})$ denote the unknown nodal electric potential and associated finite-element basis function at node i, whereas σ_a and $\psi_a(\mathbf{x})$ denote the nodal conductivity, and associated basis function at node a. Hence, $\Phi_h(\mathbf{x})$ and $\sigma_h(\mathbf{x})$ represent the finite-element approximations of the electric potential and conductivity fields. Within each triangular element, both quantities are obtained by interpolated from their nodal values.

After assembling the element matrices and using Eq.(2) and Eq.(3), the discrete forward problem can be written as the block linear system

$$\begin{bmatrix} \mathbf{K}(\boldsymbol{\sigma}) + \mathbf{C} & \mathbf{B} \\ \mathbf{B}^T & \mathbf{D} \end{bmatrix} \begin{bmatrix} \mathbf{u}^{(p)} \\ \boldsymbol{\Phi}^{(p)} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{I}^{(p)} \end{bmatrix}, \tag{8}$$

where $\mathbf{u}^{(p)} \in \mathbb{R}^{N_n}$ is the nodal potential vector, $\boldsymbol{\Phi}^{(p)} \in \mathbb{R}^L$ is the electrode-voltage vector, and $\mathbf{I}^{(p)} \in \mathbb{R}^L$ is the applied current vector for the p-th current-injection pattern. Here, the global admittance matrix $\mathbf{K}(\boldsymbol{\sigma})$ is obtained by assembling the local matrices over all elements, with entries

$$K_{ij}(\boldsymbol{\sigma}) = \int_\Omega \sigma_h(\mathbf{x}) \nabla\varphi_i(\mathbf{x}) \cdot \nabla\varphi_j(\mathbf{x}) \, d\mathbf{x}. \tag{9}$$

The electrode contact-impedance matrix is $\mathbf{C}_{ij} = \sum_{\ell=1}^{L} z_\ell^{-1} \int_{E_\ell} \varphi_i(\mathbf{x}) \varphi_j(\mathbf{x}) \, dS$. The nodal electrode coupling

matrix is $\mathbf{B}_{i\ell} = -z_\ell^{-1} \int_{E_\ell} \varphi_i(\mathbf{x})\, dS$, and the electrode matrix is diagonal, with $\mathbf{D}_{\ell m} = \delta_{\ell m}|E_\ell|/z_\ell$, where z_ℓ is the contact impedance, $|E_\ell|$ is the length of electrode E_ℓ, and $\delta_{\ell m}$ is the Kronecker delta.

For the p-th current-injection pattern and the q-th voltage-measurement pattern, the predicted differential voltage is obtained from the electrode voltages as

$$v_{pq}(\boldsymbol{\sigma}) = \mathbf{m}_q^T \boldsymbol{\Phi}^{(p)}(\boldsymbol{\sigma}), \tag{10}$$

where $\mathbf{m}_q$ defines the q-th differential voltage measurement. Equivalently, if $\mathbf{C}^d$ denotes the measurement matrix that converts electrode voltages into differential measurements, then

$$\mathbf{v}^{(p)}(\boldsymbol{\sigma}) = \mathbf{C}^d \boldsymbol{\Phi}^{(p)}(\boldsymbol{\sigma}). \tag{11}$$

Stacking the voltage measurements from all P current-injection patterns yields the nonlinear forward map

$$\mathbf{v} = \mathbf{F}(\boldsymbol{\sigma}) = \begin{bmatrix} \mathbf{C}^d \boldsymbol{\Phi}^{(1)}(\boldsymbol{\sigma}) \\ \mathbf{C}^d \boldsymbol{\Phi}^{(2)}(\boldsymbol{\sigma}) \\ \vdots \\ \mathbf{C}^d \boldsymbol{\Phi}^{(P)}(\boldsymbol{\sigma}) \end{bmatrix} \in \mathbb{R}^M, \tag{12}$$

where M is the total number of differential voltage measurements. Although $\mathbf{K}(\boldsymbol{\sigma})$ depends linearly on the nodal conductivity values in Eq.(7), the forward map $\mathbf{F}(\boldsymbol{\sigma})$ is nonlinear because the electrode voltages are obtained by solving the conductivity-dependent CEM system in Eq.(8).

C. Adjoint Sensitivity Matrix

The Jacobian $\mathbf{J} = \partial \mathbf{F}/\partial \boldsymbol{\sigma} \in \mathbb{R}^{M \times N}$ relates small conductivity perturbations to voltage perturbations. Since the conductivity is described in Eq.(7) by nodal basis functions, the element stiffness matrix on a triangular element T_e is

$$K_{ij}^{(e)}(\boldsymbol{\sigma}) = \int_{T_e} \sigma_h(\mathbf{x}) \nabla \varphi_i(\mathbf{x}) \cdot \nabla \varphi_j(\mathbf{x})\, d\mathbf{x}. \tag{13}$$

Therefore, the derivative of the local stiffness matrix with respect to σ_a is

$$\frac{\partial K_{ij}^{(e)}}{\partial \sigma_a} = \begin{cases} \displaystyle\int_{T_e} \psi_a(\mathbf{x}) \nabla \varphi_i(\mathbf{x}) \cdot \nabla \varphi_j(\mathbf{x})\, d\mathbf{x}, & a \in \mathcal{N}_e, \\ 0, & a \notin \mathcal{N}_e, \end{cases} \tag{14}$$

where $\mathcal{N}_e$ is the set of global conductivity nodes connected to element T_e. After finite-element assembly, the corresponding global derivative matrix is

$$\frac{\partial \mathbf{K}}{\partial \sigma_a} = \sum_{e:\, a \in \mathcal{N}_e} \mathbf{P}_e^T \left(\frac{\partial \mathbf{K}^{(e)}}{\partial \sigma_a} \right) \mathbf{P}_e, \tag{15}$$

where $\mathbf{P}_e$ is the element-to-global assembly operator. This expression shows that only elements sharing node a contribute to the derivative with respect to σ_a. For the p-th current-injection pattern, Eq. (8) can be written in compact form as

$$\mathbf{A}(\boldsymbol{\sigma}) \mathbf{x}^{(p)} = \mathbf{b}^{(p)}, \tag{16}$$

where $\mathbf{x}^{(p)}$ denotes the full CEM state vector which contains the nodal potentials and electrode potentials, $\mathbf{b}^{(p)}$ contains the imposed current pattern and reference constraints, and $\mathbf{A}(\boldsymbol{\sigma})$ is the assembled CEM system matrix. For fixed contact impedances and fixed electrode geometry, the dependence on the conductivity vector $\boldsymbol{\sigma}$ enters only through the domain stiffness matrix $\mathbf{K}(\boldsymbol{\sigma})$. Differentiating Eq. (16) with respect to the nodal conductivity parameter σ_a gives

$$\mathbf{A}(\boldsymbol{\sigma}) \frac{\partial \mathbf{x}^{(p)}}{\partial \sigma_a} = -\frac{\partial \mathbf{A}}{\partial \sigma_a} \mathbf{x}^{(p)}. \tag{17}$$

The direct computation of Eq.(17) for every conductivity node would require one linear solve per unknown parameter, which becomes computationally expensive for large meshes.

The adjoint method avoids this cost by transferring the sensitivity calculation from the parameter space to the measurement space. Let $\mathbf{c}_m$ be the measurement vector that extracts the m-th voltage datum from the full state vector, so that $F_m^{(p)}(\boldsymbol{\sigma}) = \mathbf{c}_m^T \mathbf{x}^{(p)}$. The corresponding adjoint field $\boldsymbol{\lambda}_m$ is obtained from

$$\mathbf{A}^T(\boldsymbol{\sigma}) \boldsymbol{\lambda}_m = \mathbf{c}_m. \tag{18}$$

Combining Eqs. (17) and (18), the Jacobian entry associated with measurement m, current pattern p, and conductivity node a is

$$J_{ma}^{(p)} = \frac{\partial F_m^{(p)}}{\partial \sigma_a} = -\boldsymbol{\lambda}_m^T \frac{\partial \mathbf{A}}{\partial \sigma_a} \mathbf{x}^{(p)}. \tag{19}$$

Since $\partial \mathbf{A}/\partial \sigma_a$ is nonzero only in the stiffness block, Eq. (19) can also be evaluated using only the nodal-potential parts of the forward and adjoint solutions. For multiple current patterns, (16)-(19) are evaluated for each forward solution and the resulting rows are stacked to form the full sensitivity matrix. In practice, the matrix inverse is not formed explicitly; instead, the same factorization or iterative solver used for the CEM forward problem can be reused to solve the adjoint systems. This formulation is computationally efficient and is consistent with standard finite-element Jacobian calculations for EIT based on the complete electrode model [20].

III. Hybrid L_1/L_2 Reconstruction Model

The reconstruction of the conductivity distribution in EIT is formulated as a nonlinear inverse problem because the relationship between the conductivity distribution and the measured boundary voltages is nonlinear [7], [8]. The objective is to estimate the unknown nodal conductivity vector $\boldsymbol{\sigma}$ from the measured voltage data by minimizing a hybrid objective functional composed of data-fidelity and prior-regularization terms. The proposed hybrid reconstruction objective is denoted by $\mathcal{J}(\boldsymbol{\sigma})$ and is defined as

$$\begin{aligned} \mathcal{J}(\boldsymbol{\sigma}) = \zeta \|\boldsymbol{r}(\boldsymbol{\sigma})\|_1 + \frac{1-\zeta}{2} \|\boldsymbol{r}(\boldsymbol{\sigma})\|_2^2 \\ + \beta \left[\eta \|\boldsymbol{p}(\boldsymbol{\sigma})\|_1 + \frac{1-\eta}{2} \|\boldsymbol{p}(\boldsymbol{\sigma})\|_2^2 \right], \end{aligned} \tag{20}$$

where $\zeta \in [0,1]$ controls the balance between robust L_1 and quadratic L_2 data fidelity, $\eta \in [0,1]$ controls the balance between sparsity-promoting and smooth prior regularization, and $\beta > 0$ is the global regularization parameter. This formulation

provides flexible control over measurement robustness, edge preservation, and reconstruction stability.

The data residual is defined as

$$\boldsymbol{r}(\boldsymbol{\sigma}) = \mathbf{F}(\boldsymbol{\sigma}) - \boldsymbol{\Phi}_{\mathrm{meas}}, \tag{21}$$

where $\mathbf{F}(\boldsymbol{\sigma})$ denotes the nonlinear forward operator that maps the conductivity distribution to the predicted boundary voltage measurements, and $\boldsymbol{\Phi}_{\mathrm{meas}}$ is the measured electrode-voltage vector over all current-injection and voltage-measurement patterns [8].

The prior residual is defined in the transformed roughness domain as

$$\boldsymbol{p}(\boldsymbol{\sigma}) = \boldsymbol{\Lambda}\mathbf{R}(\boldsymbol{\sigma} - \boldsymbol{\sigma}_0), \tag{22}$$

where $\mathbf{R}$ is a discrete roughness operator, $\boldsymbol{\Lambda}$ is a diagonal spatial scaling matrix, and $\boldsymbol{\sigma}_0$ is the reference conductivity distribution. In this work, $\mathbf{R}$ acts as a discrete gradient-like operator on the mesh, while the associated quadratic penalty $\mathbf{R}^T\mathbf{R}$ has a graph-Laplacian-like smoothing effect. Therefore, $\boldsymbol{\Lambda}$ acts on the roughness residuals and controls the local strength of the prior penalty over mesh edges. If $\boldsymbol{\Lambda} = c\mathbf{I}$, where $c > 0$ is a scalar constant and $\mathbf{I}$ is the identity matrix, its effect is equivalent to rescaling β. Thus, a nonuniform $\boldsymbol{\Lambda}$ is required to impose spatially varying regularization.

The proposed hybrid formulation provides a continuous transition between classical least-squares reconstruction and robust sparsity-promoting regularization. When $\zeta = 0$, the data-fidelity term reduces to the conventional quadratic least-squares form, which is efficient under approximately Gaussian noise but can be sensitive to outliers [10]. When $\zeta = 1$, the data-fidelity term becomes purely L_1-based, reducing the influence of large residuals and improving robustness to corrupted measurements and faulty electrode channels [16]. Intermediate values of ζ provide a trade-off between statistical efficiency and robustness.

Similarly, the parameter η controls the structure of the prior regularization. Smaller values of η produce smoother, Tikhonov-like reconstructions, whereas larger values promote sparse deviations in the transformed roughness domain and help preserve localized conductivity changes. Such hybrid formulations are useful in ill-posed inverse problems where the measured data may be corrupted and the prior information may be imperfect [6], [14].

The four limiting configurations evaluated in this work have direct interpretations. The pair $(\zeta, \eta) = (0, 0)$ represents quadratic data fidelity with a smooth prior, whereas $(1, 0)$ represents robust data fidelity with a smooth prior. The configuration $(0, 1)$ combines quadratic data fidelity with a sparsity-promoting prior, and $(1, 1)$ corresponds to the fully hybrid formulation, in which robust data fidelity is combined with sparsity-promoting prior regularization.

IV. LM-IRLS Optimization

The objective function in Eq.(20) is nonlinear because of the CEM forward map and is nonsmooth in the limiting L_1 case. To obtain a stable numerical update, the nonlinear forward map is locally linearized and the L_1 terms are approximated by an iteratively reweighted least-squares (IRLS) scheme. At iteration k, the forward map is linearized as

$$\mathbf{F}(\boldsymbol{\sigma}_k + \boldsymbol{\delta}) \approx \mathbf{F}(\boldsymbol{\sigma}_k) + \mathbf{J}_k\boldsymbol{\delta}, \tag{23}$$

where $\mathbf{J}_k$ is the sensitivity matrix and $\boldsymbol{\delta}$ is the conductivity update. The L_1 penalty is approximated by the differentiable function $\phi_\epsilon(x) = \sqrt{x^2 + \epsilon^2}$, which approaches $|x|$ as $\epsilon \to 0$. This approximation gives the diagonal IRLS weighting matrices as

$$\mathbf{W}_{d,k}^{(1)} = \mathrm{diag}\left(\frac{1}{\sqrt{r_{i,k}^2 + \epsilon^2}}\right), \tag{24}$$

$$\mathbf{W}_{p,k}^{(1)} = \mathrm{diag}\left(\frac{1}{\sqrt{p_{j,k}^2 + \epsilon^2}}\right). \tag{25}$$

These weights reduce the influence of large residuals and therefore improve robustness against outliers, corrupted voltage measurements, and faulty-electrode channels [15].

The hybrid objective combines quadratic and robust components through the parameters ζ and η. The corresponding data and prior weighting matrices are

$$\mathbf{W}_{d,k} = \zeta\mathbf{W}_{d,k}^{(1)} + (1 - \zeta)\mathbf{I}, \tag{26}$$

$$\mathbf{W}_{p,k} = \eta\mathbf{W}_{p,k}^{(1)} + (1 - \eta)\mathbf{I}. \tag{27}$$

Here, $\mathbf{W}_{d,k}$ controls the contribution of the voltage residuals, whereas $\mathbf{W}_{p,k}$ controls the contribution of the transformed roughness residuals.

The Levenberg-Marquardt IRLS update is written as

$$\begin{aligned}\left(\mathbf{J}_k^T\mathbf{W}_{d,k}\mathbf{J}_k + \beta\mathbf{R}^T\boldsymbol{\Lambda}^T\mathbf{W}_{p,k}\boldsymbol{\Lambda}\mathbf{R} + \mu_k\mathbf{I}\right)\boldsymbol{\delta}_k \\ = -\left(\mathbf{J}_k^T\mathbf{W}_{d,k}\boldsymbol{r}_k + \beta\mathbf{R}^T\boldsymbol{\Lambda}^T\mathbf{W}_{p,k}\boldsymbol{p}_k\right).\end{aligned} \tag{28}$$

where $\mu_k > 0$ is the Levenberg-Marquardt damping parameter [21]. Larger values of μ_k improve numerical stability and make the update more similar to a gradient-descent step, whereas smaller values approach the Gauss-Newton direction.

After the search direction is computed, a trial conductivity is estimated and projected onto the admissible set:

$$\boldsymbol{\sigma}_{k+1} = \Pi_{\mathcal{C}}\left(\boldsymbol{\sigma}_k + \alpha_k\boldsymbol{\delta}_k\right), \tag{29}$$

where $\alpha_k \in (0, 1]$ is a step length parameter and $\Pi_{\mathcal{C}}$ denotes componentwise projection onto the admissible conductivity set $\mathcal{C} = \{\boldsymbol{\sigma} : \sigma_{\min} \le \sigma_i \le \sigma_{\max}, \quad i = 1, \ldots, N\}$. This projection enforces physically meaningful conductivity bounds after each trial step [19].

The step acceptance is determined from the ratio between the actual and predicted reductions. Defining $\boldsymbol{s}_k = \boldsymbol{\sigma}_k^{\mathrm{trial}} - \boldsymbol{\sigma}_k$, the actual reduction is

$$\Delta\mathcal{J}_k^{\mathrm{act}} = \mathcal{J}_\epsilon(\boldsymbol{\sigma}_k) - \mathcal{J}_\epsilon(\boldsymbol{\sigma}_k^{\mathrm{trial}}), \tag{30}$$

and the quadratic-model predicted reduction is

$$\Delta\mathcal{J}_k^{\mathrm{pred}} = -\boldsymbol{g}_k^T\boldsymbol{s}_k - \frac{1}{2}\boldsymbol{s}_k^T\mathbf{H}_k\boldsymbol{s}_k, \tag{31}$$

where $\boldsymbol{g}_k = \mathbf{J}_k^T \mathbf{W}_{d,k} \boldsymbol{r}_k + \beta \mathbf{R}^T \mathbf{\Lambda}^T \mathbf{W}_{p,k} \boldsymbol{p}_k$, and $\mathbf{H}_k = \mathbf{J}_k^T \mathbf{W}_{d,k} \mathbf{J}_k + \beta \mathbf{R}^T \mathbf{\Lambda}^T \mathbf{W}_{p,k} \mathbf{\Lambda} \mathbf{R} + \mu_k \mathbf{I}$. The acceptance ratio is then $\rho_k = \frac{\Delta \mathcal{J}_k^{\mathrm{act}}}{\Delta \mathcal{J}_k^{\mathrm{pred}}}$. The trial step is accepted when $\rho_k \geq 0.25$ and rejected otherwise. The damping parameter is decreased when $\rho_k > 0.75$ and increased when $\rho_k < 0.25$.

The local linearized reconstruction matrix is approximated by

$$\mathbf{K}_{\mathrm{rec}} = \left[\mathbf{J}^T \mathbf{W}_d \mathbf{J} + \beta \mathbf{R}^T \mathbf{\Lambda}^T \mathbf{W}_p \mathbf{\Lambda} \mathbf{R} + \mu \mathbf{I} \right]^{-1} \mathbf{J}^T \mathbf{W}_d. \quad (32)$$

This matrix maps small voltage perturbations to the corresponding linearized conductivity updates. Therefore, the magnitude $|\mathbf{K}_{\mathrm{rec}}|$ indicates how strongly each measurement channel influences each reconstructed node. In practice, Eq.(32) should be evaluated by solving the associated linear systems rather than by forming an explicit matrix inverse. The reconstruction matrix is useful for identifying high-leverage measurements and for assessing how faulty-electrode corruption affects the inverse mapping.

V. Simulation Setup and Implementation

A. Conductivity Phantom and Meshes

The numerical experiments were conducted on a normalized circular two-dimensional domain with $L = 32$ boundary electrodes. In the normalized coordinate system used for the phantom, the outer circle has radius 1 and therefore diameter 2 normalized length units. The background conductivity was set to $0.17\ \mathrm{S/m}$ and the hemorrhagic inclusion conductivity was set to $0.67\ \mathrm{S/m}$ [22]. The inclusion was centered at $(0.4, 0.4)$ and had radius 0.20, with the center coordinates and radius expressed in the same normalized length units. To reduce inverse-crime effects, synthetic data were generated on a finer forward mesh with 1941 nodes and 3368 triangular elements, whereas reconstruction was performed on a coarser inverse mesh with 1238 nodes and 2218 elements. The CEM contact impedance was fixed at $z_\ell = 0.01$ for all electrodes [8]. In this two-dimensional implementation, this value represents an effective numerical contact impedance scaled by boundary length.

B. Current-Injection, Measurement, and Faulty-Channel Model

Current injection was performed using a skip-4 protocol. For each injection pattern, a current of amplitude $I_0 = 1\ \mathrm{mA}$ was applied between electrode ℓ and electrode $(\ell + 4) \bmod L$, defined as

$$I_{\ell'} = \begin{cases} +I_0, & \ell' = \ell, \\ -I_0, & \ell' = (\ell + 4) \bmod L, \\ 0, & \text{otherwise}, \end{cases} \quad (33)$$

Separated-pair current-injection and electrode-addressing patterns are well established in EIT [23]. Adjacent voltage-difference measurements were computed using electrode pairs with offsets 1 and 2.

The synthetic observed data were generated as

$$\mathbf{\Phi}_{\mathrm{meas}} = \mathbf{\Phi}_{\mathrm{clean}} + \boldsymbol{\varepsilon}_{\mathrm{bg}} + \boldsymbol{\varepsilon}_{\mathrm{fault}}, \quad (34)$$

where $\mathbf{\Phi}_{\mathrm{clean}}$ is the clean simulated voltage vector, $\boldsymbol{\varepsilon}_{\mathrm{bg}}$ denotes zero-mean additive Gaussian noise with standard deviation 0.001, and $\boldsymbol{\varepsilon}_{\mathrm{fault}}$ denotes the larger localized perturbation associated with the faulty electrode channel. Electrode number 23 (E23) was treated as faulty. A sample was marked faulty when E23 participated either in the current-injection pair or in the voltage-measurement pair. Faulty samples received additional Gaussian perturbations with standard deviation 10 times the background noise and a bias equal to 0.3 times the standard deviation of the clean voltage vector.

C. Regularization Parameters and Evaluation Metrics

The hybrid method was evaluated for $\beta \in \{0.01, 0.1, 1.0\}$ and $(\zeta, \eta) \in \{(0,0), (1,0), (0,1), (1,1)\}$. Reconstruction quality was assessed using RMSE, relative error, Dice coefficient, intersection-over-union, peak-conductivity error, and contrast-to-noise ratio. The root-mean-square error (RMSE) was computed as

$$\mathrm{RMSE} = \sqrt{\frac{1}{N} \sum_{i=1}^{N} (\sigma_i^{\mathrm{true}} - \sigma_i^{\mathrm{rec}})^2}, \quad (35)$$

where $\boldsymbol{\sigma}^{\mathrm{true}}$ and $\boldsymbol{\sigma}^{\mathrm{rec}}$ denote the true and reconstructed conductivity distributions, respectively. The relative error is given by

$$\mathrm{RelErr} = \frac{\|\boldsymbol{\sigma}^{\mathrm{true}} - \boldsymbol{\sigma}^{\mathrm{rec}}\|_2}{\|\boldsymbol{\sigma}^{\mathrm{true}}\|_2}. \quad (36)$$

The peak conductivity error is computed as

$$\mathrm{PeakErr} = \left| \sigma_{\max}^{\mathrm{true}} - \sigma_{\max}^{\mathrm{rec}} \right|. \quad (37)$$

To evaluate inclusion localization and segmentation accuracy, let Ω_{true} and Ω_{rec} denote the true and reconstructed inclusion regions obtained after thresholding. The Dice coefficient and IoU are defined as

$$\mathrm{Dice} = \frac{2|\Omega_{\mathrm{true}} \cap \Omega_{\mathrm{rec}}|}{|\Omega_{\mathrm{true}}| + |\Omega_{\mathrm{rec}}|}, \qquad \mathrm{IoU} = \frac{|\Omega_{\mathrm{true}} \cap \Omega_{\mathrm{rec}}|}{|\Omega_{\mathrm{true}} \cup \Omega_{\mathrm{rec}}|}. \quad (38)$$

The contrast-to-noise ratio (CNR) in decibels is computed as

$$\mathrm{CNR}_{\mathrm{dB}} = 20 \log_{10} \left(\frac{|\mu_{\mathrm{inc}} - \mu_{\mathrm{bg}}|}{\sigma_{\mathrm{bg}}} \right), \quad (39)$$

where μ_{inc} is the mean reconstructed conductivity inside the inclusion, and μ_{bg} and σ_{bg} are the mean and standard deviation of the reconstructed background conductivity, respectively.

VI. Results

A. Faulty Measurement Data

Fig. 1 shows the effect of localized faulty-electrode corruption on the simulated EIT voltage measurements. Fig. 1(a) compares the clean voltage measurements with the measurements affected by the faulty E23 electrode, whereas Fig. 1(b) presents the corresponding residual. The residual is concentrated in specific measurement-index ranges because each index corresponds to a particular current-injection and voltage-measurement configuration. This behavior indicates that the fault is sparse in the measurement domain but produces

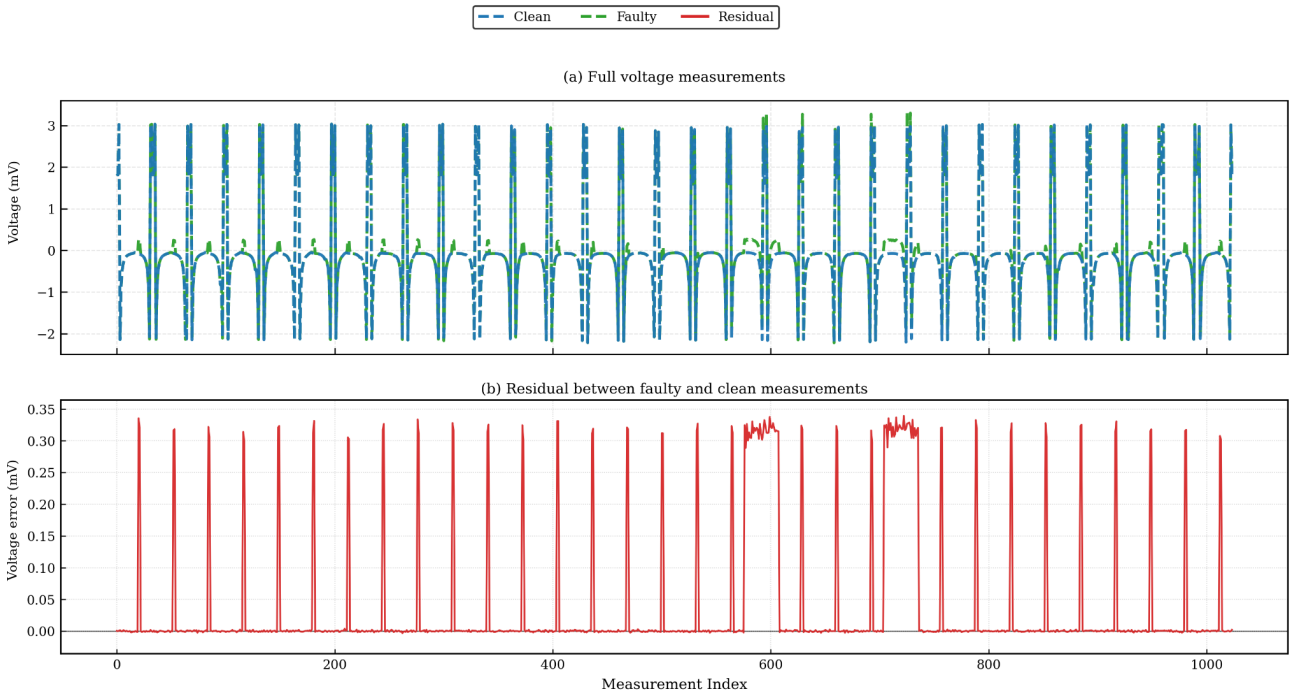

Fig. 1. Effect of faulty-channel corruption on the simulated EIT voltage measurements. (a) compares the clean data with the measurements affected by the faulty E23 electrode. (b) shows the residual between faulty and clean measurements.

localized errors with relatively large amplitudes. The clean and faulty voltage traces exhibit similar overall measurement patterns; which indicates that the fault does not affect all measurements uniformly. However, clear deviations appear at the measurement indices associated with electrode E23. These deviations are more clearly observed in Fig. 1(b), where sharp high-amplitude peaks and localized elevated regions indicate measurement samples affected by the faulty channel. Such sparse, high-amplitude errors can significantly degrade purely quadratic data-fitting methods, since a small number of corrupted residuals may dominate the least-squares objective. This observation supports the use of robust data-fidelity terms and adaptive weighting strategies in the proposed hybrid L_1/L_2 reconstruction framework.

B. Qualitative Reconstructions

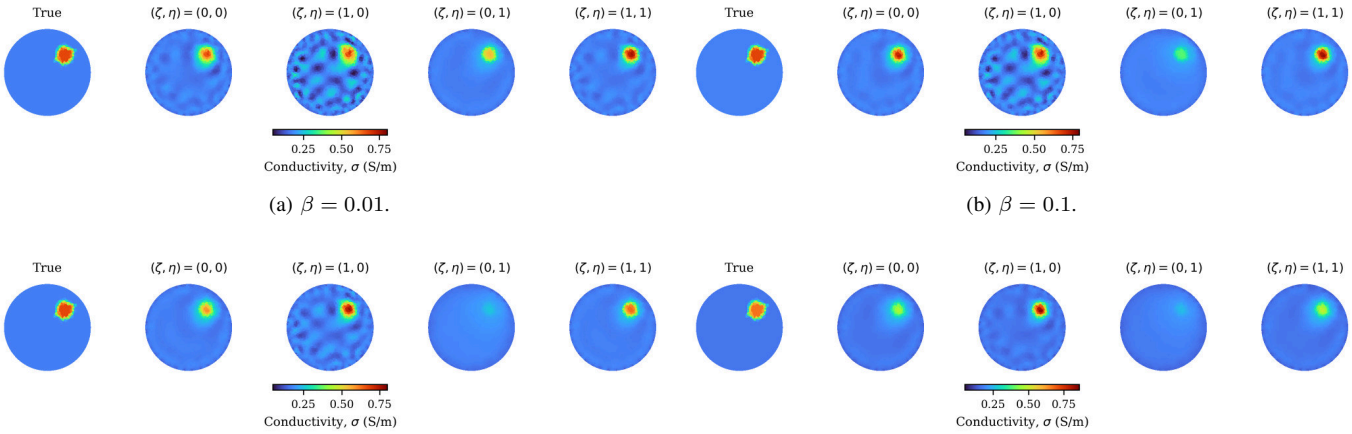

Fig. 2 compares the true conductivity map with reconstructions obtained for the four hybrid settings and different values of β. The quadratic baseline $(0, 0)$ localizes the inclusion but produces diffuse contrast and background artifacts. The robust-data/smooth-prior setting $(1, 0)$ improves inclusion localization and maintains strong threshold-based overlap across regularization levels. The quadratic-data/sparse-prior setting $(0, 1)$ suppresses the inclusion for moderate and large β, showing that prior sparsity alone cannot overcome corrupted data. The fully hybrid setting $(1, 1)$ provides the best overall balance for small to moderate regularization by preserving lesion contrast while reducing background artifacts.

C. Reconstruction Matrix Structure

Fig. 3 shows a representative reconstruction-matrix comparison at $\beta = 0.1$ using $\log_{10}(|\mathbf{K}_{\text{rec}}| + \epsilon_{\log})$, where $\epsilon_{\log}$ is a small positive offset used only to avoid the singularity of $\log_{10}(0)$. The vertical bands correspond to measurement channels with a stronger influence on the reconstructed nodal conductivity values, indicating that the inverse solution is not equally sensitive to all voltage measurements. These sensitivity patterns are determined by the electrode configuration, the skip-4 current-injection protocol, the adjacent voltage-measurement scheme, the adaptive data weights, and the regularization term. In particular, the robust-data configurations modify the relative leverage of inconsistent channels while retaining the broad sensitivity structure of the inverse mapping.

D. Quantitative Performance

Table I summarizes the quantitative reconstruction performance under faulty electrode measurements. The regularization weight was varied over $\beta \in \{0.01, 0.1, 1, 10\}$, and four combinations of the data-fidelity and prior-regularization parameters were evaluated. For $\beta = 0.01$, the fully hybrid setting $(1, 1)$ achieves the lowest RMSE and relative error and the highest Dice, IoU, and CNR. For $\beta = 0.1$, $(1, 1)$ again gives the lowest RMSE and relative error and the highest CNR, whereas $(1, 0)$ gives the highest Dice and IoU. At $\beta = 1$, $(1, 1)$ retains the lowest RMSE, peak error, relative error, and highest CNR, while $(1, 0)$ gives the best spatial overlap. At $\beta = 10$, $(1, 0)$ gives the best RMSE, Dice, IoU, CNR, and relative error. Thus, $(1, 1)$ is the strongest balanced configuration at $\beta = 0.01$-0.1, whereas

(a) $\beta = 0.01$. (b) $\beta = 0.1$.

(c) $\beta = 1$. (d) $\beta = 10$.

Fig. 2. Comparison of the true conductivity distribution and reconstructed images for different regularization parameters β. The background and inclusion conductivities are 0.17 and 0.67 $\mathrm{S/m}$, respectively.

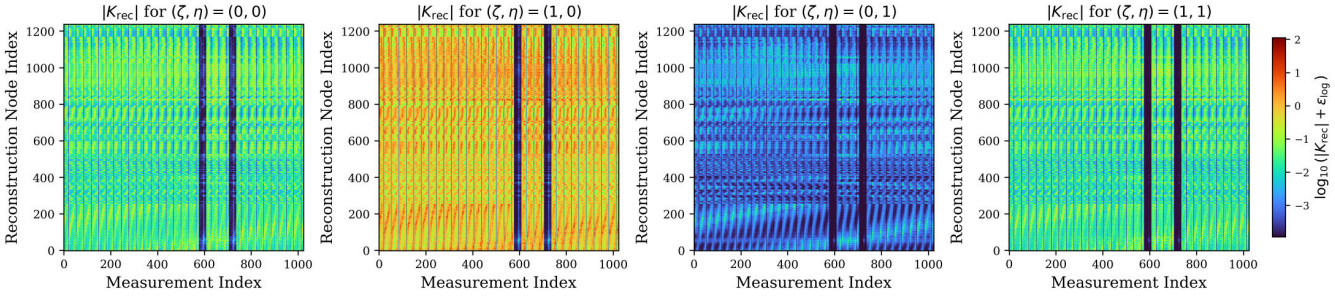

Fig. 3. Representative logarithmic magnitude of the local reconstruction matrix at $\beta = 0.1$ for the four hybrid configurations. The horizontal axis denotes measurement index and the vertical axis denotes reconstruction-node index. Vertical bands indicate measurement channels with relatively high leverage.

$(1,0)$ becomes the most reliable overlap-oriented choice as regularization is strengthened, and it gives the best overall metric profile at $\beta = 10$. This pattern supports the central observation that robust data fidelity is more important than prior sparsity alone when a small subset of measurements is strongly corrupted.

VII. Discussion

The numerical results demonstrate that robust data fidelity is essential for stable EIT reconstruction under localized faulty-electrode corruption generate sparse, high-amplitude voltage residuals. With quadratic data fitting, large faulty-electrode residuals dominate the optimization and may be interpreted as nonphysical conductivity changes. In contrast, the IRLS weights associated with the robust data term reduce the influence of large residuals and allow the reconstruction to rely more strongly on measurements that remain consistent with the CEM forward model.

The prior parameter plays a complementary role. A smooth prior provides conservative stabilization and maintains spatial overlap as β increases, whereas a sparsity-promoting prior can preserve localized contrast when regularization is small. The fully hybrid configuration therefore gives the best balanced performance for small-to-moderate regularization, while the robust-data/smooth-prior setting is preferable when overlap stability is the main objective. These findings are consistent with robust EIT formulations and elastic-net-style regularization in nonlinear inverse problems [11], [12].

The Gaussian-plus-bias perturbation creates finite outliers and is useful for testing the influence function of the data term, but it does not reproduce a completely disconnected electrode. A saturated voltage-sensing channel would likely be strongly downweighted because it generates persistent large residuals. A further limitation is that the quantitative study uses one representative faulty electrode, E23. The present results therefore establish robustness for that configuration but not electrode-position invariance. A second fault location, multiple locations, and hard-disconnection/saturation models should be included in a broader validation study. Other limitations are the two-dimensional circular geometry, fixed contact impedance, synthetic rather than experimentally measured voltages, and one hemorrhage location. Future work should include three-dimensional head models, experimental phantoms, contact-impedance uncertainty, multiple lesions and electrode faults, and adaptive parameter selection.

VIII. CONCLUSION

This paper presented a hybrid L_1/L_2 reconstruction framework for hemorrhagic stroke EIT under localized faulty-electrode corruption. The method combines the CEM, a nodal-conductivity finite elements discretization with Gaussian quadrature, hybrid data and prior penalties, and LM-IRLS optimization. For the representative E23 fault, the numerical results indicate that robust data fidelity is essential for suppressing faulty-channel residuals, while the prior controls the trade-off between smoothness, edge preservation, and contrast recovery. The fully hybrid configuration provides the best balanced performance for small-to-moderate regularization, whereas robust data fidelity with a smooth prior remains more stable as regularization becomes stronger. These results are a numerical proof of concept for localized additive corruption and should not be interpreted as experimental validation or as direct evidence for complete electrode disconnection.

***Abstract*—Accurate artery–vein segmentation in fundus images is challenging due to thin vessels, crossing ambiguities and strong class imbalance. This work proposes a hybrid ViT–CNN W-Net for simultaneous segmentation of arteries, veins and complete vessel tree. The architecture comprises two consecutive U-shaped modules: the first predicts the three vascular channels, while the second refines artery and vein maps using the vessel-tree output as a structural anchor. Each module combines DINOv3 transformer features, Fidelity-Aware Projection Modules, a full-resolution convolutional stem and a U-Net-like decoder. Low-Rank Adaptation is used to efficiently adapt the transformer attention layers. The proposed model was evaluated on the Fundus-AVSeg dataset using three-fold cross-validation and an independent held-out test set. Five configurations were compared to investigate the effects of transformer backbone size, image enhancement, parameter-efficient adaptation and complete backbone freezing. The best configuration, based on DINOv3-Large with Low-Rank Adaptation and image enhancement, achieved Dice scores of 0.8985, 0.9074 and 0.9397 for arteries, veins and complete vessel tree, respectively, resulting in a mean Dice score of 0.9152. The Base and Large backbones achieved comparable results when adapted with Low-Rank Adaptation, whereas freezing the transformer reduced the mean Dice score to 0.8990. Image enhancement produced only marginal and inconsistent improvements. External validation on the HRF and LES-AV datasets yielded mean Dice scores of 0.7010 and 0.8126, respectively, indicating reduced cross-dataset performance compared with the primary evaluation on Fundus-AVSeg. Nevertheless, qualitative results indicates that the main arterial, venous and vessel-tree structures were consistently recovered, suggesting that differences in image characteristics and annotation protocols may partially account for the quantitative degradation. Overall, these results support the proposed hybrid ViT–CNN W-Net as a feasible framework for joint retinal vessel segmentation and artery–vein differentiation while retaining the flexibility to incorporate alternative transformer backbones.**

I. Introduction

Retinal vessel segmentation is a fundamental step for the development of computational tools for ophthalmic image analysis. The vascular structure observed in color fundus images carries relevant clinical information, since changes in vessel caliber, tortuosity, branching patterns and artery-vein organization may be associated with systemic and ocular conditions such as hypertension, diabetes and cardiovascular diseases [1]–[4]. In this context, accurate vessel segmentation is not only useful as an isolated image-processing task, but also as a prerequisite for downstream diagnostic and decision-support systems.

Convolutional encoder-decoder networks, especially U-Net-based models, have been widely used for biomedical image segmentation [5]. For retinal vessel analysis, cascaded U-shaped architectures have also been explored, forming W-shaped networks in which a first U-Net produces an initial segmentation and a second U-Net refines this output. This strategy is particularly attractive for artery-vein segmentation, since the model must not only identify the vascular tree, but also distinguish visually similar arterial and venous structures. Previous recurrent W-Net approaches have proposed repeated refinement steps to improve segmentation consistency [6], [7]. In previous work, we observed that this type of refinement may improve performance, but its benefit depends strongly on the training regime and on the amount of effective supervision available [8].

More recently, self-supervised vision transformers have become strong feature extractors for medical imaging. Among them, DINOv3 has shown high transferability across visual tasks [9]. In parallel, U-shaped has been proposed as a way of combining frozen DINOv3 representations with U-Net-like decoding for medical image segmentation [10]. In this architecture, intermediate transformer representations are adapted into multi-scale feature maps and used as skip connections in a decoder. However, the original U-shaped formulation was not designed specifically for artery-vein segmentation and its application to fundus imaging was mainly evaluated in optic disc and cup segmentation. Therefore, its use for simultaneous

artery, vein and full vessel-tree segmentation remains an open and relevant question.

In this work, we propose and evaluate a hybrid Vision Transformer–convolutional neural network (ViT–CNN) W-Net for the simultaneous segmentation of retinal arteries, veins and the complete vessel tree. The architecture comprises two consecutive hybrid U-shaped modules. The first module receives the fundus image and produces an initial three-channel prediction, whereas the second receives the sigmoid-normalized outputs of the first stage and refines only the artery and vein maps. The vessel-tree prediction is preserved as a structural anchor, providing anatomical context while allowing the second U-shaped branch to correct artery–vein inconsistencies produced by the initial segmentation stage.

Each hybrid module combines intermediate transformer representations, Fidelity-Aware Projection Modules (FAPMs) [10], a full-resolution convolutional stem and a U-Net-like convolutional decoder. The transformer features are converted into spatial maps and adapted by the FAPMs, which project the high-dimensional representations into stage-specific channel dimensions before constructing the decoder feature pyramid. In parallel, the convolutional stem extracts local information directly from the input and provides a full-resolution skip connection to the decoder. This design combines the semantic representation capacity of a pretrained ViT with the spatial detail supplied by convolutional processing, which is particularly important for segmenting thin retinal vessels. Although the architecture is not restricted to a specific transformer backbone, DINOv3 was adopted in this implementation because of the quality of its visual representations and its demonstrated effectiveness in medical image segmentation [10].

We investigate five experimental configurations using the Fundus-AVSeg dataset [11]. The experiments compare DINOv3-Base and DINOv3-Large backbones, with and without contrast-based image enhancement and evaluate lightweight Low-Rank Adaptation (LoRA) [12] against a completely frozen transformer backbone. LoRA adapts selected attention projections while introducing only a small number of trainable parameters. This strategy is particularly relevant for large pretrained vision encoders, for which full fine-tuning may be computationally expensive and prone to overfitting when only small medical imaging datasets are available.

The main contributions of this work are: (1) the introduction of a hybrid ViT–CNN W-Net for joint artery, vein and vessel-tree segmentation, in which the vessel-tree prediction is preserved as a structural anchor during refinement; (2) the evaluation of LoRA-based transformer adaptation in comparison with a fully frozen backbone; (3) a comparison between DINOv3-Base and DINOv3-Large under the same training and evaluation protocol; and (4) an analysis of the effect of contrast-based fundus image enhancement on segmentation performance. The implementation was developed in PyTorch [13], with sliding-window inference and evaluation supported by MONAI [14] and preprocessing based on scikit-image and CLAHE [15], [16]. Performance was primarily assessed using the Dice–Sørensen coefficient, complemented by sensitivity, specificity, precision, ROC AUC and precision–recall AUC.

II. Methods

A. Study design and Data

This paper evaluated five experiments with different configurations of a W-shaped retinal vessel segmentation model based on DINOv3 encoders and convolutional decoders. Task was defined as a three-channel segmentation problem, with different outputs for arteries, veins and the complete vascular tree. All experiments used the same data split, training protocol and evaluation pipeline, allowing the comparison of the effect of the backbone size, image enhancement, LoRA adaptation and full backbone freezing, under similar conditions.

Fundus-AVSeg [11] was selected because it comprises 100 pairs of fundus images and their corresponding annotations. It is a publicly available dataset specifically designed for the training and evaluation of artificial intelligence models for automatic retinal vessel segmentation. The main reason for selecting this dataset is its size, as other publicly available datasets commonly used for this purpose contain considerably fewer images with artery and vein annotations.

Among the main alternatives are HRF [17], [18], which contains 45 image-mask pairs, RITE [19], with 40 image-mask pairs and LES-AV [20], with only 22 image-mask pairs. Another advantage of Fundus-AVSeg is that its 100 images were acquired from 100 different subjects, as reported in [11]. Therefore, there is no subject overlap within the dataset, eliminating the risk of patient-level data leakage between the training and testing sets.

The fixed random seed 42 was used to split the data into a held-out test set and a training-validation subset. Twenty-five unique images were reserved for final testing and the other 75 images were used in a three-fold cross-validation scheme. In each fold, 50 images were used for training and 25 images for validation. The final test prediction was obtained through the average probability maps produced by all the three fold-specific models.

B. Image and segmentation mask preprocessing

Original images on Fundus-AVseg have two different resolutions: 2656×1992 or 1280×1280. To ensure a standardization, non-square images were cropped on both sides and resized to 1280×1280. Input images were read as RGB fundus images (Fig.1(a)) and normalized to the unit interval. A binary field-of-view (FOV) mask was estimated from the largest connected component of the retinal region and was used to restrict the loss and evaluation metrics to the retinal area. As in ref. [7], original color-coded annotations (as seen in Fig.1(c)) were converted into three binary channels: artery (A) on red channel, vein (V) on green channel and total vessel tree (BV) on blue channel (as seen in Fig.1(d)). Ambiguous or unknown vessel pixels were included in the total vessel channel.

Two preprocessing settings were evaluated: (i) In the non-enhanced setting, the normalized RGB image was used directly; (ii) In the enhanced setting (Fig.1(b)), a contrast-enhancement pipeline was applied into the retinal field of view, based on ref. [7]. This pipeline combines a mild zoom-based background composition, CLAHE in the luminance channel, Gaussian background subtraction and normalization within the FOV. Comparison between enhanced and non-enhanced images was included to assessment, whether this classical preprocessing step improved the proposed model.

C. Model architecture

The proposed model is designed as a hybrid Vision Transformer–convolutional neural network (ViT–CNN) W-Net composed of two consecutive U-shaped modules (Fig. 2). Each module combines a ViT-based encoder, Fidelity-Aware Projection Modules (FAPMs), a shallow convolutional stem and a U-Net-like convolutional decoder. In the present implementation, DINOv3 is adopted as the transformer backbone and adapted using LoRA. The architecture took its inspiration in the U-shaped architecture. However, unlike its original adapter, which uses a Spatial Prior Module to generate multi-scale convolutional priors that interact with the transformer representations, our model employs a simplified full-resolution convolutional stem. The stem provides local spatial information directly to the decoder, while the intermediate DINOv3 representations are independently adapted by the FAPMs and resized to form the remaining decoder skip levels.

The first hybrid U-shaped module receives the fundus image and produces an initial three-channel segmentation map corresponding to arteries, veins and the complete vessel tree, denoted by A_0, V_0 and BV_0, respectively. The second module receives the sigmoid-normalized maps produced by the first stage and refines only the artery and vein predictions. The vessel-tree channel BV_0 is preserved and used as a structural vascular anchor during refinement, since it represents the global vessel topology estimated by the first module. The final prediction therefore combines the refined artery and vein outputs, A_1 and V_1, from the second module with the vessel-tree output BV_0 inherited from the first module. Thus, the first U-shaped branch estimates the overall vascular structure and an initial artery–vein separation, whereas the second branch corrects artery–vein inconsistencies conditioned on the initial predictions, resulting in the W-shaped architecture shown in Fig. 2.

Each U-shaped module receives a three-channel input. The input was then normalized using ImageNet statistics before being passed to the DINOv3 encoder. The encoder extracted intermediate transformer representations from four selected blocks. For the DINOv3-Base experiments, the extracted blocks were 2, 5, 8 and 11. For the DINOv3-Large LoRA experiments, the extracted blocks were 5, 11, 17 and 23.

Since DINOv3 is a Vision Transformer with a patch size of 16 and internal resolution of 512×512, its transformer representations are produced on a patch grid rather than as a natural convolutional feature pyramid. Only the patch tokens were used to construct the spatial feature maps, class and register tokens were not used for this purpose. The selected patch tokens were reshaped into two-dimensional feature maps and then processed by FAPMs. Each FAPM projected a transformer feature map from the DINOv3 embedding dimension to a task-specific number of channels. The resulting feature maps were resized to form a multi-scale representation suitable for the U-Net-like convolutional decoder.

In each U-shaped module, a shallow convolutional stem is applied in parallel to the DINOv3 branch. The stem receives the same ImageNet-normalized three-channel input used by the transformer branch: the RGB fundus image in the base module and the three sigmoid-normalized prediction maps in the refinement module. It is composed of two consecutive 3×3 convolutional layers with stride 1 and padding 1, each followed by batch normalization and ReLU activation. The convolutions do not use bias terms and produce 32 feature channels. Since no pooling or strided convolution is used, the stem preserves the full spatial resolution of the input. Its output is used as the highest-resolution skip connection of the decoder, complementing the lower-resolution DINO-FAPM feature maps and providing local spatial information that may be weakened by the transformer patch representation.

Inside each FAPM, the projection is performed through a combination of a shared low-dimensional basis and a stage-specific basis. The shared basis generates modulation parameters that condition the stage-specific representation in a FiLM-like manner [21]. The modulated features are then refined by a lightweight convolutional block composed of pointwise convolution, batch normalization, ReLU activation, depthwise separable convolution and squeeze-and-excitation recalibration. A shortcut projection is added to preserve information from the modulated representation. In our implementation, the four FAPM stages produced 64, 128, 256 and 512 channels, respectively, using a projection rank of 256.

The decoder follows the standard U-Net principle. Starting from the deepest adapted feature map, transposed convolutions progressively recover spatial resolution. At each level, the upsampled representation is concatenated with the corresponding encoder skip connection and processed by two convolutional layers with batch normalization and ReLU activation. A final 1×1 convolution produces the segmentation logits. In the first U-shaped module, this layer produces three channels, corresponding to arteries, veins and the complete vessel tree. In the second module, it produces two channels, corresponding only to the refined artery and vein predictions.

D. Loss Function

The model was trained using a masked binary cross-entropy loss. Let $\hat{Y}^{(0)} = (\hat{A}_0, \hat{V}_0, \widehat{BV}_0)$ denote the logits produced by the first U-shaped module and let $\hat{Y}^{(1)} = (\hat{A}_1, \hat{V}_1)$ denote the refined artery and vein logits produced by the second U-shaped module. The corresponding ground-truth masks are denoted by A, V and BV.

Because artery and vein labels are not reliable in every pixel, the artery and vein losses were computed only over pixels with

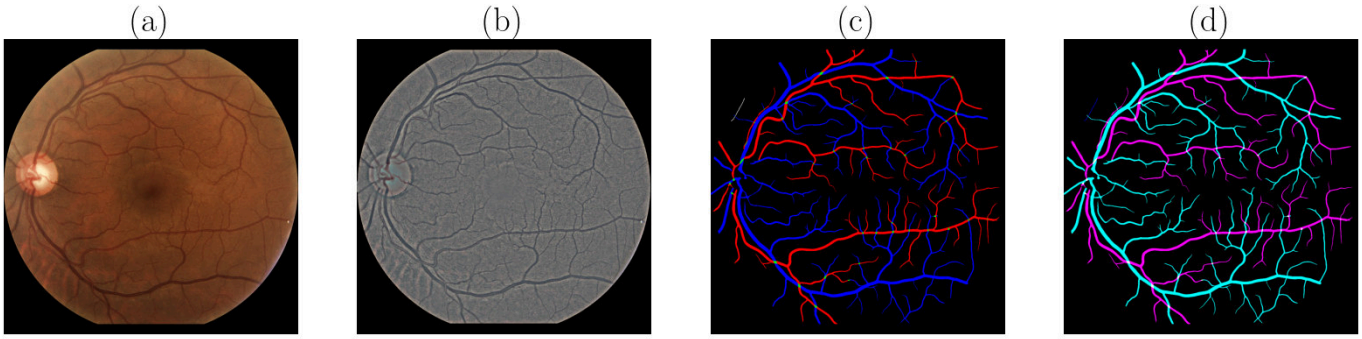

Fig. 1. (a) Raw fundus image; (b) preprocessed and input for the model; (c) original ground truth segmentation mask; (d) adjusted ground truth segmentation mask.

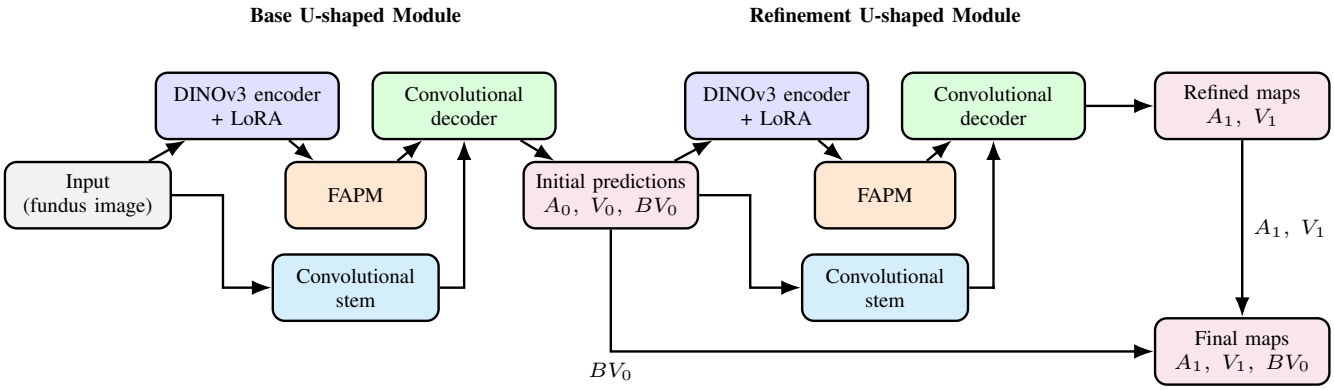

Fig. 2. Schematic representation of the proposed W-shaped architecture. The first U-shaped receives the input fundus image and produces initial predictions for arteries (A_0), veins (V_0) and the complete blood vessel tree (BV_0). The second U-shaped receives these initial maps and refines only the artery and vein predictions. The final blood vessel map remains fixed and is inherited from the first stage.

valid artery-vein annotations. In contrast, the total vessel loss was computed over the complete annotated vessel mask. The masked binary cross-entropy for a predicted logit map $\hat{y}$, target mask y and binary validity mask m was defined as

$$\mathcal{L}_{\mathrm{BCE}}(\hat{y}, y; m) = \frac{\sum_p m_p \,\mathrm{BCEWithLogits}(\hat{y}_p, y_p)}{\sum_p m_p + \epsilon}, \quad (1)$$

where p indexes image pixels and ϵ is a small constant used for numerical stability.

The first module was supervised using the three initial predictions,

$$\begin{aligned}\mathcal{L}_0 &= \mathcal{L}_{\mathrm{BCE}}(\hat{A}_0, A; m_{AV}) + \mathcal{L}_{\mathrm{BCE}}(\hat{V}_0, V; m_{AV}) \\ &+ \mathcal{L}_{\mathrm{BCE}}(\widehat{BV}_0, BV; m_{BV}), \end{aligned} \quad (2)$$

where m_{AV} indicates pixels with valid artery-vein labels and m_{BV} indicates pixels used for vessel supervision. The refinement module was supervised only on the artery and vein outputs,

$$\mathcal{L}_1 = \mathcal{L}_{\mathrm{BCE}}(\hat{A}_1, A; m_{AV}) + \mathcal{L}_{\mathrm{BCE}}(\hat{V}_1, V; m_{AV}). \quad (3)$$

The final loss was defined as

$$\mathcal{L} = \mathcal{L}_0 + \mathcal{L}_1. \quad (4)$$

This loss encourages the first module to learn a complete vascular representation while forcing the second module to specialize in artery-vein refinement. Since the blood vessel channel is inherited from the first module, no additional vessel-tree loss is applied to the second module.

E. Backbone adaptation strategies

The five experiments were designed to assess the effects of transformer backbone size, image enhancement and backbone adaptation strategy. Experiments 1 and 2 used DINOv3-Large with LoRA [12], without and with image enhancement, respectively. Experiments 3 and 4 used DINOv3-Base with LoRA, also without and with image enhancement, respectively. Experiment 5 used DINOv3-Base with image enhancement but removed LoRA, keeping the transformer backbone completely frozen.

For the first four experiments, LoRA matrices were injected into the attention projections `q_proj`, `k_proj`, `v_proj` and `o_proj` of the pretrained DINOv3 backbone [12]. The LoRA rank was 16, the scaling parameter was 32 and the dropout probability was 0.05. In these experiments, the task-specific modules, including the stem, feature-adaptation modules, projection layers and decoder, were also trained. The fifth experiment removed LoRA and kept the DINOv3 backbone

completely frozen. In this setting, only the task-specific modules were optimized. This experiment was included to estimate how much performance was provided by the frozen pretrained representation alone, without adapting the transformer attention layers.

F. Training protocol

Models were trained with AdamW using an initial learning rate of 5×10^{-4} and a weight decay of 10^{-2} during the main training stage. During this stage, the learning rate followed a cosine annealing schedule, decreasing from its initial value to a minimum value of 1×10^{-6}. The main training stage was validated every ten epochs and stopped early when validation performance did not improve for 120 epochs, corresponding to 12 consecutive validation checks without improvement. After the main training stage, each fold was fine-tuned from its best validation checkpoint using a fixed lower learning rate of 1×10^{-4}. Fine-tuning was validated every two epochs and stopped early when validation performance did not improve for 60 epochs, corresponding to 30 consecutive validation checks without improvement. All experiments used the same training, validation and test splits.

Training was performed on random image crops of size 896×896 extracted from the original 1280×1280 images and masks. The augmentation pipeline included random color perturbation, random affine transformations, spatial cropping, horizontal and vertical flips and cutout (same as in ref. [7]). Validation and test evaluation were performed without any augmentation.

For this paper, no hyperparameter optimization or ablation techniques were performed, aiming to compare only the performance of the chosen backbones under similar circumstances. No references of similar approach were found on the literature and comparison of results are made to recent techniques using U-Net like architectures. All models were trained in Google Colab using an NVIDIA RTX PRO 6000 GPU with 96 GB of VRAM. Code, models and results are available at: https://github.com/labviaunb/cbeb2026.

G. Evaluation

During evaluation, predictions were generated at the original image resolution using the `sliding_window_inference` function from MONAI [14]. Since the model was trained on cropped image patches, full-resolution fundus images were processed by applying the network over overlapping windows with the same spatial size used during training. MONAI then aggregated the window-level logits to reconstruct the complete segmentation maps for the artery, vein and vessel channels. All quantitative metrics were computed from these reconstructed full-image predictions.

Performance was evaluated on the held-out test set using the ensemble of the three fold-specific models. For each test image, the probability maps from the three models were averaged, with threshold at 0.5, to obtain binary masks. Metrics were computed inside the retinal field of view.

Primary metric is the Dice coefficient, computed separately for artery, vein and total vessel tree. The mean Dice reported in the tables corresponds to the average of these three channel-wise Dice values. Sensitivity, specificity, precision, area under the ROC curve and area under the precision-recall curve were computed for each channel. The final validation Dice is reported as the mean and standard deviation across the three folds after fine-tuning.

III. Results and Discussion

Table I summarizes the test performance of the five experiments. The best mean test Dice was obtained by Exp. 2, which used the DINOv3-Large backbone with LoRA and image enhancement, reaching a mean Dice on the test set of 0.9152. The difference among the four LoRA-based experiments was small: minimum and maximum mean Dice values were 0.9139 and 0.9152. This suggests that, under the current training protocol, both DINOv3-Base and DINOv3-Large provided similarly strong representations when LoRA adaptation was used.

The frozen-backbone experiment showed a clear drop in performance. Exp. 5, using DINOv3-Base without LoRA, achieved a mean Dice of 0.8990 on the test set. This result indicates that the frozen DINO representation alone was useful, but adapting the backbone through LoRA improved segmentation quality, particularly for artery and vein separation.

The effect of image enhancement was not consistent across the two LoRA-adapted backbones. With DINOv3-Large, enhancement slightly increased the mean Dice from 0.9146 in Exp. 1 to 0.9152 in Exp. 2. Furthermore, with DINOv3-Base, enhancement slightly decreased the mean Dice from 0.9142 in Exp. 3 to 0.9139 in Exp. 4. Since the differences are small, they must be interpreted with caution, suggesting that the DINO-based models were already able to extract useful vessel information from the normalized RGB images. In this setting, the contrast-enhancement preprocessing adopted from Morano et al. [6], [7] did not provide a consistent performance advantage.

DINOv3-Large and DINOv3-Base showed very similar performance when LoRA was used. Without image enhancement, Exp. 1 with DINOv3-Large achieved a mean Dice of 0.9146, while Exp. 3 with DINOv3-Base achieved 0.9142. With enhancement, Exp. 2 with DINOv3-Large achieved 0.9152, while Exp. 4 with DINOv3-Base achieved 0.9139. These results indicate that increasing the backbone size from Base to Large did not lead to a large improvement in this dataset and training setting.

Comparison between the LoRA-based Base model and the frozen Base model, in Exp. 4 and Exp. 5, indicates that LoRA adaptation was beneficial. The mean Dice decreased from 0.9139 to 0.8990 when LoRA was removed. The largest drops were observed in the artery and vein channels, which are more complex tasks than total vessel segmentation.

Segmentation of total vessel channel was very consistent in all experiments, even when DINOv3 backbone was frozen. The vessel-tree Dice ranged from 0.9319 to 0.9399, whereas

artery Dice ranged from 0.8763 to 0.8985 and vein Dice ranged from 0.8888 to 0.9075. This behavior is expected because the vessel-tree prediction is generated by the first U-shaped module and preserved as a structural anchor, while the second U-shaped module refines only the artery and vein predictions.

In Table II all the experiment metrics are reported. All experiments achieved high specificity, above 0.992 for all channels, indicating that false positives were relatively controlled. It is very important in retinal vessel segmentation, because most pixels inside the field of view correspond to

background. Sensitivity was lower than specificity, especially in the frozen-backbone experiment, suggesting that missed vessel pixels were main error source. The precision–recall AUC values were also high, particularly for the total vessel channel, where all LoRA-based experiments achieved values above 0.985.

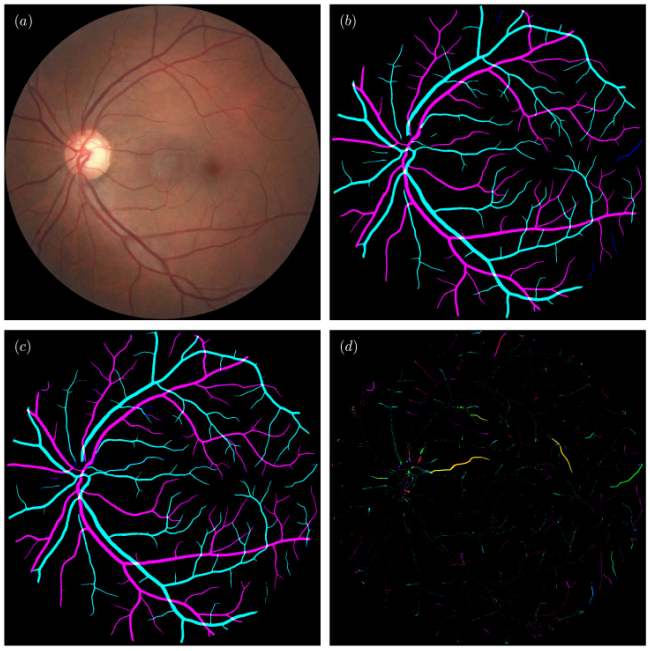

Fig. 3. (a) Raw fundus image from the Fundus-AVSeg dataset [11]; (b) adjusted ground-truth segmentation mask; (c) segmentation predicted by the DINOv3-Large model; and (d) absolute difference between the ground-truth and predicted masks. The predicted segmentation achieved Dice scores of 0.9481 for arteries, 0.9415 for veins and 0.9608 for the complete vessel tree, with a mean Dice score of 0.9501, indicating excellent agreement between the predicted and ground-truth masks.

Figures 3– 5 show comparison between ground truth, prediction and their subtraction. Figure 3 reports test analysis in the same dataset of the training [11], achieving high scores and excellent agreement with ground truth, with mean Dice of 0.9501. On the other hand, Figures 4 and 5 reports the model test in images of the LES-AV [20] and HRF [17], [18] datasets, respectively. These results shows good qualitatively representation of the arteries, veins and vessel tree. In the LES-AV image the mean Dice score reduced to 0.8165, while in the HRF image the mean Dice score reduced to 0.8171.

Table III reports the external validation performance of the proposed model on the HRF and LES-AV datasets. On HRF, the model achieved mean Dice scores of 0.6711, 0.7145 and 0.7175 for arteries, veins and the complete vessel tree, respectively. Higher cross-dataset performance was observed on LES-AV, with corresponding Dice scores of 0.7928, 0.8120 and 0.8330. A similar trend was observed for the ROC AUC and PR AUC metrics, with LES-AV consistently yielding higher values than HRF.

Finally, Tables IV and V provide a contextual comparison with the results reported by Morano *et al.* [7] and Zeng *et al.* [22], respectively, whose W-Net-like models were trained

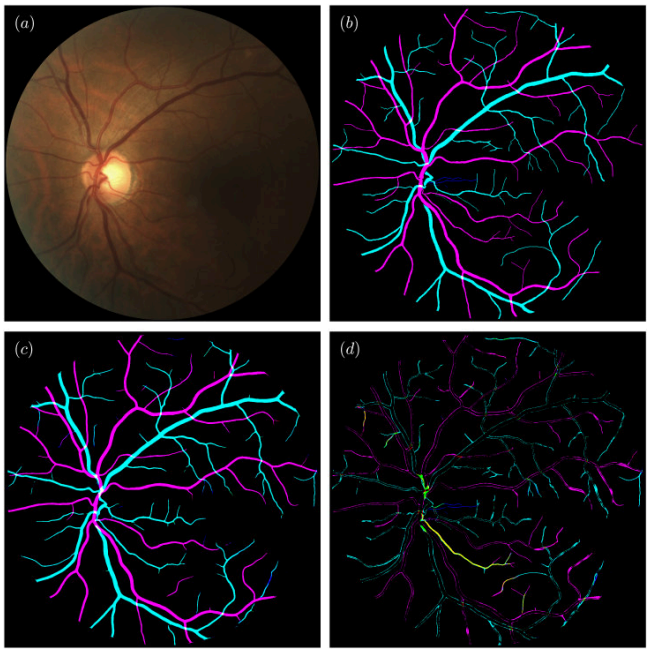

Fig. 4. (a) Raw fundus image from the LES-AV dataset [20]; (b) adjusted ground-truth segmentation mask; (c) segmentation predicted by the DINOv3-Large model; and (d) absolute difference between the ground-truth and predicted masks. The predicted segmentation achieved Dice scores of 0.8158 for arteries, 0.8020 for veins and 0.8317 for the complete vessel tree, with a mean Dice score of 0.8165, indicating good agreement between the predicted and ground-truth masks.

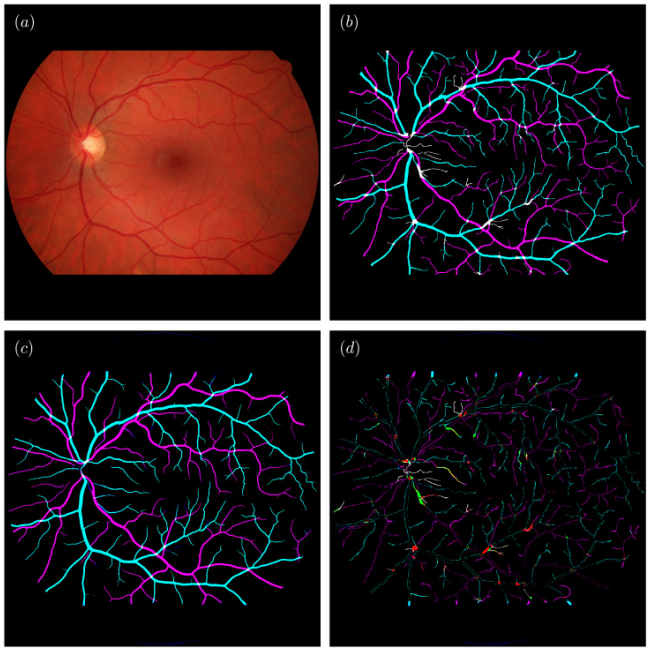

Fig. 5. (a) Raw fundus image from the HRF dataset [17], [18]; (b) adjusted ground-truth segmentation mask; (c) segmentation predicted by the DINOv3-Large model; and (d) absolute difference between the ground-truth and predicted masks. The predicted segmentation achieved Dice scores of 0.7884 for arteries, 0.8276 for veins and 0.8352 for the complete vessel tree, with a mean Dice score of 0.8171, indicating good agreement between the predicted and ground-truth masks.

and evaluated on datasets such as RITE [19], LES-AV [20] and HRF [17], [18]. In contrast, our model was trained on Fundus-AVSeg [11], while Table III reports its external validation on previously unseen HRF and LES-AV images. Therefore, direct comparisons are not appropriate, as differences in training data, annotation protocols, preprocessing and evaluation settings may substantially affect the reported metrics. Then, Tables IV and V should thus be interpreted only as references to the performance range reported in the literature. Despite the lower quantitative performance observed in the external validation, the qualitative examples in Figs. 4 and 5 show that the model still recovered the main arterial, venous and vessel-tree structures in both datasets, with discrepancies likely influenced by differences in image characteristics and annotation criteria. Within these limitations, the results support the use of hybrid ViT–CNN U-shaped modules with parameter-efficient LoRA adaptation as a competitive alternative to fully convolutional W-Net architectures.

IV. Conclusion

This work proposed a hybrid ViT–CNN W-Net for the simultaneous segmentation of retinal arteries, veins and the complete vessel tree. The architecture uses two consecutive U-shaped modules, preserving the vessel-tree prediction from the first stage as a structural anchor for artery–vein refinement in the second stage. The experiments showed that LoRA provides an effective parameter-efficient strategy for adapting the transformer backbone, outperforming the completely frozen configuration. DINOv3-Base and DINOv3-Large produced comparable results, suggesting that increasing backbone size provides limited gains in this setting, while contrast-based image enhancement had only a marginal and inconsistent effect. Overall, the results support the use of hybrid ViT–CNN modules in W-shaped architectures for accurate retinal vessel segmentation and artery–vein differentiation.

The main limitation of this study is that model training and primary evaluation were restricted to Fundus-AVSeg, limiting conclusions about generalization across acquisition devices, populations and annotation protocols. External validation on HRF and LES-AV showed reduced quantitative performance despite good qualitatively vascular predictions, suggesting sensitivity to cross-dataset differences in image characteristics and annotation criteria. Future work should include training and systematic evaluation across multiple datasets, dedicated ablation studies of the proposed architecture, comparisons with full transformer fine-tuning and other parameter-efficient adaptation strategies and assessment of the clinical relevance of the predicted masks through retinal vascular biomarkers.

***Abstract*—Cardiac troponin is the reference biomarker for myocardial injury; however, its measurement depends on laboratory analysis, which may delay clinical decision-making in emergency settings. In contrast, the electrocardiogram (ECG) is inexpensive, non-invasive, and immediately available. This study proposes a one-dimensional convolutional neural network (1D-CNN) for the identification of elevated cardiac troponin using standard 12-lead ECG recordings. ECG signals were preprocessed using a 0.67–40 Hz band-pass filter, resampled to 500 Hz, and used to train the proposed model on a private clinical dataset. In addition, an exploratory experiment evaluated a CNN previously trained for myocardial infarction detection on the Physikalisch-Technische Bundesanstalt XL (PTB-XL) database by directly applying it to the private troponin dataset without fine-tuning or domain adaptation. On the validation subset, the proposed model achieved an accuracy of 73.83%, with a sensitivity of 63.6% and a specificity of 75.0% for the positive class; given the low prevalence of elevated troponin in the cohort (11%), the corresponding positive predictive value was 23.3%. The pretrained myocardial infarction model achieved a lower accuracy of 59.61% on the troponin dataset but retained partial discriminative capability. Because myocardial infarction detection and troponin elevation constitute distinct prediction targets, this observation is described as an exploratory internal association rather than as evidence of successful biomarker transfer. Given the limited size of the cohort and the absence of external validation, these findings should be regarded as hypothesis-generating rather than as evidence of clinical applicability.**

***Index Terms*—Electrocardiogram, Convolutional Neural Networks, Cardiac Troponin, Myocardial Infarction.**

I. Introduction

Cardiovascular diseases (CVDs) remain the leading cause of mortality worldwide, accounting for a substantial proportion of hospital admissions and healthcare expenditures [1]–[3]. Among these conditions, myocardial infarction (MI) represents one of the most critical clinical emergencies, requiring rapid diagnosis and treatment to minimize myocardial damage and improve patient outcomes [4], [5]. Early identification of myocardial injury is therefore essential for effective risk stratification and timely therapeutic intervention [5].

The diagnosis of MI relies on a combination of clinical assessment, electrocardiographic findings, and laboratory biomarkers [4], [5]. Among these biomarkers, cardiac troponins are currently considered the reference biomarker for detecting myocardial injury due to their high sensitivity and specificity [4], [6]. Elevated troponin levels are strongly associated with myocardial necrosis and play a central role in contemporary diagnostic guidelines [4].

In clinical practice, physicians often need to make critical decisions while awaiting laboratory troponin results, particularly during the initial evaluation of patients presenting with chest pain. Although high-sensitivity cardiac troponin assays have significantly reduced turnaround times, blood collection, sample processing, and laboratory analysis still introduce delays that may postpone diagnostic confirmation and therapeutic decisions [6], [7]. Furthermore, because cardiac troponins are structural proteins released into the bloodstream after myocardial cell injury, rather than direct markers of cardiac electrical activity, their elevation follows a time-dependent release pattern after symptom onset [4], [8], [9]. In contrast, electrocardiogram (ECG) abnormalities may be absent, transient, or non-specific during the early stages of myocardial infarction, particularly in non-ST-elevation acute coronary syndromes [5], [10]. Consequently, ECG findings and troponin measurements provide complementary information rather than equivalent diagnostic evidence, reinforcing the need for computational approaches capable of identifying latent ECG patterns associated with subsequent troponin el-

evation [8], [11].

Because the ECG is fast, non-invasive, inexpensive, and widely available, it remains the first-line diagnostic test in the evaluation of patients with suspected acute myocardial infarction [5]. Beyond its established role in detecting arrhythmias, conduction abnormalities, ischemia, and ST-segment elevation, the ECG provides real-time information about the heart's electrical activity that may contain subtle signatures of myocardial injury [5], [12]. However, many of these patterns are difficult to recognize through conventional visual interpretation, particularly in patients with non-specific or atypical presentations [13], [14]. This limitation has motivated the development of artificial intelligence methods capable of automatically extracting complex electrophysiological features from raw ECG signals.

Recent advances in deep learning have substantially improved automatic ECG analysis by enabling the extraction of complex electrophysiological patterns directly from raw signals. In the context of myocardial infarction (MI), convolutional neural networks have consistently achieved excellent diagnostic performance. For example, Alghamdi et al. [15] proposed a transfer learning framework based on VGG-Net that achieved accuracies above 99% for MI detection on the PTB database, demonstrating the feasibility of deep learning for automated ECG interpretation . Subsequently, He et al. [16] introduced a lightweight multi-feature branch convolutional network with a lead-attention mechanism capable of exploiting the complementary information from the 12 ECG leads. Their method achieved 99.63% accuracy under intra-patient evaluation and remained competitive under patient-specific settings, while also supporting deployment on resource-constrained devices.

Although deep learning approaches have demonstrated remarkable performance, important methodological challenges remain. Many studies evaluate their models using intra-patient protocols or relatively homogeneous datasets, which may overestimate real-world performance. Addressing this issue, Moghadam and Asl [17] proposed an interpretable approach based on morphological ECG features and random forests, reporting 96.54% accuracy for MI detection and 80.98% accuracy for MI localization under the more clinically relevant inter-patient evaluation protocol.

More recently, deep learning models have been extended beyond conventional ECG interpretation to estimate laboratory biomarkers directly from the electrical activity of the heart. Chaudhari et al. [11] developed a convolutional neural network using more than 64,000 paired ECG–troponin examinations, demonstrating that elevated cardiac troponin I could be identified directly from standard 12-lead ECGs, with an Area Under the Receiver Operating Characteristic Curve (AUC) of 0.783 for clinically relevant troponin thresholds. Their findings suggest that ECG signals contain latent information associated with biomarker-defined myocardial injury that is not readily apparent through conventional visual interpretation . Subsequent studies have further reinforced the potential of AI-based ECG analysis for identifying myocardial injury and supporting early clinical decision-making [18].

Despite the promising results reported in the literature, important challenges remain. Relatively few investigations have explored the relationship between ECG representations learned from myocardial infarction detection tasks and their applicability to related clinical outcomes such as troponin elevation [11], [18]. Understanding whether knowledge acquired from large public ECG repositories can generalize to independent clinical cohorts remains an important research question [19], [20].

In this context, the present study investigates the use of a one-dimensional convolutional neural network (1D-CNN) for the automatic identification of elevated cardiac troponin from standard 12-lead ECG recordings. The proposed approach was evaluated using a private clinical dataset collected in a hospital environment under approval from the local Research Ethics Committee. ECG signals were preprocessed through band-pass filtering and resampling to ensure compatibility with the adopted deep learning architecture.

Additionally, an exploratory generalization analysis was conducted using a model previously trained for myocardial infarction detection on the PTB-XL database [19]. Unlike conventional transfer learning approaches, no fine-tuning or domain adaptation was performed. The model was directly applied to the private clinical dataset labeled according to troponin levels, allowing the investigation of whether ECG representations learned from infarction-related patterns contain information associated with myocardial injury as reflected by troponin elevation.

II. Materials and Methods

A. Private Clinical Dataset

The experiments were conducted using a private clinical dataset collected in a hospital environment. The study was approved by the local Research Ethics Committee (Approval No. 3.493.714; CAAE: 15824819.2.0000.8069), and all participants provided written informed consent before enrollment.

The dataset comprises standard 12-lead electrocardiographic recordings acquired from patients admitted for clinical evaluation, together with the corresponding cardiac troponin measurements obtained from each patient's laboratory records. Each ECG recording consists of 12 simultaneously acquired leads sampled at 1200 Hz, containing 13,440 samples per lead. An example of a raw ECG recording from the private dataset is shown in Fig. 1, illustrating the signal morphology prior to preprocessing.

High-sensitivity cardiac troponin I (hs-cTnI) was measured using an immunometric assay with a detection limit of 0.004 ng/mL. For the purposes of this study, a binary classification task was defined using the assay's diagnostic threshold corresponding to the 99th percentile. Samples with hs-cTnI concentrations ≥ 0.04 ng/mL were labeled as positive, indicating myocardial injury, whereas values < 0.04 ng/mL were labeled as negative. Although patients were clinically classified as having type 1 myocardial infarction (plaque rupture) or type 2 myocardial infarction (oxygen supply–demand

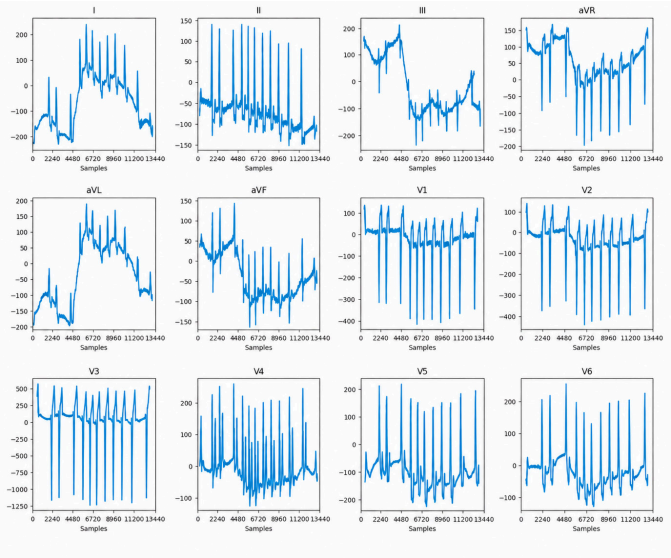

Fig. 1. Example of a raw 12-lead ECG recording from the private clinical dataset before preprocessing. Each recording consists of 12 simultaneously acquired leads sampled at 1200 Hz, containing 13,440 samples per lead.

TABLE I

Validation	92	11	103
Total	306	37	343

imbalance) according to clinical, laboratory, and imaging criteria, these distinctions were not used as prediction targets in the proposed model.

The private dataset was divided into training and validation subsets at the patient level, ensuring that all recordings from a given patient were assigned to a single subset and that no patient contributed data to both partitions. The training set consisted of 240 ECG recordings, including 214 negative and 26 positive examinations, whereas the validation set comprised 103 recordings, including 92 negative and 11 positive cases. This distribution reveals a marked class imbalance, which reflects the prevalence of patients without elevated troponin in the collected clinical cohort.

The class distribution of the private dataset is summarized in Table I. As can be observed, the dataset is considerably imbalanced, with positive cases representing approximately 11% of the available ECG recordings.

B. PTB-XL Dataset

The second experiment employed the publicly available PTB-XL database [19], one of the largest annotated 12-lead ECG repositories currently available. The database contains 21,837 clinical ECG recordings acquired from 18,885 patients, each consisting of a standard 10-second, 12-lead examination annotated by expert cardiologists according to the SCP-ECG standard. Owing to its size, standardized annotations, and public availability, PTB-XL has become a widely adopted benchmark for developing and evaluating deep learning models for automated ECG analysis.

TABLE II
DISTRIBUTION OF THE PTB-XL DATASET USED FOR MYOCARDIAL INFARCTION CLASSIFICATION.

Subset	Normal	MI	Total
Training	6,351	1,791	8,142
Validation	2,722	768	3,490
Total	9,073	2,559	11,632

Fig. 2. ECG preprocessing pipeline adopted in this study. Raw 12-lead ECG signals sampled at 1200 Hz were filtered using a 0.67–40 Hz band-pass filter, resampled to 500 Hz, normalized to the range $[-1, 1]$, and organized into a 12×5000 input tensor.

For this study, the PTB-XL database was used exclusively to train a CNN for myocardial infarction detection. ECG recordings labeled as *NORM* were assigned to the negative class, whereas recordings corresponding to myocardial infarction (*MI*) were assigned to the positive class. After excluding the remaining diagnostic categories, the resulting dataset comprised 11,632 ECG recordings, including 9,073 normal examinations and 2,559 myocardial infarction cases. The class distribution adopted in this study is summarized in Table II.

C. ECG Preprocessing

The ECG preprocessing pipeline adopted in this study is illustrated in Fig. 2. As shown in the figure, the preprocessing consisted of four sequential stages: band-pass filtering, resampling, amplitude normalization, and tensor organization for CNN input.

Initially, the raw 12-lead ECG recordings, originally sampled at 1200 Hz, were processed using a band-pass filter with cutoff frequencies of 0.67 Hz and 40 Hz. This filtering stage attenuates baseline wander and high-frequency noise while preserving the frequency components that are clinically relevant for cardiac analysis.

Subsequently, the filtered signals were resampled to 500 Hz using polyphase resampling. To ensure a fixed-length input compatible with the PTB-XL dataset and the proposed CNN architecture, the central 5000 samples of each resampled recording were retained, corresponding to approximately 10 s of ECG acquisition. An example of a preprocessed ECG

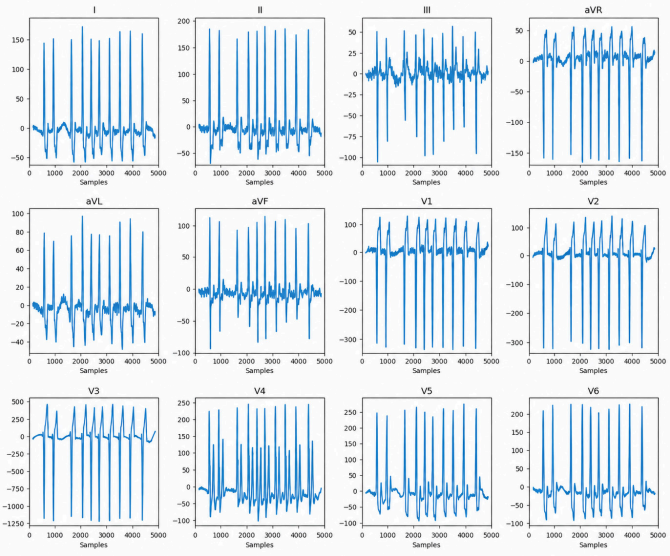

Fig. 3. Example of a 12-lead ECG recording from the private clinical dataset after band-pass filtering (0.67–40 Hz) and resampling to 500 Hz, before amplitude normalization. Each subplot corresponds to one of the 12 simultaneously acquired leads and contains 5000 samples, representing approximately 10 s of ECG acquisition.

recording after band-pass filtering and resampling, but before amplitude normalization, is presented in Fig. 3.

Finally, amplitude normalization was applied independently to each recording by scaling the signal to the interval $[-1, 1]$. After preprocessing, each ECG was represented as a tensor of dimensions 12×5000, corresponding to 12 simultaneously acquired leads with 5000 samples each, which was used as the input to the convolutional neural network. An equivalent preprocessing pipeline was adopted for the PTB-XL dataset. The only difference was that the resampling stage was omitted, since PTB-XL recordings are already provided at a sampling frequency of 500 Hz. Because amplitude normalization was applied on a per-recording basis, no normalization statistics were computed from the private dataset, and no information from the private cohort was used at any stage of the PTB-XL training procedure. Lead ordering followed the standard sequence (I, II, III, aVR, aVL, aVF, V1–V6) in both datasets, and both were represented as 12×5000 tensors corresponding to 10 s of acquisition at 500 Hz. This ensures that the model trained on PTB-XL received inputs of identical dimensionality, lead ordering, and amplitude scale when applied to the private recordings.

D. Convolutional Neural Network

A one-dimensional convolutional neural network (1D-CNN) was designed to process multichannel ECG signals directly, eliminating the need for handcrafted feature extraction. The overall architecture is illustrated in Fig. 4.

The proposed network consists of five one-dimensional convolutional layers with 16, 32, 64, 128, and 256 filters, respectively. Each convolutional layer is followed by Batch Normalization (BatchNorm) and the Rectified Linear Unit

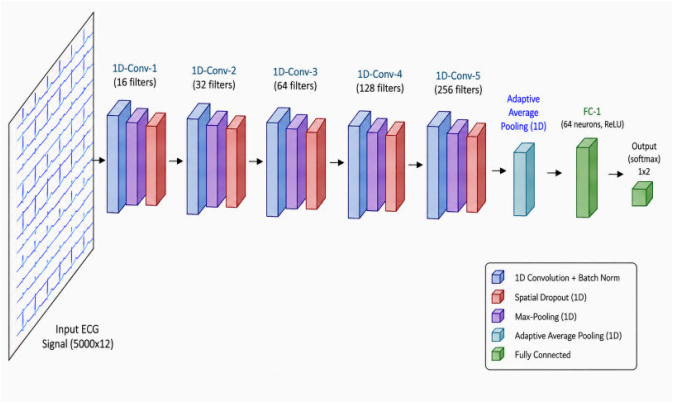

Fig. 4. Proposed one-dimensional convolutional neural network (1D-CNN) architecture for ECG classification.

(ReLU) activation function to improve optimization stability and enhance nonlinear feature learning. A Spatial Dropout layer is applied after each convolutional block to reduce overfitting by randomly suppressing entire feature maps during training. Subsequently, Max-Pooling layers progressively reduce the temporal resolution while preserving the most informative features.

After the final convolutional block, an Adaptive Average Pooling layer aggregates the extracted feature maps into a fixed-length representation, independent of the temporal dimension. This representation is then passed to a fully connected layer with 64 neurons and ReLU activation, followed by a Softmax output layer with two neurons for binary classification.

The resulting architecture is lightweight while maintaining sufficient representational capacity to learn hierarchical temporal features from 12-lead ECG recordings, making it suitable for cardiovascular classification tasks based on ECG signals.

E. Training Configuration

The network was trained using the Adam optimizer with a learning rate of 1×10^{-4} and a batch size of 16. One-dimensional convolutional kernels of size 4 were used throughout the network, and a Spatial Dropout rate of 0.1 was applied after each convolutional block. To mitigate the effect of class imbalance, the network was optimized using a class-weighted cross-entropy loss in which the weight assigned to each class was inversely proportional to its frequency in the training set. The model trained on the PTB-XL database for myocardial infarction classification was optimized for 50 epochs, whereas the model trained on the private clinical dataset for hs-cTnI classification was optimized for 500 epochs. In both cases, the final model was selected as the checkpoint achieving the lowest validation loss. Predictions were obtained by applying a fixed decision threshold of 0.5 to the Softmax output corresponding to the positive class. All experiments were implemented in PyTorch 2.3.0.

F. Experimental Protocol

Two complementary experiments were performed in this study. The first experiment investigated the generalization capability of ECG representations learned from a clinically related task. For this purpose, the proposed CNN was trained on the PTB-XL database for myocardial infarction detection and subsequently applied directly to the private clinical dataset labeled according to hs-cTnI levels, without performing fine-tuning, domain adaptation, or parameter optimization. Since the target labels differ between the two datasets, this experiment should not be interpreted as a conventional transfer learning evaluation, but rather as an exploratory analysis of whether representations learned for myocardial infarction detection are also informative for identifying elevated troponin levels.

The second experiment consisted of training and validating the proposed CNN directly on the private clinical dataset to identify patients presenting elevated hs-cTnI from standard 12-lead ECG recordings. This experiment was designed to evaluate the predictive performance of a model optimized specifically for the troponin classification task and to compare its performance with that of the exploratory generalization analysis.

G. Performance Evaluation

The predictive performance of the proposed model was assessed using four standard classification metrics: Accuracy, Precision, Recall, and F1-score. Let TP, TN, FP, and FN denote the numbers of true positives, true negatives, false positives, and false negatives, respectively.

Accuracy measures the overall proportion of correctly classified samples, as expressed in (1).

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}. \tag{1}$$

Precision evaluates the reliability of positive predictions by quantifying the proportion of predicted positive samples that are actually positive, as shown in (2).

$$\text{Precision} = \frac{TP}{TP + FP}. \tag{2}$$

Recall, also referred to as sensitivity, measures the ability of the model to correctly identify positive cases, as given in (3).

$$\text{Recall} = \frac{TP}{TP + FN}. \tag{3}$$

The F1-score corresponds to the harmonic mean of Precision and Recall, providing a balanced evaluation metric, particularly in the presence of class imbalance, as formulated in (4).

$$\text{F1} = 2 \cdot \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}. \tag{4}$$

In addition to these quantitative metrics, confusion matrices were analyzed to provide a detailed visualization of the prediction outcomes, highlighting the distribution of true positives, true negatives, false positives, and false negatives. During training, the convergence behavior of the proposed CNN was monitored through the evolution of the training loss and classification accuracy over successive epochs.

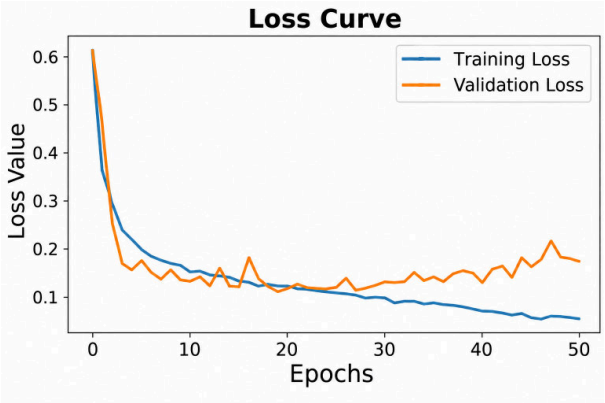

Fig. 5. Training and validation loss during myocardial infarction classification on the PTB-XL dataset.

III. Results and Discussion

This section presents the experimental results in two stages. First, an exploratory analysis evaluates whether ECG representations learned for myocardial infarction detection on the PTB-XL database can generalize to the prediction of elevated hs-cTnI in an independent clinical cohort. Subsequently, the performance of the proposed 1D-CNN trained directly for hs-cTnI prediction on the private clinical dataset is presented and discussed.

A. Exploratory Generalization Analysis Using PTB-XL

Before investigating the relationship between myocardial infarction and troponin elevation, the proposed 1D-CNN was first evaluated on its original task using the PTB-XL database. The model was trained to discriminate myocardial infarction from the normal recordings, and its convergence behavior was monitored through the evolution of the training and validation loss.

Fig. 5 shows the corresponding learning curves. Both training and validation losses decreased during the initial epochs, indicating effective optimization of the network parameters. After approximately 20 epochs, the validation loss stabilized while the training loss continued to decrease gradually, suggesting a slight tendency toward overfitting in the later stages of training. Nevertheless, the validation loss remained stable throughout the optimization process, indicating that the learned representations retained generalization capability on unseen PTB-XL samples.

The quantitative performance obtained on the PTB-XL validation subset is summarized in Table III. The proposed model achieved an overall accuracy of 95.65%, with a precision of 93.91%, recall of 91.64%, and an F1-score of 92.76% for the myocardial infarction class

The confusion matrix obtained on the PTB-XL validation subset is presented in Fig. 6. The model correctly classified

TABLE III
PERFORMANCE OBTAINED FOR MYOCARDIAL INFARCTION CLASSIFICATION ON THE PTB-XL DATASET.

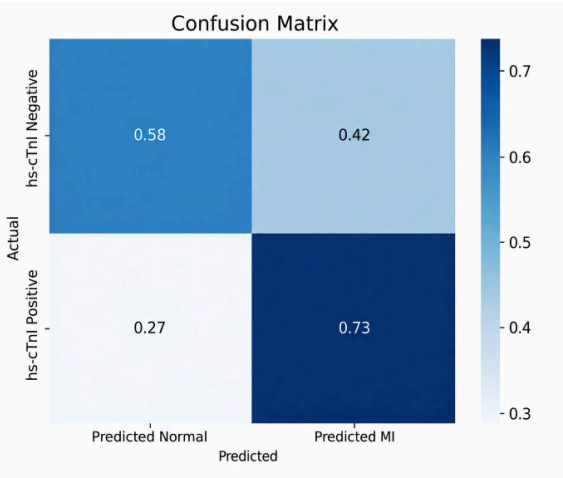

Fig. 7. Confusion matrix obtained by directly applying the CNN trained on PTB-XL to the private clinical dataset labeled according to troponin levels.

approximately 97% of the negative examinations and 92% of the myocardial infarction cases, with false-positive and false-negative rates of only 3% and 8%, respectively. These results confirm that the network learned electrophysiological features associated with myocardial infarction before being evaluated on the independent troponin classification task.

Having established that the proposed CNN effectively learned myocardial infarction-related representations on the PTB-XL dataset, the trained model was subsequently evaluated on the private clinical dataset labeled according to troponin levels, without performing fine-tuning, transfer learning, or any parameter adaptation. This experiment aimed to investigate whether ECG representations learned from myocardial infarction could retain information relevant for identifying elevated troponin in an independent clinical cohort.

The predictive performance is shown in Table IV. The model achieved an overall accuracy of 59.61%, with a macro precision of 55.97%, macro recall of 65.50%, and macro F1-score of 49.90%. As expected, these results are considerably lower than those obtained for myocardial infarction classification on the PTB-XL dataset, reflecting both the domain shift between the public and private datasets and the difference between the prediction tasks.

Fig. 7 presents the corresponding confusion matrix. Since no adaptation was performed after training on the PTB-XL dataset, the observed prediction errors are expected and should be interpreted as a consequence of applying a model optimized for myocardial infarction detection to a different, although clinically related, endpoint.

Although the predictive performance decreased compared with the original myocardial infarction task, the model remained capable of identifying part of the patients presenting elevated troponin. This observation suggests that the representations learned from myocardial infarction are not entirely task-specific and preserve electrophysiological information associated with myocardial injury. However, the performance gap between this experiment and the model trained directly on the private dataset indicates that these representations alone are insufficient for accurate troponin classification without additional adaptation or retraining.

B. Troponin Classification on the Private Dataset

The proposed 1D-CNN was trained using the private clinical dataset to identify patients presenting elevated hs-cTnI directly from 12-lead ECG recordings. Fig. 8 shows the evolution of the training and validation accuracy throughout the optimization process. The validation accuracy increases during the initial epochs and stabilizes after approximately 150 epochs, whereas the training accuracy remains lower and exhibits pronounced oscillation throughout optimization. This pattern is attributable to the small number of positive training examples ($n = 26$) combined with the stochastic regularization applied during training. The reported validation metrics should be interpreted in light of this behavior.

Table V summarizes the performance obtained on the validation subset. The proposed model achieved an overall accuracy of 73.83%. Because the two classes are strongly imbalanced, macro-averaged and positive-class metrics are

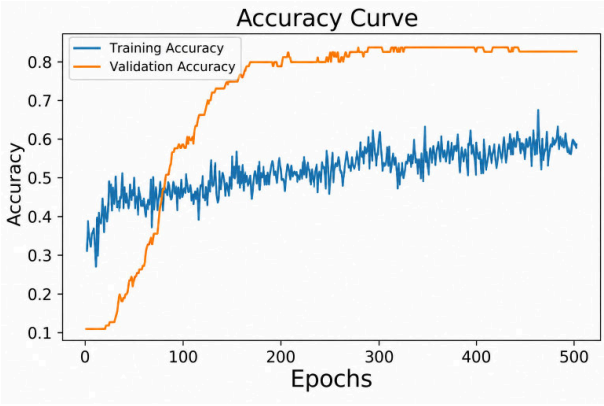

Fig. 8. Training and validation accuracy during the optimization process.

TABLE V
CLASSIFICATION PERFORMANCE OF THE PROPOSED 1D-CNN FOR HS-CTNI PREDICTION ON THE PRIVATE CLINICAL DATASET (VALIDATION SUBSET, $n = 103$; 11 POSITIVE CASES). CONFIDENCE INTERVALS ARE WILSON 95% INTERVALS.

Metric	Value (%)
Accuracy	73.83
Macro Precision	59.01
Macro Recall	69.50
Macro F1-score	58.98
Sensitivity (positive class)	63.6 (35.4–84.8)
Specificity (negative class)	75.0 (65.3–82.7)
Positive predictive value	23.3 (11.8–40.9)
Negative predictive value	94.5 (86.7–97.9)
Positive-class F1-score	34.1

reported separately. The macro-averaged precision, recall, and F1-score were 59.01%, 69.50%, and 58.98%, respectively. For the positive class, which corresponds to elevated hs-cTnI, the model identified 7 of the 11 positive cases (sensitivity 63.6%) while producing 23 false-positive predictions among the 92 negative cases (specificity 75.0%). The resulting positive predictive value was 23.3% and the negative predictive value was 94.5%. This combination of moderate sensitivity and low positive predictive value is a direct consequence of the low prevalence of positive cases in the cohort and should be taken into account when interpreting the overall accuracy.

Fig. 9 presents the confusion matrix obtained on the private dataset. The model correctly classified approximately 75% of the negative cases and 64% of the positive cases. Conversely, 25% of negative examinations were incorrectly classified as positive, while 36% of positive examinations were missed. This behavior is consistent with the relatively lower macro precision reported in Table V, indicating that the classifier tends to generate false-positive predictions while preserving a comparatively higher sensitivity.

The low positive predictive value observed in this experiment is partly a consequence of the class-weighted loss adopted during training, which assigned to the minority class a weight approximately eight times larger than that of the majority class. This choice deliberately favors sensitivity over precision at the fixed 0.5 decision threshold, a trade-off that is appropriate when the intended application is screening rather than diagnostic confirmation, but which necessarily increases the number of false-positive predictions.

From a clinical perspective, this trade-off may be acceptable for screening applications, where failing to identify patients with myocardial injury generally has more serious consequences than requesting additional confirmatory laboratory testing. Considering that the proposed model relies exclusively on ECG recordings, without incorporating demographic information, clinical variables, or laboratory measurements, the obtained results suggest that standard 12-lead ECGs contain discriminative electrophysiological patterns associated with elevated hs-cTnI concentrations. These findings are consistent with recent studies demonstrating that deep learning models can extract latent ECG representations correlated with biochemical markers of myocardial injury [11], [18].

The lower performance observed for hs-cTnI prediction compared with myocardial infarction classification can be explained by the intrinsic differences between the two prediction tasks. In the PTB-XL experiment, the model learned to identify myocardial infarction directly from ECG patterns, whereas in the private dataset the target variable corresponded to a biochemical marker rather than an electrocardiographic diagnosis. Elevated hs-cTnI reflects myocardial cell injury and may occur in patients presenting subtle, non-specific ECG findings, particularly during the early stages of disease or in non-ischemic conditions associated with myocardial injury. Consequently, the relationship between ECG morphology and troponin elevation is inherently more indirect, making the prediction task substantially more challenging.

Interestingly, although the direct application of the PTB-XL model produced inferior performance, the model trained specifically for hs-cTnI substantially improved all evaluation metrics. This result suggests that, although myocardial infarction and troponin elevation share common electrophysiological characteristics, task-specific optimization is required to

fully capture the ECG patterns associated with biochemical evidence of myocardial injury.

Although a direct quantitative comparison is not possible because previous studies primarily reported AUC values rather than accuracy, the present results are consistent with the growing evidence that deep learning models can identify elevated cardiac troponin from standard 12-lead ECG recordings. Chaudhari et al. [11] reported an AUC of 0.783 using more than 64,000 paired ECG–troponin examinations, whereas the present study was conducted on a considerably smaller private clinical dataset. Despite these differences, both studies support the existence of ECG patterns associated with biochemical evidence of myocardial injury.

C. Limitations

Several limitations should be considered when interpreting these results. The private cohort comprised 343 recordings from a single center, of which only 37 were positive, and the evaluation subset contained 11 positive cases. Estimates derived from so few positive examples carry wide confidence intervals, and the reported metrics should be regarded as imprecise. No independent test partition was available, so all reported values correspond to internal validation and are subject to optimistic bias. No external validation on an independent cohort was performed, which limits any assessment of the generalizability of the proposed model.

The binary label was defined by a single hs-cTnI measurement exceeding the 99th-percentile threshold. This definition does not incorporate the rise-and-fall kinetics required by the fourth universal definition of myocardial infarction [4] and therefore captures myocardial injury of any etiology rather than acute myocardial infarction specifically. In addition, type 1 and type 2 myocardial infarction were collapsed into a single positive class despite differing pathophysiological mechanisms and electrocardiographic substrates.

Finally, the model outputs were not calibrated, and no comparison was performed against clinical risk scores or against alternative architectures incorporating attention mechanisms or data augmentation. Such comparisons would be required to establish whether the observed performance derives from the proposed approach or from the general capacity of convolutional architectures applied to ECG signals.

IV. Conclusion

This study presented a one-dimensional convolutional neural network for the identification of elevated cardiac troponin using standard 12-lead ECG recordings. Without relying on handcrafted feature extraction or additional clinical variables, the proposed model achieved an accuracy of 73.83% on the validation subset of a private clinical dataset, with a sensitivity of 63.6% and a positive predictive value of 23.3% for the positive class. These results are consistent with the presence of discriminative information associated with myocardial injury in the ECG, although the small number of positive cases limits the precision of the estimate.

A second exploratory experiment investigated whether representations learned from myocardial infarction detection could be transferred to a related clinical endpoint. A CNN trained on the PTB-XL database for myocardial infarction classification achieved 95.65% accuracy on its original task and, when directly applied to the private troponin dataset without fine-tuning, obtained an accuracy of 59.61%. Although a reduction in predictive performance was observed, the model preserved partial discriminative capability, suggesting that myocardial infarction and troponin elevation share common electrophysiological characteristics encoded in ECG signals.

Overall, within this cohort, the model trained directly for troponin prediction outperformed the model transferred from myocardial infarction classification. Because myocardial infarction detection and troponin elevation constitute distinct prediction targets, the performance obtained on PTB-XL should not be interpreted as evidence of successful biomarker transfer. The observed retention of partial discriminative capability is better described as an exploratory internal association that requires confirmation in larger, externally validated cohorts.

Future work will focus on validating the proposed framework using larger multicenter cohorts, investigating transfer learning and domain adaptation strategies for improving cross-dataset generalization, and incorporating explainable artificial intelligence methods to enhance the clinical interpretability of the learned ECG representations.

***Abstract*—The micronucleus test is one of several recommended tests for assessing genetic damage caused by chemicals under development for use as biomaterials, cosmetics, or drugs. The test involves analyzing cultured cells *in vitro* treated with the compounds and determining the frequency of cells containing one, two, or multiple nuclei. This work presents the implementation of a YOLOv7 neural network architecture for the automatic identification of cells in micronucleus assays, which are used to assess genotoxicity. To facilitate use by non-specialists, two prototypes were developed that directly integrate the original YOLOv7 `detect.py` script without altering its inference logic: (i) a Python/PyQt desktop application featuring a thumbnail gallery, a progress bar, and interactive zoom, converted into a standalone executable using PyInstaller; and (ii) a Flask-based web service capable of handling multiple uploads and allowing users to configure input size and confidence thresholds. On the held-out test set, the model achieved a precision of 0.855, recall of 0.887, and *mAP@0.5* of 0.905 for the three cell classes represented in that split. Neither impurity nor micronucleus instances were present in the test set, preventing their quantitative evaluation; qualitative inference nevertheless showed missed micronucleus detections. Performance tests indicated that CPU-based processing of large batches takes 5 to 10 minutes, highlighting the advantages of using a GPU or optimized model variants. The proposed solutions enhance the accessibility of genotoxicity analyses, offering potential applications in both laboratory settings and remote services.**

***Index Terms*—convolutional neural networks, YOLOv7, genotoxicity, micronucleus assay, computer vision**

I. Introduction

Genotoxicity refers to the ability of chemical or physical agents to cause damage to the genetic material of cells, resulting in gene mutations, chromosomal breaks, or changes in chromosome number. Among the methods used to assess this risk, the *in vitro* micronucleus assay stands out for its simplicity and sensitivity; it is recommended by OECD Guideline 487 [1] and ISO standard 10993-3 [2] for the evaluation of pharmaceuticals, cosmetics, and medical devices. In the classic protocol, cytochalasin B blocks cytokinesis following mitosis, causing cells that have completed nuclear division to remain joined as binucleated cells; The cut off of the test is the binuclear counting once the cytochalasin B is used to keep the cells as binocular. The presence of mononuclear or multinuclear becomes a data which indicates the quality of the cells in the test. The counting of the mucronucleus in binuacleates cells, the rare event in the cells, is sensitive enough to characterize the compound as genotoxics, once the micronucleous is a fragment of the main cell DNA and can be more than one in the same cell, depending on the aggressivity of the chemical compound. [1] (as shown in Fig. 1) — are counted.

The cells observed in the assay fall into five annotation classes — mononuclear, binuclear, multinuclear, impurity, and micronucleus — of which the first four correspond to distinct *biological* cell categories, while *impurity* is a non-cell artifact class (debris, stain residue, or out-of-focus objects) used only to keep the detector from misfiring on non-cellular structures; it carries no biological score. Among the four cell categories, event counting is performed only on binucleated cells, as they confirm that recent cell division has occurred. Furthermore, the ratio of binucleated to mononucleated cells provides a measure of the assay's cytotoxicity and proliferative efficiency [1]. Seager et al. [3] demonstrated the high reproducibility of this assay across human cell lines and highlighted the potential for image-processing-based automation to enhance the efficiency and consistency of genotoxicity assessment, a process currently performed primarily by manual means.

In recent years, convolutional neural networks have achieved high performance in object detection tasks. Modern algorithms such as the R-CNN (*Region-based CNN*) and YOLO (*You Only Look Once*) families have revolutionized the field by enabling the identification and localization of multiple objects with high accuracy; in particular, the YOLO family stands out for performing single-shot detection, unifying class and position prediction into a single inference step. This yields significantly higher speed compared to two-stage approaches without drastically sacrificing precision. YOLOv7 [4] repre-

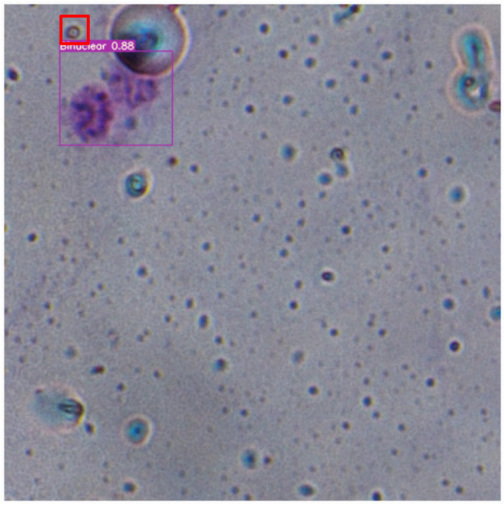

Fig. 1. Binucleated cell with a micronucleus (framed in red).

sents the current state of the art in this family, incorporating techniques such as Extended Efficient Layer Aggregation Networks (E-ELAN) and a "bag-of-freebies" (a set of trainable training adjustments) that boost accuracy without additional inference cost. Its ability to capture patterns at multiple scales makes it well-suited for microscopy images, where cells and micronuclei are small, appear at high densities, and exhibit subtle contrast against the background. Prior to this work, no literature was found specifically on the use of *object-detection* neural networks for cell identification under genotoxic conditions in the micronucleus assay; Section IV situates this work relative to other automated approaches to micronucleus scoring.

Given this scenario, the general objective of this work is to implement and validate a YOLOv7 architecture for the automatic detection and classification of cells in micronucleus assay images. A specific objective is the development and validation of software solutions — a desktop application and a web service — that utilize the trained model to provide accessible, reliable, and efficient interfaces for non-specialist users.

II. Methodology

A. Dataset

The dataset consists of 50 optical microscopy images in TIFF format (2560×1920 pixels), acquired under genotoxicity conditions. Each cell in the images was classified into one of the five classes introduced in Section I (mononuclear, binuclear, multinuclear, impurity, or micronucleus). The micronucleus class was the most significant, as it directly indicates genotoxic damage, yet it was also the rarest by a wide margin: only 2 micronucleus instances were annotated in the original, pre-augmentation dataset, against a much larger pool of mononuclear, binuclear, and multinuclear instances that made up the bulk of the annotated cells.

This extreme imbalance is the central limiting factor discussed throughout the Results and Discussion sections: with only 2 original examples, even a 10× augmentation (Section II-C) yields around 22 micronucleus instances in total, an order of magnitude below the hundreds typically required for a deep detector to learn a reliable visual signature, which is consistent with the model's failure to reach usable confidence for this class (Section III-A).

B. Preprocessing and Annotation

Due to the computational cost imposed by the original resolution, the images were cropped into 512×512-pixel blocks using a Python script developed by the authors; this script also proportionally adjusted the corresponding bounding boxes, resulting in 200 images. The annotations were then manually reviewed using the labelImg tool [5], following the standard YOLOv7 format — class and coordinates (x, y, width, and height) normalized relative to the image size [6] — with classes mapped as 0: Mononuclear, 1: Binuclear, 2: Impurity, 3: Micronuclear, and 4: Multinuclear. Crops containing no annotated cells were discarded, resulting in a final set of 146 images.

C. Balancing and Splitting the Dataset

The Micronucleus class was represented by only two examples in the original dataset, making the direct training of a deep learning model unfeasible [7], [8]. To mitigate this imbalance, data augmentation was applied using the Albumentations library [9] — including horizontal and vertical flips, random brightness and contrast adjustments, rotations, and scaling shifts — generating ten new samples per original image, with bounding boxes automatically adjusted to the applied transformations. The dataset was then split into training (80%), validation (10%), and testing (10%) sets by original source image rather than on the pooled augmented set: all ten augmented variants of a given original micrograph were kept together in a single split, so no augmented copy of a training image could appear in validation or testing. This directly addresses the risk of data leakage between splits, while still maintaining independent subsets for model tuning and evaluation [10].

D. Evaluation Metrics

The detector's performance was monitored using four metrics common to object detection tasks. The box loss, which YOLOv7 calculates using Complete Intersection over Union (CIoU), penalizes errors in predicting the position and size of bounding boxes:

$$\mathrm{CIoU} = 1 - \left(\mathrm{IoU} - \frac{\rho^2(b, b^{gt})}{c^2} - \alpha v \right), \qquad (1)$$

where IoU is the ratio of the intersection area to the union area of the predicted and ground-truth boxes, $\rho^2(b, b^{gt})$ is the squared Euclidean distance between their centers, c^2 is the squared diagonal of the smallest rectangle enclosing them, and αv penalizes the difference in the width-to-height aspect ratio between the boxes. Precision measures the proportion of correct detections among all detections made, while recall

TABLE I
TRAINING HYPERPARAMETERS

Hyperparameter	Value
Effective input size (training and evaluation)	544×544 px
Batch size	8
Epochs	180
Initial learning rate (lr_0)	0.01
Momentum	0.937
Weight decay	0.0005
Warm-up epochs	3

measures the proportion of actual objects the model successfully detected:

$$\text{Precision} = \frac{TP}{TP + FP}, \qquad \text{Recall} = \frac{TP}{TP + FN}, \tag{2}$$

where TP, FP, and FN are, respectively, true positives, false positives, and false negatives. The third metric, mean Average Precision with an IoU threshold of 0.5 (*mAP@0.5*), summarizes the average precision across all C classes of the problem:

$$\text{mAP@0.5} = \frac{1}{C} \sum_{i=1}^{C} AP_i^{IoU=0.5}, \tag{3}$$

where AP_i is the area under the precision-recall curve for class i. High values across all three metrics indicate a detector that correctly localizes and classifies cells with few false positives and false negatives.

E. Model Training

The model was trained starting from the `yolov7.pt` pre-trained weights, using the official YOLOv7 implementation [4], [11] on a Google Colaboratory instance equipped with an NVIDIA Tesla T4 GPU — an approach that reduced the duration of each epoch to a few minutes, compared to the tens of hours estimated for an equivalent run on a local CPU. Table I summarizes the key hyperparameters used, which were defined based on the standard YOLOv7 configuration file for training from scratch.

Throughout training, box loss and the metrics described in Section II-D were monitored on the validation split. The command requested 518×518-pixel input, which YOLOv7 automatically adjusted to 544×544 pixels to satisfy the model's 32-pixel maximum stride. The held-out test set was evaluated with `test.py` using the same effective 544×544 resolution, a batch size of 8, a confidence threshold of 0.001, a non-maximum-suppression IoU threshold of 0.65, and the `--task test` option. Thus, the reported validation and test metrics use the same effective input dimensions. The `detect.py` script was used separately, with a confidence threshold of 0.5, only to generate the qualitative examples shown in Fig. 3.

III. RESULTS

A. Detection Performance

Fig. 2 shows the evolution of the metrics throughout training. The training box loss dropped from approximately 0.07 to 0.025 (Fig. 2a), while validation *mAP@0.5* exceeded 0.80 after the 80th epoch and stabilized near 0.85–0.90 (Fig. 2b); validation precision and recall rose rapidly during the first 50 epochs and stabilized between 0.75 and 0.90 (Fig. 2c-d). At the end of 180 epochs, validation precision, recall, *mAP@0.5*, and *mAP@0.5:0.95* were 0.937, 0.756, 0.869, and 0.588, respectively. On the held-out test set, the corresponding aggregate values were 0.855, 0.887, 0.905, and 0.603 for the three cell classes represented in that split. The test result therefore did not show a performance decrease relative to validation, although both subsets were small.

TABLE II
HELD-OUT TEST-SET RESULTS BY REPRESENTED CLASS

Class	Inst.	P	R	mAP@0.5
Mononuclear	5	0.788	0.751	0.747
Binuclear	11	0.901	0.909	0.973
Multinuclear	3	0.876	1.000	0.995
All represented classes	19	0.855	0.887	0.905

Neither the validation nor the test split contained annotated micronucleus instances, so quantitative performance for this class could not be established. Qualitative inference nevertheless produced missed micronucleus detections, which is consistent with the scarcity of original examples for this class (Section II-A) even after data augmentation.

Fig. 3 presents qualitative examples of the detections generated over the test set. Panels (a)–(c) confirm that the model correctly localizes cells even in scenarios involving overlap and low contrast; panel (d) illustrates the model's main failure mode: it correctly detects the parent binucleated cell (magenta box) but does not flag the micronucleus itself (red box, added manually to mark the missed event), which is the direct, visual counterpart of the class-imbalance limitation discussed in Section II-A. Table II summarizes the quantitative test-set results by class.

No impurity or micronucleus instances were present in the test split; therefore, quantitative metrics could not be calculated for these classes. This absence is why Table II reports only the three represented cell classes.

B. Software Prototype

Based on the trained model, two user interfaces were developed (Fig. 4). The desktop application, built with Python/PyQt, incorporates the original `detect.py` script as a subroutine without altering its inference logic; it allows the user to define image size and the confidence threshold, mirroring command-line functionality. An indeterminate progress bar keeps the user informed during inference, and results are displayed in a thumbnail gallery with interactive zooming — a feature particularly useful given the high resolution of microscopy images. These interface choices align with Nielsen's usability heuristics [12] and a clean visual design that avoids irrelevant elements, highlighting only the actual detections. The program was converted into a standalone executable using PyInstaller in "one-folder" mode [13], eliminating the need for the end-user to install dependencies. Meanwhile, the web service — built

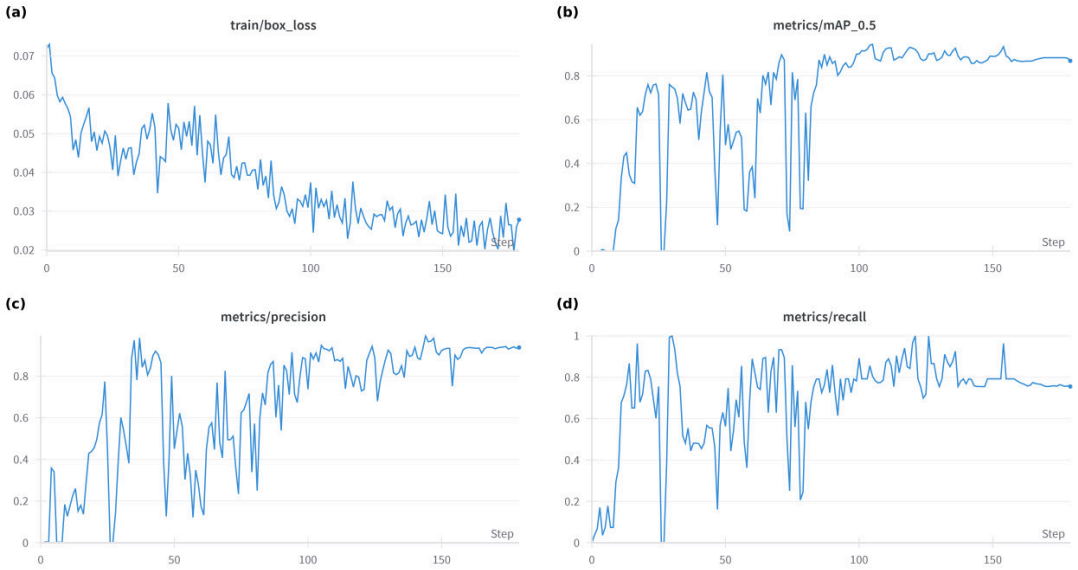

Fig. 2. Training metrics per epoch, tracked on the validation split: (a) *box loss*; (b) *mAP@0.5*; (c) *precision*; (d) *recall*. mAP@0.5 and precision both stabilize above 0.85 by epoch $\sim$100, while recall settles closer to 0.75–0.80, indicating the model trades a small amount of recall for higher precision once training converges.

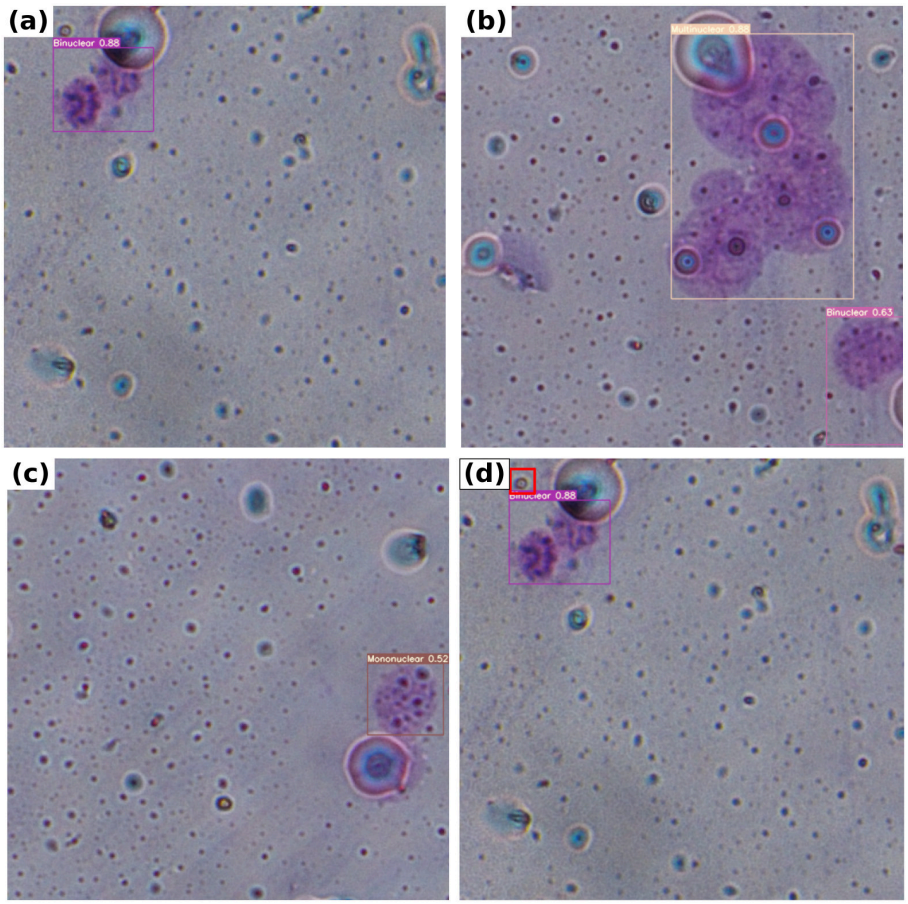

Fig. 3. Qualitative examples of predictions on the test set. (a)–(c) Correct detections of binuclear, multinuclear, and mononuclear cells. (d) A representative failure case: the parent binucleated cell is correctly detected (magenta box, "Binuclear 0.88") but the micronucleus itself is missed by the model (red box, added manually to highlight the miss).

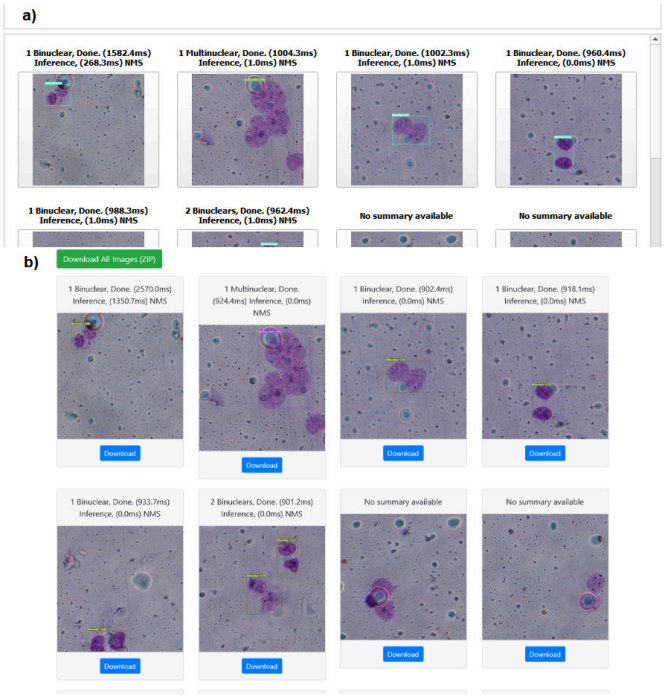

Fig. 4. Detection results as displayed to the end user: (a) desktop application; (b) web service. Both panels show the result gallery produced by the corresponding interface.

using Flask and Jinja2 templates [14] — accepts simultaneous upload of multiple images via a form, supporting multiple files and configurable parameters for input size and confidence threshold, and returns a dynamic HTML page featuring a gallery of annotated images and a batch-download option. Both solutions use the same trained weights and inference logic as the original script, fully preserving the model's accuracy and demonstrating its viability for deployment either locally or as a web-accessible service, as illustrated by the side-by-side detection outputs in Fig. 4.

C. Computational Performance

On hardware without a dedicated GPU, CPU processing proved to be the main bottleneck. In the desktop application, a single image was processed in a few seconds, but the sequential analysis of large batches — such as the dozens of crops obtained from an original image — proved time-consuming: a batch of 18 cropped images, or a single image of 2560×1920 pixels, took 5 to 10 minutes to process, highlighting practical limitations in high-volume data scenarios. In the web service, this limitation is aggravated by the memory and CPU-time restrictions imposed by free or low-cost hosting platforms, such as the one considered for this project (Render), which do not offer GPU acceleration; in practice, deploying the model in this type of environment led to slow responses and instability under large requests. The size of the model itself (tens of millions of parameters and a weights file of hundreds of megabytes) further aggravates load time and memory consumption in these environments, unless paid services with hardware-acceleration support are used.

IV. Discussion

Comparing this detector to other automated approaches to micronucleus scoring helps put its performance in context. Much of the prior automation work has relied on classification-oriented deep learning applied to imaging flow cytometry rather than on object detection over microscopy fields: Wills et al. scaled a CNN-based classifier ("DeepFlow") for the cytokinesis-block micronucleus assay across three independent laboratories, showing that dose-response conclusions matched manual scoring despite differences in imaging site [15]. In the flow citometer technique the cell membrane is broken and only the nucleus with the DNA is analyzed. By this technique, the different classes of cells are not identified and the quality of the cells for the test is not trackable causing misinterpretation of the genotoxicity [1]. More recently, object-detection architectures purpose-built for micronucleus detection have appeared in the literature: Wei et al. proposed STD-YOLOv7, a YOLOv7-based detector combining a CA attention mechanism and a Res-ACmix module specifically tuned for micronucleus morphology, trained on a purpose-built dataset expanded to 13,309 images [16] — roughly three orders of magnitude larger than the two original micronucleus examples available in the present work. This contrast is informative rather than discouraging: it points to dataset scale for the rare class, rather than to a shortcoming of the YOLOv7 architecture itself, as the main gap between the two studies. It reframes the present result: a general-purpose YOLOv7 model, without any micronucleus-specific architectural changes, already reaches full detection performance on the three well-represented cell classes, and closing the remaining gap to specialized micronucleus detectors is plausibly a matter of dataset scale for that one rare class rather than of the underlying detection approach.

The comparison between the two interfaces also highlights a trade-off between accessibility and performance. The desktop version is more appropriate for individual use or in laboratory environments, being able to exploit local hardware resources, including GPUs when available, and mitigating the impact of waiting through continuous visual feedback; the gallery structure, with summarized labels above each thumbnail, facilitated quick interpretation of results, partially compensating for the waiting time inherent to CPU execution. The web version stands out for its convenience in not requiring local installation, but it depends on a more robust infrastructure to achieve acceptable performance in production: without a GPU, the inference throughput drops significantly relative to the hundreds of frames per second reported for YOLOv7 in optimized scenarios [4]. Model optimization techniques — such as quantization or the use of lighter variants, for example YOLOv7-tiny [17] — emerge as natural ways to reduce this bottleneck, as well as the adoption of asynchronous processing queues (e.g., Celery/Redis) in the web back end, in order to avoid timeouts and improve scalability under load.

V. Conclusion

This work implemented and validated a YOLOv7 model for the automatic detection of cells in genotoxicity assays, integrated into two accessible interfaces — desktop and web — that fully preserve the original model's accuracy. The detector demonstrated consistent performance in identifying mononuclear, binuclear, and multinuclear cells but failed to achieve sufficient reliability for detecting the rare micronucleus event; this limitation is attributed to the scarcity of examples of this class in the original dataset, even after data augmentation, and is consistent with the much larger training sets used by specialized micronucleus-detection architectures [16]. Nevertheless, the proposed solutions demonstrate the feasibility of democratizing genotoxicity analysis, with potential applications in laboratories and remote services.

Future work should prioritize expanding the dataset for the micronucleus event — including through machine learning techniques specifically aimed at this rare event — as well as adopting optimized variants of the model (e.g., YOLOv7-tiny, post-training quantization) to enable its execution on the CPU. In the web service, introducing asynchronous processing (e.g., queues with Celery/Redis) would avoid timeouts under load, and migrating the back end from Flask to Django would make it easier to create user accounts and store individualized results. Finally, exposing a RESTful API would allow the detector to be integrated with laboratory management systems and automated image analysis flows, expanding the reach of the solution to third-party batch processing scenarios.

***Abstract*—This paper presents an image-based system for automatically estimating passage times during the 12-minute running test, a component of the Physical Fitness Test adopted by the Parana State Military Police. The method combines convolution-based image processing and Kalman filter-based multi-object tracking to identify runners and estimate passage times at predefined reference points. Performance was evaluated using 405 repeated passage records from three volunteers across three videos (135 records per runner; 45 per runner in each video). The software was compared with a reference evaluator and with the mean of nine additional human evaluators. Bland–Altman analysis identified statistically significant negative biases in the software comparisons. Inter-rater agreement among all ten evaluators was quantified using a two-way random-effects intra-class correlation coefficient with absolute agreement [ICC(2,1) = 0.99994; 95% CI: 0.99991–0.99996]. These findings characterize agreement within the evaluated recordings and do not establish participant-level validation, test-retest reliability, or performance under different camera and environmental conditions. Further validation is required before routine or official use.**

I. Introduction

Indirect estimation of maximal oxygen uptake (VO_2max) is one of the most widely used approaches for assessing aerobic fitness in military forces and sports settings, as it enables the evaluation of cardiorespiratory fitness without the need for complex laboratory equipment. According to the American College of Sports Medicine [1], several field tests, such as running, walking, and progressive exercise protocols, can estimate VO_2max using validated equations that consider time, distance, heart rate, and individual characteristics. The running test developed by Cooper [2] was one of the first protocols to demonstrate a significant correlation between field performance and biomedical variables of interest based on the distance covered in a 12-minute interval. The indirect estimation of VO_2max as a practical alternative for assessing aerobic capacity in large groups is discussed in several studies [1], [3], [4]. Classic studies such as McArdle et al. [3] validated the proposed regression equation, which shows a high correlation with laboratory cardiopulmonary exercise tests. In military settings, the 12-minute run is used as an assessment of aerobic endurance, and recent research has examined its relationship with other measures of physical work capacity in military personnel [12]. Physical performance is also relevant to operational endurance and prolonged effort [5]. Military and security-force personnel are exposed to physically and psychologically demanding occupational conditions, reinforcing the importance of structured training and preparation for operational demands [15]. Due to the high incidence of cardiovascular risk factors in police officers, Adero et al. [6] recommend periodic assessment of health and physical performance. The Paraná State Military Police has more than 20,000 active members, and the 12MR is administered annually to approximately 4,000 to 6,000 members. An image-based system may assist with measurement and recording while reducing manual inconsistencies. Greater standardization and fairness are potential future benefits, but they require validation under routine testing conditions. This work proposes an image-based system that combines omnidirectional image acquisition, digital image processing, and Kalman filter-based tracking to estimate runners' positions and passage times.

II. Materials and Methods

A. System Data Acquisition

The proposed system was designed considering that, in the 12-minute running test, the runner's instantaneous position

is not the primary variable of interest, since performance is evaluated based on the total distance covered at the end of the test. Therefore, digital image processing provides a suitable approach for estimating runners' positions at predefined reference points. Image acquisition was performed using an Insta360 X4 camera with an 8K resolution (7680 $\times$ 3840 pixels) operating at 24 frames per second. This setup enabled continuous visualization of the runners throughout the test, provided that no significant occlusion occurred between participants.

To implement the image processing and runner tracking algorithms, MATLAB® (MathWorks, USA) was used due to its capabilities for numerical computation, data analysis, and graphical visualization. In the current implementation, all video data were processed offline after completion of the running test. Execution time, processing throughput, memory use, and end-to-end latency were not benchmarked; therefore, the present study does not demonstrate real-time capability. Transition to real-time processing would require profiling each stage on the intended hardware, sustaining the required video throughput without unacceptable frame loss or latency, and testing performance with larger groups and more frequent occlusions.

The offline strategy was used for this initial agreement assessment. Three videos were analyzed, each containing the same three runners and 45 passage records per runner, corresponding to 15 reference points over three laps. This yielded 135 passage records per runner and 405 repeated passage records overall. These records are repeated measurements nested within three individuals and should not be interpreted as 405 independent participants.

The images presented in this article depict the authors themselves, who provided written informed consent for publication. A group of three volunteers participated in the data collection procedures. After receiving detailed information about the study protocol, each participant completed the 12-minute running test on a 300-meter track under the supervision of a certified physical education professional. Passage times were recorded at each predefined cone and subsequently analyzed by a panel of evaluators as well as by the proposed image-based system.

Passage times were analyzed by ten evaluators in total: one evaluator designated a priori as the reference based on previous experience with the 12-minute running test protocol and nine additional evaluators. No predefined or formally randomized evaluation order was imposed. Each evaluator reviewed the same videos independently and asynchronously, at a time and location determined by individual availability, without access to measurements recorded by the other evaluators or by the software.For REF $\times$ AVG EVAL comparisons, AVG EVAL denotes the mean of the nine additional evaluators and therefore does not include the reference evaluator.

B. Image Fiducials and Processing

For the application of the system, pre-established reference points (fiducials) were used to determine the relative position of the runners during the race. Orange cones were selected because their color stood out from the runners. The camera was placed in the center of the 300-m track, composed of two straight lines and two arcs. Fiducials were placed 20 m apart, representing 15 reference points around the track.

The processing sequence is shown in Fig. 1. One frame out of every six was analyzed. The current frame was subtracted from the previous frame, a threshold was applied, small objects were removed, connected moving regions were identified, and bounding boxes were generated for object localization.

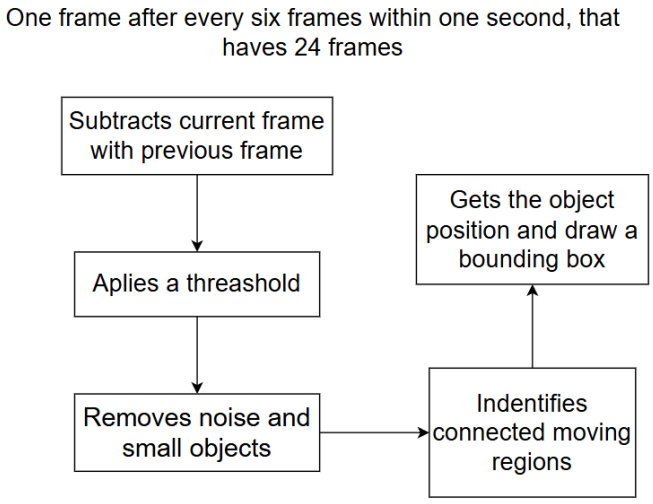

Fig. 1. Flowchart of the proposed image processing pipeline for frame subtraction and object localization.

Frame timestamps were converted to seconds by dividing the frame index by the video frame rate of 24 frames per second. To reduce computational cost, the method processed one out of every six frames, which effectively increased the temporal spacing between analyzed frames from 1/24 s to 0.25 s.

Consequently, consecutive analyzed frames were separated by 0.25 s, limiting the temporal resolution of the passage-time estimates to 0.25 s rather than the original frame-level resolution of approximately 0.042 s. At an average running speed of approximately 3 m/s, a 0.25-s sampling interval corresponds to approximately 0.75 m of distance traveled between consecutive analyzed frames.

Fig. 2 shows the runner and one predefined fiducial marker. Under the evaluated recording conditions, the system enabled localization of the predefined fiducial markers. During initialization, the user selected the position of each cone once. These coordinates were stored and used as fixed spatial references for estimating the runners' positions throughout the test.

The subtraction function highlights the difference between consecutive frames and then applies a predefined threshold. Next, the MATLAB `bwareaopen` function removes objects smaller than 25 pixels. The remaining connected objects are labeled using the `bwlabel` function. Finally, a bounding box is generated for each detected object, and its position is

Fig. 2. Original image acquired during the 12-minute running test showing the runner and one of the predefined fiducial markers (orange cone).

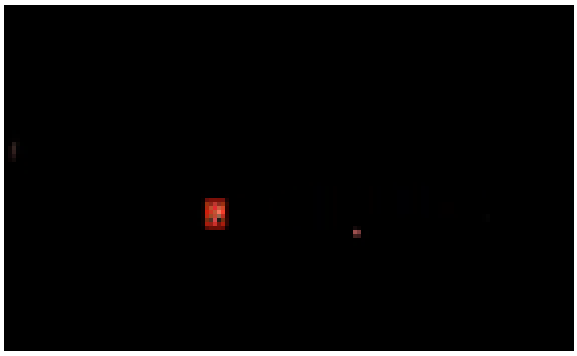

Fig. 3. Processed image showing runner detection after color segmentation.

recorded for subsequent tracking. This technique highlighted movement in all evaluated videos. However, it alone cannot track runners when they overlap and subsequently overtake one another. Therefore, runners wore different colored clothing to enable color-based segmentation and individual identification under the evaluated conditions.

Under the evaluated clothing colors and recording conditions, this approach enabled the runners to be identified individually. After segmentation, the RGB mask isolates the runner from the background, allowing the runner's position to be estimated before the tracking stage, as illustrated in Fig. 3.

C. Running-Track Position Estimation

Once the runner's position has been determined in the image, it is necessary to estimate the corresponding position on the running track. This is accomplished by using the predefined fiducial markers (orange cones) as spatial references. Runner position is most directly associated with a predefined track location when the runner passes in front of a fiducial marker.

The major problem occurs when the camera does not have visibility for every runner. With multiple runners, one may block the view of another, requiring position estimation. This is consistent with common challenges in multi-object tracking, where temporary occlusions prevent direct measurement and predictive filters are used to maintain continuity [11]. Occlusion effects could be minimized by acquiring video from an elevated viewpoint. Considering a camera-to-track distance of approximately 25 m and an average athlete height of 1.80 m, an approximate camera height of 11 m would be required for an additional 5 m of vertical clearance. Since the available recording did not achieve this elevation, position estimates were generated during periods of invisibility.

To address this limitation, a Kalman filter was implemented based on the state-space filtering and prediction framework originally introduced by Kalman [14]. In the proposed system, the filter was employed to infer the runner's position during intervals of lost visual tracking using previously observed motion as a state predictor. This approach allows the estimated state to be propagated when direct visual measurements are temporarily unavailable. Similar predictive filtering strategies have been adopted in athlete-tracking applications [7].

The selected Kalman filter used a constant velocity model, with measurement standard deviations set to [200, 50] and process standard deviations set to [100, 25]. The measurement noise covariance matrix R was diag([40000, 2500]). The initial velocity estimate was [0, 0] because no prior motion information was available before detection. Instantaneous velocity and acceleration estimated from the image sequence were included in the runner state. Acceleration was included to account for changes in apparent image velocity associated with perspective; its effect was not evaluated separately in an ablation analysis. Additional parameters, including permissible blob size, ageing threshold, and non-visible time, must be adapted to camera resolution, camera-to-track distance, group size, and the frequency of occlusions [8].

The current tracking approach has limitations when multiple runners are simultaneously present. During prolonged occlusions, direct visual measurements may become temporarily unavailable, requiring the Kalman filter to propagate the estimated runner state based on previously observed motion. As the duration and complexity of an occlusion increase, uncertainty in the predicted position may also increase. Because only three volunteers were evaluated in the present study, performance under more frequent or prolonged occlusions was not established. Future studies should evaluate larger simultaneous groups and alternative camera configurations, including multiple viewpoints, to determine whether these approaches improve tracking continuity under more complex occlusion conditions.

D. Real Time Processing Limitations.

The proposed solution relies on first segmenting the image into moving and non-moving objects, a stage that can be efficiently parallelized on a GPU, using large baches of images, and therefore contributes positively to real-time feasibility. However, the main bottleneck of the pipeline lies in the current implementation of the Kalman filter. The tracking process and the differentiation between runners depend on the previous state of each track, which inherently imposes sequential dependencies and severely limits parallelization.

Although certain matrix operations within the Kalman filter can, in principle, be offloaded to the GPU, the overall performance gain remains limited. Due to the sequential nature of state updates, frames cannot be processed in large batches; they must be handled individually. This constraint introduces a significant bottleneck related to memory transfer between RAM and GPU, ultimately restricting the scalability of the system and hindering real-time deployment. As a consequence, most of the processing remains confined to the CPU, which is comparatively slow for this type of operation because the workload consists of numerous small state-dependent computations.

Some additional algorithms evaluation is required to explore the potential to reduce the computational cost of the system, these improvement should be a priority for the future development of a a real time processing solution.

E. Validation and Statistical Analysis

Human passage times were determined exclusively from the video recordings. All ten evaluators identified when each runner crossed each predefined reference point. The reference evaluator was compared with the mean of the nine additional evaluators, whereas inter-rater agreement was calculated among all ten evaluators. The dataset contained 405 repeated passage records: 135 per runner and 45 per runner in each of three videos. All runners covered the same distance and performed the same number of repeated passages, ensuring a fully balanced design across participants. Because each individual contributed repeated crossings, the observations were treated as measurements nested within three participants rather than as independent participant-level observations.

All evaluators analyzed the same video recordings and applied the same criteria for identifying passage events; however, viewing equipment and environmental conditions were not formally standardized. Data processing for the proposed software was performed using Python with the NumPy, Pandas, Matplotlib, and Math libraries.

Statistical analyses were performed using R (R Foundation for Statistical Computing, Vienna, Austria). Bland–Altman analysis was used to characterize agreement between the software (SW), the reference evaluator (REF), and the mean of the nine additional evaluators (AVG EVAL) [9], [10].

Inter-rater agreement among all ten evaluators was assessed using a two-way random-effects intraclass correlation coefficient with absolute agreement. Single-measure ICC [ICC(2,1)] and average-measure ICC [ICC(2,10)] were calculated with 95% confidence intervals [16]. Descriptive agreement was also summarized by runner and video using the mean absolute deviation among evaluators and the REF minus AVG EVAL bias with 95% limits of agreement.

Because passage times were cumulative and repeated within only three participants, ICC values were interpreted together with absolute differences and were not treated as participant-level validation.

TABLE I
BLAND–ALTMAN AGREEMENT ANALYSIS

Comparison	Mean bias (s)	95% LoA (s)	p-value
REF–AVG EVAL	-0.71	-1.34 to -0.09	< 0.001
SW–REF	-0.65	-4.32 to 3.02	< 0.001
SW–AVG EVAL	-1.36	-4.91 to 2.19	< 0.001

TABLE II
STRATIFIED DESCRIPTIVE AGREEMENT BY RUNNER AND VIDEO

Group	n	ICC(2,1)	MAD (s) / REF–AVG9 bias (95% LoA), s
Overall	405	0.99994	0.54 / -0.71 (-1.33 to -0.09)
Runner AZL	135	0.99994	0.53 / -0.66 (-1.25 to -0.07)
Runner AMR	135	0.99994	0.53 / -0.71 (-1.30 to -0.12)
Runner LRJ	135	0.99994	0.56 / -0.76 (-1.41 to -0.11)
Video 1	135	0.99993	0.59 / -0.58 (-1.01 to -0.14)
Video 2	135	0.99994	0.51 / -0.75 (-1.49 to -0.02)
Video 3	135	0.99994	0.52 / -0.80 (-1.36 to -0.25)

III. RESULTS

A. Overall Agreement Analysis

Table I summarizes the Bland–Altman agreement analysis for the three comparisons performed in this study.

Inter-rater analysis among all ten evaluators yielded an ICC(2,1) of 0.99994 (95% CI: 0.99991–0.99996) for an individual evaluator and an ICC(2,10) of 0.999994 (95% CI: 0.999991–0.999996) for the mean of ten evaluators. Across 405 repeated passage records, the mean within-passage standard deviation was 0.70 s, the mean absolute deviation from the corresponding ten-evaluator mean was 0.54 s, and the mean range was 2.03 s. The REF minus AVG EVAL bias, with AVG EVAL calculated from the nine additional evaluators, was -0.711 s (95% limits of agreement: -1.326 to -0.095 s).

Participant- and video-stratified values were similar within the evaluated dataset. These summaries remain descriptive because the records are repeated measurements from only three runners; they do not provide independent participant-level validation of the software.

B. Reference Evaluator Versus Average Human Evaluation

The Bland–Altman analysis compared REF with AVG EVAL. Most observations were distributed near the mean difference (Fig. 4). The limits of agreement ranged from -1.34 s to -0.09 s, and the mean difference was statistically different from zero ($p < 0.001$), with a negative bias of approximately -0.71 s. The entirely negative limits of agreement indicate that REF generally recorded lower passage times than AVG EVAL within the evaluated dataset. The relatively narrow interval between the limits describes limited dispersion of the differences around the systematic offset observed between the human evaluations.

C. Software Versus Reference Evaluator

The proposed image-based software (SW) was compared with REF (Fig. 5). Most measurements were located within the 95% limits of agreement. The mean difference was statistically significant ($p < 0.001$), with limits of agreement ranging from

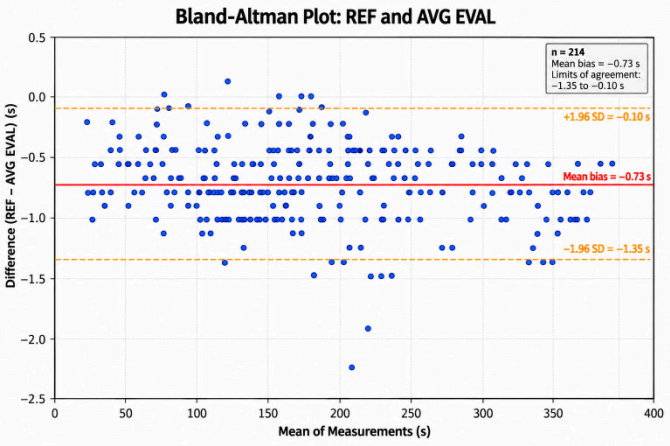

Fig. 4. Bland–Altman plot comparing the reference evaluator (REF) and the average of the evaluators (AVG EVAL).

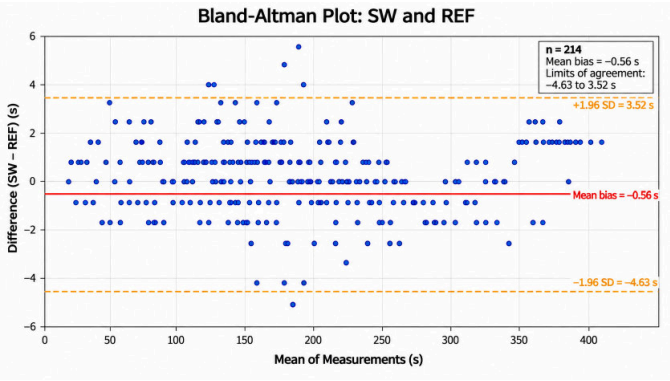

Fig. 5. Bland–Altman plot comparing the proposed software (SW) and the reference evaluator (REF).

-4.32 to 3.02 s. The distribution of the differences extended across zero, indicating that individual software estimates could be either lower or higher than the corresponding REF measurements. The interval between the lower and upper limits of agreement was 7.34 s, indicating greater dispersion than that observed in the REF versus AVG EVAL comparison.

D. Software Versus Average Human Evaluation

The proposed software was compared with AVG EVAL (Fig. 6). Most measurements were located within the 95% limits of agreement. The mean difference was statistically significant ($p < 0.001$), and the negative mean bias was -1.36 s, with 95% limits of agreement from -4.91 to 2.19 s. The distribution of the differences extended across zero, indicating that individual software estimates could be either lower or higher than the corresponding AVG EVAL measurements. The interval between the lower and upper limits of agreement was 7.10 s, showing greater dispersion than that observed between REF and AVG EVAL.

E. Practical Interpretation of the Systematic Bias

Table III converts the absolute mean temporal biases into equivalent running distances at a pace of 5:00 min/km, at

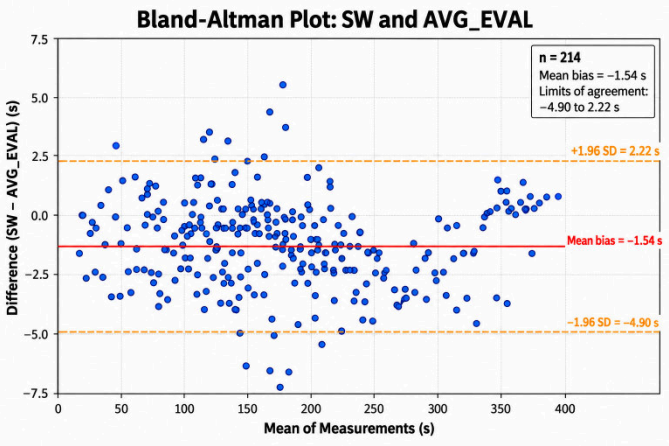

Fig. 6. Bland–Altman plot comparing the proposed software (SW) and the average of the evaluators (AVG EVAL).

TABLE III
PRACTICAL INTERPRETATION OF SYSTEMATIC BIAS AT 5:00 MIN/KM

Comparison	Absolute mean bias (s)	Equivalent distance (m)
REF × AVG EVAL	0.71	2.38
SW × REF	0.65	2.16
SW × AVG EVAL	1.36	4.53

which each second corresponds to approximately 3.33 m traveled. At this pace, the mean biases observed for REF × AVG EVAL, SW × REF, and SW × AVG EVAL corresponded to approximately 2.38 m, 2.16 m, and 4.53 m, respectively. The largest equivalent distance was observed for the SW × AVG EVAL comparison, consistent with its larger absolute mean temporal bias. These values provide a distance-based representation of the systematic differences observed between the compared measurements. The difference between the smallest and largest distance equivalents was approximately 2.37 m. Both comparisons involving the software produced distance equivalents derived directly from the temporal biases observed in the Bland–Altman analyses. Expressing these temporal differences in meters facilitates their interpretation in the context of a running test in which the final performance outcome is determined by the distance covered.

IV. DISCUSSION

The Bland–Altman analyses identified systematic differences between the compared measurements. Because cumulative passage times span a broad range, the very high ICC values should be interpreted together with the absolute differences and the nested repeated-measure structure.

For REF versus AVG EVAL, no visible proportional trend was observed across the range of cumulative passage times. The statistically significant negative bias of approximately -0.71 s indicates a systematic offset rather than an absence of disagreement. Within the evaluated recordings, the reference evaluator showed small absolute differences relative to the mean of the nine additional evaluators. These results support

its use as the reference for the present comparison but do not establish test-retest reliability or reproducibility across sessions.

For SW versus REF, the differences remained approximately constant over cumulative passage time, without a visible increase in variability as the running test progressed. The statistically significant negative bias indicates systematic underestimation by the software rather than absence of disagreement. At a running pace of 5:00 min/km, the limits of agreement from -4.32 to 3.02 s correspond to distance differences of approximately -14.4 to 10.1 m. A passage-time difference of this magnitude could affect estimated final distance and may change the classification of runners whose results are close to a classification threshold. Calibration may reduce the systematic component, but post-calibration agreement was not evaluated.

For SW versus AVG EVAL, the differences likewise did not show a visible increase in variability over cumulative passage time. The negative bias indicates that the software systematically underestimated passage times relative to the evaluator mean. Similar agreement patterns were observed in the SW $\times$ REF and SW $\times$ AVG EVAL comparisons. This similarity describes the behavior of the software within the present dataset; it does not demonstrate independence from the evaluator, reproducibility across sessions, or performance under different camera setups. In sports tracking, computer vision-based systems have also been evaluated through criterion validity and test-retest reliability, providing a methodological basis for assessing both measurement accuracy against a reference method and reproducibility across repeated testing conditions [13].

The absolute mean biases corresponded to estimated positional differences of 2.38 m for REF $\times$ AVG EVAL, 2.16 m for SW $\times$ REF, and 4.53 m for SW $\times$ AVG EVAL at a pace of 5:00 min/km. Although these values represent a small proportion of the total distance covered, measurements near a classification threshold could affect the final distance classification. The practical effect depends on the decision threshold and on where the runner finishes relative to that threshold. Calibration may reduce the systematic component, but this possibility was not tested after correction in the present study.

The distinction between systematic bias and the dispersion represented by the limits of agreement is relevant when interpreting the software performance. A calibration procedure could potentially correct part of the mean systematic offset, but it would not necessarily reduce the variability of individual differences between the software and human evaluations. Therefore, future assessments should examine both the residual bias and the limits of agreement after calibration rather than relying only on changes in the mean difference. This distinction is particularly relevant for measurements obtained near performance classification thresholds, where individual deviations may be more consequential than the average bias. Repeated measurements under independent testing conditions would also help determine whether the observed systematic differences remain stable across sessions.

This study has several limitations. Only three volunteers were included, and each contributed repeated passage records; consequently, the effective participant-level sample remained three despite the 405 recorded crossings. Occlusion frequency and complexity were limited compared with routine tests involving larger groups. The recordings represented a restricted set of camera, lighting, weather, background-motion, and track conditions. Only one camera configuration was examined, without repeated testing sessions or alternative camera positions. Computational execution time, throughput, memory use, and end-to-end latency were not benchmarked, and real-time operation was not demonstrated. Therefore, test-retest reliability, repeatability across sessions, evaluator independence, real-time performance, and performance across different acquisition or environmental conditions were not established. Routine use, fairness, and application in official physical fitness assessments remain potential future applications requiring validation with larger participant samples, larger simultaneous groups, more frequent and prolonged occlusions, repeated sessions, varied environmental conditions, different camera configurations, and explicit computational benchmarking on the intended hardware.

V. Conclusions

The proposed software was evaluated by comparison with a reference evaluator and the mean of nine additional human evaluators using Bland–Altman analysis. Inter-rater agreement was assessed among all ten evaluators. Under the evaluated conditions, the human evaluators showed small absolute differences, while the software exhibited statistically significant negative biases relative to the reference evaluator and the evaluator mean. These biases represent systematic underestimation and should not be interpreted as absence of disagreement.

The observed results indicate that the proposed system was able to generate passage-time estimates that could be systematically compared with human measurements under the evaluated recording conditions. However, the presence of negative biases and the width of the limits of agreement indicate that correction of the mean offset alone would not be sufficient to establish measurement interchangeability. Future validation should therefore assess whether calibration reduces the systematic bias while preserving acceptable limits of agreement across independent participants and repeated sessions. Particular attention should be given to measurements near performance classification thresholds, where individual differences may influence the final distance classification.

The analyses provide an initial assessment based on repeated passage measurements from three participants. They do not establish test-retest reliability, repeatability across sessions, evaluator independence, or reproducibility across camera configurations. The system may have future applications in training, performance monitoring, and official physical fitness assessment. These applications require calibration and validation with larger groups, more frequent and prolonged occlusions, repeated sessions, and different camera positions

and acquisition conditions. Although the method was developed according to the protocol adopted by the Paraná State Military Police, adaptation to other institutions or protocols should be investigated rather than assumed from the present data. Future studies should also establish predefined acceptable measurement-error thresholds according to the operational criteria of the physical fitness test. Such thresholds would allow the observed agreement to be interpreted in relation to its practical effect on final performance classification.

ETHICAL CONSIDERATIONS

This study involved image-based measurements collected during the routine 12-minute run physical fitness test of the Paraná State Military Police (PMPR). No additional running session or physical effort was required specifically for research purposes. Participants performed the test under the standard conditions of their regular physical fitness assessment, and the images were recorded exclusively for subsequent analysis. All participants provided written informed consent for participation in the study and image acquisition.

ACKNOWLEDGMENT

The authors express their gratitude for making the infrastructure of the sports practice facilities of the Paraná Military Police (PMPR) available for this research.

***Abstract*—In medical computer vision, it is commonly assumed that prior extraction of the pathological region improves subsequent classification performance. However, this assumption requires validation in the context of ultrasound imaging. The clinical assessment of ovarian masses relies not only on their internal structure but also on their contours, walls, septa, acoustic features, and surrounding anatomical context. This study aimed to evaluate the impact of different pixel mask utilization strategies on ovarian tumor classification in ultrasound images. Experiments were conducted using the publicly available MMOTU/OTU-2D dataset, comprising 1,202 locally preprocessed images with corresponding masks. Two classification tasks were investigated: a seven-class classification of ovarian mass morphological types and a binary classification distinguishing simple cysts from other lesions. Eight input representation variants were generated from each original image-mask pair: the full frame, a masked crop with a zeroed background, bounding-box crops with margins of 0%, 10%, 30%, 50%, and 80%, and the full frame augmented with the mask as an additional channel. To isolate the effect of input representation, a single EfficientNet-B0 architecture was employed across all primary experiments. Each variant was trained four times using different random seeds. A total of 72 results were obtained, comprising 64 individual training runs and eight ensemble models generated by averaging the predicted probabilities across the eight input representations. In the seven-class task, the full-frame approach achieved a macro-F1 score of 0.4971 ± 0.0185, whereas the masked crop with a zeroed background reached 0.6052 ± 0.0231 (paired difference: +0.1082; 95% CI, +0.0477 to +0.1687; Holm-adjusted p = 0.0537). In the binary classification task, the effect was less pronounced: the full-frame approach yielded a macro-F1 score of 0.6752 ± 0.0266, the masked crop achieved 0.7236 ± 0.0222, and the ensemble reached 0.7728 ± 0.0303. These findings indicate that segmentation masks serve not merely as auxiliary annotations but as mechanisms that redefine the informational framing of the classification task. Consequently, the choice of region-of-interest representation should be considered an independent and critical component of experimental design.**

I. Introduction

Ultrasound imaging is widely used in gynecology because of its accessibility, noninvasiveness, and ability to provide dynamic assessment of pelvic organs. In clinical practice, standardized approaches such as IOTA and O-RADS are used to evaluate ovarian masses. These systems consider mass morphology, the number of locules, papillary projections, acoustic characteristics, and vascularity [1]–[4]. However, the automated analysis of ultrasound (US) images remains challenging because they are often affected by speckle noise and imaging artifacts [5]–[7], frequently contain embedded measurement calipers and text annotations [8], [9], exhibit variations in scale and anatomy [7], and are acquired under heterogeneous imaging conditions across operators, institutions, and ultrasound systems [5], [7], [9]. These factors become particularly relevant when training neural network models on relatively small medical datasets [1].

For ovarian tumor and cyst classification, the use of prior mass annotations is a natural approach. When a segmentation mask is available, the background can be removed, the lesion can be enlarged, or the model can be explicitly provided with information regarding the location of the region of interest (ROI). At first glance, such strategies are expected to enhance classification performance by reducing the influence of technical artifacts and providing a more focused representation of the pathological region. This rationale is consistent with common practices in medical image analysis, in which localization of the pathological region frequently precedes classification [1].

For ultrasound imaging, however, this rationale is not universally applicable. Clinical assessment relies not only on the internal structure of the mass but also on its contour, wall characteristics, septa, acoustic features, relationship to surrounding tissues, and the scale and position of the lesion within the field of view [2]–[4], [10], [11]. When a mask is

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

applied too restrictively, diagnostically relevant information may be removed together with the background. Consequently, the key question is not whether a mask is necessary, but rather how it should be incorporated into the input representation provided to the classifier.

Previous studies have demonstrated that neural network models can effectively classify ovarian tumors from US images, including comparisons with O-RADS classifications and expert assessments [12], the application of convolutional neural network (CNN) ensembles [13], the classification of multiple histological subtypes [14], and the development of models targeting complex O-RADS categories [15]. However, these studies rarely investigate the representation of the ROI as an independent experimental variable. The present study specifically addresses this intermediate stage between mass annotation and classification.

This work investigates the impact of eight ROI representation strategies on the performance of ovarian tumor classification in US images. The primary hypothesis is that a single pixel mask can give rise to multiple input representations and that these representations are not equivalent from the classifier's perspective, even when the model architecture remains unchanged.

The main contribution of this study lies in the controlled comparison of eight input representation strategies using a single EfficientNet-B0 architecture. In contrast to studies that compare different models, this experimental design isolates the effect of mask utilization. The analysis encompasses two classification tasks: a detailed seven-class classification and a binary classification distinguishing simple cysts from all other masses. Four independent training runs were performed for each representation, ensuring that the results reflect not only peak performance but also the consistency of the observed effects. The findings indicate that, in the seven-class task, ROI-based representations yield higher mean macro-F1 values, whereas their impact is less pronounced in the binary classification task. Moreover, the ensemble combining all eight input representations outperformed every individual variant, suggesting that these representations provide complementary information.

II. Background and Problem Statement

A. ROI Representation Strategies for Ultrasound Classification

In medical image analysis, the ROI can be incorporated in several ways, including as a standalone segmentation task, as a prior localization step, an image-cropping strategy, or supplementary information provided to the classifier [1]. The most restrictive approach retains only the pixels contained within the mask while suppressing all background information. A less restrictive strategy consists of extracting a bounding box around the mask, thereby preserving part of the surrounding anatomical context. Alternatively, the full image can be maintained while incorporating the mask as an additional input channel.

These input representations evaluate distinct hypotheses regarding the information required for classification. A strict crop assumes that the most relevant diagnostic information is confined to the mass itself. A bounding-box crop presumes that both the lesion and its immediate surroundings contribute to classification performance. A full-frame representation supplemented with a mask assumes that the model benefits from access to the entire image while receiving explicit information about the lesion's location. Finally, an ensemble of multiple input representations assumes that different views may provide complementary information. This distinction is particularly important in ovarian ultrasound, as clinical risk assessment systems rely not only on the presence of a mass but also on a range of morphological characteristics that may be partially lost through excessive cropping [2]–[4].

B. MMOTU/OTU-2D Dataset

The MMOTU/OTU-2D dataset is one of the few publicly available datasets for the analysis of ultrasound images of ovarian tumors. It comprises two-dimensional ultrasound (US) images, contrast-enhanced ultrasound (CEUS) images, global class labels, and pixel-level masks [10]. In this study, a locally preprocessed subset of OTU-2D containing 1,202 image-mask pairs was employed. CEUS images were excluded because they represent a different imaging modality.

In the original MMOTU study, the primary emphasis was placed on segmentation and knowledge transfer across imaging modalities [10]. In contrast, the masks in the present work were not used as segmentation targets but rather as mechanisms for generating distinct input representations for subsequent classification. Consequently, the proposed task is related to, yet conceptually distinct from, the original MMOTU framework.

This study does not address the screening task, that is, determining whether an ovarian mass is present in an arbitrary ultrasound image. Instead, it considers a more restricted formulation in which the input consists of preprocessed images from the MMOTU/OTU-2D dataset, for which the presence of an ovarian mass and its corresponding class label are already known.

III. Materials and Methods

A. Data and Splitting

The class distributions and data partitions adopted for the seven-class formulation are presented in Table I. We stratified the official OTU-2D training partition (820 images) into training and validation sets (80:20; random state = 42); the official test partition (382 images) was unchanged. Table II summarizes the composition of the image sets used in the binary formulation. This binary classification task exhibited a marked class imbalance, particularly in the test set, which contained only 19 simple cysts compared with 363 cases belonging to the remaining categories. Consequently, overall accuracy was not considered the primary evaluation metric, as it may provide an overly optimistic assessment of performance under highly imbalanced conditions.

B. Input Image Variants

Eight input representations were generated from each original image and its corresponding mask (Table III, Fig. 1).

The masked crop with a zeroed background was generated by automatically determining the bounding box from the non-zero pixels of the binary lesion mask. Both the original image and the corresponding mask were then cropped using this bounding box. Subsequently, all pixels outside the mask but within the cropped region were set to zero, preserving only the lesion pixels. For the zero-margin variant, the bounding box corresponded exactly to the boundaries of the binary mask, with no additional expansion of the cropped region. When lesions were located near the image boundaries, the crop was constrained by the original image dimensions, and no external padding was applied. For the 10%, 30%, 50%, and 80% margin variants, the bounding box was proportionally expanded around the mask while remaining constrained by the

original image boundaries, with no padding added beyond the image frame. Crops were generated at their original resolution, and resizing to 224 × 224 was performed subsequently in the dataloader. For the validation and test sets, a deterministic Resize(224, 224) transformation was applied, whereas RandomResizedCrop(224, scale = (0.75, 1.0)) was used during training as part of the augmentation pipeline.

TABLE I. DISTRIBUTION OF IMAGES BY CLASS IN THE 7-CLASS FORMULATION

CLASS	TRAINING SET	VALIDATION SET	TEST SET	TOTAL
Endometriotic cyst	181	45	110	336
High-grade serous carcinoma	30	8	15	53
Mucinous cystadenoma	57	14	33	104
Serous cystadenoma	122	31	66	219
Simple cyst	38	9	19	66
Teratoma	182	46	108	336
Theca-cell tumor	46	11	31	88
Total	656	164	382	1202

TABLE II. DISTRIBUTION OF IMAGES IN THE BINARY FORMULATION

CLASS	TRAINING SET	VALIDATION SET	TEST SET	TOTAL
OTHER OVARIAN MASSES	618	155	363	1136
SIMPLE CYST	38	9	19	66
TOTAL	656	164	382	1202

TABLE III. EVALUATED INPUT REPRESENTATION VARIANTS

NO	Input variant	What the model sees	Tested hypothesis
1	Full frame	The entire original US image	Is the whole frame sufficient without explicitly indicating the ROI?
2	Masked, zeroed background	Crop around the mask; pixels outside the exact mask are set to zero	Is the primary signal contained solely within the mass?
3	Bounding box, 0% margin	Bounding box crop around the mask with no extra padding	Is a minimal bounding box around the object sufficient?
4	Bounding box, 10% margin	The mass and a small surrounding area	Does immediate context help?
5	Bounding box, 30% margin	The mass and wider surroundings	Does moderate field-of-view expansion improve performance?
6	Bounding box, 50% margin	Enlarged area around the mass	Is a broader context needed?
7	Bounding box, 80% margin	Large fragment of the original frame	What happens when the expansion approaches the full frame?
8	Full frame + mask	Full frame with the mask as an additional channel	Is explicitly indicating the object's location without removing the background sufficient?

The eight-input ensemble was constructed independently. For each training run, the predicted probabilities produced by the eight models trained on the different input representations were averaged.

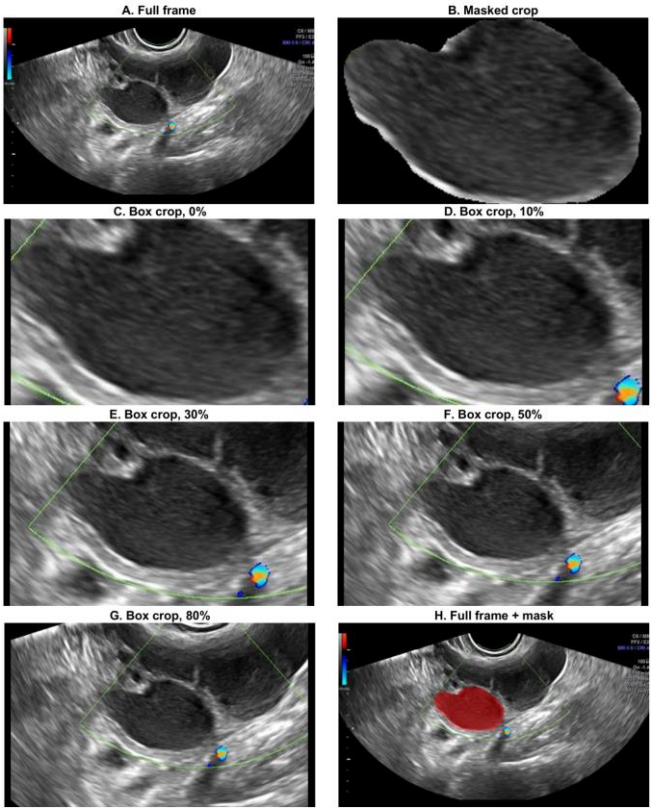

Fig. 1. Eight input representations generated from a single US image and mask: full frame (A), masked crop (B), bounding box crops with various margins (C-G), and full frame with an overlaid mask (H).

C. *Model and Training*

A single EfficientNet-B0 architecture was employed throughout all primary experiments. The EfficientNet family was introduced as a framework for uniformly scaling the depth, width, and input resolution of convolutional neural networks while maintaining an effective balance between predictive performance and computational efficiency [11]. In the present study, EfficientNet-B0 was not selected to identify the optimal architecture, but rather to serve as a fixed baseline classifier, enabling a controlled comparison of input representations under identical modeling conditions.

TABLE IV. MAIN TRAINING AND EVALUATION PARAMETERS

Parameter	Value
Architecture	EfficientNet-B0
Input size	224x224
Number of epochs	25
Number of runs	4
Random seed values	42, 43, 44, 45
Optimizer	AdamW
Learning rate scheduler	CosineAnnealingLR
Model saving criterion	Best val_macro_f1 value
Primary metric	macro-F1 on the test set
Secondary metrics	balanced accuracy, AUROC, overall accuracy
Handling class imbalance	Weighted loss function and balanced image sampling during training

The total volume of the experimental grid is presented in Table V.

TABLE V. VOLUME OF THE EXPERIMENTAL GRID

Task	Input Variants	Runs	Model Training	Ensembles	Total Results
7 CLASSES	8	4	32	4	36
2 CLASSES	8	4	32	4	36
Total	16	4	64	8	72

D. Evaluation Metrics and Statistical Analysis

The primary evaluation metric was macro-F1, as it averages the F1-score across all classes and prevents dominant classes from obscuring errors associated with minority classes. The use of this metric is particularly important in imbalanced classification tasks, in which overall accuracy may overestimate model performance [16].
For a single class:

$$F1 = 2 \cdot \frac{precision \cdot recall}{precision + recall}. \quad (1)$$

For a multi-class task:

$$macro - F1 = mean\ F_1 \text{across all classes.} \quad (2)$$

Additionally, balanced accuracy, defined as the mean recall across classes, and AUROC (for the binary formulation) or macro-AUROC (using a one-vs-rest strategy for the seven-class task) were employed, together with confusion matrices, to characterize the distribution of classification errors. All results reported herein correspond to the test set. For each input representation, the mean and standard deviation across four independent runs are presented. In the multiclass setting, AUROC was interpreted as an extension of the area under the ROC curve to multiple classes [17]. All metrics were computed using standard implementations available in the scikit-learn library [18].

Because all input variants used the same four random seeds, comparisons with the full-frame baseline were paired by seed. Mean paired macro-F1 differences were accompanied by two-sided 95% Student-t confidence intervals and evaluated using paired t-tests; within each task, p values for the eight comparisons were adjusted by Holm's procedure. These intervals describe variation across training initializations rather than patient-sampling uncertainty.

IV. RESULTS

A. Seven-Class Classification

In the seven-class task, all variants incorporating a mask or a bounding box surrounding the mask achieved higher mean macro-F1 scores than the full-frame approach (Table VI, Fig. 2). The masked crop had the highest mean macro-F1 among individual representations. The full-frame approach yielded a balanced accuracy of 0.4933 and a macro-AUROC of 0.8338, whereas the masked crop with a zeroed background increased these values to 0.6303 and 0.8883, respectively. The eight-input ensemble further improved performance, achieving a balanced accuracy of 0.6947 and a macro-AUROC of 0.9226. The confusion matrices indicate that this improvement cannot be attributed solely to an increase in correct predictions for the majority classes. Instead, the most significant benefit lies in reducing confusion among morphologically similar categories, although rare classes remain susceptible to misclassification because of the limited number of available samples. Relative to the full-frame baseline, the seed-paired macro-F1 difference was +0.1082 (95% CI, +0.0477 to +0.1687; Holm-adjusted p = 0.0537) for the masked crop and +0.2055 (95% CI, +0.1675 to +0.2434; Holm-adjusted p = 0.0030) for the ensemble. Thus, only the ensemble remained significant at $p < 0.05$ after correction.

B. Binary Classification

In the binary task, the effect of selecting different input representations was less pronounced (Table VII, Fig. 3). The full-frame baseline remained competitive, and the differences between most bounding box variants and the full frame amounted to only a few hundredths in macro-F1.

The masked crop again had the highest mean macro-F1 among individual representations; however, its advantage over the full-frame approach was less pronounced than in the seven-class task. This observation is consistent with the nature of the binary formulation, which represents a less complex classification problem, requiring the model only to distinguish simple cysts from all other masses rather than to differentiate among multiple morphological categories.

TABLE VI. RESULTS OF THE 7-CLASS CLASSIFICATION ON THE TEST SET

Input Variant	Runs	macro-F1, Mean ± SD	Difference from Full Frame
Full frame	4	0.4971 ± 0.0185	-
Masked, zeroed background	4	0.6052 ± 0.0231	+0.1082
Bounding box, 0% margin	4	0.5805 ± 0.0305	+0.0834
Bounding box, 10% margin	4	0.5703 ± 0.0194	+0.0732
Bounding box, 30% margin	4	0.5693 ± 0.0405	+0.0723
Bounding box, 50% margin	4	0.5755 ± 0.0169	+0.0784
Bounding box, 80% margin	4	0.5386 ± 0.0126	+0.0415
Full frame + mask	4	0.5734 ± 0.0290	+0.0764
8-input ensemble	4	0.7025 ± 0.0123	+0.2055

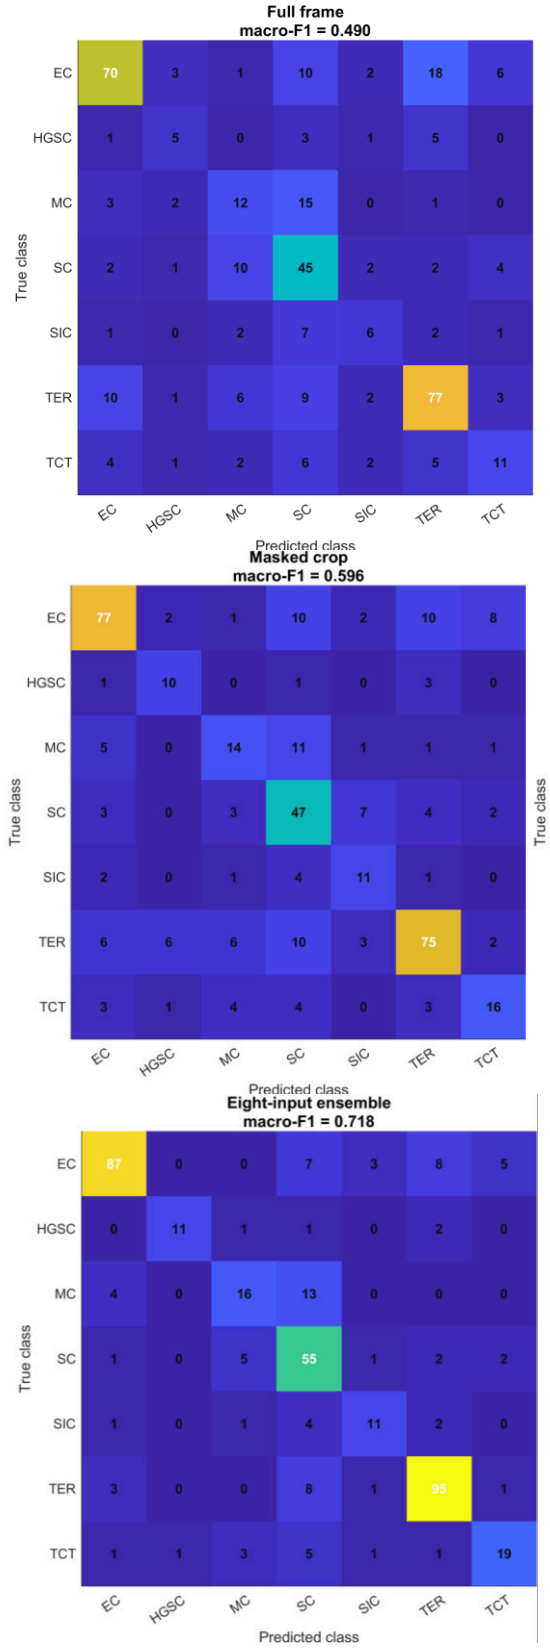

Fig. 2. Confusion matrices for the 7-class task on the same random seed run: full frame, masked crop, and 8-input ensemble. Class abbreviations: EC – endometriotic cyst, HGSC – high-grade serous carcinoma, MC – mucinous cystadenoma, SC – serous cystadenoma, SIC – simple cyst, TER – teratoma, TCT – theca-cell tumor.

TABLE VII. RESULTS OF THE BINARY CLASSIFICATION ON THE TEST SET.

Input Variant	Runs	Macro-F1, Mean ± SD	Difference from Full Frame
Full frame	4	0.6752 ± 0.0266	-
Masked, zeroed background	4	0.7236 ± 0.0222	+0.0484
Bounding box, 0% margin	4	0.6804 ± 0.0241	+0.0053
Bounding box, 10% margin	4	0.6901 ± 0.0210	+0.0150
Bounding box, 30% margin	4	0.6792 ± 0.0360	+0.0041
Bounding box, 50% margin	4	0.6965 ± 0.0681	+0.0213
Bounding box, 80% margin	4	0.6927 ± 0.0365	+0.0176
Full frame + mask	4	0.6925 ± 0.0323	+0.0173
8-input ensemble	4	0.7728 ± 0.0303	+0.0976

In terms of AUROC, the full-frame approach achieved a value of 0.8298, whereas the masked crop reached 0.8733 and the ensemble attained 0.9175. The bounding-box variant with a 50% margin yielded a relatively high mean AUROC of 0.9043 but exhibited substantial variability in macro-F1, with a standard deviation of 0.0681. This finding suggests that its performance was highly dependent on the specific training run and the resulting distribution of predicted probabilities. For macro-F1, the corresponding paired differences were +0.0484 (95% CI, -0.0159 to +0.1127; Holm-adjusted p = 0.6730) for the masked crop and +0.0976 (95% CI, +0.0133 to +0.1820; Holm-adjusted p = 0.2776) for the ensemble; neither remained significant after correction.

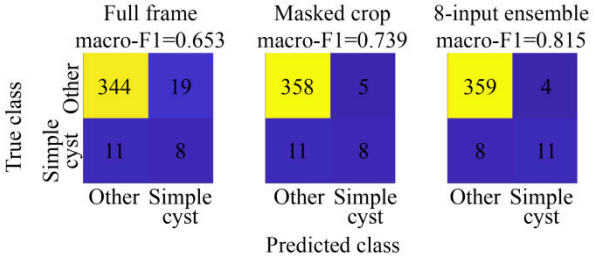

Fig. 3. Confusion matrices for the binary task on the same random seed run: full frame, masked crop, and 8-input ensemble. The "Other" class aggregates all masses except the simple cyst.

C. Input Representation Ensemble

The ensemble had the highest mean macro-F1 in both tasks. In the seven-class task, it increased the macro-F1 score from 0.4971 for the full-frame approach to 0.7025. In the binary task, the macro-F1 score improved from 0.6752 to 0.7728.

These findings indicate that the input representations are not entirely redundant. The full-frame approach preserves the global scene, the masked crop emphasizes lesion morphology, bounding boxes with different margins retain varying amounts of contextual information, and the full frame augmented with a mask explicitly conveys the lesion's location. Averaging the predicted probabilities integrates these complementary sources of information, resulting in improved classification performance.

V. Discussion

The results support the primary hypothesis that ROI representation constitutes an independent factor influencing ultrasound classification performance. The mask should not be regarded merely as an auxiliary segmentation annotation. When incorporated into the classification process, it modifies the distribution of input images, the scale of the lesion, the amount of contextual information available, and the set of features upon which the model can rely.

The results obtained in this study complement existing research on neural network-based ovarian tumor classification. Previous studies by Chen et al.[12], Hsu et al.[13], and Wu et al. [14] have primarily focused on determining whether a model can discriminate between benign and malignant masses or among multiple histological subtypes. In contrast, the present study addresses a different question: given that the mass mask is available, which strategy for incorporating this information leads to a more robust classifier? In this regard, the proposed approach occupies an intermediate methodological position between segmentation and classification.

For the seven-class task, strict localization had the highest mean macro-F1 among individual representations. A plausible explanation is that detailed classification of morphological subtypes requires the model to capture subtle characteristics related to the internal structure and shape of the lesion, whereas the full-frame representation may contain excessive irrelevant information for a lightweight architecture such as EfficientNet-B0. This consideration is particularly important for lesions containing solid mineral inclusions, such as microcalcifications, whose detection in ultrasound imaging depends on specific acoustic patterns that are more effectively characterized within a focused ROI [19]. Under these conditions, suppressing the background and enlarging the lesion provides a substantial advantage. This observation is consistent with the findings reported by Wu et al., who also identified mass annotation and cropping as factors influencing the performance of detailed histological subtype classification [14]. Cropping changes both background content and lesion scale, so the gain cannot be assigned to either mechanism alone.

For the binary classification task, the findings are less definitive. The full-frame representation already contains sufficient information to distinguish simple cysts from other lesions, and many bounding-box variants provide only modest improvements. This observation has important practical implications: results obtained for one classification task cannot be directly generalized to another. Consequently, the choice of input representation should be evaluated independently for each clinical application. This conclusion is consistent with the principles underlying the IOTA and O-RADS frameworks, in which different diagnostic questions rely on distinct sets of features rather than on a universal preprocessing strategy [2]–[4].

Augmenting the full-frame representation with the mask as an additional channel improved performance relative to the standard full-frame approach, although it did not emerge as the best-performing individual variant. This finding suggests that explicitly providing lesion location information does not necessarily ensure that the model will exploit such annotations optimally. In some cases, directly modifying the image representation, for example by enlarging the lesion region and suppressing portions of the background, may constitute a more effective strategy.

The ensemble had the highest mean macro-F1 in both tasks. This pattern suggests that different input representations capture complementary diagnostic information. However, ensemble models are computationally more demanding and more challenging to implement and maintain. Therefore, in practical applications, two distinct scenarios should be considered: the best-performing individual representation as a simple and lightweight solution, and the ensemble as a more accurate yet computationally intensive alternative.

This study has several limitations. First, the experiments were conducted using a single publicly available dataset [10]. Assessing generalizability requires external validation on independent clinical datasets acquired with different ultrasound systems and across multiple institutions. This consideration is particularly important in ultrasound imaging, where image quality and artifact characteristics are strongly influenced by the equipment, acquisition protocol, and operator. Patient identifiers were unavailable in the released index, precluding patient-level splitting and patient-clustered confidence intervals.

Second, the analysis was performed using pre-annotated images in which the presence of a mass was already known. Consequently, the results do not represent the entire clinical workflow, which also includes organ localization, lesion detection, image quality assessment, video analysis, and information integration across multiple image slices.

Third, mask quality was assumed to be an intrinsic characteristic of the dataset. No expert re-annotation was performed; consequently, the results reflect the influence of the available masks rather than that of idealized manual annotations. Clinical translation therefore requires repeating the analysis with automatically predicted masks and explicitly evaluating empty or implausible masks.

Fourth, the binary classification task is highly imbalanced. As a result, overall accuracy may provide a misleading impression of performance, making it necessary to rely on macro-F1, balanced accuracy, AUROC, and confusion matrices for a more comprehensive evaluation [16], [17].

Fifth, EfficientNet-B0 was adopted as a fixed architecture to enable a controlled comparison of input representations [11]. The objective of this study was not to identify the state-of-the-art architecture for the MMOTU/OTU-2D dataset. Although more advanced models may improve absolute performance metrics, they do not diminish the importance of evaluating ROI representation strategies.

Sixth, statistical power was limited by the use of only four random seeds per input variant. Although four runs are common in controlled experiments, larger numbers would be required to detect smaller effect sizes or to establish statistical

significance for individual ROI representations. The ensemble results, however, were robust and statistically significant.

Future studies may also benefit from validation using anatomically realistic three-dimensional printed phantoms, which offer controlled ground-truth conditions for the systematic assessment of ROI preprocessing strategies across different tumor morphologies [20], [21]. Existing ovarian-mass pipelines use segmentation-derived crops or detector-segmenter-classifier cascades [22], [23], but do not isolate ROI representation under fixed classification conditions.

VI. Conclusion

The use of segmentation masks in ovarian tumor classification from ultrasound images should be regarded as an independent experimental hypothesis rather than an inherently beneficial preprocessing strategy. In the seven-class task, the masked crop with a zeroed background increased the macro-F1 score, increasing it from 0.4971 ± 0.0185 to 0.6052 ± 0.0231. In contrast, the effect was less pronounced in the binary task, for which the macro-F1 score increased from 0.6752 ± 0.0266 to 0.7236 ± 0.0222. After correction for multiple comparisons, however, the masked-crop differences were not statistically significant.

The ensemble had the highest mean macro-F1 in both tasks, attaining macro-F1 scores of 0.7025 ± 0.0123 for the seven-class formulation and 0.7728 ± 0.0303 for the binary formulation. Only the seven-class ensemble remained statistically significant after Holm correction. The differences observed between the seven-class and binary tasks suggest that the optimal strategy for ROI utilization depends on the specific clinical application. Before clinical adoption, this approach should undergo external validation using independent datasets, together with a dedicated assessment of mask quality. For practical implementation, we recommend evaluating at least three ROI representations—the full frame, the masked crop, and a bounding box with a 30% margin—and selecting the configuration that yields the best performance for the target task, since the optimal representation is task-dependent.

***Abstract*—Voluntary stopping is a deliberate, self-initiated attempt to stop walking. Voluntary stopping requires actively decelerating forward momentum and stabilizing your center of gravity. Involuntary stopping is the unintentional act of stop walking. In Parkinson's disease (PD), this phenomenon of sudden mobility loss is called Freezing of Gait (FOG). To better characterize the FOG episode and gain a deeper understanding of its underlying nuances, this study aims to compare the voluntary and involuntary stop in people with PD with FOG using inertial sensors. Ten people with PD with history of FOG performed four motor tasks with three sensors attached to the body, two on the pelvis, and one on the shank of the side most affected by PD. Sessions were video-recorded and each event was annotated. For the purpose of this work, the voluntary stop and the FOG episode are the events of interest. Tri-axial accelerometer and gyroscope signals were segmented by event and processed in R; for each sensor–axis–signal combination, amplitude metrics (standard deviation, range, and peak count) were calculated. Voluntary stopping and FOG were compared using linear mixed models, with significance assessed via Wald chi-square tests (Type II) and Benjamini-Hochberg correction for multiple comparisons. Of 108 sensor–axis–feature combinations tested, 95 showed significant differences after correction, with FOG episodes consistently showing greater amplitude than voluntary stops across standard deviation, peak count, and range. These results indicate that FOG episodes involve more irregular movement in the lower limbs than deliberate stopping, consistent with the loss of motor control characteristic of freezing. Quantifying these kinematic differences increases the information about FOG episodes and may inform the development of objective, sensor-based methods for detecting and helping alleviate FOG.**

***Index Terms*—Parkinson's disease, Freezing of gait, inertial measure unit, signal processing, voluntary stopping.**

I. Introduction

Freezing of gait (FOG) is one of the most disabling symptoms of Parkinson's disease (PD), which is a brief episodic absence or marked reduction in stride progression, despite the intention to walk [1]. This sudden inability to begin or continue movement can affect performance in daily activities and subject the individual to frequent falls [2].

There are three types of FOG: (I) Akinetic, the blocked gait, when the feet seem to be glued to the ground, without movement in the trunk and limbs, like complete or partial akinesia; (II) Festination, when the normal gait rhythm changes to a shuffling gait, with faster and shorter steps until the stop; and (III) Trembling place, a local tremor when the lower limbs may show signs of tremor while fixed to the ground, with quick and alternating knee movements [1], [8].

According to Bartels et al. [3], the prevalence of people diagnosed with PD in whom the FOG symptom manifests, ranges from 7% in the early stages to 60% in the severe stages. Morris et al. [4] reported that progressively more people who experience FOG restrict walking and reduce their level of physical activity to avoid triggering the motor disorder.

The risk of fall increases because the most frequent presentation of FOG is not the akinetic type in which there is no movement at all. Video studies did, in fact, show that FOG is commonly associated with an effort to overcome the block, the trembling in place or festination types of FOG. Akinetic freezers who accept the block and wait for spontaneous resolution may be less prone to fall [8].

It is of paramount importance to better characterize the FOG episode and gain a deeper understanding of its underlying nuances because its pathophysiology is still not clear enough [3]. So for means of comparison, the involuntary stop referred in this paper is the FOG episode.

There is an effort to develop some technologies that would be able to remove the person from the freeze state or even avoid the FOG episode to happen. These devices are based on external cues that can bring consciousness to the walking process and improve gait performance [4]–[6]. A critical limitation of these cueing systems, however, is their dependence on accurate real-time FOG detection. Detection algorithms often fail to distinguish a freezing episode from other gait interruptions, such as a voluntary stop, which is a deliberate, self-initiated attempt to stop walking. Improving the specificity of these algorithms therefore requires a clear characterization of how FOG episodes differ kinematically from other stopping behaviors that share superficial similarities.

This study aims to compare the voluntary and involuntary stop in people with PD with FOG using inertial sensors by directly comparing the kinematic signatures of voluntary stops and FOG episodes across Inertial Measure Unit (IMU) based analysis, considering both the OFF and ON medication states.

II. METHOD

The study was conducted according to the guidelines of the Declaration of Helsinki, and all protocols were approved by the Ethics Committee of the Federal University of Uberlândia, Brazil, under protocol number 38885720.3.0000.5152. Informed consent was obtained from all subjects involved in the study. The experiment was performed in a place destined for the clinical care of Parkinson's disease patients.

A. Subjects

Ten PD patients with a history of FOG were enrolled for this study; the number of subjects was based on previous works [9], [10]. The experimental group of the present study, named GFOG+, had six female and four male participants.

Table I shows the clinical information about the participants. The Unified Parkinson's disease Rating Scale from de Movement Disorder Society (MDS-UPDRS) evaluates daily living activities (Part II) and the severity of motor symptoms in PD (Part III) [11]. The motor examination was performed during both medication states. The New FOG Questionnaire is a subjective measure of the severity of FOG [12] and the MiniMental test assesses the cognitive functioning.

TABLE I
CLINICAL CHARACTERISTICS OF STUDY PARTICIPANTS. VALUES ARE PRESENTED AS MEAN ± STANDARD DEVIATION. GFOG+: PD PATIENTS WITH FREEZING OF GAIT.

Characteristics	State	GFOG+
Age (years)	–	60.8 ± 7.48
Time since diagnosis (years)	–	12.5 ± 5.75
MDS-UPDRS Part II	–	17.1 ± 10.78
MDS-UPDRS Part III	OFF	57.5 ± 27.66
	ON	41.7 ± 24.47
New FOG-Q	–	19.2 ± 4.7
MiniMental	–	26.6 ± 2.27

B. Technology

The acquisition of motion data was performed using accelerometer and gyroscope sensors [13]–[15]. The Movement Disorder Monitoring System (NetMD) was used to acquire motion data from participants. NetMD is based on the combined action of an Android mobile phone with three Bluetooth smartwatch devices (Sony Smartwatch 3 SWR50) [17]. The smartwatches were attached to the participant's body using adjustable belts on the pelvis and shank [18]. The X-axis is the horizontal axis (side-to-side axis), the Y-axis is the vertical axis (longitudinal axis), and the Z-axis is the depth axis (anterior-posterior axis). A tripod was used to position a standard cell phone camera (iPhone 12 Pro Max) in the environment in order to record the experiment.

C. Dataset

The participants performed four motor tasks. Three valid trials were collected for each task. The PD participants executed the tasks during the OFF-medication state, 12 hours without taking the levodopa medicine; and during the ON-medication state, 30-50 minutes after taking levodopa. The ON state refers to when medication is effectively controlling symptoms and the OFF state occurs when medication effects wear off, leading to a resurgence of PD symptoms [19].

Task 1 is the Voluntary Stop, a modified version of the Timed Up and Go test, in which the participant stays standing for 10 seconds before turn [7]. Task 2 is the standard Timed Up and Go test (TUG), taken as the golden standard physical mobility task for gait analysis in PD [20].

Task 3 the WalkMaze Test (WMT) and Task 4 is the Cognitive WalkMaze Test (CWMT). Both WMT and CWMT are physical mobility motor tasks developed to trigger FOG in PD [18]. The difference between tasks 3 and 4 is that the CWMT involves a cognitive load, requiring participants to walk while simultaneously performing the Digital Monitoring Task (DMT) [21].

This dataset was generated by the research group and the full experimental protocol was published in 2023 [22].

D. Preprocessing

Data from the three-dimensional accelerometer and three-dimensional gyroscope embedded in each smartwatch was acquired with a sampling frequency of 50 Hz [15]–[17]. The data were stored in the Android mobile phone and transferred to a computer for further processing. The inertial data were resampled at a frequency of 100 Hz using spline interpolation in R to improve the temporal resolution.

E. Data annotation

The inertial signals and the video were synchronized to enable data annotation with the aid of visual information. The videos of the experiment were watched by two specialist professionals and the FOG episodes and the task events were manually annotated using ATLAS, a graphical tool for annotating multimodal data [23]. An example of the identified events for the first task is shown below.

- Task 1 - Voluntary Stop (VS): (VS1) stand up; (VS2) start walking; (VS3) first walk for three meters; (VS4) ten seconds standing; (VS5) 180 degree turn; (VS6) second walk for three meters; (VS7) 180 degree turn to sit; and (VS8) sit down.

F. Events of interest

The final dataset is a data frame with 98,934 observations and 12 variables. The first column, file name, indicates the path to the .csv file containing the raw signal, structured as two variables, time and signal. This .csv file is already separated by sensor position, type and axis. Followed by subject ($1 \rightarrow 10$), state (ON/OFF), task ($1 \rightarrow 4$), trial ($1 \rightarrow 3$), imu id (right pelvis, left pelvis, shank), sensor (acc/gyr), axis (x, y, z), event, that is the windowed event showed in the previous subsection, and window, with the initial and final time of the event annotated. To allow the FOG assessment, there is a column named 'qq', a binary value that assumes 0 when no FOG was registered and 1 if there is a FOG episode in that task event, and a column named fog with the annotation

of initial and final time of FOG episodes, in the existence of one.

The events of interest for this study are the FOG events triggered by the four tasks and the voluntary stop, the forth event of the first task of data collection (VS4), in which the participant stays standing for 10 seconds.

Table II shows the number of observations in the data frame of events of interest. GFOG+OFF is before taking levodopa and GFOG+ON is after.

TABLE II
NUMBER OF EVENTS BY STOP TYPE AND MEDICATION STATE

Stop type	Group	n
Voluntary stop	GFOG+OFF	450
Voluntary stop	GFOG+ON	486
FOG	GFOG+OFF	2622
FOG	GFOG+ON	522

G. Feature Extraction

After visualization of the FOG episode and voluntary stop signals, it was assumed that simple features of amplitude could demonstrate statistically significant difference between the stop types. Three descriptive metrics were computed for each sensor–axis–signal combination: standard deviation, range, and peak count.

The standard deviation of the signal within a given time window is defined as

$$\sigma = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(x_i - \bar{x})^2}, \tag{1}$$

where x_i is the i-th sample of the signal within the window, $\bar{x}$ is the mean signal value in that window, and N is the total number of samples in the window. Equation 1 quantifies the overall variability of the signal around its mean, with higher values indicating greater amplitude fluctuation.

The range of the signal within the same window is given by

$$R = x_{max} - x_{min}, \tag{2}$$

where x_{max} and x_{min} are, respectively, the maximum and minimum signal values observed within the window. Equation 2 captures the total spread of the signal, regardless of how the values are distributed between these two extremes.

Finally, the peak count of the signal within the window is defined as

$$P = \sum_{i=2}^{N-1} \mathbb{1}\left(x_i > x_{i-1} \wedge x_i > x_{i+1}\right), \tag{3}$$

where x_i is the signal sample at index i, N is the number of samples in the window, and $\mathbb{1}(\cdot)$ is the indicator function, which returns 1 if the evaluated condition is true, and 0 if it is false. In this case, the evaluated condition is $x_i > x_{i-1} \wedge x_i > x_{i+1}$, i.e., that x_i is a local maximum. Equation 3 reflects the frequency of abrupt oscillatory events within the signal, with higher peak counts indicating more irregular movement.

Together, Equations 1–3 were used to describe the amplitude characteristics of voluntary stops and FOG episodes across all sensor–axis–signal combinations, and were subsequently compared between the two event types using linear mixed models.

H. Statistical Analysis

To compare voluntary stopping and FOG episodes across the extracted amplitude metrics, linear mixed models (LMMs) were fitted separately for each sensor–axis–signal combination using the `lmer` function from the *lme4* package in R. Stop type (voluntary stop or FOG) was included as a fixed effect, and subject was included as a random intercept, i.e., (1 | subject), to account for repeated measures within participants.

The significance of the fixed effect of stop type was assessed using a Type II Wald chi-square test, implemented with the `Anova` function from the *car* package. To control the false discovery rate arising from multiple comparisons across the sensor–axis–feature combinations tested, p-values were adjusted using the Benjamini–Hochberg method. Adjusted p-values below 0.05 were considered statistically significant.

III. RESULTS

Figure 1 shows an example of voluntary stop of Subject 1, the linear acceleration from the accelerometer on the shank on the X axis is represented in milisseconds.

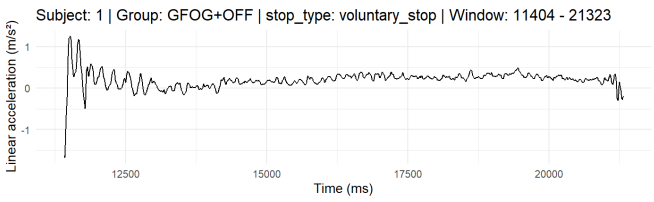

Fig. 1. Linear acceleration on X axis from the right shank of Subject 1.

Figure 2 shows an example of voluntary Stop of Subject 4 during the OFF medication state. The scale of the signal amplitude axis is different from Figure 1.

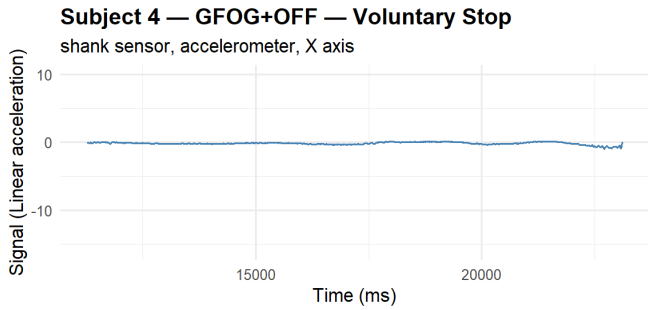

Fig. 2. Voluntary stop of Subject 4. The signal shows the linear acceleration in m/s^2 of the X axis on the shank.

Figure 3 shows an example of FOG episode of Subject 4, that has the akinetic type. This FOG type can manifest as

complete akinesia, in which the entire body is frozen, or partial akinesia, in which only the lower body is frozen.

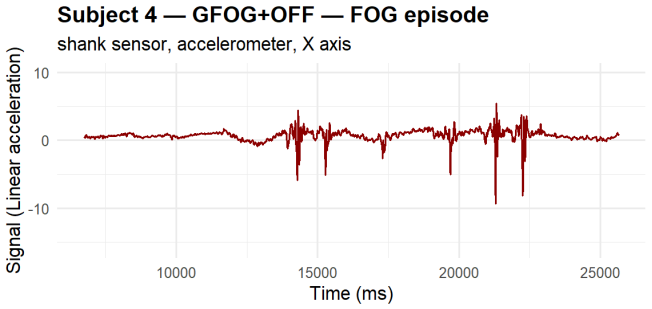

Fig. 3. FOG episode of Subject 4.The signal shows the linear acceleration in m/s^2 of the X axis on the shank.

Even though the walking event is not an event of interest in this paper, we decided to put a signal of example to show the amplitude of walking of Subject 4 during the ON state, in Figure 4, by means of comparison.

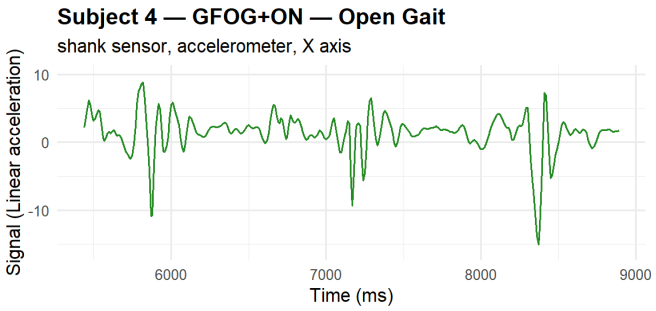

Fig. 4. Behavior of the accelerometer signal during walking in straight line for more than 3 seconds.

Figure 5 shows a comparison between the voluntary and involuntary stop of Subject 9. Both events had similar time duration.

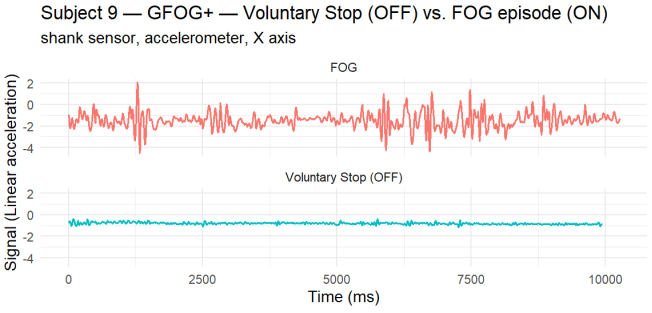

Fig. 5. Involuntary and Voluntary Stop of Subject 9.

Voluntary stopping and involuntary stopping (FOG) were compared using linear mixed models, with stop type as a fixed effect and a random intercept per subject. Significance was assessed via Type II Wald chi-square tests, with Benjamini-Hochberg correction applied across all sensor-axis-feature combinations.

Table III reports the five most significant axis-state combinations for the shank accelerometer, based on the signal standard deviation (sd_val). The estimate is the estimated mean difference in standard deviation between the two conditions (FOG vs. Voluntary Stop). It reflects the effect size of stop type in that model, i.e., how much greater sd_val was during FOG episodes compared to voluntary stops. The p-value column represents the raw test result (Wald chi-square from the lmer model, via car::Anova). The Adj. p-value column shows that same result after applying the Benjamini-Hochberg correction. Each row corresponds to a separate linear mixed model, fitted independently for a given accelerometer axis (X, Y, or Z) and medication state.

TABLE III
TOP 5 SHANK ACCELEROMETER COMBINATIONS BY ADJUSTED P-VALUE (FEATURE: SD_VAL)

Axis	State	Estimate (m/s^2)	p-value	Adj. p-value
X	OFF	1.46	1.45×10^{-15}	2.60×10^{-14}
Z	OFF	1.90	2.02×10^{-15}	3.11×10^{-14}
Z	ON	2.44	2.80×10^{-13}	2.33×10^{-12}
X	ON	1.32	4.24×10^{-13}	3.27×10^{-12}
Y	OFF	1.58	5.40×10^{-12}	2.65×10^{-11}

[a]Shank sensor most affected by Parkinson's disease, accelerometer.

Of the 108 sensor-axis-feature combinations tested, 95 (88.0%) remained statistically significant after correction, all in the direction of FOG episodes exhibiting greater signal amplitude than voluntary stops. Significance rates varied by feature: sd_val showed the highest proportion of significant combinations (34/36), followed by peak (31/36) and range_val (30/36).

Figure 6 shows the boxplots of the sd values for the voluntary stop (blue) and FOG episode (red). The feature exhibited was extracted from the linear acceleration from the accelerometer on the shank. The figure shows the axes X, Y and Z.

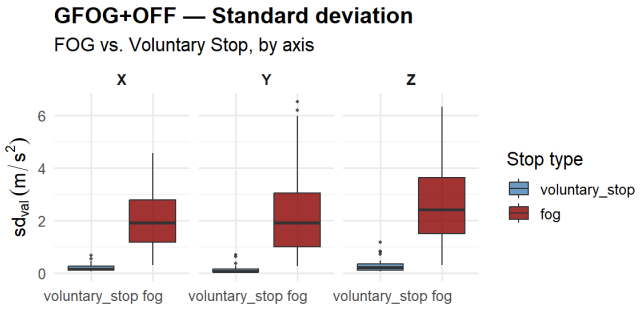

Fig. 6. Distribution of the standard deviation for the shank accelerometer in the OFF medication state. Boxplots compare voluntary stops and FOG episodes on axes X, Y and Z.

An Excel file containing the complete linear mixed model results (estimates, test statistics, raw and adjusted p-values) for all sensor-axis-state-feature combinations is available as Supplementary Material [24].

IV. Discussion

This study demonstrates the potential of inertial measurement units feature extraction and could give insights into the pathophysiology of FOG in PD. Alongside, the findings provide evidence that could inform the detection logic of devices used to aid people with FOG in PD, regardless of medication state.

The inertial sensors allowed to quantify the amplitude of the movements and to better characterize the events. Figure 1 illustrates a typical voluntary stop, in which the deceleration phase is evident between milliseconds 11404 and 13000. Following this interval, it can be inferred that the subject achieved stabilization of the center of gravity.

Figures 1 and 2 show the stability of the signal value, the amplitude of the signal is around 1 m/s^2 during the voluntary stop.

Figures 2, 3, and 4 are all derived from the same subject. Subject 4 presents the rigid-akinetic phenotype of PD and has experienced FOG since the early stages of the disease. The akinetic type is perceived in video recordings because of the lack of movement in the trunk and limbs during the FOG episode.

Figure 2 shows the complete absence of movement during the voluntary stop. Figure 3 illustrates a representative FOG episode from Subject 4 (GFOG+OFF), recorded from the shank accelerometer (X axis) during the dual-task condition. The episode, lasting approximately 20 seconds, is characterized by multiple discrete spikes in signal amplitude. These recurrent spikes likely reflect successive attempts to initiate movement during the FOG episode.

FOG is defined as a brief, episodic absence or marked reduction in stride progression despite the intention to walk. This is evident in Figure 3, where the signal amplitude fails to reach the threshold required to produce effective movement, remaining well below the amplitude range observed during normal walking for the same subject (maximum of 8 m/s^2 and minimum of -15 m/s^2, as shown in Figure 4). It is reasonable to associate the spikes observed at 14,000 ms (-6 m/s^2), 15,500 ms (-6 m/s^2), 21,500 ms (-9.5 m/s^2), and 22,200 ms (-8 m/s^2) in Figure 3 with repeated attempts to initiate walking. This intention to walk has been described in previous literature, but a quantitative demonstration of how it manifests in the signal has, to our knowledge, not yet been shown.

Literature says that the person with an akinetic type of FOG is less prone to fall [1], [8]. However, video recordings of the present study made it noticeable that, after a long episode of akinetic FOG, in which, according to Figure 3 the subject is actively trying to move forward, the person adopts a risky gait pattern characterized by a forward-leaning trunk posture and rapid, shortened steps resembling a light jog. Rapidly the person enters the FOG type II, because this pattern is consistent with festination. After one FOG episode, the whole gait of the subject is compromised, becoming what we call a frozen gait. It differs from the FOG episode that happens briefly and does not prevent starting to walk again. MDS-UPDRS correlates the trouble starting to walk to the need for a cane or walker [11].

In Table III, the correction BH is applied when the original p-value is adjusted for multiple comparisons—in the case of the present study, one model per combination of sensor, sensor placement, axis, and subject medication status.

Table III presents sensor–axis–medication state combinations with the strongest adjusted significance for sd_val at the shank sensor. Most combinations remained highly significant after Benjamini-Hochberg correction (adjusted $p < 10^{-10}$), as it shows, indicating a robust and consistent difference in signal variability between FOG episodes and voluntary stops. Notably, both OFF and ON medication states appear among the top-ranked combinations, suggesting that this discriminative pattern is not restricted to the OFF state, when parkinsonian symptoms are most pronounced. This consistency across medication states reinforces the potential of shank accelerometer for distinguishing FOG from voluntary stopping, regardless of the patient's current dopaminergic status, a relevant consideration for the detection logic of wearable assistive devices.

Figure 5 shows a comparison between a FOG episode and a voluntary stop of similar duration from Subject 9, which motivated the choice of the amplitude-based features extracted in this study. Subject 9 has the trembling place type of FOG, which can be seen in the red signal. The waves are irregular and the signal has intermittent bursts of much higher amplitude than the voluntary stop, which stays nearly flat. Amplitude and frequency vary considerably across the 10-second window of FOG. One may consider that each attempt to break out of the episode has a different intensity, making the entire episode highly heterogeneous.

Figure 6 shows the distribution of sd_val for the shank accelerometer in the OFF-medication state, comparing voluntary stops and FOG episodes across the three axes (X, Y, Z). Across all axes, FOG episodes showed markedly higher sd_val values than voluntary stops. Voluntary stops presented consistently low variability, with narrow interquartile ranges close to zero, reflecting the controlled and stable nature of an intentional stopping movement. In contrast, FOG episodes exhibited substantially wider interquartile ranges and longer whiskers, particularly in the Y and Z axes, indicating greater signal variability during freezing. These results are consistent with the linear mixed-effects model results (Table III), which showed significant differences in sd_val between stop types across all three axes (adjusted $p < 0.001$).

These findings are of particular relevance to better characterize the FOG episode and gain a deeper understanding of its underlying nuances and to optimize real-time systems developed to assist individuals with freezing of gait (FOG) in overcoming or preventing freezing episodes. In particular, these results may support the discrimination of genuine freezing episodes from intentional stopping, thereby contributing to a reduction in false-positive cue activations.

V. Conclusion

It was possible to compare the voluntary and involuntary stop in people with PD with FOG using inertial sensors. Of 108 sensor–axis–feature combinations tested, 95 showed significant differences after correction, with FOG episodes consistently showing greater amplitude than voluntary stops across standard deviation, peak count, and range. These results indicate that FOG episodes involve more irregular movement in the lower limbs than deliberate stopping, consistent with the loss of motor control characteristic of freezing. Quantifying these kinematic differences may inform the development of objective, sensor-based methods for detecting and discriminating FOG from voluntary gait cessation.

Interpretable Structural-Deviation Descriptors of Osteosarcoma Radiographic Signs via the Universal Image Quality Index

A localization-conditioned feature-characterization study on public radiographs

***Abstract*—Osteosarcoma is the most common primary malignant bone tumor in adolescents, and conventional radiography remains the first-line modality in resource-limited settings. Deep learning attains strong classification performance on bone-tumor radiographs but behaves as a black box and demands large annotated datasets and specialized hardware. This work characterizes an interpretable, low-cost feature set derived from classical digital image processing, built around the Universal Image Quality Index (UIQI). The UIQI is a full-reference structural measure that factors into loss of correlation, luminance distortion, and contrast distortion; we repurpose it as a descriptor of the local structural deviation between a lesion region of interest (ROI) and a mirrored intra-image reference region, and we state—as a hypothesis, not as a validated finding—a correspondence between its three components and classical radiological signs of malignancy. To test whether the descriptors carry class-discriminative signal, an interpretable random forest is applied to them. On a binary osteosarcoma-versus-normal-bone task derived from the public multi-center BTXRD dataset (297 osteosarcomas, 1879 normal radiographs; image-level stratified splits of 1740/218/218), and adopting a symmetric extraction that controls a pipeline confound, the UIQI features reach an accuracy of 0.878 ± 0.025 and an area under the receiver operating characteristic curve (AUC-ROC) of 0.872 ± 0.020 under five-fold cross-validation; adding complementary handcrafted descriptors of texture and gradient raises the AUC-ROC to 0.931 ± 0.019 and the F1-score to 0.691 ± 0.079. Three scope conditions bound these numbers: lesion ROIs are placed using the reference segmentation, so performance is conditioned on known lesion location and does not describe an end-to-end automatic system; benign and non-osteosarcoma malignant tumors, which form the hardest differential diagnoses, are excluded; and no external validation, radiologist comparison, calibration analysis, or benchmark against explainable deep models is reported. The contribution should therefore be read as the characterization of an interpretable descriptor set and as the demonstration of an extraction confound, not as a validated diagnostic or triage tool.**

***Index Terms*—osteosarcoma, digital image processing, universal image quality index, structural similarity, radiomics, texture analysis, interpretable features, bone tumor**

I. Introduction

Osteosarcoma is the most prevalent primary malignant bone tumor in pediatric and young-adult populations, accounting for about 20% of primary bone sarcomas, with peak incidence during adolescence [5]. Because advances in neoadjuvant chemotherapy and limb-salvage surgery have substantially raised five-year survival, early and accurate diagnosis is decisive for treatment planning and prognosis. Conventional radiography remains the first-line modality for the initial evaluation of bone tumors owing to its wide availability, low cost, and ability to reveal key signs such as bone destruction, periosteal reaction (for example, the sunburst pattern and Codman's triangle), and soft-tissue extension.

Radiographic interpretation of bone tumors is nonetheless difficult. Features that overlap with benign entities such as osteomyelitis, healing fractures, and osteochondroma, subtle early-stage changes, and inter-observer variability between radiologists of differing experience hinder consistent diagnosis. These limitations motivate computer-aided diagnosis (CAD) research aimed at supporting radiologists. In the Brazilian public health system, a shortage of specialized radiologists and geographic disparities in the distribution of expertise amplify these challenges, reinforcing reliance on conventional radiographs as the principal diagnostic tool in primary and secondary care [10].

Deep learning has achieved strong performance in bone-tumor classification [7], [8]. However, such models are data-hungry, computationally demanding, and largely opaque: they report a probability without exposing which radiographic sign drove the decision. Post-hoc explanation methods partially mitigate this, but the case for models that are interpretable by construction in high-stakes clinical settings remains strong [11]. This motivates investigating whether descriptors with explicit physical meaning can encode the information radiologists actually name when reading a bone lesion.

This work therefore studies osteosarcoma radiographs as

a problem of quantifying structural deviation with classical digital image processing (DIP). Our central instrument is the Universal Image Quality Index (UIQI) of Wang and Bovik [1], a full-reference measure used here not to assess image fidelity but repurposed as a structural-deviation descriptor: it compares a suspect lesion ROI with a reference bone region and factors the deviation into three components with distinct physical meanings. The contributions of this paper are:

- A compact, interpretable feature set (20 descriptors) derived entirely from the local UIQI decomposition between a lesion ROI and a mirrored intra-image reference, in which every dimension has an explicit physical meaning.
- The identification, quantification, and control of an ROI-extraction confound that inflates apparent performance by roughly 0.10 AUC-ROC when the two classes follow geometrically distinct extraction paths—a failure mode that, to our knowledge, is not routinely reported in handcrafted bone-radiograph pipelines.
- A hypothesis, stated explicitly as such, mapping the three UIQI components onto named radiological signs, together with a discussion of the sign-level annotations that would be required to test it.

A. Scope and what this paper does not claim

Because the framing of this kind of study is easily overstated, we state the boundaries up front. (i) The lesion ROI is placed using the reference segmentation provided with the dataset; no lesion detector is part of the pipeline. All reported metrics are therefore *conditioned on correct lesion localization* for positive cases and describe the discriminative power of the descriptors, not the performance of an automatic triage system. (ii) The task is binary (osteosarcoma versus radiographically normal bone); benign tumors and non-osteosarcoma malignancies, which in practice constitute the difficult differential, are excluded. (iii) The correspondence between UIQI components and radiological signs is a working hypothesis: the dataset contains no sign-level annotation against which it could be verified. (iv) No external cohort, no reader study, no calibration assessment, and no comparison against convolutional or transformer baselines are reported. Statements about deployment on commodity hardware concern computational cost only, and are not claims of clinical readiness.

II. Related Work

Full-reference image quality metrics were introduced to predict perceived fidelity. The UIQI [1] models distortion as the product of loss of correlation, luminance distortion, and contrast distortion, and inspired a broad family of structural and perceptual metrics, including the Structural Similarity Index [2]. Although designed for quality assessment, these structural measures have been adopted as region-comparison and change-detection descriptors across imaging domains, which motivates their use here as descriptors of the local structural deviation between suspect and reference bone.

Classical radiomic and texture analysis remains widely used in musculoskeletal imaging [3]. Gray-level co-occurrence matrix (GLCM) features capture second-order texture such as trabecular disorganization and matrix heterogeneity, while local binary patterns encode micro-texture robustly to illumination [4].

Prior work on bone-tumor radiographs is predominantly based on deep-learning classifiers, frequently trained on private datasets [8], [9]. Interpretability in that line of work is typically obtained post hoc, through gradient-based saliency such as Grad-CAM [12], or, in transformer architectures [7], [13], through attention-based visualizations. Such maps indicate *where* the model looked, but not *which radiographic property* was abnormal there, and their faithfulness to the underlying decision is itself contested [11]. The present work sits on the opposite side of that trade-off: it computes named quantities directly and accepts a lower ceiling on predictive performance in exchange. We emphasize that we do not benchmark against explainable deep models or vision transformers here. A fair comparison would require training such models under the identical localization-conditioned protocol and image-level splits used below; absent that, this paper makes no claim about the relative accuracy of handcrafted structural descriptors and modern deep architectures, and the interpretability–performance trade-off remains uncharacterized. We flag this comparison as necessary future work in Section VIII.

Reporting for machine-learning studies in medical imaging is increasingly guided by checklists such as CLAIM [15]; Section III-A follows its recommendations on data provenance, case selection, unit of analysis, and partition definition.

III. Materials and Methods

A. Dataset, case selection, and study design

Experiments use the Bone Tumor X-Ray Radiograph Dataset (BTXRD), a three-center collection released in 2024 for bone-tumor analysis [6]. The full release contains 3746 radiographs (1879 radiographically normal, 1525 benign tumor, and 342 malignant tumor), provided as JPEG images in an `images` folder, with segmentation polygons and bounding boxes in LabelMe (`.json`) format in an `Annotations` folder, and image-level labels and clinical metadata consolidated in `dataset.csv`. Each tumor image carries a segmentation polygon and a bounding box; normal images carry no annotation. Acquisition parameters (device, exposure, post-processing) are not standardized across the three contributing centers, and the release does not expose them per image; the heterogeneity is therefore inherited by our pipeline and is not corrected beyond the intensity normalization described in Section III-B. Detailed patient-level characteristics of the source cohorts are given in the original dataset publication [6].

Case and control selection. From the 3746 radiographs we retained the 297 images labeled as osteosarcoma (a subset of the 342 malignant tumors; the remaining 45 form the other-malignant category) and the 1879 normal-bone images, giving 2176 radiographs with an approximate 1:6.3 positive-to-negative ratio (Table I). The 1525 benign tumors and the 45 non-osteosarcoma malignancies were excluded by design,

to isolate the structural contrast between osteosarcoma and normal bone. We stress that this exclusion removes precisely the categories that dominate the clinical differential diagnosis, so the reported separability is an optimistic bound with respect to the multiclass problem a radiologist actually faces.

Unit of analysis and partition unit. The unit of analysis is the radiograph. The public release used here does not provide a patient identifier that would allow multiple radiographs of the same patient (for instance, frontal and lateral views of the same limb) to be grouped; consequently all partitions are performed at the image level, and we cannot rule out that images of the same patient appear in different partitions. This is a source of optimistic bias that we could not eliminate and that patient-level grouping would resolve; it is restated in Section VII.

Partitions. Two protocols are used. Protocol (i) is a single stratified image-level split into 1740 training (237 osteosarcoma / 1503 normal), 218 validation (30 / 188), and 218 held-out test images (30 / 188). Protocol (ii) is stratified five-fold cross-validation over all 2176 images, reporting mean, standard deviation, and an interval across folds, adopted because the number of positives (297) is modest. Feature definitions, classifier hyperparameters, and the decision threshold were fixed using training and validation data only, as detailed in Section III-G; the held-out test set of protocol (i) was evaluated once.

TABLE I
COMPOSITION OF THE BINARY SUBSET EXTRACTED FROM BTXRD

Class	Total	C1	C2	C3	F/L/O
Osteosarcoma	297	215	66	16	187/89/21
Normal bone	1879	–	–	–	–
Total	2176				

C1–C3: acquisition centers; F/L/O: frontal, lateral, and oblique views. Counts are radiographs, not patients; patient-level grouping is not available in the release.

B. Preprocessing

Each radiograph is converted to single-channel intensity and preprocessed to standardize acquisition variability while preserving diagnostic structure: (1) intensity normalization to the range 0–1 by clipping between the first and ninety-ninth percentiles, reducing the influence of outliers; and (2) contrast-limited adaptive histogram equalization (CLAHE, clip limit 0.01) to enhance trabecular and cortical detail. Both operations are applied identically to every image, independently of class and of any label, and their parameters were fixed a priori rather than selected by performance. We note that CLAHE alters local contrast and therefore acts directly on the quantity that the contrast component of the UIQI measures; because it is applied identically to the lesion region and to its reference within the same image, it does not by itself induce a systematic difference between the two, but it does compress the absolute interpretation of the contrast term. Region-of-interest definition follows Section III-E.

C. The Universal Image Quality Index as a structural-deviation descriptor

Let $x = \{x_i\}$ and $y = \{y_i\}$, $i = 1, \ldots, N$, be co-located samples from the reference bone region and the suspect lesion region, respectively. The UIQI [1] is

$$Q = \frac{4\,\sigma_{xy}\,\bar{x}\,\bar{y}}{(\sigma_x^2 + \sigma_y^2)\,(\bar{x}^2 + \bar{y}^2)}, \tag{1}$$

where $\bar{x}, \bar{y}$ are the sample means, σ_x^2, σ_y^2 the variances, and σ_{xy} the covariance. As shown by the authors, (1) factors into three interpretable terms:

$$Q = \underbrace{\frac{\sigma_{xy}}{\sigma_x \sigma_y}}_{Q_c\ \text{(corr.)}} \cdot \underbrace{\frac{2\bar{x}\bar{y}}{\bar{x}^2 + \bar{y}^2}}_{Q_l\ \text{(lum.)}} \cdot \underbrace{\frac{2\sigma_x \sigma_y}{\sigma_x^2 + \sigma_y^2}}_{Q_s\ \text{(contr.)}}, \tag{2}$$

with Q in the range $[-1, 1]$ and $Q = 1$ if and only if $x_i = y_i$ for all i. Following [1], Q is not computed globally but with a sliding window of size $B \times B$ (with $B = 8$) over the ROI pair, and the overall index is the mean of the local values, yielding a spatial structural-deviation map $Q(u, v)$ and its component maps $Q_c(u, v)$, $Q_l(u, v)$, $Q_s(u, v)$ (Fig. 1).

D. Hypothesized correspondence with radiographic signs

We propose, as a working hypothesis, that each component tracks a distinct family of radiological findings, as summarized in Table II. A decrease in the correlation term Q_c would be expected where the spatial coherence of the trabecular pattern is broken, as in trabecular disorganization or periosteal reaction. A decrease in the luminance term Q_l would be expected where mean density departs from the reference, as in osteolysis or osteoblastic mineralization. A decrease in the contrast term Q_s would be expected where the local dynamic range changes, as in cortical destruction or a heterogeneous tumor matrix.

This correspondence is stated as a hypothesis and is not verified in this work. The three components are mathematical functions of local means, variances, and covariance, and each of them can also be driven by non-pathological factors: exposure and detector response affect Q_l; soft-tissue superposition, projection obliquity, and CLAHE affect Q_s; noise and mirroring misalignment affect Q_c. Testing the hypothesis requires radiographs annotated at the level of individual signs—for example, expert delineation of osteolytic regions, of periosteal reaction, and of cortical breach—which BTXRD does not provide. Accordingly, throughout this paper we say that a component *may reflect* a sign, and we do not treat a low Q_l as a measurement of osteolysis or a low Q_s as a measurement of cortical destruction.

E. Reference-region definition, symmetric extraction, and confound control

The definition of the two regions is critical and can, if poorly designed, introduce bias. A naive approach extracts the lesion ROI from the mask for tumor images and a generic ROI for normal images; the two classes then follow geometrically distinct extraction paths, and the classifier can learn the

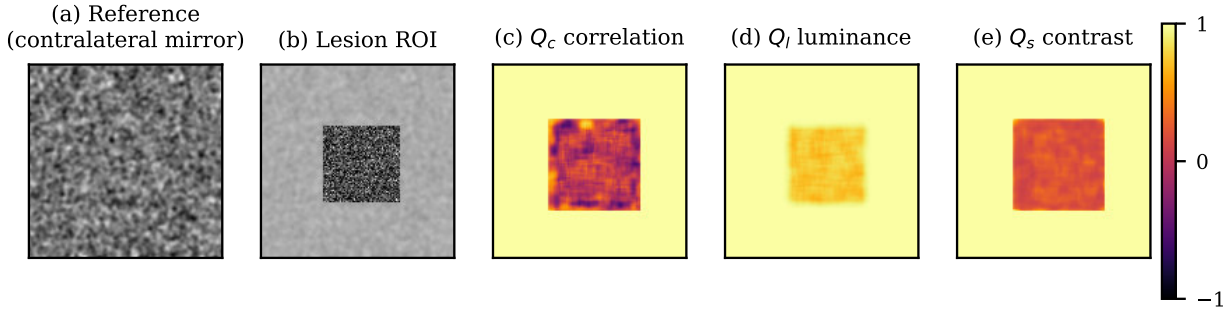

Fig. 1. Synthetic illustration of the UIQI used as a structural-deviation descriptor. (a) Reference region; (b) suspect region, here constructed with a radiolucent area and a heterogeneous matrix; (c)–(e) local maps of the components Qc, Ql, and Qs. This figure is a didactic construction from synthetic data, not a patient radiograph; it illustrates how the decomposition localizes and factors a deviation and is not evidence for the correspondence hypothesized in Table II.

TABLE II
HYPOTHESIZED CORRESPONDENCE BETWEEN UIQI COMPONENTS AND OSTEOSARCOMA RADIOGRAPHIC SIGNS (NOT VALIDATED AGAINST SIGN-LEVEL ANNOTATIONS)

Component	**Image property measured**	**Candidate radiological sign (hypothesis)**
Q_c (correlation)	Structural coherence	Trabecular disorganization; periosteal reaction (sunburst, Codman)
Q_l (luminance)	Mean density	Osteolysis / osteoblastic sclerosis
Q_s (contrast)	Local dynamic range	Cortical destruction; heterogeneous matrix

The middle column states what the term computes; the right column states what we hypothesize it may reflect. Only the middle column is established.

pipeline signature (ROI size, position, overlap) rather than the pathology. To remove this confound we adopt a *symmetric extraction*: every image, normal or tumoral, undergoes the same operation, comparing a square box against the region obtained by reflecting the same box coordinates about the vertical midline of the image. For tumor images the box is positioned from the lesion annotation; for normal images it is positioned at the center of the bone. The only systematic difference remaining between the classes is thus the presence of pathological tissue inside the box. Section V quantifies how much of the apparent performance the naive variant owed to the extraction path.

What the mirrored region is, and when the symmetry assumption fails. Most bone radiographs in BTXRD image a single limb or region, so the reflected box is generally *not* a true contralateral bone. It is a within-image control region acquired under identical exposure, detector, and processing conditions, which is why we call it a *mirrored intra-image reference* rather than a contralateral analog. No anatomical registration, rotation correction, or laterality normalization is applied, and no test verifies that the reflected box actually falls on bone. Four situations degrade the reference: (a) the limb is not centered or is rotated, so the reflected box samples a different anatomical level; (b) the reflected box falls on soft tissue or on background, in which case it is clipped to the image bounds and the resulting deviation reflects the tissue mismatch rather than pathology; (c) the lesion is large or near the midline, so the reflected box partly overlaps the lesion itself and the deviation is attenuated, biasing positives toward the negative class; and (d) periosteal reaction or soft-tissue mass extends beyond the annotated box. Because the identical operation is applied to both classes, this noise is not class-specific by construction and does not reintroduce the extraction confound, but it is not eliminated: it inflates the within-class variance of all descriptors and is a plausible contributor to the limited recall reported in Section V. Quantifying it would require a per-image assessment of reference validity, which we did not perform.

F. Feature set

For each ROI pair we compute the four UIQI maps (Q, Q_c, Q_l, Q_s) and summarize each by five descriptors—mean, minimum, standard deviation, fifth percentile, and altered-area fraction (fraction of pixels below a fixed threshold)—totaling 20 low-dimensional features. The minimum and the fifth percentile capture the worst local point of the suspect region, whereas the altered-area fraction quantifies the extent of the deviation.

Optionally, a complementary set of 24 handcrafted descriptors is extracted from the lesion ROI to capture signals the UIQI does not encode (Fig. 2): five first-order intensity statistics (mean, variance, skewness, kurtosis, entropy); five GLCM texture measures [3] (contrast, correlation, energy, homogeneity, angular second moment) averaged over four orientations; ten bins of the uniform local binary pattern histogram [4] ($P = 8$, $R = 1$); and four gradient and edge descriptors (mean and standard deviation of the Sobel gradient magnitude, its ninety-fifth percentile, and the Canny edge density).

All descriptors are produced by fixed closed-form operators with parameters chosen a priori. No label-driven feature selection, ranking, or dimensionality reduction was performed at any stage, so no information from the validation or test data entered the feature definition.

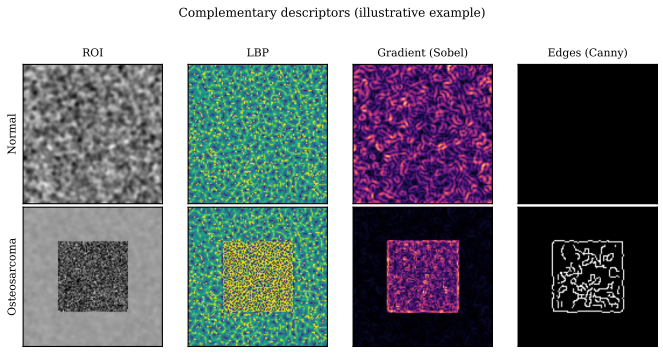

Fig. 2. Complementary descriptors extracted from the ROI, shown for one normal and one osteosarcoma case selected for illustration. Columns: ROI, local binary pattern (LBP) map, Sobel gradient magnitude, and Canny edges. The figure conveys qualitative intuition for what the descriptors encode; being a two-case example, it is not evidence of a consistent group difference. Group-level distributions are given in Fig. 4.

G. Classification protocol

The features (20 from the UIQI, or 44 with the complementary block) are classified by a random forest with 400 trees and balanced class weighting, chosen for robustness on small tabular feature sets and for exposing importance rankings. Tree depth, split criterion, and the remaining hyperparameters are the library defaults. These settings were fixed a priori: no grid search, randomized search, or manual tuning was carried out, so no hyperparameter information leaked from the validation or test partitions. In protocol (i) the decision threshold is chosen by maximizing F1 on the validation set alone and applied unchanged to the held-out test set. In protocol (ii) we report AUC-ROC, which is threshold-independent, together with point metrics computed at the fixed default threshold of 0.5, without per-fold threshold optimization. The classifier serves to test the separability of the descriptors; it is not itself the contribution, and no attempt was made to optimize it.

H. Evaluation metrics

Let TP, TN, FP, and FN denote true and false positive and negative counts for the osteosarcoma class. We report

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN}, \quad \text{Prec} = \frac{TP}{TP+FP}, \tag{3}$$

$$\text{Rec} = \frac{TP}{TP+FN}, \quad \text{Spec} = \frac{TN}{TN+FP}, \tag{4}$$

$$F_1 = \frac{2\cdot\text{Prec}\cdot\text{Rec}}{\text{Prec}+\text{Rec}} = \frac{2TP}{2TP+FP+FN}, \tag{5}$$

together with the threshold-independent AUC-ROC. Given the class imbalance (1:6.3), accuracy is reported for completeness only and is dominated by the negative class; F1, recall, and AUC-ROC carry the informative content.

For protocol (ii), let $m_1, \ldots, m_5$ be the per-fold values of a metric, with mean $\bar{m}$ and standard deviation s. We report $\bar{m} \pm s$ and the interval

$$\bar{m} \pm t_{0.975,\,4}\,\frac{s}{\sqrt{5}} \;=\; \bar{m} \pm 1.24\,s, \tag{6}$$

with $t_{0.975,4} = 2.776$. This interval summarizes fold-to-fold variability of the estimate within this dataset; because the folds are drawn from a single cohort and are not independent samples of the target population, it must not be read as a confidence interval for performance on new institutions or populations.

IV. Experimental Setup

The pipeline is implemented in Python with open-source libraries (NumPy, SciPy, scikit-image, scikit-learn) and runs entirely on the CPU, without a GPU, on a commodity workstation. The UIQI is computed with an 8-by-8 sliding window and the random seed is fixed for reproducibility; library versions and the seed are reported alongside the released code. No GPU-specific or accelerator-specific operation is used at any stage.

V. Results

A. Confound control in extraction

Table III contrasts the naive extraction (distinct geometric paths per class) with the symmetric extraction of Section III-E, on the same held-out test set of 218 images (30 osteosarcoma, 188 normal). The naive variant yields markedly high metrics (AUC-ROC 0.981; F1 0.815), but a large share of that performance is attributable to the pipeline signature: equalizing the extraction operation across classes lowers the AUC-ROC to 0.882 and the F1-score to 0.511 on the identical split, driven mainly by a collapse in recall from 0.733 to 0.400. Specificity is high in both variants, which is expected under a 1:6.3 imbalance and is not by itself informative. We therefore report the symmetric variant as the main result and regard the naive figures as an artifact, included only to document the size of the effect. Given the 30 positives in this split, all point estimates in Table III rest on few events and are correspondingly unstable; the cross-validated results of Table IV are the more reliable summary.

TABLE III
Effect of Confound Control on the Same Held-Out Test Split (218 Images: 30 Osteosarcoma, 188 Normal)

Metric	Naive (biased)	Symmetric
TP / FP / FN / TN	22 / 2 / 8 / 186	12 / 5 / 18 / 183
Accuracy	0.954	0.895
AUC-ROC	0.981	0.882
Precision	0.917	0.706
Recall	0.733	0.400
Specificity	0.989	0.973
F1-score	0.815	0.511

Single split, threshold selected on the validation set only. The naive column is reported to quantify the confound, not as a result of the method.

B. Classification performance and ablation

Table IV reports five-fold cross-validation with symmetric extraction, for the UIQI features alone and for the extended set including the complementary texture and gradient descriptors. The UIQI alone reaches an AUC-ROC of 0.872 ± 0.020 and an F1-score of 0.560 ± 0.024, indicating that the structural

decomposition separates the two classes with a consistent, if moderate, signal. Adding the complementary descriptors raises the AUC-ROC to 0.931 ± 0.019 and the F1-score to 0.691 ± 0.079, with the largest gain in recall (0.570 to 0.681), the metric where the UIQI alone was weakest. The intervals of the two feature sets do not overlap for AUC-ROC or recall, while they do overlap for precision, whose fold-to-fold variability is large. Fig. 3 summarizes the ablation and shows the test confusion matrix.

Two caveats bound the reading of this ablation. First, we did not evaluate the complementary texture and gradient block *in isolation*; consequently these experiments do not establish that the UIQI contributes information beyond what a conventional GLCM/LBP/gradient baseline already provides, and the gain observed here is compatible with the complementary block carrying most of the discriminative weight. An isolated-baseline comparison is required before any claim of complementarity can be made, and we abstain from that claim. Second, the predicted probabilities of the random forest were not calibrated or assessed for calibration; the threshold-dependent metrics therefore describe ranking behaviour at a fixed operating point rather than reliable probability estimates.

TABLE IV
CLASSIFICATION PERFORMANCE AND ABLATION (5-FOLD STRATIFIED CV, SYMMETRIC EXTRACTION, IMAGE-LEVEL FOLDS)

	UIQI (20 feat.)		**UIQI + Compl. (44 feat.)**	
Metric	Mean±SD	95% int.	Mean±SD	95% int.
Accuracy	0.878 ± 0.025	[0.847, 0.909]	$\mathbf{0.914 \pm 0.033}$	[0.873, 0.955]
AUC-ROC	0.872 ± 0.020	[0.847, 0.897]	$\mathbf{0.931 \pm 0.019}$	[0.907, 0.955]
Precision	0.581 ± 0.083	[0.478, 0.684]	$\mathbf{0.716 \pm 0.138}$	[0.545, 0.887]
Recall	0.570 ± 0.117	[0.425, 0.715]	$\mathbf{0.681 \pm 0.041}$	[0.630, 0.732]
F1-score	0.560 ± 0.024	[0.530, 0.590]	$\mathbf{0.691 \pm 0.079}$	[0.593, 0.789]

Intervals are Student-t intervals over the five folds ($\bar{m} \pm 1.24\,s$) and describe fold-to-fold variability within this dataset only. Folds are stratified at the image level; patient-level grouping is not available.

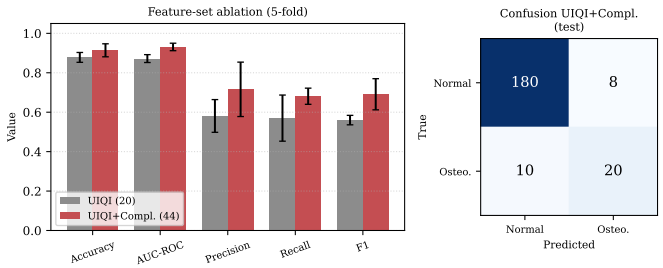

Fig. 3. Left: feature-set ablation (UIQI versus UIQI plus complementary) over five folds, with standard-deviation bars. Right: confusion matrix on the held-out test split for the UIQI plus complementary model with symmetric extraction; counts refer to the 218 test images described in Section III-A.

C. Descriptor distributions and model importances

Fig. 4 shows the class-wise distributions of key descriptors over the 2176 radiographs. The distributions of the minimum values of Q and Q_c differ between classes, with osteosarcoma ROIs concentrating at more pronounced local deviations; osteosarcoma ROIs also show a larger fraction of area with altered luminance and a lower mean contrast term. The direction of these shifts is consistent with what the hypothesis of Table II would predict, but consistency with a hypothesis is not a test of it: the same shifts would arise from exposure differences or from reference-region mismatch, and no sign-level annotation is available to discriminate between these explanations.

The random-forest importances are dominated by the minimum descriptors of the components (Q_{min}, $Q_{l,min}$, $Q_{s,min}$, $Q_{c,min}$), suggesting that the fitted model relies chiefly on the worst local point of the suspect region rather than on region-wide averages. This should be read descriptively and with care. Impurity-based importances are known to be biased toward continuous predictors and to distribute importance arbitrarily among correlated ones [14], and the 20 UIQI descriptors are strongly correlated by construction, since all four maps derive from the same local statistics and the five summaries of each map are functions of the same distribution. The ranking therefore describes one fitted model on this dataset; it does not establish that one radiographic sign is intrinsically more informative than another, and we draw no clinical conclusion from it. Permutation importance with grouped features, or a conditional importance scheme, would be needed for that.

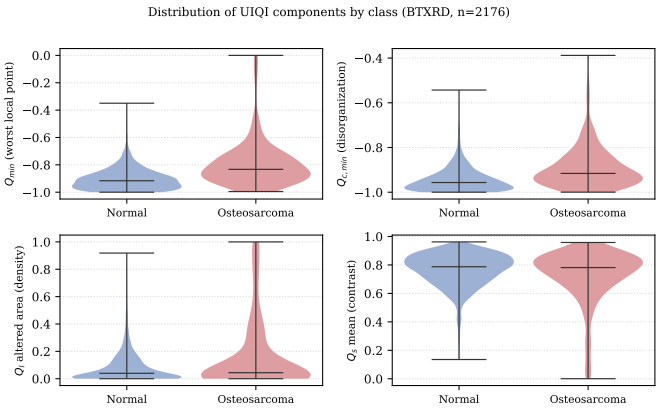

Fig. 4. Class-wise distributions of the UIQI component descriptors (BTXRD, $N = 2176$ radiographs; patient-level grouping unavailable): normal bone (blue) versus osteosarcoma (red).

VI. DISCUSSION

The framework studied here treats osteosarcoma radiographs as a structural-deviation problem and asks whether descriptors with explicit physical meaning retain discriminative signal. Two findings support an affirmative but bounded answer.

The first is methodological and, we argue, the more transferable. When the two classes follow distinct ROI-extraction paths, the resulting classifier attains an AUC-ROC of 0.981—a figure that would look publishable and is largely an artifact of the pipeline geometry. Equalizing the extraction operation across classes removes roughly 0.10 AUC-ROC and 0.30 F1. The confound is subtle because nothing in the code is

obviously wrong: it arises from the fact that positives and negatives are cropped by different rules. Any handcrafted pipeline that uses annotation-derived regions for one class and heuristic regions for the other is exposed to it, and we recommend that such pipelines report the symmetric-extraction control as a matter of course.

The second is that, under the corrected extraction, the UIQI descriptors still separate the classes with an AUC-ROC of about 0.87, rising to about 0.93 with classical texture and gradient descriptors. We interpret this as a localization-conditioned quantity. The lesion ROI for positives is placed from the reference annotation, so the number characterizes the descriptors given a correct region, not a system that must find the region first. A fully automatic pipeline would need a candidate-region detector applied identically to both classes, and its errors would compound with those measured here; the end-to-end figure would be lower, by an amount this study cannot estimate. For the same reason, we avoid the word screening for what is reported: nothing here has been evaluated as a triage instrument.

On interpretability, we deliberately weakened the claim relative to our initial framing. The decomposition of (2) is exact and its terms have unambiguous mathematical meaning; the step from those terms to named clinical phenomena is an inference we have not tested. Equating a low luminance term with osteolysis, or a low contrast term with cortical destruction, would require radiographs annotated per sign, so that one could check whether the component drops where the radiologist marks the sign and stays flat where they do not. That study is feasible with modest annotation effort and is, in our view, the single most valuable next step: it is what would convert a plausible mapping into a validated one, and it is also what would let the method offer per-sign output that a radiologist could audit. Until then, the honest description of the contribution is a compact, physically meaningful feature set with a hypothesis attached.

What remains genuinely favourable is computational cost. The pipeline runs on CPU-only commodity hardware, which matters for research groups and services without accelerators. This is a statement about resources, not about clinical readiness, and it does not offset the absence of external validation, reader comparison, and multiclass evaluation discussed next.

VII. Limitations

We group the limitations by the kind of claim each one restricts.

Task definition. The experiments cover only osteosarcoma versus radiographically normal bone. Benign tumors (1525 images in the source dataset) and non-osteosarcoma malignancies (45 images) were excluded, and these are precisely the categories that generate diagnostic difficulty in practice. The reported separability is therefore an upper bound with respect to the clinically relevant multiclass problem, and it is plausible that descriptors which distinguish osteosarcoma from normal bone perform substantially worse against an aggressive benign lesion or osteomyelitis.

Localization dependence. Lesion ROIs for positives derive from the reference segmentation. No detection stage exists, and the complete diagnostic pipeline was consequently not evaluated.

Reference-region validity. The mirrored intra-image reference assumes approximate symmetry that single-limb radiographs, rotation, and positioning variation frequently violate (Section III-E); large lesions may partly overlap their own reference. No per-image validity check was performed.

Data and partitioning. A single public dataset was used, with no external cohort from independent institutions and no evaluation across distinct acquisition protocols or patient populations. Partitions are at the image level because patient identifiers are unavailable, so same-patient leakage across folds cannot be excluded, and the cross-validation was run once rather than repeated with multiple seeds. With 297 positives, all estimates carry appreciable variance, as the intervals in Table IV show.

Modelling and evaluation. Predicted probabilities were not calibrated or assessed. The complementary descriptor block was not evaluated in isolation, so complementarity with the UIQI is not established. No comparison was made against explainable deep learning or vision transformers under a matched protocol, leaving the interpretability–performance trade-off uncharacterized. Feature importances are impurity-based and affected by correlation among descriptors.

Clinical validation. There is no reader study: the descriptors were not compared with radiologists' assessments, nor were they evaluated as decision support in any workflow. The hypothesized mapping of Table II has no sign-level ground truth behind it. Recall of about 0.68 in the best configuration would in any case be insufficient for autonomous use.

VIII. Future Work

The limitations above define a concrete agenda. (1) Sign-level validation: annotate a subset of radiographs for osteolysis, periosteal reaction, and cortical breach, and test whether each UIQI component responds selectively to its hypothesized sign. (2) Automatic candidate-region detection applied identically to both classes, enabling end-to-end evaluation and removing the localization conditioning. (3) Multiclass extension to benign and other malignant tumors, so that performance is measured against the real differential diagnosis. (4) External multi-center validation on cohorts from independent institutions, with repeated patient-level partitioning, calibration assessment, and confidence intervals derived from that setting. (5) Matched baselines: the texture and gradient block alone, and explainable convolutional and transformer models trained under the identical protocol, to characterize the interpretability–performance trade-off. (6) Prospective clinical evaluation with radiologist comparison, including reader-with-model studies. (7) Hybrid models using UIQI maps as interpretable priors or auxiliary channels.

IX. Conclusion

We presented an interpretable, low-cost digital-image-processing feature set for osteosarcoma radiographs, built

around the Universal Image Quality Index used as a structural-deviation descriptor between a suspect region and a mirrored intra-image reference. The decomposition into correlation, luminance, and contrast provides descriptors whose mathematical meaning is explicit, and we propose—as a hypothesis requiring sign-level annotation to test—that these components track trabecular and periosteal disorganization, density change, and cortical destruction. Under a symmetric ROI extraction that controls an extraction confound whose magnitude we quantify (about 0.10 AUC-ROC and 0.30 F1), the UIQI features separate osteosarcoma from normal bone with an AUC-ROC of 0.872 ± 0.020, and 0.931 ± 0.019 when combined with classical texture and gradient descriptors, under image-level five-fold cross-validation and conditioned on known lesion location. These results characterize a descriptor set and document a confound; they do not describe a triage system. Validation against expert sign-level annotations, an integrated detection stage, multiclass evaluation, and external multi-center testing are required before any clinical claim can be made.

ACKNOWLEDGMENT

The authors thank the creators and curators of the BTXRD dataset and acknowledge the support of the Federal University of Pernambuco (UFPE) and the Cancer Hospital of Pernambuco (HCP).

***Abstract*—Neste artigo, são propostas e avaliadas estratégias de decisão baseadas em janelas acumulativas e sua influência no desempenho de modelos de aprendizado de máquina na tarefa de detecção *online* de crises convulsivas. Para esse fim, são testados modelos autocodificadores (*autoencoders*), além de *One-Class SVM* e *Isolation Forest*. Para tanto, foi utilizada a estratégia de treinamento *Open Set* em conjunto com uma abordagem sequencial para emular o cenário *online*. Para a avaliação de desempenho, foram calculadas várias métricas, em especial a sensibilidade e a precisão. Os melhores desempenhos foram obtidos pelos modelos *autoencoders* usando janela acumulativa não causal.**

***Index Terms*—crises epilépticas; eletroencefalograma; detecção *online* de anomalias; janela de decisão.**

I. Introdução

Crises epilépticas são anomalias cerebrais que afetam o sistema nervoso de um indivíduo e fazem com que seus emissores de impulsos elétricos enviem sinais em excesso, provocando convulsões [1]. Esta patologia pode ser diagnosticada através de exames de EEG de escalpo em que eletrodos são colocados no couro cabeludo para capturar e gravar os sinais elétricos do cérebro. No entanto, a análise dos sinais de EEG por um profissional treinado consome muito tempo e pode, eventualmente, induzir a erros de diagnóstico. Por isso, a utilização de técnicas semiautomatizadas com o intuito de auxiliar esses profissionais na correta tomada de decisão é alvo de intensa pesquisa na área de Engenharia Biomédica [2].

Embora seja um tópico que vem sendo pesquisado há anos, percebe-se que grande parte dos trabalhos desenvolvidos visando o uso de técnicas de aprendizado de máquina para detecção de anomalias (*e.g.*, crises epilépticas) ou não abordam ou não dão a devida atenção a questões relacionadas ao uso mais próximo da prática clínica, principalmente o monitoramento em tempo real de pacientes em UTIs, em que um alerta imediato é crucial para a devida conduta médica [3].

Isto posto, neste trabalho investiga-se o desempenho de detectores de anomalias em sinais de EEG quando inseridos em cenários de treinamento sequencial do modelo e o seu subsequente teste em tempo real. Para tal cenário, destaca-se a forte correlação temporal dos dados adquiridos, em virtude da natureza contínua da atividade elétrica cerebral [4]. Tendo isso em mente, serão avaliadas diferentes técnicas de janelamento para tomada de decisão sequencial com o intuito de reduzir a quantidade de alarmes falsos na tarefa de detecção de anomalias em sinais de EEG.

O restante do artigo está organizado da seguinte forma: a Seção II trata dos modelos utilizados na tarefa de detecção de anomalias. A Seção III introduz as técnicas de janelamento de decisões propostas. A metodologia é apresentada na Seção IV, enquanto que os resultados são reportados na Seção V. O artigo é concluído na Seção VI.

II. Modelos de Detecção de Anomalias

Modelos **autocodificadores** são algoritmos de aprendizado utilizados na detecção de anomalias com base no erro de reconstrução dos vetores de atributos através de etapas de codificação e decodificação, conforme ilustrado na Figura 1. Tais detectores são treinados apenas com os vetores de atributos rotulados como negativos (EEG não convulsivo). O erro quadrático de reconstrução correspondente ao k-ésimo vetor de treinamento é dado por $e_k^2 = \|\mathbf{x}_k - \hat{\mathbf{x}}_k\|^2$, $k = 1, \ldots, N$ e $\|.\|$ denota a norma euclidiana do vetor diferença entre o vetor de atributos original $\mathbf{x}_k \in \mathbb{R}^{p\times 1}$ e o vetor reconstruído $\hat{\mathbf{x}}_k \in \mathbb{R}^{p\times 1}$.

Ao final do treinamento, uma etapa adicional usando os próprios dados de treino, mas sem ajuste de parâmetros, faz-se necessária a fim de computar o limiar de decisão L como o percentil $P\%$ dos erros quadráticos de reconstrução obtidos com dados de treino[1]. Sendo A_t a classificação da amostra t, onde os valores -1 e 1 correspondem, respectivamente, a amostras normais e anômalas, a seguinte regra de decisão pode ser usada para fins de detecção de anomalias nos sinais de EEG dos p canais:

$$A_t = \begin{cases} +1, & \text{se} \quad \|\mathbf{x}_{\text{teste}} - \hat{\mathbf{x}}_{\text{teste}}\|^2 > L \\ -1, & \text{caso contrário} \end{cases} \tag{1}$$

ou seja, $\|\mathbf{x}_{\text{teste}} - \hat{\mathbf{x}}_{\text{teste}}\|^2 \leq L$ indica que o vetor de atributos contém trechos não convulsivos dos canais de EEG.

À CAPES (finance code 001), ao CNPq (processo 313251/2023-1) e ao Centro de Referência em Inteligência Artificial - CEREIA, convênios 23067.055633/2021-19 (UFC) / 2020/09706-7 (FAPESP), pelo apoio financeiro.

[1]Isto equivale a encontrar um valor de L para o qual $P\%$ dos valores dos erros de reconstrução no treino estão abaixo desse valor.

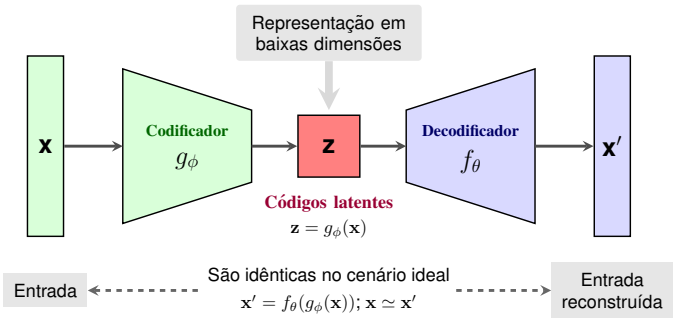

Fig. 1. Arquitetura geral de um modelo autocodificador. Adaptado de [5]. Código vetorial gerado com o auxílio de Inteligência Artificial (Gemini).

Neste artigo, avalia-se um modelo autocodificador linear (*linear autoencoder*, LAE) baseado em Análise de Componentes Principais (PCA) e modelos autocodificadores não lineares (*nonlinear autoencoders*, NLAE) implementados por redes *Multilayer Perceptron* (MLP) com 1 e 3 camadas ocultas.

O modelo ***One-Class Support Vector Machine*** (OCSVM) é uma variação de SVM desenvolvida para lidar com problemas de detecção de anomalias [6]. Seu funcionamento baseia-se na execução, por meio do truque do *kernel*, do produto interno de vetores em um espaço de Hilbert de reprodução [7]. A implementação deste modelo baseou-se na biblioteca `sklearn.svm`[2].

O modelo ***Isolation Forest*** (IF) baseia-se na premissa de que anomalias são observações raras e incomuns no conjunto de dados [8]. Tipicamente, conjuntos de dados de problemas de detecção de anomalias são bastante desbalanceados, contendo uma quantidade significativamente maior de instâncias negativas em relação às positivas (ou anômalas) [9]. A detecção de anomalias via IF é realizada por meio da construção de uma floresta de árvores de decisão onde subconjuntos destes dados são amostrados e particionados aleatoriamente. Instâncias que são isoladas com caminhos curtos nas árvores são mais propensas a serem classificadas como anômalas, enquanto observações negativas exigem mais partições para serem separadas. A aplicação do modelo IF nesta pesquisa fez uso da biblioteca `sklearn.ensemble`[3].

Por fim, também se fez uso de um ***ensemble*** **de modelos detectores** construído com os modelos anteriormente descritos. O comitê utilizou a estratégia de voto majoritário, levando em consideração a classificação realizada por cada modelo de maneira independente.

III. Estratégias de Janelamento da Decisão Propostas

Um dos grandes desafios na utilização de sinais de EEG para a tarefa de detecção de anomalias é a elevada quantidade de disparos errôneos em decorrência da natureza não estacionária e dos artefatos do exame [10]. Por este motivo, neste artigo são propostas e comparadas estratégias de decisão acumulativas dentro de uma janela de tempo a fim de diminuir a ocorrência de falsos positivos.

Janela Acumulativa Causal (JAC): Inspirado por [10], esta estratégia consiste em um pós-processamento baseado na contagem de decisões anômalas ocorrendo dentro de uma janela de comprimento K, mitigando a quantidade de alarmes falsos decorrentes de uma detecção incorreta isolada. Em vez de acionar a detecção de anomalia em um intervalo Δ_t, contam-se as anomalias ocorridas dentro de uma janela de tamanho $K \cdot \Delta_t$. A anomalia só é detectada quando a contagem de anomalias ao final da janela $K \cdot \Delta_t$ for igual a K. Matematicamente, esta regra de decisão é implementada como

$$\text{JAC}_t = \begin{cases} +1, & \text{se } \sum_{j=0}^{K-1} A_{t-j} = K, \\ -1, & \text{caso contrário.} \end{cases} \tag{2}$$

em que A_t está definida na Eq. (1).

Janela Acumulativa Não Causal (JANC): Também foi explorada a implantação de uma estratégia não causal inspirada em [11], porém adaptada para uso no pós-treino do modelo e com percentis. Seja $W = \{A_{t-K}, \ldots, A_{t+K}\}$ a janela móvel de decisões centralizada em A_t, assim o janelamento da decisão é implementado como $\text{JANC}_t = P_q(W)$ tal que $P_q(W)$ representa o percentil q dos valores da janela W. Logo, uma amostra será considerada anômala após a janela de decisão se $(100 - q)\%$ das amostras contidas na janela de comprimento $2K + 1$ também forem desse tipo.

Para viabilizar o uso da JANC em uma aplicação *online*, será empregado um *buffer* de comprimento $2K + 1$, de modo que JANC_t será calculado apenas após a classificação de A_{t+K}.[4] Ademais, serão realizados preenchimentos (*paddings*) de tamanho K e valor 0 no início e no fim do sinal de amostragem.

IV. Materiais e Métodos

O **conjunto de dados** utilizado neste trabalho pertence ao projeto *CHB-MIT Scalp EEG Dataset* [12] e consiste em gravações contínuas de EEG de escalpo, realizadas em 23 pacientes pediátricos no Hospital Infantil de Boston, Massachusetts, EUA, após a suspensão da medicação anticonvulsiva. Entre os pacientes, 6 são do sexo masculino, com idades variando de 3 a 22 anos, e 17 são do sexo feminino, com idades entre 1,5 e 19 anos. O conjunto de dados completo e descompactado corresponde a um total de 42,6 GB de dados. Todos os sinais foram gravados a uma taxa de amostragem de 256Hz, com 16 *bits* de resolução. Os arquivos contêm sinais oriundos de 23 canais de EEG, que foram gravados utilizando o sistema de posicionamento internacional de eletrodos 10-20. A Figura 2 mostra um exemplo de sinal de EEG capturado pelo canal 1 do paciente chb01, destacando os períodos antes (pré-ictal), durante (ictal) e após (pós-ictal) uma crise convulsiva.

Pré-Processamento e Extração de Atributos: Para este trabalho, visando viabilizar o tempo de processamento com-

[2]https://scikit-learn.org/stable/api/sklearn.svm.html

[3]https://scikit-learn.org/stable/modules/generated/sklearn.ensemble.IsolationForest.html

[4]Gerando um atraso de K amostras para o início da classificação final.

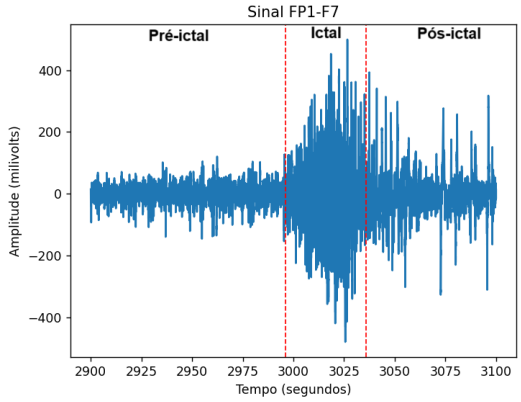

Fig. 2. Sinal extraído do canal 1 do paciente chb01.

putacional nesta etapa exploratória, foram utilizados os arquivos referentes às medições de EEG de um subconjunto de 6 pacientes (chb01, chb03, chb05, chb07, chb14 e chb18). Os arquivos destes pacientes passaram pela etapa de extração de atributos e foram criados novos arquivos com os respectivos rótulos. Os arquivos coletados possuem dimensões $p \times N$, onde p é o número de canais e N o número de amostras contidas no arquivo .edf. Então, são removidos todos os canais que possuam desvio padrão nulo, tendo em vista que estes possuem dados constantes que não auxiliam na detecção das convulsões. Após isso, os sinais são separados em épocas de duração $\Delta_t = 2$s, intervalo de tempo considerado mínimo para determinar se o paciente está ou não tendo uma crise convulsiva [13]. Consequentemente, a uma taxa de amostragem de 256Hz, em $\Delta_t = 2$s, são processadas 512 amostras.

Para cada segmento de duração $\Delta_t = 2$s, os atributos correspondentes a cada canal são extraídos a partir da estimação da densidade espectral de potência (*power spectral density*, PSD) média em 4 bandas de frequência, a saber: faixa Delta ($0,5$Hz $-$ 4Hz), faixa Teta (4Hz $-$ 8Hz), faixa Alfa (8Hz $-$ 12Hz) e faixa Beta (13Hz $-$ 30Hz). A PSD dessas faixas é estimada para cada canal, sendo todo o conjunto de $4p$ atributos agrupado em um único vetor [14]. O vetor gerado é, então, rotulado como positivo (anômalo), recebendo o rótulo numérico $y_t = +1$, se qualquer um dos p canais apresentar pelo menos 1 s de trechos convulsivos no atual intervalo $\Delta_t = 2$s; caso contrário, recebe rótulo negativo ($y_t = -1$). Os segmentos de duração $\Delta_t = 2$s não possuem superposição. Assim, para arquivos de 1 h de duração, são gerados 1800 ($3600/\Delta_t$) vetores de atributos, um por segmento de duração $\Delta_t = 2$s. Os atributos são, enfim, normalizados via *z-score*.

Configuração dos Modelos: Para a parametrização dos classificadores, o modelo autocodificador linear (LAE) foi implementado via PCA com preservação de 99% da variância dos dados originais. Para a definição do limiar de anomalia do modelo LAE, foi escolhido (após experimentação) o percentil 98% dos erros quadráticos de reconstrução obtidos com os dados de treino.

Nas arquiteturas NLAE, o número de neurônios da primeira camada oculta é definido como metade da dimensão do vetor de atributos (arredondado para cima), e as camadas subsequentes reduzem o tamanho da camada anterior pela metade até a camada central. Para as camadas decodificadoras, o tamanho da camada seguinte será o dobro do tamanho da camada atual, resultando num arranjo simétrico do modelo NLAE. O treinamento dos modelos utilizou a função de ativação sigmoide logística e o otimizador Adam com taxa de aprendizado adaptativa (*adaptive learning rate*). Para garantir a convergência e a reprodutibilidade, definiu-se um tamanho de lote (*batch size*) de 64 amostras, máximo de 1000 épocas de treinamento, tolerância de 10^{-5} e semente aleatória (*seed*) fixada em 42. Como técnica de regularização para mitigar o sobreajuste (*overfitting*), empregou-se a parada antecipada (*early stopping*). Assim como no caso do modelo LAE, foi adotado o percentil 98% para determinação do limiar de anomalia.

O modelo OCSVM foi configurado com *kernel* sigmoide e hiperparâmetros $\gamma = 0,01$ e $\nu = 0,1$. O modelo IF empregou os hiperparâmetros `contamination=0,01`, `max_samples=512` e `n_estimators=10`. Para ambos (OCSVM e IF), adotou-se uma adaptação na determinação do limiar: após o treino do modelo, calculou-se o percentil 98% do negativo das distâncias das instâncias ao hiperplano de separação (obtidas através da função *decision_function*), sendo este valor utilizado como limiar de anomalia durante a fase de testes (já que, originalmente, distâncias positivas representam instâncias negativas).

A **metodologia de treino/teste** dos modelos envolve a realização dos experimentos de maneira totalmente sequencial, emulando uma aplicação de uso dos detectores de anomalias em tempo real. Para tal, foi considerada a ordem temporal em que os sinais de EEG de cada paciente estão sendo coletados[5], sendo os modelos treinados com os primeiros N_{files} arquivos sequenciais de um dado paciente e testados com os seus arquivos subsequentes. Cabe ressaltar que a variável N_{files} diz respeito estritamente à quantidade de arquivos de registro (sessões contínuas de EEG) utilizados para o treinamento inicial, e não ao número de pacientes. O valor adequado de N_{files} foi alvo de experimentação e os resultados obtidos serão mostrados na Seção V. Por fim, os modelos são treinados com as primeiras amostras coletadas pelo equipamento e podem ser utilizados para detectar anomalias presentes nos demais sinais em tempo real. Além disso, durante o treinamento fez-se uso da estratégia *Open Set* conforme descrito por [15]. De acordo com esta estratégia, assume-se que todas as primeiras leituras do EEG sejam consideradas negativas, mesmo que algumas (poucas) instâncias positivas estejam presentes durante a fase de treinamento dos modelos detectores.

No tocante às **métricas de desempenho** utilizadas, foram destacadas a sensibilidade (*recall*, R), a precisão (P), a taxa

[5]Consideramos que o paciente está em ambiente de UTI e a coleta está sendo feita no leito onde o paciente se encontra.

TABLE I
RESULTADOS DOS TESTES INICIAIS COM O MODELO LAE.

Modelo	Recall (%)	Precisão (%)	F2-Score	$\mathbf{FAR_{24h}}$
LAE ($N_{\text{files}} = 1$)	98,84	1,36	6,46	7.278,91
LAE ($N_{\text{files}} = 2$)	96,51	2,34	10,67	4.099,01
LAE ($N_{\text{files}} = 3$)	91,45	3,27	14,32	2.431,24
LAE ($N_{\text{files}} = 4$)	90,58	3,48	15,06	2.054,83

de alarmes falsos (FAR) [12] e o F2-Score[6], uma vez que, em conjunto, essas métricas refletem o *trade-off* entre o desempenho do modelo e a frequência de detecções errôneas. Uma atenção especial deve ser atribuída à sensibilidade, uma vez que uma sensibilidade baixa indica que o modelo não está reconhecendo bem amostras positivas (anômalas), o que não é desejável em uma aplicação da área médica. As métricas FAR e F2-Score são definidas como

$$\text{FAR}_{24\text{h}} = \frac{FP \times 86400}{T} \quad \text{e} \quad \text{F2-Score} = \frac{5 \times P \times R}{4R + P}, \quad (3)$$

onde FP é o número de falsos positivos em T segundos.

V. RESULTADOS E DISCUSSÃO

Inicialmente, foram realizados testes com o modelo LAE e dados do paciente CHB01 a fim de investigar a influência do valor de N_{files}[7]. Os resultados desta investigação preliminar estão registrados na Tabela I. Os resultados mostram que o desempenho do modelo melhora à medida que se aumenta o número de arquivos utilizados no treino, o que é relativamente esperado. O importante é que este valor seja o menor possível; logo, não faz sentido avaliar valores de N_{files} maiores que 4. Assim, considerando que o ganho de desempenho ao se aumentar a quantidade de arquivos de 3 para 4 não foi tão grande quanto nos aumentos anteriores e tendo ainda em vista a importância da sensibilidade para o problema em questão, decidiu-se que $N_{\text{files}} = 4$ é o valor adequado para o treinamento dos detectores.

Prosseguiu-se, então, para o refinamento dos hiperparâmetros das técnicas de decisão acumulativas propostas. Para tal, fez-se uso novamente do modelo LAE com dados do paciente CHB01 para definir os tamanhos das janelas e percentis, avaliando-se os valores de $K \in [1, 10]$ para a JAC e as combinações de $K \in [1, 5]$ com $q \in \{25, 50, 75\}$ para a JANC. Os hiperparâmetros ótimos encontrados com o LAE foram então replicados para os demais modelos testados. Reconhece-se que a adoção dos parâmetros otimizados de um modelo linear (LAE) para as demais técnicas e considerando os dados de apenas um paciente constitui uma limitação metodológica do presente estudo, adotada com o intuito prático de reduzir o elevado custo computacional de uma busca exaustiva de hiperparâmetros para cada modelo individualmente. A Tabela II mostra alguns destaques dos resultados obtidos, onde JAC$-K$ representa a janela de decisão causal de tamanho K e JANC$-K/q$ denota a janela não causal de tamanho K e percentil q.

[6]O F2-Score foi escolhido por dar um peso maior à sensibilidade do que o F1-Score.

[7]Número de arquivos para treinamento do detector.

TABLE II
RESULTADOS DO REFINAMENTO DAS TÉCNICAS PROPOSTAS.

Técnica	Recall (%)	Precisão (%)	F2-Score	$\mathbf{FAR_{24h}}$
JAC-2	83,33	11,40	36,84	529,10
JAC-6	60,87	53,16	59,15	43,80
JANC$-3/25$	81,16	40,29	67,47	98,24
JANC$-5/25$	76,09	50,72	69,17	60,37
JANC$-5/50$	92,75	15,90	47,16	400,67
JANC$-5/75$	98,55	6,14	24,58	1.229,82

Os resultados mostram o potencial das decisões acumulativas sobre intervalos maiores em melhorar a precisão do modelo. Dentre os testes com a técnica JAC causal, destacaram-se a JAC-6, com o melhor F2-Score da categoria, e a JAC-2, sendo esta escolhida por ter proporcionado uma melhora considerável na precisão[8] mantendo um valor elevado para o *recall*. Já dentre as técnicas não causais, destacaram-se as janelas com $q = 25$ devido à melhora substancial na precisão, sendo escolhida a JANC$-3/25$ por ter obtido uma melhora considerável na precisão mantendo um *recall* elevado.

Após a definição dos hiperparâmetros, foi realizada uma comparação entre os modelos de detecção avaliados, sem e com a utilização das técnicas de decisão acumulativas propostas. As métricas finais desses experimentos encontram-se nas Tabelas III a V.

Os resultados indicam que modelos de detecção de anomalias que usam janelas de decisão acumulativas sequenciais obtêm bons resultados, sugerindo que seu uso em situações de detecção *online* pode ser viável. Dentre os modelos avaliados, o detector NLAE com 3 camadas ocultas foi o que apresentou um melhor desempenho, uma vez que obteve os maiores valores de *recall* enquanto consistentemente alcançava valores elevados de F2-Score. Além disso, os achados permitem inferir que a aplicação das estratégias propostas impactou positivamente na precisão dos modelos. Paralelamente, destaca-se uma diminuição significativa na quantidade de falsos positivos, alcançando até 96,7% de redução na $\text{FAR}_{24\text{h}}$ no paciente CHB01.

As métricas também demonstram que a tendência decorrente da adição dos filtros (melhora na precisão acompanhada de ligeira piora no *recall*) se mantém mesmo em outros pacientes. Em especial, destaca-se que os baixos valores observados nos resultados do paciente CHB14 sugerem que os modelos possuem mais dificuldades em detectar crises epiléticas nesse paciente, seja por conta de problemas na coleta ou devido a outras condições cerebrais adversas.

Dentre os pós-processamentos, a JANC destaca-se por proporcionar o ganho mais expressivo na precisão dos modelos, alcançando F2-Score de 80,67, precisão de 61,11% e $\text{FAR}_{24\text{h}}$ de 50,56. Contudo, o aumento na precisão impacta negativamente no *recall* do modelo, métrica essencial na área de saúde. Desse modo, ressalta-se a possibilidade de escolher e calibrar o modelo de acordo com as necessidades da aplicação. Do ponto de vista clínico, é imperativo discutir o impacto da latência introduzida pela técnica JANC. Como a estratégia

[8]A diferença de 8% na precisão representa uma redução de 2500 FPs.

necessita de um atraso de K épocas para fechar a janela de decisão centralizada, e sabendo que $\Delta_t = 2$s, um atraso de $K = 3$ resulta em uma latência adicional de 6s para a emissão do alerta. Em ambientes de UTI, um retardo de poucos segundos na detecção automática de uma crise é considerado amplamente aceitável frente ao ganho substancial na redução de falsos alarmes, fator crucial para mitigar o fenômeno de fadiga de alarme (*alarm fatigue*) na equipe médica.

Nessa perspectiva, foram esboçadas curvas *Precision-Recall* [16] para ilustrar o *trade-off* entre tais métricas e analisar os principais pontos de operação dos modelos utilizados. A Figura 3 mostra algumas curvas de destaque nos resultados obtidos para o paciente CHB01. A Figura 3(a) mostra a curva para o modelo NLAE com 3 camadas ocultas, esboçando uma queda brusca na precisão do modelo após uma pequena redução no limiar de anomalia, de modo que a precisão só atinge valores consideráveis quando o *recall* apresenta as menores taxas. Já as Figuras 3(b) e 3(c) revelam que a adição do janelamento acumulativo das decisões torna essas curvas bem mais expressivas, de maneira que se torna viável uma análise de otimização sobre a escolha do limiar de anomalia a fim de encontrar um equilíbrio desejável entre as métricas. Vale salientar que o ponto destacado nas imagens se refere ao limiar sob o qual o modelo apresenta o melhor valor de F2-Score, podendo ser escolhidos diferentes pontos de operação dependendo do contexto de aplicação.

Na sequência, a Figura 4 mostra uma comparação entre as curvas de outros modelos utilizados sobre os dados do paciente CHB01, ressaltando o melhor desempenho do modelo NLAE-3.

VI. CONCLUSÕES

Neste trabalho, foram propostas e avaliadas duas estratégias de decisão baseadas em janelas de decisão acumulativas e sua influência no desempenho de modelos de aprendizado de máquina na tarefa de detecção *online* de crises convulsivas em sinais de EEG. Para este fim, foram avaliados modelos autocodificadores, OCSVM e IF. Foi utilizada também a estratégia de treinamento *Open Set* em conjunção com uma abordagem sequencial para emular o treino e teste *online* dos modelos. Os melhores desempenhos foram verificados para o autocodificador não linear com 3 camadas ocultas usando estratégia cumulativa não causal, sendo proposta a utilização de um *buffer* para viabilizar o uso *online* da técnica proposta. Algumas limitações do trabalho devem ser destacadas, como a não utilização de modelos mais complexos de aprendizado de máquina e a subotimização de hiperparâmetros decorrente do uso de apenas um modelo sobre os dados de um único paciente para sua definição. Desse modo, propõe-se a realização de trabalhos futuros com o intuito de realizar experimentos utilizando uma maior diversidade de modelos, bem como processos de otimização de hiperparâmetros mais complexos, a fim de verificar as mudanças nos resultados obtidos com tais abordagens. Como conclusão geral, pode-se afirmar que os resultados obtidos foram promissores, verificando-se como viável o uso dos modelos autocodificadores avaliados para detecção *online* de anomalias em sinais de EEG.

***Abstract*—The exercise stress test is routinely used for the diagnosis of cardiac conditions, including ischemia and arrhythmias. During the test, blood pressure is commonly measured using the manual auscultatory method, which is susceptible to motion artifacts and background noise. Previous studies have shown that noise can impair Korotkoff sound detection and BP measurement accuracy. However, no database of Korotkoff sounds under treadmill noise is currently available. Therefore, this study proposes a synthetic database of Korotkoff sounds contaminated with treadmill noise and compares different filtering techniques, including neural network based and deterministic methods. Their effectiveness is evaluated based on their ability to recover Korotkoff sounds and restore the performance of an established automatic BP detection algorithm under noisy conditions.**

***Index Terms*—Blood pressure, Korotkoff sounds, noise filtering, automatic methods, exercise stress test.**

I. Introduction

Blood pressure (BP) is one of the main physiological indicators used to assess early cardiovascular risk, and it is crucial for preventing serious complications such as myocardial infarction and stroke [1] , [2]. During stress test, this measure is crucial for monitoring the cardiovascular response to exercise, identifying abnormal BP patterns, and detecting potential signs of ischemia, hypertension, or hemodynamic instability that may not be evident at rest [3] , [4].

Traditionally, BP can be measured using different techniques. The intra-arterial method is considered the gold standard for BP measurement, as it is highly accurate and can provide continuous monitoring. However, because it is an invasive procedure, requiring the insertion of a catheter into an artery, it is impractical in most clinical situations, including during stress tests, and is, therefore, limited to specific hospital settings [1] , [2].

The oscillometric method, widely used in automatic devices, estimates BP from oscillations generated by the brachial artery under cuff compression. However, despite its widespread use under rest conditions, the oscillometric method is generally not recommended for BP measurement during exercise according to major guidelines [5], [6].

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior — Brasil (CAPES) — Finance Code 001.

In contrast, the auscultatory method is considered a clinical reference for BP measurement and can be regarded as a practical gold-standard method in clinical stress tests settings, given the complexity and invasiveness of the intra-arterial approach [1] , [2], [5] . Auscultation is based on the detection of Korotkoff sounds (KS) during cuff deflation by a trained professional, preferably a physician according to medical stress test guidelines [6] .

During gradual cuff deflation, the re-establishment of arterial blood flow produces a characteristic sequence of five Korotkoff phases (I-V): appearance, softening, sharpening, muffling, and disappearance of the sounds. Phase I, marked by the first clear tapping sounds, is conventionally associated with systolic blood pressure (SBP), whereas phase V, defined by complete sound disappearance, is usually associated with diastolic blood pressure (DBP) [1] , [2]. Nevertheless, there is still divergence regarding the definition of DBP, particularly as to whether it should be determined from the muffling of Korotkoff sounds in phase IV or from their complete disappearance in phase V [7], [8], [9].

Hence, despite the importance of the auscultatory method in clinical practice, manual detection of KS is highly vulnerable to operator-dependent factors, even under standard resting clinical conditions. For instance, the auscultatory gap, a transient disappearance of KS during cuff deflation [1], is commonly observed, especially in hypertensive patients, which may lead to underestimation of SBP [10]. In addition, DBP measurement can be particularly challenging due to the attenuation of phase IV KS and the onset of phase V that may be difficult to identify in some patients. In some cases, KS may persist down to very low cuff pressures, or even until 0 mmHg, making the disappearance of blood flow sounds an unreliable marker for DBP estimation [1], [4], [6].

Other studies, have reported that background noise can interfere with the accuracy of BP estimation due to psychoacoustic masking [11]. This challenge is further amplified in exercise stress test, where motion artifacts, footsteps, and treadmill noise can overlap with the frequency and temporal characteristics of KS, making their accurate detection and BP estimation substantially more difficult [3], [4].

In this context, there is growing interest in the development of automatic BP measurement methods that provide greater

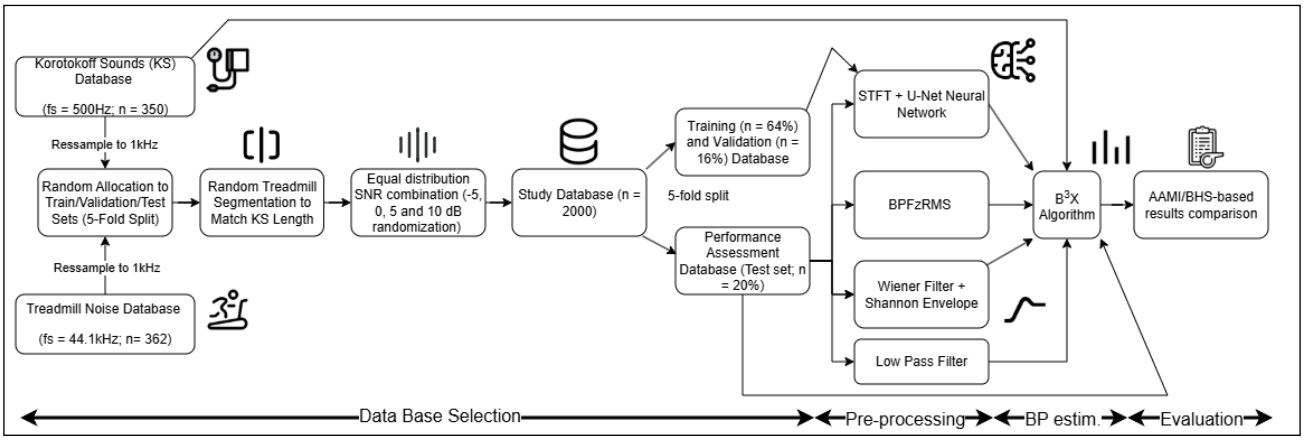

Fig. 1. Methodology overview diagram. The pseudo-algorithm, detailed throughout the Methodology section, summarizes the data selection process for method testing, the preprocessing techniques evaluated in this study, and the assessment of the B³X blood pressure estimation algorithm according to medical standards.

accuracy and clinical safety while facilitating repeated measurements. One example of a promising automatic auscultatory algorithms is the B³X proposed by [12]. Based on the literature review conducted in this work, no studies have evaluated the B³X method under exercise stress test protocols. In this scenario, ensuring robust noise suppression becomes essential not only for B³X but also for any automatic auscultatory BP measurement algorithm [3], [10]. Indeed, one of the main challenges involving auscultatory methods in stress testing lies in separating KS from possible exercise-related noise [4], [13].

II. Objective

The objective of this work is to evaluate different preprocessing filtering techiniques for Korotkoff sounds artificially contaminated with treadmill running noise. The effectiveness of these techniques will be evaluated based on the improvement in the measurement accuracy of both SBP and DBP obtained by B³X algorithm.

III. Methodology

A. Methodological Overview

Fig. 1 presents an overview of the main steps covered throughout this section. The diagram highlights the construction of the study dataset, the preprocessing and corruption of KS signals with treadmill noise, the application of the proposed filtering methods, and the subsequent performance evaluation based on automatic BP estimation and relevant clinical standards.

B. Dataset

Public access databases containing KS are scarce in scientific literature [14]. When considering the context of exercise stress testing, their availability becomes even more limited. Although no databases dedicated to KS recorded during exercise testing were found, it is possible to preliminary combine data from databases containing KS measured at rest with audio recordings of treadmill exercise sounds.

For KS, one of the main reference databases in the literature is the "Auscultatory and Oscillometry BP Data" [15]. This dataset contains 350 records of non-invasive BP measurements, sampled at 500 Hz, collected from human volunteers in a controlled environment, following the recommendations of the ANSI/AAMI SP10 standard. Although participant profiles were not provided in the official database access [15], several studies report the demographic variability of this dataset summarized in Table I , [12], [16], [17], [18]. It should be noted that the 350 recordings were not labeled according to participant identity. Therefore, due to the lack of subject-level information, the recordings were treated as independent and uncorrelated. Each sample consists of audio signals containing KS, the cuff pressure curve throughout the deflation process, expressed in mmHg, the oscillometric signal associated with arterial oscillations, and reference SBP and DBP values. Hereafter, this dataset will be referred to as KS Database.

TABLE I
Demographic and blood pressure characteristics of the KS Database [18].

Parameter	Value
Recordings	350
Participants	155
Male	87 (56.1%)
Female	68 (43.9%)
Age	52.0 ± 21.6 years (23–97)
Age (male)	51.1 ± 20.3 years
Age (female)	53.1 ± 23.4 years
Arm circumference	10–35 cm
Systolic blood pressure	81–191 mmHg
Diastolic blood pressure	37–104 mmHg
Mean arterial pressure	56–118 mmHg

For noise sounds of individuals exercising on treadmills, a recent study [19] consolidated a database containing 40 hours of audio, divided into 363 recordings acquired under different speeds, runners, and gym environments. This dataset was originally recorded with a sample rate of 44.1 kHz. Although this database does not contain treadmill exercise

sounds recorded in clinical settings, its data may serve as an initial approximation for testing noise immunity in the proposed model. Hereafter, this dataset will be referred to as Noise Database or Treadmill Database.

C. 2000 Samples Generation

A database containing 2,000 artificially contaminated KS recordings was generated (this dataset will be referred to as Study Database) with the combination of the two databases previously mentioned in Section III-B. First, all signals were resampled to 1 kHz, since most Korotkoff sound spectral content lies below 250 Hz [11]. Second, treadmill noise recordings were randomly segmented into non-overlapping parts to match the duration of each KS recording. Afterwards, DC offsets were removed from both KS and treadmill noise signals, which were then independently normalized to a common RMS level. The normalized signals were subsequently mixed at controlled SNR levels of -5, 0, 5 and 10 dB and balanced across the generated dataset. Similar amplitude normalization has been applied to phonocardiogram (PCG) signals [20], [21], which share similar acoustic characteristics with KS [7], [22].

For the selection of samples in the Study Database, KS and treadmill recordings, noise segments and SNR levels were randomly selected using independent random generators with fixed seeds to ensure reproducibility. Each KS-treadmill recording pair was used only once to avoid duplication regardless of the SNR or noise segment. However, the same KS recording could be combined with multiple treadmill recordings to increase noise variability and reduce artificial correlations between a singular KS to a singular treadmill sample.

Since one denoising method relies on a neural network baseline (U-net), the study dataset, composed of 2,000 samples, was divided using a group-based 5-fold cross-validation procedure. In each fold, approximately 64% of the samples were assigned to the training subset, 16% to the validation subset, and 20% to the test subset. Because individual KS and treadmill samples were randomly assigned to a specific subset before the database synthesis, no data leakage occurred between subsets. To ensure comparability among all evaluated methods, the remaining methodologies were assessed using the corresponding test subset of each U-Net fold.

D. Noise and Korotkoff signal characterization

To evaluate the ability of the filtering methods to restore the performance of the B³X algorithm under noisy conditions, it is important to characterize both the KS and noise profiles.

An example of a noise segment, a clean KS sample, and a corrupted KS signal with added noise $SNR = 1.0$ dB is shown using a mel-spectrogram representation in Fig. 2. The same samples are also presented in a normalized frequency spectrum in Fig. 2. For bandwidth comparison, all signals were resampled to 1 kHz, since this sampling rate was adopted in the generation of the study dataset.

In the Mel spectrogram, the KS sample exhibits quasi-periodic pulsatile events, with most of its energy concentrated below 50 Hz during silent intervals and transient components extending up to approximately 200 Hz over short time frames. A similar pulsatile pattern is also present in the treadmill noise sample, although its energy is more broadly distributed across the time-frequency domain and presents rapidly varying temporal patterns. As a result, in the noisy KS signal, the treadmill noise masks much of the KS high-frequency content, while the low-frequency pulsatile components remain faintly visible. Indeed, the normalized frequency spectrum clarifies the bandwidth of both KS and noise signals, showing that most of the KS energy is concentrated below 100 Hz, whereas the noise is more prominent between 80 Hz and 450 Hz.

E. Korotoff sounds filtering methods

In this paper, several approaches that were not originally designed to address the noise conditions encountered during exercise stress testing are evaluated according to their ability to preserve the accuracy of automatic BP detection of B³X: Fourth-order 70-Hz Butterworth low-pass filter, Wiener filtering followed by a Shannon envelope [23], band-pass filtering combined with z-score normalization and RMS envelope weighting [18], hereafter referred to as BPFzRMS, and a convolutional U-Net neural network [24].

1) Wiener Filtering and Shannon Envelope: A preprocessing method based on Wiener filtering followed by a Shannon envelope has been proposed to filter KS signals [23]. For Wiener filtering [25], the corrupted signal ($x[n]$) is considered as the sum of the KS ($s[n]$) and a noise component ($w[n]$):

$$x[n] = s[n] + w[n] \tag{1}$$

Assuming that the KS itself is uncorrelated with environmental and patient movement noise, the autocorrelation of the estimated KS signal ($\hat{s}[n]$) is given by:

$$\mathbf{R}_{\hat{s}\hat{s}} = \mathbf{R}_{xx} - \mathbf{R}_{\hat{w}\hat{w}} \tag{2}$$

where $\mathbf{R}_{\hat{w}\hat{w}}$ is the autocorrelation matrix of the estimated noise component, obtained from the first second of the corrupted signal. The coefficients of the Wiener FIR filter, $h[n]$, are obtained by solving the following system of linear equations:

$$\begin{bmatrix} r_{xx}[0] & r_{xx}[1] & \cdots & r_{xx}[M-1] \\ r_{xx}[1] & r_{xx}[0] & \cdots & r_{xx}[M-2] \\ \vdots & \vdots & \ddots & \vdots \\ r_{xx}[M-1] & r_{xx}[M-2] & \cdots & r_{xx}[0] \end{bmatrix} \begin{bmatrix} h[0] \\ h[1] \\ \vdots \\ h[M-1] \end{bmatrix} = \begin{bmatrix} r_{\hat{s}\hat{s}}[0] \\ r_{\hat{s}\hat{s}}[1] \\ \vdots \\ r_{\hat{s}\hat{s}}[M-1] \end{bmatrix} \tag{3}$$

Once $h[n]$ is obtained, the estimated KS signal is given by:

$$\hat{s}[n] = h[n] * x[n] \tag{4}$$

where $(*)$ denotes the convolution operator.

The filter length was defined as $M = 0.25\%$ of the Korotkoff signal length, following the procedure adopted in [23]. To avoid excessively long filters and preserve the local temporal characteristics of the KS, M was limited to a maximum duration of 80 ms. In this study, the filter was estimated and applied to the entire signal, without window-based segmentation or temporal overlap [21].

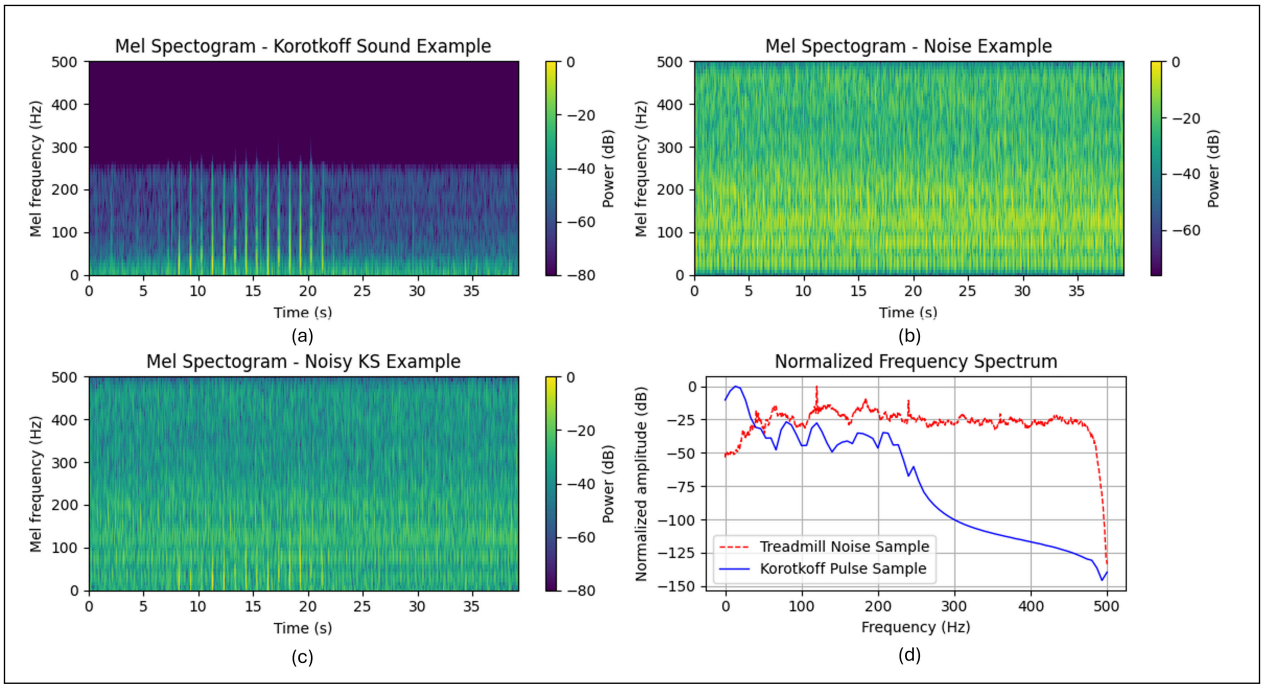

Fig. 2. Korotkoff sound and treadmill noise mel spectrograms. (a) Mel spectrogram of a KS sample (b) Mel spectrogram of a treadmill noise sample (c) Mel spectrogram of the noisy KS signal (d) Normalized frequency spectra of the same KS and noise samples.

For the Shannon envelope, the Korotkoff signal was processed using the Shannon energy envelope, defined as:

$$E[n] = -\frac{1}{N_w}\sum_{i=0}^{N_w-1} z_i^2[n]\log\left(z_i^2[n]\right) \tag{5}$$

where $z_i[n]$ is given by:

$$z_i[n] = \frac{\hat{s}_i[n]}{max|\hat{s}_i[n]|} \tag{6}$$

with the Shannon energy computed using 40 ms windows and 50% overlap. Then, E was normalized using z-score normalization:

$$P[n] = \frac{E[n] - \mu_E}{\sigma_E} \tag{7}$$

Up to this point, the procedure followed the concepts described by [23], [25]. Subsequently, the resulting vector was then used as a mask applied to the original Korotkoff signal:

$$y[n] = (1-\alpha)\hat{s}[n] + \alpha(P[n]\hat{s}[n]) \tag{8}$$

with $\alpha = 0.3$.

2) Band-Pass Filtering Combined with Z-Score Normalization and RMS Envelope Weighting (BPFzRMS): In the present study, isolated high-amplitude artifacts from KS were suppressed. Detected peaks from the absolute KS signal that exceeded twice the amplitude of the second largest peak were zeroed in a ±500 ms window around it. Additionally, boundary peaks located within the first or last 100 ms of the signal were zeroed if they corresponded to the most prominent peak within a 500 ms window. The resulting signal was then filtered using a 20–250 Hz band-pass filter. The method follows with the computation of the RMS energy envelope using a zero-phase moving average filter with a Hamming window [18]:

$$p[n] = x_{\text{filt}}^2[n] \tag{9}$$

$$RMS[n] = \sqrt{\sum_{m=0}^{N_w-1} w[m]p[n-m]} \tag{10}$$

Afterwards, the Korotkoff signals were standardized using z-score normalization, while the RMS envelope was normalized between 0 and 1 in order to preserve regions with higher energy and attenuate regions with lower energy:

$$x_{\text{norm}}[n] = \frac{x_{\text{filt}} - \mu_x}{\sigma_x} \tag{11}$$

$$RMS_{\text{norm}}[n] = \frac{RMS[n] - RMS_{\text{min}}}{RMS_{\text{max}} - RMS_{\text{min}}} \tag{12}$$

Finally, the resulting signal was then weighed by the normalized RMS envelope, so that regions with higher RMS energy were preserved while lower-energy regions were attenuated:

$$g[n] = 0.25 + 0.75RMS_{\text{norm}}[n] \tag{13}$$

$$y[n] = x_{\text{norm}}[n]g[n] \tag{14}$$

3) STFT + U-Net convolutional neural network: Finally, a convolutional U-Net has been proposed for processing phonocardiogram (PCG) signals, i.e., signals that acoustically represent the closure of cardiac valves [24]. Although they are different, KS and PCG signals share similar acoustic

TABLE II
BRITISH HYPERTENSION SOCIETY (BHS) CLASSIFICATION CRITERIA.

Classification	$\lvert Error \rvert$ ≤ 5 mmHg	$\lvert Error \rvert$ ≤ 10 mmHg	$\lvert Error \rvert$ ≤ 15 mmHg
A	$\geq 60\%$	$\geq 85\%$	$\geq 95\%$
B	$\geq 50\%$	$\geq 75\%$	$\geq 90\%$
C	$\geq 40\%$	$\geq 65\%$	$\geq 85\%$
D	$< 40\%$	$< 65\%$	$< 85\%$

characteristics, and this methodology could therefore be tested in this context [7], [22]. This is the only method among those previously described that involves machine learning in the context of noise reduction.

The proposed approach consists of segmenting the signal into 1.5 s frames, computing the short-time Fourier transform (STFT) using an FFT length of 128 and a Hann window with 50% overlap, and separating the transform into real and imaginary channels. The resulting representation is then resized to $(2, 64, 64)$ and used as input to a U-Net for noise reduction [24]. In this study, the proposed architecture was implemented in PyTorch and adapted to process KS signals instead of PCG signals. Unlike the original study, the network was trained for up to 150 epochs with an early-stopping patience of 20 epochs, as well as a learning rate of 0.001.

F. Evaluation Metrics

The Brazilian Guidelines for Exercise Testing do not establish a BP measurement precision and accuracy criteria for automatic devices in clinical exercise testing [6]. Moreover, this lack of standardization is also evident in studies conducted in different international settings [13], [26], [27] that evaluated automated devices for BP measurement during stress testing. In the absence of specific standardized criteria for exercise conditions, these studies resorted to criteria originally established for BP measurement under resting conditions, such as those proposed by the Association for the Advancement of Medical Instrumentation (AAMI) [28] and the British Hypertension Society (BHS) [29]. Thus, this study compared B³X performance across the different preprocessing approaches using the validation criteria established by these organizations.

In 2018, AAMI, ESH, and ISO experts proposed a universal protocol for BP device validation [30]. The consensus retained the ANSI/AAMI/ISO 81060-2 limits of a mean error within ± 5 mmHg and an SD ≤ 8 mmHg for both SBP and DBP, while also considering at least 85% of errors within 10 mmHg acceptable [28], [30]. In contrast, the BHS protocol grades performance from A to D according to the percentage of absolute errors within 5, 10, and 15 mmHg, with all thresholds of a given grade required to be satisfied (Table II) [29].

The AAMI/ESH/ISO protocol also requires a minimum of 85 participants, with a specified distribution across BP ranges, to ensure that the validation sample adequately represents the intended population [30]. As mentioned in Section III-C, the database used in this work satisfies the minimum sample-size requirement. Nonetheless, because the KS database does not provide subject-level labels, only the BP error criteria of these standards were considered (despite previous recommendations emphasizing the importance of population-related requirements for proper validation [31]). Additionally, the use of AAMI and BHS error thresholds alone as performance benchmarks has also been adopted in BP estimation studies [32].

IV. RESULTS

A. Computational Cost

The proposed methodology was conducted on a virtual machine (VM) hosted in Google Colab equipped with a 2.20 GHz Intel(R) Xeon(R) CPU with 12 cores, 167.1 GB of RAM, and an NVIDIA A100-SXM4 GPU with 80 GB of VRAM. All code was developed in Python, with the U-Net architecture and training procedures implemented using the PyTorch framework. The U-Net training took 34 minutes in total, averaging 6.8 ± 1.3 minutes per fold, with 0.38 GB peak GPU memory usage and 0.57 GPU-hours. Each fold used the same 487,226-parameter architecture, which is relatively compact and could potentially be deployed on low to mid-complexity embedded systems after being trained beforehand and used only for inference.

Finally, the mean inference time of each method was measured across all five test folds, including both the filtering procedure and the subsequent B³X BP estimation. Table III summarizes the corresponding computational results.

TABLE III
MEAN INFERENCE COMPUTATIONAL COST ($n = 2000$)

Method	**Mean Inference Time per sample (ms)**
Clean Samples	5.96
Noisy Samples	5.97
Low-pass filter	7.91
Wiener + Shannon	30.58
BPFzRMS	24.25
U-Net	36.30

The low-pass filter achieved the shortest inference time, while all methods remained fast relative to practical BP measurement. The U-Net was the slowest, although its inference time was close to Wiener + Shannon. BPFzRMS was the second fastest, despite increasing the overall B³X estimation time by approximately four times.

B. Performance of the B³X Algorithm in a Noise Context

Initially, the performance of the B³X algorithm was evaluated without any preprocessing filter, in order to assess the robustness of the algorithm to the noise profile proposed. Fig. 3 shows the correlation and Bland-Altman plots comparing the reference and estimated SBP and DBP values. These plots include all samples from the test subsets of the five-fold cross-validation described in Section III-C.

SBP estimation yielded a linear regression of $y = 0.833x + 28.93$, with an R^2 of 0.403, whereas DBP yielded $y = 0.609x + 17.62$, with an R^2 of 0.214. These results indicate limited correlation, influenced by low-SNR samples.

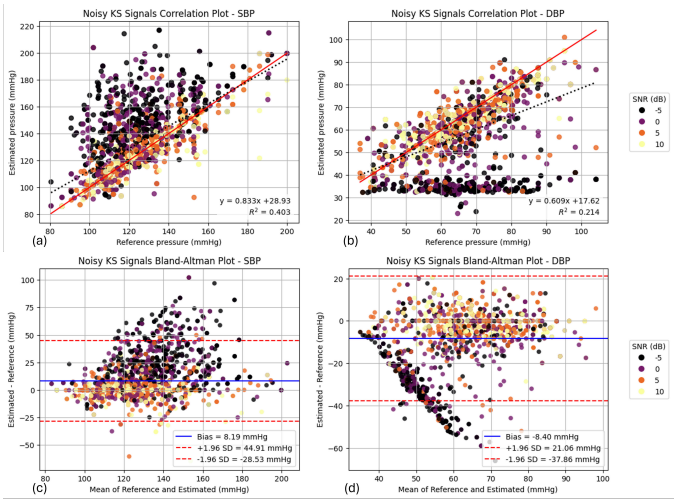

Fig. 3. Correlation plots of B³X-estimated values for (a) SBP and (b) DBP, and Bland–Altman plots for (c) SBP and (d) DBP.

Bland–Altman analysis showed a bias of 8.19 mmHg for SBP, with limits of agreement from -28.53 to 44.91 mmHg, and a bias of -8.40 mmHg for DBP, with limits of agreement from -37.86 to 21.06 mmHg.

The results indicate a lack of robustness of the algorithm to noise, especially at low SNR levels. Although high-SNR samples still show a moderate correlation with the reference values in Fig. 3, low-SNR samples show unacceptable overestimation of SBP and underestimation of DBP according to the AAMI/ESH/ISO criteria. Fig. 4 also highlights the deterioration in algorithm performance as SNR decreases across all five folds. In addition, higher BP values, for both SBP and DBP, were associated with greater estimation errors, regardless of the SNR level.

Table IV shows that B³X meet the AAMI criteria and achieve a BHS grade A classification. However, when applied to noisy KS signals without preprocessing, the B³X algorithm failed to comply with the AAMI requirements under both noise conditions, although it achieved a BHS grade B classification for SNR > 0 dB.

C. BP Estimation Performance Through Filtering Methods

The results presented in Table IV summarize the performance of each preprocessing method across the five folds, reported as the mean $\pm$ standard deviation across folds. The results are stratified by SNR levels of ≤ 0 dB and > 0 dB. Noise-free KS, noisy KS without preprocessing, and each filtering technique are compared according to the corresponding AAMI and BHS validation criteria.

When corrupted KS were filtered, improvements were observed in all evaluated methods, particularly under higher-noise conditions (SNR $\leq$ 0 dB), while gains were more modest under lower-noise conditions (SNR $>$ 0 dB). Both the low-pass filter and BPFzRMS achieved classifications similar to those of the noisy samples. Nevertheless, the low-pass filter enhanced all metrics and achieved a BHS grade B classification for DBP under low-noise conditions. Although BPFzRMS provided greater improvements, particularly at low SNR, it was the only method to yield a worse classification than the noisy samples in one scenario (grade C for SBP at SNR > 0 dB).

Among the evaluated methods, the U-Net achieved the best overall performance for noise suppression in KS signals, meeting the AAMI criteria for both SBP and DBP and being the only method to achieve BHS grade A, although only for SBP under high-SNR conditions. Fig. 4 supports the U-Net results in the AAMI/ESH/ISO $\leq$ 10 mmHg error criterion across all SNR levels, although greater fold-to-fold variability is observed at lower SNRs.

At last, Wiener + Shannon accomplished competitive results to those of the U-Net in DBP, meeting the AAMI criteria for both DBP in both SNR levels and achieving BHS grade B for DBP and for SBP under SNR > 0 dB conditions (despite achieving only grade C for SBP at SNR ≤ 0 dB).

V. Discussion

Across all evaluated methods, performance was consistently better for DBP estimation than for SBP estimation. This difference may be related to the intrinsic characteristics of B³X estimation method, which shows strong effectiveness for DBP estimation, particularly when compared with other BP estimation methods reported in the literature [12]. Indeed, because all filtering methods were evaluated using the same BP estimation algorithm, their measured capability is inherently bounded by the estimation accuracy of B³X.

Fig. 4 shows improved results and reduced fold-to-fold variability with increasing SNR for both SBP and DBP, particularly in the ≤ 10 mmHg metric. This trend may reflect the relative robustness of B³X to noisy samples, although its performance at low SNR remained insufficient to meet the AAMI criteria. Despite the improvements in BP estimation achieved through KS noise filtering, it should be noted that B³X also relies on the oscillometric signal as a complementary input. Under real stress-testing conditions, motion artifacts may degrade not only the KS signal but also the oscillometric signal, potentially reducing the overall performance of the algorithm. Therefore, the apparent robustness of the evaluated methods at low SNR levels may be overestimated when compared with real exercise conditions.

Finally, most methods showed limited improvement under high-noise conditions, particularly for SBP estimation, for which only the U-Net met the AAMI criteria. As discussed in Section IV-A, inference times were sufficiently low for the intended application across methods. Considering its favorable balance among computational cost, relatively compact model size, and results, the U-Net represents a promising preprocessing approach for KS noise filtering to support BP estimation during stress testing. Overall, it achieved the best performance among the evaluated methods, despite not reaching BHS grade A in all scenarios.

TABLE IV

PERFORMANCE COMPARISON GROUPED BY PRESSURE TYPE AND SNR LEVEL.

ME and SD are reported in mmHg. The remaining values (≤ 5, ≤ 10, and ≤ 15) represent mmHg percentages.

SBP, SNR ≤ 0 dB ($n = 1000$)

Model	ME	SD	≤ 5	≤ 10	≤ 15	AAMI	BHS
Clean samples	-1.45 ± 0.85	6.06 ± 0.42	72.50 ± 6.33	91.37 ± 2.44	95.69 ± 1.17	Pass	A

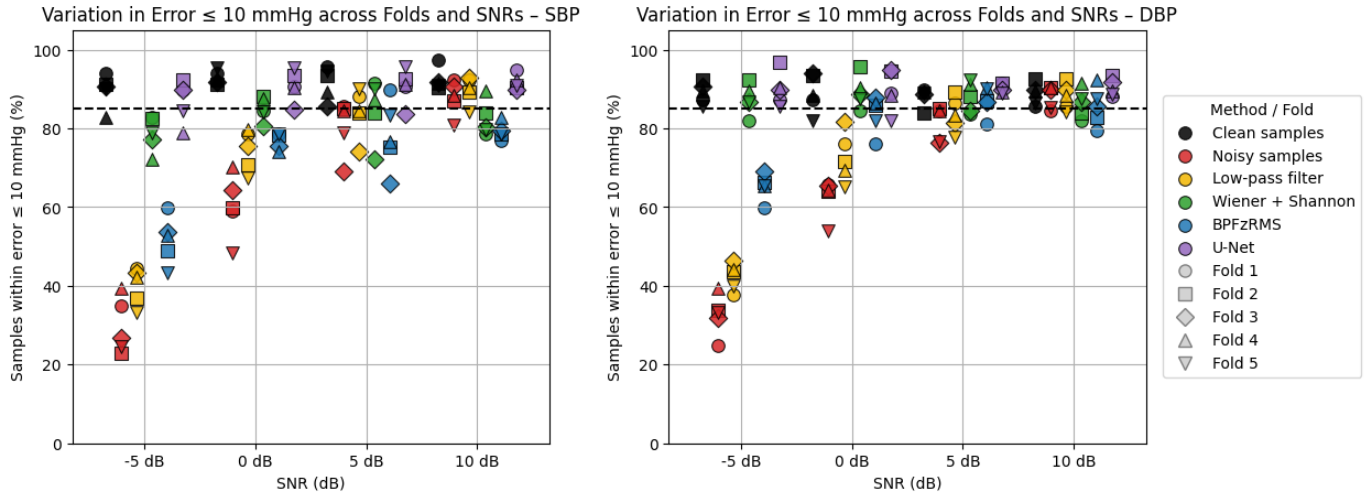

Fig. 4. Variation in the percentage of errors ≤ 10 mmHg across folds and SNR levels for (a) SBP and (b) DBP. The dashed line indicates the 85% threshold considered acceptable according to ANSI/AAMI/ISO.

A. Limitations and Future Work

Despite the promising results on noise filtering for BP detection, this study presents relevant limitations that could be overcome in future work.

First, as mentioned in Subsection III-C, it is important to reinforce the absence, as far as this study could find in the literature, of an available KS signals database in treadmill stress tests or functional assessment protocols. The proposed Study Database is a synthesized database designed to simulate noise conditions BP measurements during exercise. It should be noted that the noise profile of real measurements may present acoustic differences, such as cuff and microphone rubbing against the patient's arm, in addition to treadmill footstep noise captured from a microphone position different from that used in the Noise Database.

Second, since the reference for the KS Database does not relate samples to patient profiles (i.e. age, sex, health condition, etc), future work should rely on a dedicated stress test database with different patient profiles, including KS signals, cuff pressure curves, linkage between each sample and the corresponding de-identified patient profile, and ground truth SBP and DBP collected by physicians. The database should preferably be collected at different medical centers to evaluate the generalizability of the proposed methods.

Third, all filtering methods were tested with the B³X Algorithm. Future work should evaluate these methods with other algorithms under similar noise conditions. Although B³X shows promising results for BP detection, it relies on the oscillometric signal, which may be unreliable during exercise due to motion artifacts. Therefore, future studies should investigate algorithms that do not depend on oscillometric signals and assess the impact of the proposed filtering methods under these conditions.

Finally, sequential combinations of methods, such as U-Net followed by Wiener + Shannon or other filtering pipelines, could also be investigated to improve performance. Future optimization could also help the methods more consistently satisfy the established criteria.

VI. CONCLUSION

This work extends the current literature by introducing a data augmentation pipeline for generating synthetic exercise-

related KS datasets. It also refines existing KS filtering approaches, evaluates these techniques under simulated exercise stress test noise conditions, and demonstrates the feasibility of transferring a U-Net architecture originally developed for PCG denoising to KS filtering. These contributions show that filtering techniques can substantially enhance automatic blood pressure estimation from Korotkoff signals artificially contaminated by treadmill noise. Among the evaluated methods, U-Net achieved the best overall performance, restoring the B³X algorithm to levels close to those obtained with noise-free signals.

***Abstract*—This scoping review analyzes 16 studies on computational methods for the analysis of cardiac arrhythmias, ventricular pre-excitation associated with Wolff-Parkinson-White syndrome, and glycemic disorders. The corpus was compiled from records identified in the IEEE Xplore, PubMed, and Scopus databases, supplemented by searches using the Consensus tool. The studies were compared regarding datasets, input representations, computational methods, validation protocols, performance, explainability, and limitations. The results demonstrate high performance, particularly on controlled datasets, but also reveal recurring limitations, including beat-level data splitting without patient-level separation, limited external validation, small sample sizes, reliance on pre-trained models, predominantly qualitative explainability assessment, and insufficient control of confounding factors. Regarding ventricular pre-excitation, further research is needed to integrate segmentation, fiducial features, temporal signals, time-frequency representations, and explainability methods with more robust clinical validation. As for glycemic alterations, the findings support the use of the ECG as a complementary marker for hyperglycemia and hypoglycemia, although it does not replace reference glucose measurements. Overall, the review highlights the potential of ECG-derived physiological features for machine learning models aimed at detecting cardiac and metabolic anomalies, while emphasizing the need for more robust validation and clinically grounded assessment.**

***Keywords*—scoping review, cardiac arrhythmias, ventricular pre-excitation, Wolff-Parkinson-White, glycemic abnormalities, explainability.**

I. Introduction

The electrocardiogram (ECG) remains one of the most accessible tools for assessing cardiac electrical activity. The digitization of large clinical datasets and the expansion of wearable sensors have fostered the development of methods capable of detecting peaks, segmenting waves, and classifying rhythms directly from the signal. Convolutional networks, recurrent models, and hybrid architectures have outperformed strictly rule-based approaches in several tasks, particularly when the objective is to recognize complex morphological or temporal abnormalities [1]–[3].

However, improved predictive performance does not eliminate methodological and clinical challenges, because accuracy values near or above 99% may be directly associated with factors such as controlled datasets, beat-level partitions, synthetic balancing, or indirect reuse of the same individuals during model training and testing. In addition, explanations produced by Grad-CAM, SHAP, or LIME are often evaluated only through visual inspection, without measures of fidelity, stability, or clinical agreement. Distinguishing a plausible explanation from one that faithfully reflects the model's decision-making mechanism is particularly important in ECG analysis, where small changes in duration, amplitude, and slope may carry diagnostic significance.

Wolff-Parkinson-White (WPW) syndrome represents a relevant example of this challenge, because its interpretation relies on the joint assessment of the PR interval, the onset of the QRS complex, the delta wave, and ventricular depolarization duration [4]. Specific approaches remain scarce, and general arrhythmia models may exhibit reduced sensitivity when externally evaluated for WPW [5]. In parallel, another line of research uses morphological and autonomic ECG changes to infer prediabetes, hyperglycemia, or hypoglycemia, with the aim of providing non-invasive support for screening and continuous monitoring [6]–[9].

In this context, ventricular pre-excitation associated with Wolff-Parkinson-White (WPW) syndrome and glycemic disorders constitute the two main focuses of this scoping review. Methods for R-peak detection, fiducial point delineation, arrhythmia classification, multimodal ECG representation, and explainable artificial intelligence (XAI) provide the methodological basis for analyzing these topics. This review aims to identify key computational approaches, limitations, and research gaps in beat-level ECG analysis, with an emphasis on temporal, morphological,

and time-frequency representations, multimodal machine learning models, and XAI techniques.

II. Review Methodology

This study consists of a scoping review of computational approaches applied to ECG signal analysis, focusing on Wolff-Parkinson-White (WPW) ventricular pre-excitation syndrome and glycemic disorders. The review followed a predefined methodology comprising the formulation of the research question, search strategy, eligibility criteria, study selection, data extraction, and qualitative synthesis. Study identification, screening, eligibility assessment, and reporting followed the PRISMA-ScR framework [10].

During title and abstract screening, records were excluded if they described purely clinical studies without computational methods, did not analyze ECG signals (e.g., studies based exclusively on PPG), or were unrelated to arrhythmias, WPW syndrome, or glycemic disorders. Following screening and report retrieval, 65 reports underwent full-text eligibility assessment. Studies were eligible for inclusion if they applied computational methods to ECG analysis, provided sufficient methodological information for data extraction and comparison, and addressed topics relevant to the scope of the review. At the full-text stage, reports were excluded if they were restricted to ECG preprocessing, filtering, or signal reconstruction without subsequent computational analysis, focused on specific conditions outside the scope of the review, or provided insufficient methodological detail for analysis and data extraction. From the included studies, information was extracted on datasets, populations, ECG configuration, preprocessing and segmentation, computational models, validation strategies, performance metrics, explainability methods, and reported limitations. The analysis also considered subject-wise data partitioning, sample representativeness, risk of data leakage, external validation, and quantitative assessment of explainability.

The PCC framework (Population/Problem, Concept, and Context) guided the formulation of the research question and search strategy [11]. The main and extended search strings combined terms related to ECG, R-peak detection, beat segmentation, fiducial points, QRS complexes, morphological, temporal, and time-frequency features, machine and deep learning, multimodal approaches, and XAI, with additional terms related to WPW and glycemic disorders. Searches were conducted in IEEE Xplore, Scopus, and PubMed, complemented by a supplementary search using Consensus, and were restricted to studies published between 2021 and 2026. A total of 156 records were identified through IEEE Xplore (n = 43), Scopus (n = 64), PubMed (n = 9), and the supplementary Consensus search (n = 40). After removing 14 duplicates and 35 records for other reasons, 107 records were screened, of which 28 were excluded. Among the 79 reports sought for retrieval, 14 could not be retrieved, leaving 65 reports for eligibility assessment. Of these, 49 were excluded according to the predefined criteria, resulting in 16 studies being included in the review. Figure 1 summarizes the PCC structure, the research question, the search strings, and the PRISMA-ScR study selection flow.

Given the heterogeneity of populations, datasets, ECG representations, computational models, performance metrics, and validation protocols, a qualitative narrative synthesis was performed. The analysis focused on methodological patterns, limitations, research gaps, subject-wise validation, external validation, and the integration of morphological, temporal, time-frequency, multimodal, and explainable approaches. A meta-analysis was not performed because of this methodological heterogeneity. The main characteristics and findings of the included studies are summarized in Table I.

III. Literature Review

A. Studies on Cardiac Arrhythmias and Wolff-Parkinson-White Syndrome

Reliable beat-level ECG analysis depends on accurate R-peak detection, fiducial point delineation, and consistent beat segmentation. These steps are essential for extracting temporal and morphological features from the P wave, QRS complex, and T wave, particularly in conditions such as ventricular pre-excitation. Although deep-learning models have improved ECG classification performance, limited interpretability remains a barrier to clinical application. Therefore, explainability methods should be evaluated not only visually, but also in terms of robustness, reproducibility, and consistency with cardiological knowledge.

Wang, Pan, and Meng [2] directly addressed R-peak detection under noisy conditions using a 1D ResU-Net that combined an encoder-decoder structure, residual blocks, skip connections, and channel attention. The method achieved an F1-score of 99.79% on the MIT-BIH Arrhythmia Database and approximately 99.5% in cross-database evaluations using INCART and the QT Database. Under extreme noise at -6 dB, F1-scores remained between 96.28% and 97.49%. This robustness is favorable for continuous applications, although the 36.4-million-parameter architecture and the potential leakage introduced by overlapping windows require caution.

Prakash et al. [3] extended R-peak alignment to the explicit delineation of the onsets and offsets of the P, QRS, and T waves. They proposed a modified 1D U-Net trained on the Lobachevsky University Database (LUDB) and used it to extract more than 12 temporal and morphological features, which were subsequently classified using a Random Forest. Segmentation accuracies ranged from 99.12% to 99.99%, but the patient-specific beat evaluation was conducted predominantly within the same record, reducing test independence and limiting data generalizability.

Merbouti and Cherifi [4] proposed a seven-stage processing pipeline combining the discrete wavelet transform,

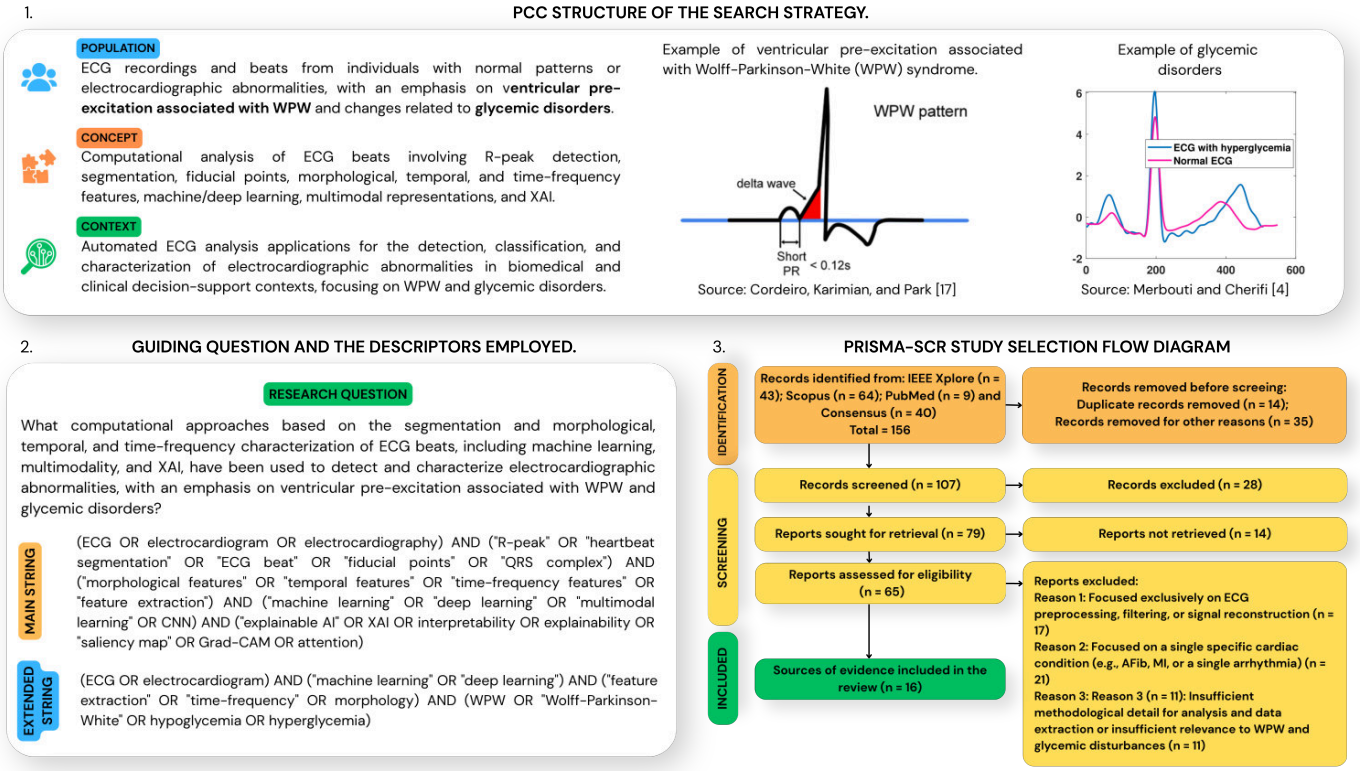

Figure 1. Search and study selection strategy, including the PCC framework with examples of ventricular pre-excitation associated with Wolff–Parkinson–White (WPW) syndrome and glycemic abnormalities, the research question, search strings, and the PRISMA flow for study identification, screening, and inclusion. In the flowchart, AFib refers to atrial fibrillation and MI to myocardial infarction.

adaptive peak scanning, and neural-network, KNN, and Naïve Bayes models. The method explicitly seeks to locate the delta wave and verify criteria associated with ventricular pre-excitation, such as PR-interval shortening and morphological relationships among the P, Q, R, and S waves. Neural networks achieved a mean accuracy of 99.25% and sensitivity of 97.16%. However, the sample was limited to only 21 WPW segments and 101 sinus-rhythm segments. In addition, the absence of conditions with similar electrocardiographic characteristics, such as bundle branch blocks, ventricular hypertrophy, and the Lown-Ganong-Levine pattern, restricted the evaluation of differential diagnoses and prevented a more realistic estimate of the method's specificity for identifying the delta wave and pre-excitation pattern.

Canto et al. [1] used asymmetric 600-ms segments containing 216 samples from lead MLII to preserve the P, QRS, and T waves. The proposed 1D CNN classified ten categories with 99.40% accuracy, 99.40% precision, and 99.32% recall. Grad-CAM was used for explainability and indicated activations consistent with morphological regions, but the use of a single dataset, dependence on annotated peaks, and lack of external validation limit the strength of the study's evidence.

Pantelidis et al. [5] developed ECG-XPLAIM, a multiscale 1D CNN with Inception modules and residual connections. The model was trained on MIMIC-IV and externally validated on PTB-XL. External AUC values ranged from 0.878 to 0.994. For WPW, sensitivity was 0.773, specificity was 0.973, and AUC was 0.895. These results demonstrate that a large-scale architecture can generalize across datasets, but also show that high specificity does not fully compensate for reduced sensitivity under rare conditions.

Singh and Sharma [12] combined a ResNet-inspired CNN, ECANet channel attention, and the K-GradCam method. Adding attention increased the overall F1-score from 97.40% to 98.88%. K-GradCam achieved a Dice coefficient of 0.82 relative to Grad-CAM and 0.71 relative to SHAP, with lower computational cost. However, agreement among methods does not constitute direct evidence of clinical fidelity. The author do not state whether the explanations were compared with the cardiologists annotations.

Neves et al. [13] evaluated LIME, SHAP, and Permutation Sample Importance in k-NN and 1D CNN classifiers. The inter-patient split and comparison with shapelets strengthened the study design. LIME applied to amplitude and derivative representations achieved a Jaccard similarity of 0.88 ± 0.27, whereas SHAP performed close to the random baseline. In a study involving three readers and 20 ECGs, the explanations did not consistently improve di-

agnostic accuracy and received low overall utility ratings. This finding highlights that computational plausibility and clinical utility are distinct criteria.

Sathi et al. [14] introduced federated learning using LSTM, FedAvg, and nine fiducial features. Classification of arrhythmia, ischemia, and healthy condition achieved an accuracy of $92.3 \pm 0.7\%$, an F1-score of 0.91 ± 0.02, and an AUC of 0.99 ± 0.01. SHAP and LIME highlighted P- and R-wave amplitudes, RR, PR, and QT/QTc intervals, and QRS duration. Although subject-wise separation is a strength, each diagnosis was associated with a different dataset, creating a risk that the model learned database-specific characteristics rather than the clinical condition.

Duranay et al. [15] compared 17-layer CNNs trained on the 1D lead-II signal and on a grayscale image generated from the same tracing. The 2D modality achieved 97.44% accuracy and an F1-score of 97.38%, outperforming the 93.07% accuracy and 92.99% F1-score obtained with the 1D modality. MM-GradCAM synchronized temporal and visual explanations, which were qualitatively evaluated by a cardiologist. It should be noted that the image is an alternative representation of the same ECG signal and does not constitute an independent physiological modality. Furthermore, processing this 2D representation of the ECG involves higher computational costs for training and storage than 1D ECG processing.

Alqudah and Alfraihat [16] combined ECG and phonocardiogram signals in a CNN-BiLSTM architecture with Squeeze-and-Excitation blocks, self-attention, and cross-attention. Overall accuracy was 97.0%, with a mean AUC of 0.989. Grad-CAM, SHAP, and Integrated Gradients were evaluated by three cardiologists, with an agreement of $\kappa = 0.82$. Despite this advance, a substantial portion of the public signals was synthetically paired by diagnosis without preserving the electromechanical relationship between the ECG and heart sound of the same individual.

According to the studies reviewed, the robustness of detection and segmentation depends on the accurate identification of ventricular depolarization, the definition of physiologically appropriate windows, and the correct delineation of P and T waves. In cases of ventricular pre-excitation, this delineation is particularly relevant due to the temporal relationship between the P wave, the PR interval, and the onset of the QRS complex. Regarding explainability, aspects such as model fidelity, stability against perturbations, and clinical consistency must be considered. However, the literature still relies predominantly on visual inspection, with limited use of quantitative validation or validation by multiple experts. In multimodal approaches, it is crucial to distinguish the integration of distinct modalities from a simple change in representation. Temporal signals, derived features, and time-frequency representations can provide complementary information, but their incremental contribution and potential redundancy must be quantified. In turn, physiologically distinct modalities, such as ECG and phonocardiography, require simultaneous acquisition or previously validated synchronization in the same patient.

B. Studies on metabolic monitoring and the detection of glycemic disturbances based on ECG

The search for noninvasive methods or approaches complementary to conventional glucose-monitoring systems has motivated studies investigating ECG as an indirect marker of metabolic abnormalities. The central hypothesis is that variations in glucose concentration can affect cardiac electrical conduction, autonomic nervous system regulation, and specific morphological and temporal characteristics of the electrocardiographic signal. These changes may manifest in intervals, waves, amplitudes, and heart-rate-variability patterns, providing potentially useful features for machine-learning models aimed at screening for prediabetes, hyperglycemia, and other glycemic abnormalities.

Among approaches aimed at identifying metabolic abnormalities from ECG, Kulkarni et al. [6] developed DiaBeats, an XGBoost-based model using beats extracted from 12-lead ECGs of 1,262 participants. Each beat was represented by 1,200 features, and the data were divided into training, validation, and test sets in proportions of 85%, 5%, and 10%, respectively. The model achieved an accuracy of 96.8% and an F1-score of 96.6%, while *temperature scaling* reduced the expected calibration error from 10.36% to 6.32%. However, partitioning was performed at the beat level without explicit participant separation, potentially allowing samples from the same individual to appear in different subsets and thereby favoring optimistic performance estimates. In addition, the DISFIN cohort consisted of Sindhi families from Nagpur with a history of type 2 diabetes, with prevalences of approximately 30% for diabetes and 14% for prediabetes. Therefore, although the results indicate potential for discriminating among different glycemic states, population-level screening still requires external validation and subject-independent partitioning.

Koga et al. [7] presented DiaCardia, based on LightGBM and morphological and temporal features extracted from ECG. The model achieved an AUC of 0.851 in internal testing and 0.785 in external validation conducted at another institution using different equipment. The lead-I-only version achieved an AUC of 0.844, with no statistically significant difference from the 12-lead model. Strengths included subject-wise data separation, control of confounding factors, and external validation. However, the positive predictive value of approximately 21% demonstrates that good discriminative performance does not eliminate the influence of prevalence and false positives.

Cordeiro, Karimian, and Park [17] investigated hyperglycemia identification from ECG fiducial changes using a ten-layer fully connected deep neural network. The model extracted 18 features per heartbeat, consisting of distances and slopes between fiducial points, thereby reducing di-

mensionality compared to using the full cardiac cycle. Figure 2 shows examples of heartbeats from individuals with and without hyperglycemia, visually highlighting morphological differences between the two conditions. The dataset included 1,119 participants and 1,963 single-lead ECG recordings, totaling 51,518 segments after preprocessing. In testing, the model achieved an AUC of 94.53%, sensitivity of 87.57%, and specificity of 85.04%, as well as a mean AUC of 93.65% in ten-fold cross-validation. However, participants were not fasting even though hyperglycemia was defined as glucose above 100 mg/dL, which may introduce label uncertainty because of postprandial elevations. In addition, the 80/20 split was performed at the beat level, without an explicit description of participant-wise separation, potentially increasing similarity between training and test sets. The absence of external validation in another population or device further limits the evidence regarding the broad applicability oh the method.

Vyas et al. [8] investigated the complementarity between ECG morphology and inter-beat dynamics for identifying glycemic excursions in ten young adults with type 1 diabetes. They compared morphological information, RR-interval sequences, statistical heart-rate and variability features, and a late-fusion strategy. The combined model achieved the best performance, with a mean AUC of approximately 0.68 for hypoglycemia and 0.70 for hyperglycemia. The use of windows adapted to the RR interval also increased the AUC for hypoglycemia from 52.2% to 56.1% ($p = 0.008$). Morphology contributed more strongly to hypoglycemia, whereas beat timing was more relevant to hyperglycemia, and combining the sources outperformed either representation alone for both tasks. However, evaluation was personalized for each participant without separation between individuals, and the small sample size limits generalization to population-level models. In addition, the higher frequency of hyperglycemic episodes may have favored better performance for that condition.

Islam, Islam, and Hossain Shuvo [18] evaluated Random Forest (RF), Gradient Boosting Machine (GBM), and MLP models for personalized hypoglycemia detection using single-lead ECG from the D1NAMO dataset. Of the nine participants with type 1 diabetes, only four were included because of the availability of hypoglycemic episodes. A total of 74 morphological, interval-based, and HRV features were extracted, 44 of which were related to heart-rate variability. RF and GBM achieved a mean AUC of 0.97 and an F1-score of 0.86; after removing HRV features, the F1-score decreased to 0.74 and 0.73, respectively. SHAP analysis highlighted the PQ interval, QRS duration, QT/QTc parameters, and HRV features. However, the models were trained separately for each participant using an internal 70/30 split and were not validated on unseen individuals. The exclusion of five participants and the lack of external *subject-wise* validation limit the method's generalization.

Dave et al. [9] evaluated a personalized approach for detecting glycemic excursions under free-living conditions using ECG and CGM data from 12 adults with type 1 diabetes monitored for 14 days. Individual models were developed by combining intra-beat morphology and HRV features, together with classifiers trained at different glycemic thresholds. The fusion model achieved an AUC of 0.75 ± 0.10 for hypoglycemia and 0.80 ± 0.06 for hyperglycemia, outperforming the isolated representations. Five-fold cross-validation used one-hour temporal blocks to reduce correlation between training and test sets. Nevertheless, precision for hypoglycemia was only 0.10 ± 0.03, with a high false-positive rate. Event-level evaluation yielded 2.07 false alarms per day, demonstrating that high AUC does not guarantee adequate operational performance and reinforcing the importance of metrics such as precision and false-alert frequency.

The evidence analyzed indicates that ECG-based detection performance for glycemic disturbances is strongly influenced by the study's validation protocol. Results obtained using beat-level data splitting can overestimate model performance compared to subject-level or external validation strategies. Personalized approaches suggest that ECG morphological features and heart rate variability can provide complementary information; however, their generalizability remains limited. These findings underscore the importance of subject-level data splitting, external validation, and the use of performance metrics beyond AUC to ensure a more reliable assessment of model robustness.

IV. Discussion, Trends, and Research Gaps

A. Apparent performance and external validity

The reviewed studies are not directly comparable due to differences in analysis units, class prevalence, number of categories, and data partitioning. Datasets with thousands of heartbeats may still represent few individuals, and heartbeat-level splitting can place data from the same patient in both training and test sets, increasing the risk of information leakage and overly optimistic performance. Patient-level splitting therefore provides a more reliable estimate of generalization, while external validation assesses robustness across populations, institutions, acquisition protocols, and devices. Pantelidis et al. [5], Wang et al. [2], and Koga et al. [7] showed that external evaluation can reveal effects not evident internally, including reduced WPW sensitivity, stable R-peak detection across datasets, and lower AUC in glycemic screening. These findings reinforce the need to consider both partitioning strategy and external validation when interpreting model performance and clinical applicability.

B. Explainability as a validation process

The reviewed literature primarily uses Grad-CAM to identify relevant signal regions, SHAP to estimate feature

Table I

SUMMARY OF THE REVIEWED STUDIES. THE FINAL COLUMN PROVIDES A DESCRIPTIVE METHODOLOGICAL ASSESSMENT EMPHASIZING PARTICIPANT SEPARATION, EXTERNAL VALIDATION, POTENTIAL LEAKAGE, EXPLAINABILITY EVALUATION, AND OTHER STUDY-SPECIFIC LIMITATIONS.

Author	Objective	Methodology	Data and input	Main results	Methodological assessment and limitations
Studies on Cardiac Arrhythmias and Wolff-Parkinson-White Syndrome					
Canto et al. (2025)	Classify ten heartbeat types and explain relevant regions.	1D CNN; asymmetric R-centered window; class weights; Grad-CAM.	MIT-BIH; MLII; 600 ms; 216 samples.	Accuracy 99.40%; precision 99.40%; recall 99.32%.	Single dataset; split not explicitly inter-patient; annotated peaks; no external validation.
Wang et al. (2025)	Detect R peaks under noise and across different databases.	1D ResU-Net; residual blocks; attention; focal loss; *augmentation*.	MIT-BIH, INCART, QT, and Noise Stress Test; 5-s windows.	F1 99.79% on MIT-BIH and approximately 99.5% across databases; F1 >96% at −6 dB.	Large model; overlapping windows; R peak only; no prospective validation.
Prakash et al. (2023)	Delineate P/QRS/T and classify beats using transparent features.	1D U-Net; fiducial features; personalized Random Forest.	LUDB and MIT-BIH; 12 and 2 leads.	Segmentation 99.12-99.99%; class-wise accuracy 93.64-98.98%.	Evaluation partly conducted on records used for adaptation; low precision for rare classes.
Merbouti and Cherifi (2023)	Identify short PR interval and delta wave for WPW.	DWT; adaptive scanning; ANN, KNN, and Naïve Bayes; seven stages.	**122 segments: 21 WPW and 101 normal**; MLII; 10 s.	ANN: accuracy 99.25%; sensitivity 97.16%; mean specificity 74.37%.	Small sample; no differential controls; cumulative errors; minimal external validation.
Pantelidis et al. (2025)	Detect multiple arrhythmias with explainability and external validation.	ECG-XPLAIM; multiscale Inception CNN; residual connections; Grad-CAM.	MIMIC-IV and PTB-XL; 12 leads; 10 s.	External AUC 0.878-0.994; WPW: sens. 0.773, spec. 0.973, AUC 0.895.	Reduced sensitivity in rare classes; qualitative explanations; no calibration/AUPRC.
Singh and Sharma (2022)	Classify six beat types and improve local explanations.	1D CNN-ResNet; ECANet; K-GradCam; SHAP/LIME/Grad-CAM.	MIT-BIH; 259-sample window; SMOTE.	F1 98.88%; K-GradCam/Grad-CAM Dice 0.82.	Beat-level holdout; single dataset; agreement among XAI methods does not prove clinical fidelity.
Neves et al. (2021)	Evaluate model-agnostic explanations for ECG time series.	k-NN and CNN; LIME, SHAP, and PSI; derivative; shapelets; reader study.	MIT-BIH; inter-patient split; 600-ms beats.	Binary F1 90.3%; LIME Jaccard 0.88 ± 0.27.	Low perceived clinical utility; three readers; rare classes; high explanation cost.
Sathi et al. (2025)	Simultaneously classify arrhythmia, ischemia, and normal cardiac function using ECG fiducial markers.	FL-LSTM; FedAvg; nine fiducials; SHAP and LIME.	166 individuals; MIT-BIH, European ST-T, and FANTASIA.	Accuracy $92.3 \pm 0.7\%$; F1 0.91 ± 0.02; AUC 0.99 ± 0.01.	Simulated institutions; class confounded with dataset; SMOTE; no real clinical validation.
Duranay et al. (2026)	Compare 1D ECG and 2D images and fuse explanations.	Two 17-layer CNNs; 1D/2D Grad-CAM; MM-GradCAM.	Chapman-Shaoxing; 10,588 patients; lead II.	1D: F1 92.99%; 2D: F1 97.38%.	Single dataset; image derived from the same signal; higher cost; one cardiologist.
Alqudah and Alfraihat (2026)	Integrate cardiac electrical and mechanical activity.	CNN-BiLSTM-SE; self-attention; cross-attention; SHAP/Grad-CAM/IG.	ECG+PCG; four public datasets and an in-house cohort of 500 individuals.	Accuracy 97.0%; F1 96.7%; AUC 0.989; $\kappa = 0.82$.	Synthetic pairing; only 500 real pairs; no external multimodal validation.
Studies on metabolic monitoring and the detection of glycemic disturbances based on ECG					
Kulkarni et al. (2023)	Screen for prediabetes and diabetes using ECG beats.	DiaBeats; XGBoost; SMOTE; temperature scaling.	1,262 individuals; 10,461 beats; 12-lead ECG.	Accuracy 96.8%; F1 96.6%; calibration error reduced to 6.32%.	Beat-level split; single specific cohort; no external validation.
Koga et al. (2025)	Detect early glycemic abnormalities and evaluate a single-lead approach.	DiaCardia; LightGBM; Optuna; SHAP; confounder control.	16,766 records + 2,456 external individuals; 12 leads/lead I.	AUC 0.851 internal and 0.785 external; lead I: AUC 0.844.	Japanese population; PPV approximately 21%; not evaluated on a real wearable device.
Cordeiro et al. (2021)	Identify hyperglycemia using compact fiducial features.	Ten-layer DNN; 18 PQRST distances and slopes.	1,119 participants; 51,518 beats; single lead.	AUC 94.53%; sens. 87.57%; spec. 85.04%.	Threshold applied without fasting; participant-wise split not reported; no external validation.
Vyas et al. (2023)	Compare morphology and RR dynamics in hypo-/hyperglycemia.	CNN, CNN-LSTM, RR-LSTM, HRV, and late fusion.	Ten adults with type 1 diabetes; ECG and CGM for up to two weeks.	Fusion: AUC approximately 0.68 for hypo- and 0.70 for hyperglycemia.	Personalized models; small sample; no inter-patient validation.
Islam et al. (2025)	Detect hypoglycemia and explain ECG features.	RF, GBM, and MLP; 74 features; HRV; SHAP; LMS filter.	Four D1NAMO patients; single-lead ECG, accelerometry, and CGM.	RF/GBM: AUC 0.97 and F1 0.86; removing HRV reduced F1.	Five patients excluded; random intra-patient split; no external evaluation.
Dave et al. (2024)	Detect hypo- and hyperglycemia under free-living conditions using multi-threshold fusion.	Personalized Random Forest; morphology+HRV; temporal block validation.	12 adults with type 1 diabetes; 14 days; single-lead ECG and CGM.	AUC 0.75 for hypo- and 0.80 for hyperglycemia; hypoglycemia precision 0.10.	Few individuals; calibration required; many false alerts; no external validation.

contributions, and LIME or perturbation-based methods to generate local explanations. However, few studies jointly evaluate fidelity, stability, and correspondence with clinical knowledge. Visually salient regions localized within the QRS complex, for example, may be physiologically plausible without necessarily demonstrating that the model uses the same criteria applied in clinical interpretation. A more rigorous evaluation may combine deletion or insertion tests involving relevant regions, stability analysis under noise or small temporal shifts, expert agreement, and comparison with previously annotated fiducial points. It is also important to analyze explanations associated with classification errors rather than only correct predictions. For WPW, relevance maps can be compared with the PR interval, QRS onset, and the region corresponding to the delta wave. In glycemic studies, the importance assigned to ECG characteristics should be analyzed while considering potential confounders such as heart rate, physical-activity level, acquisition time, food intake, and medication use.

C. Multimodality, redundancy, and computational cost

The reviewed literature demonstrate that combining one-dimensional temporal signals, temporal features, and time-frequency representations expands the ways ECG information is represented, even though these inputs do not necessarily correspond to independent physiological sources. An image or map derived from the ECG itself preserves much of the original information but may also introduce characteristics related to the transformation or rendering process. Similarly, integrating ECG and phonocardiography represents a more direct form of physiological multimodality; however, it requires synchronized acquisition to preserve the relationships between cardiac electrical and mechanical events. Strategies such as late probability fusion, cross-attention, and adaptive weighting can leverage complementary information from different representations. Nevertheless, the contribution of each modality must be verified through ablation studies, alongside assessments of calibration and computational cost. For wearable device applications, factors such as power consumption, inference time, model complexity, and robustness against artifacts caused by motion or temporary signal loss must also be considered.

D. Research gaps in ventricular pre-excitation

Evidence specifically addressing automated WPW detection remains limited. Merbouti and Cherifi [4] evaluated only 21 WPW segments, whereas ECG-XPLAIM [5], despite external validation, achieved an AUC of 0.895 for WPW with sensitivity of 0.773. Together, these findings show both insufficient condition-specific representation and persistent difficulty detecting rare WPW cases under independent validation. Future studies should therefore use larger multicenter cohorts containing WPW and morphologically similar abnormalities, together with annotations of wave boundaries and cardiac intervals. Integrated models may combine robust R-peak detection, P-wave and QRS delineation, temporal signals, morphological and spectral features, and time-frequency representations. Their contribution should be verified through ablation studies, with patient-independent and, whenever possible, cross-database validation. Positive predictive value and calibration should complement sensitivity, specificity, and AUC.

E. Research gaps in glycemic detection

Glycemic-abnormality studies reveal a clear distinction between population-level and personalized models. Personalized approaches may capture subject-specific morphological and autonomic responses but require prior ECG synchronized with a reference glucose measurement, whereas population models must handle greater inter-participant variability and confounders such as age, medication, physical activity, food intake, and acquisition device. Future evaluations should prioritize prolonged ambulatory ECG-CGM recordings and explicitly account for temporal synchronization and possible physiological delays between glucose changes and cardiovascular manifestations. For alert-oriented systems, AUC alone is insufficient. Positive predictive value, false alerts per unit time, detection delay, and probability calibration are required to characterize real-world behavior. This is illustrated by Dave et al. [9], where hypoglycemia discrimination was accompanied by low precision and frequent false alerts. Overall, the evidence supports ECG as a complementary source of information associated with glycemic variation rather than as a replacement for reference glucose measurement, and favors participant-wise and external validation when population-level generalization is intended.

V. Conclusion

This study presented a scoping review based on a previously selected corpus and did not constitute a prospectively registered systematic review. No formal risk-of-bias tool was applied, and exclusion reasons were not quantified by category at all screening stages. In addition, heterogeneity in tasks, populations, datasets, and performance metrics precluded statistical synthesis. Therefore, the analysis emphasized participant independence, external validation, sample representativeness, potential data leakage, and explainability rather than ranking studies solely by reported performance.

The reviewed literature highlights the potential of ECG as a physiological signal for computational applications ranging from arrhythmia detection to the analysis of temporal, morphological, fiducial, and time-frequency features associated with ventricular pre-excitation and glycemic alterations. Regarding interpretability, current evidence remains largely qualitative, highlighting the need for quantitative assessment of explanation fidelity, stability, and clinical consistency, including the analysis of classification

errors. Multimodal and multi-representation approaches may improve discrimination by combining complementary ECG information; however, their benefit should be confirmed through ablation studies, calibration analysis, and assessment of computational cost.

Regarding ventricular pre-excitation associated with Wolff-Parkinson-White (WPW) syndrome, evidence remains limited by small sample sizes, a scarcity of databases with specific labels for the condition, and performance degradation observed during external validation. Future studies should prioritize whenever possible multicenter, publicly available datasets or, alternatively, controlled data collection protocols involving participants with a confirmed WPW diagnosis. Rigorous patient-level data separation, the exploration of complementary ECG representations, and quantitative assessment of model explainability are also recommended.

Regarding glycemic changes, the ECG also shows potential as a complementary physiological marker, although model performance is strongly influenced by data partitioning strategies, population characteristics, and validation protocols. Future studies should adopt controlled acquisition protocols, account for potential confounding factors, and conduct external validation, while ensuring synchronization between ECG signals and reference glucose measurements. Furthermore, metrics of operational relevance such as positive predictive value and the frequency of false alerts should be reported.

Overall, progress in both areas depends on evaluation protocols that ensure participant independence, test for generalizability across external cohorts, and rigorously assess the reliability and clinical consistency of model explanations. Finally, the presented results should be interpreted as a critical synthesis derived from a scoping review, rather than as evidence from a prospectively registered systematic review.

***Abstract*—This work presents the development and preliminary performance evaluation of a low-cost platform for ultrasonic transducer characterization and two-dimensional acoustic field mapping. The proposed system integrates a microcontroller-based positioning mechanism, a LabVIEW supervisory interface, and MATLAB routines for signal processing and spectral analysis, supporting manual positioning and autonomous scanning. Experimental evaluation was performed using two single-element ultrasonic transducers with nominal frequencies of 1.6 MHz and 5 MHz, together with a needle hydrophone. The agreement between signals acquired by a digital oscilloscope and those exported through the LabVIEW interface was assessed using the Pearson correlation coefficient (PCC) and normalized root mean square error (NRMSE). Both transducers exhibited high correlation between the acquired and exported signals, while their spectral characteristics were determined from the experimental frequency responses using the -6 dB bandwidth criterion. The autonomous scanning mode was demonstrated over a 20×20 mm region with a 20×20 acquisition grid, enabling the reconstruction of the two-dimensional acoustic response and the estimation of the peak negative pressure. The results demonstrate the feasibility of the proposed low-cost platform for laboratory-based ultrasonic transducer characterization and acoustic field mapping.**

***Index Terms*—ultrasound, acoustic field characterization, hydrophone measurements, ultrasonic transducers, low-cost instrumentation**

I. Introdução

A caracterização espacial e a quantificação dos campos de pressão acústica emitidos por transdutores ultrassônicos são etapas fundamentais para o desenvolvimento, calibração e validação de tecnologias médicas, ensaios não destrutivos e sistemas de instrumentação acústica [1]–[3]. A exatidão e a repetibilidade dessas medições dependem do posicionamento preciso de um sensor de referência, tipicamente um hidrofone, em relação ao emissor acústico [3], [4].

Para atender a esses requisitos, investigações laboratoriais geralmente empregam tanques de água equipados com sistemas computadorizados de varredura tridimensional (3D) [5], [6]. Embora apresentem elevada precisão, essas plataformas são frequentemente limitadas pelo alto custo e pela dependência de soluções proprietárias, o que dificulta a adaptação de software e a integração de novos periféricos. Nesse contexto, plataformas baseadas em microcontroladores e componentes eletromecânicos de baixo custo têm sido propostas como alternativas viáveis [7]. Clinard *et al.* (2022), por exemplo, desenvolveram um tanque de varredura modular baseado em Arduino com desempenho comparável ao de sistemas comerciais [8]. Entretanto, soluções baseadas exclusivamente no controle remoto por computador ainda apresentam limitações nas etapas de calibração e de alinhamento inicial do hidrofone, que requerem ajustes locais e interação em tempo real.

Este trabalho apresenta o desenvolvimento de um sistema de varredura bidimensional (2D) automatizado e de baixo custo, baseado em uma arquitetura de controle híbrida e em equipamentos amplamente disponíveis em laboratórios de instrumentação. O sistema integra uma estrutura mecânica de translação no plano x-z, uma placa microcontroladora, um módulo de acionamento de motores com resolução de micropasso e uma interface supervisória no LabVIEW. A arquitetura proposta combina um modo manual para calibração e alinhamento do hidrofone com um modo autônomo para execução automatizada das rotinas de varredura e aquisição de sinais ultrassônicos.

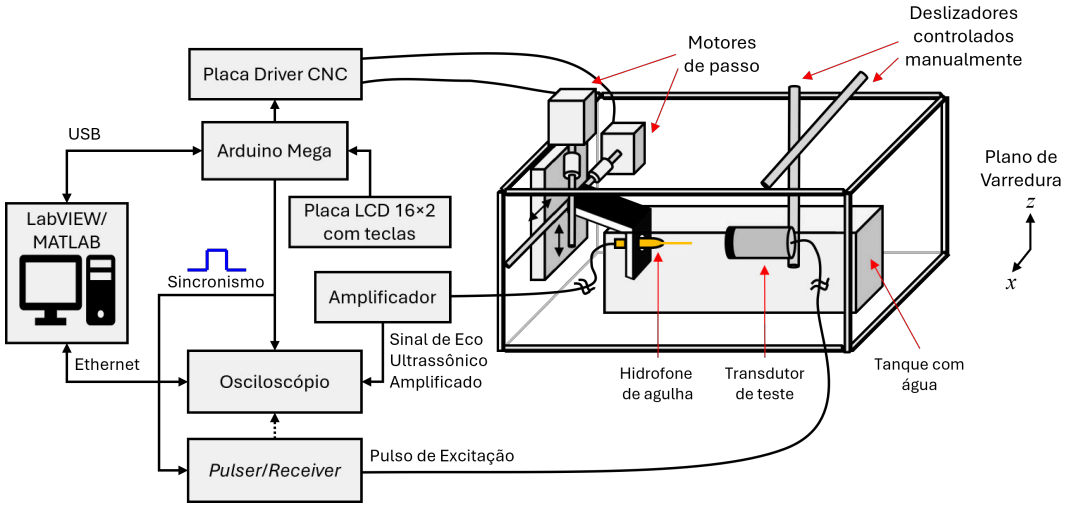

Figura 1. Diagrama de blocos funcional do sistema de varredura: integração de hardware, periféricos e fluxo de comunicação entre o Arduino Mega e o LabVIEW.

II. Materiais e Métodos

Nesta seção, é descrito o sistema de baixo custo para varredura 2D, desenvolvido com foco em aplicações em ambientes laboratoriais de ensino e prototipagem rápida.

A. Arquitetura do Sistema

O sistema proposto para aquisição de sinais ultrassônicos e mapeamento do campo acústico, ilustrado no diagrama em blocos da Fig. 1, é composto por cinco módulos principais: (i) circuito de controle e sincronismo; (ii) módulo de excitação acústica; (iii) módulo de aquisição e digitalização de sinais; (iv) módulo de armazenamento de dados; e (v) plataforma de translação 2D para o posicionamento do hidrofone.

O circuito de controle e sincronismo é constituído por uma placa Arduino Mega 2560 e uma placa CNC Shield V3, mostradas na Fig. 2, além de uma placa Display LCD Keypad Shield 16×2, utilizada para o acionamento local ou automatizado do sistema de movimentação. Esses módulos foram montados em um gabinete com dimensões de 12 × 6 × 4 cm, conforme ilustrado na Fig. 3. Além de controlar dois motores de passo para o alinhamento preciso do hidrofone e do transdutor ao longo do eixo acústico no plano x-z, o microcontrolador gera o sinal de sincronismo, utilizado pelo estágio de excitação do transdutor.

O sistema de atuação mecânica 2D responsável pelo deslocamento do hidrofone no tanque de ensaios acústicos é composto por dois motores de passo NEMA 17, com resolução nativa de 1,8° por passo, o que corresponde a 200 passos por revolução. O acionamento dos motores é realizado por dois módulos DRV8825 instalados na parte superior da CNC Shield V3. Os *drivers* DRV8825 foram configurados para operação em regime de micropasso de 1/32, o que resulta em 6.400 micropassos por revolução do motor NEMA 17 (200 passos por volta). Considerando o fuso roscado TR8×2 com quatro entradas, correspondente a um avanço linear (*lead*) de 8 mm por revolução, o sistema apresenta uma resolução de

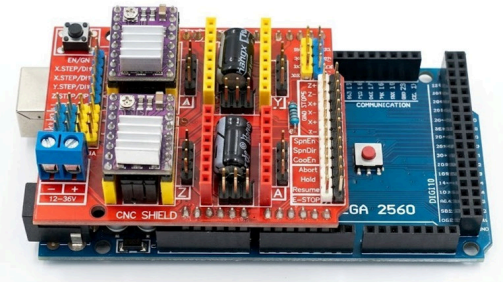

Figura 2. Placa Arduino Mega 2560 conectada à placa LCD Keypad Shield 16×2.

Figura 3. Gabinete do sistema de controle e sincronismo, contendo o Arduino Mega 2560, a placa CNC Shield V3 e o Display LCD Keypad Shield 16×2.

posicionamento de 800 passos por milímetro, equivalente a um deslocamento linear teórico de 1,25 μm por micropasso.

O modo de operação padrão é o manual, no qual o usuário pode selecionar e visualizar os sinais adquiridos pelo hidrofone e, opcionalmente, pelo transdutor. No modo autônomo, a interface envia ao Arduino as coordenadas de posicionamento do hidrofone com base nos parâmetros definidos pelo usuário, permitindo a execução da varredura espacial no plano x–z para a obtenção do mapa de pressão acústica. A etapa de excitação acústica é realizada por um equipamento *pulser/receiver* (P/R)

Olympus 5077PR, responsável pela geração de pulsos elétricos unipolares de alta tensão para excitar o transdutor ultrassônico.

Após o alinhamento inicial no modo manual, um osciloscópio digital Tektronix MDO3014 é utilizado para adquirir o sinal captado pelo hidrofone, previamente condicionado por um estágio externo de amplificação. Opcionalmente, outro canal do osciloscópio pode ser utilizado para visualizar o sinal de eco do transdutor. O osciloscópio realiza a digitalização das formas de onda com taxa de amostragem de 100 MSPS (escala horizontal ajustada para 10 µs/div), fornecendo a resolução temporal necessária para a visualização dos ecos, bem como para a caracterização e análise do campo acústico. Os dados digitalizados são transferidos para uma interface desenvolvida na plataforma LabVIEW versão 2026 Q1, que estabelece comunicação via Ethernet com o osciloscópio. Essa interface permite o armazenamento automático dos dados para posterior processamento e análise.

O sistema de segurança mecânico de calibração é composto por três chaves fim de curso (duas no eixo x e uma no eixo z), conectadas diretamente às entradas do microcontrolador. Esses sensores atuam como mecanismo de proteção contra colisões e delimitam o volume útil de translação do hidrofone, enquanto o transdutor permanece fixo durante as operações de varredura.

A alimentação do Arduino, com tensão de 5 V, é fornecida pela interface USB do computador hospedeiro, enquanto a alimentação do sistema de translação é fornecida por uma fonte chaveada externa de 12 V/20 A, conectada ao barramento de potência do CNC Shield V3. Conforme discutido em [8], o isolamento entre a alimentação de potência e a eletrônica de controle é fundamental para mitigar interferências eletromagnéticas nos sinais adquiridos pelo hidrofone no tanque.

B. Estrutura Mecânica

A plataforma mecânica é composta por uma estrutura construída com perfis comerciais de alumínio V-slot de seção transversal 20 × 20 mm, com dimensões totais de 385 × 240 × 240 mm (C × L × A). Essa estrutura serve de base para os sistemas dos eixos horizontal e vertical, responsáveis pelo deslocamento do hidrofone submerso em água nas respectivas direções. A plataforma mecânica é apresentada na Fig. 4.

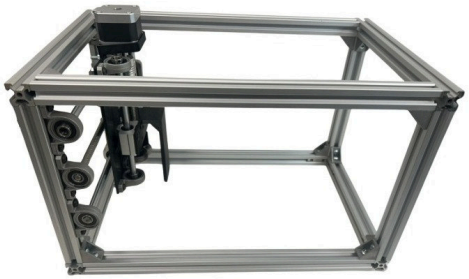

Figura 4. Visão lateral da estrutura mecânica com os sistemas dos eixos horizontal e vertical, além do suporte do hidrofone, já montados.

Cada eixo é composto pelos seguintes elementos: (i) dois eixos lineares retificados de 8 mm; (ii) um fuso roscado TR8×2 com quatro entradas; (iii) cinco mancais de apoio para eixos de 8 mm; (iv) dois *pillow blocks* para eixos de 8 mm; (v) um bloco de porca em POM para fuso TR8; (vi) um motor de passo; (vii) um suporte impresso em 3D para o motor; (viii) um acoplador para eixos de 8/6,35 mm; e (ix) elementos de fixação, como parafusos e porcas.

O motor de passo é acoplado ao fuso roscado por meio do acoplador, sendo responsável, em conjunto com o bloco de POM, pela conversão do movimento rotacional em deslocamento linear. Os *pillow blocks* são montados sobre os eixos retificados, um de cada lado do fuso, proporcionando estabilidade mecânica e mantendo o alinhamento do conjunto durante a movimentação. Esse alinhamento reduz os esforços excessivos sobre o motor de passo e minimiza o risco de travamentos. Os mancais fornecem suporte aos eixos retificados e à extremidade livre do fuso, oposta ao motor. O sistema do eixo vertical ainda possui um componente adicional destinado à fixação do hidrofone. A montagem desse sistema é apresentada em maior detalhe na Fig. 5.

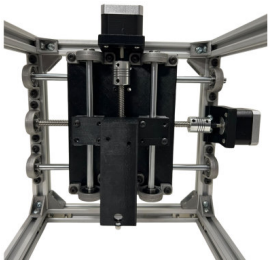

Figura 5. Montagem do eixo vertical fixado ao carro móvel do eixo horizontal.

O sistema do eixo horizontal é fixado diretamente à estrutura principal, enquanto o sistema do eixo vertical é montado sobre o carro móvel do eixo horizontal. Dessa forma, o deslocamento horizontal desloca simultaneamente todo o conjunto vertical, ao passo que o deslocamento vertical atua exclusivamente sobre o hidrofone.

Para garantir a reprodutibilidade do projeto, a lista detalhada de componentes e custos, juntamente com o código-fonte do *firmware* e os arquivos da interface supervisória, está disponível publicamente no repositório do projeto no GitHub: https://github.com/anannunciato/2D-Ultrasonic-Transducer-Characterization-System

C. Implementação do Firmware de Controle e Sincronismo

Integrado ao ambiente supervisório, o *firmware* de controle foi desenvolvido em C/C++ utilizando o Arduino IDE (versão 2.3.8). A função do Arduino no sistema é atuar como um controlador periférico em tempo real, operando de forma subordinada aos comandos locais do usuário no modo manual, realizados por meio do LCD Keypad Shield 16×2, e aos comandos remotos provenientes da interface LabVIEW no modo autônomo, conforme o fluxograma da Fig. 6.

O algoritmo implementado é responsável pela geração dos pulsos de controle dos motores de passo e do sinal

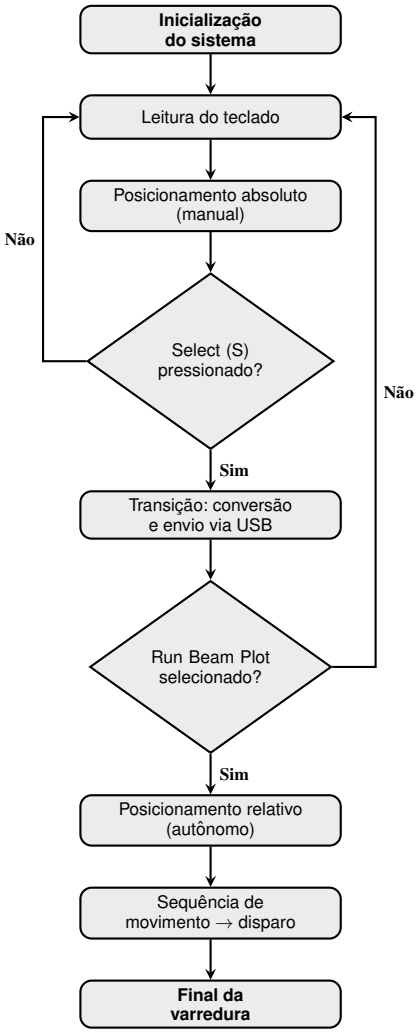

Figura 6. Fluxograma simplificado do *firmware* embarcado, mostrando a transição entre a rotina de posicionamento local e a varredura autônoma coordenada.

de sincronismo do estágio de excitação do transdutor. Para reduzir o risco de perda de passos devido à inércia ou perturbações mecânicas, o código utiliza a biblioteca *AccelStepper*, configurada para implementar perfis de aceleração e desaceleração com execução não bloqueante. Adicionalmente, a biblioteca *LiquidCrystal* é empregada para o gerenciamento da interface e atualização do LCD.

A estrutura do código é dividida em dois estágios operacionais distintos. O primeiro estágio compreende a definição do referencial absoluto de posicionamento, que estabelece a correspondência física, em milímetros (mm), dos eixos x e z no interior do tanque de ensaios acústicos, servindo de base para o posicionamento inicial do hidrofone. O operador interage localmente por meio das teclas integradas ao LCD Keypad Shield 16×2, realizando ajustes incrementais nas coordenadas espaciais por meio das teclas de incremento (▲) e decremento (▼). Os valores são exibidos no visor do LCD com precisão de três casas decimais (000.000 mm). A seleção da casa decimal é realizada por meio das teclas esquerda (◄) e direita (►).

Nessa etapa de movimentação manual, a temporização do sistema é implementada com base na função nativa `millis()`, o que permite a execução não bloqueante do programa. Esse recurso atua como um temporizador interno, possibilitando o controle incremental dos motores de passo, enquanto mantém simultâneas a atualização do LCD e a leitura das teclas. Em paralelo à movimentação dos motores, no modo manual são gerados pulsos de sincronismo externo para o P/R, com taxa de repetição de pulsos (PRF) padrão de 100 Hz. Uma vez definido o ponto inicial de operação (x_0, z_0), o usuário aciona a tecla `SELECT` (*S*) do LCD Keypad Shield 16×2, comando que converte as coordenadas de unidades métricas para passos inteiros equivalentes e envia esses dados ao LabVIEW via USB. Após o recebimento das posições iniciais x_0 e z_0, a interface LabVIEW permite a definição da área de varredura, possibilitando o ajuste da resolução espacial (passos por milímetro), dos limites de deslocamento em cada eixo e da densidade da malha de aquisição para a operação no modo autônomo – valor inicialmente ajustado para 800.

Após o acionamento do botão `Run Beam Plot` na interface supervisória desenvolvida em LabVIEW, o sistema inicia o modo autônomo de varredura, gerando inicialmente uma matriz contendo N pontos de varredura, compreendidos entre as coordenadas (x_0, z_0) e (x_{N-1}, z_{N-1}). Em seguida, as coordenadas absolutas de cada ponto são transmitidas sequencialmente ao microcontrolador, que executa os deslocamentos correspondentes. Ao atingir cada ponto da matriz, o Arduino gera um pulso de disparo para o P/R, garantindo a aquisição sincronizada dos dados acústicos. O padrão de varredura implementado neste trabalho segue uma trajetória em ziguezague, como ilustrado na Fig. 7. Paralelamente às rotinas de movimentação manual e automática, o sistema monitora continuamente o circuito de segurança composto por chaves de fim de curso.

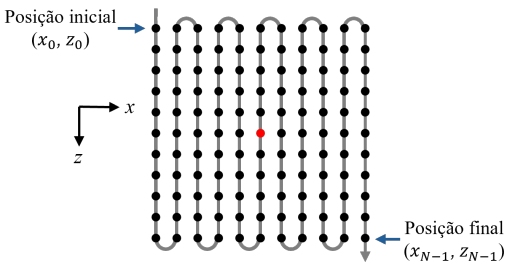

Figura 7. Padrão de varredura ultrassônica no plano x-z com a indicação dos N pontos de varredura. O ponto central da região de interesse é indicado em vermelho.

D. Sistema Supervisório Baseado em LabVIEW

A Fig. 8 apresenta a interface gráfica de usuário desenvolvida para o sistema supervisório baseado em LabVIEW. Nesse exemplo, são apresentados o sinal de eco ultrassônico bruto e seu espectro em frequência, obtido por meio da Transformada Rápida de Fourier (FFT). As principais características da interface para configuração do sistema de aquisição e varredura são descritas na Tabela I.

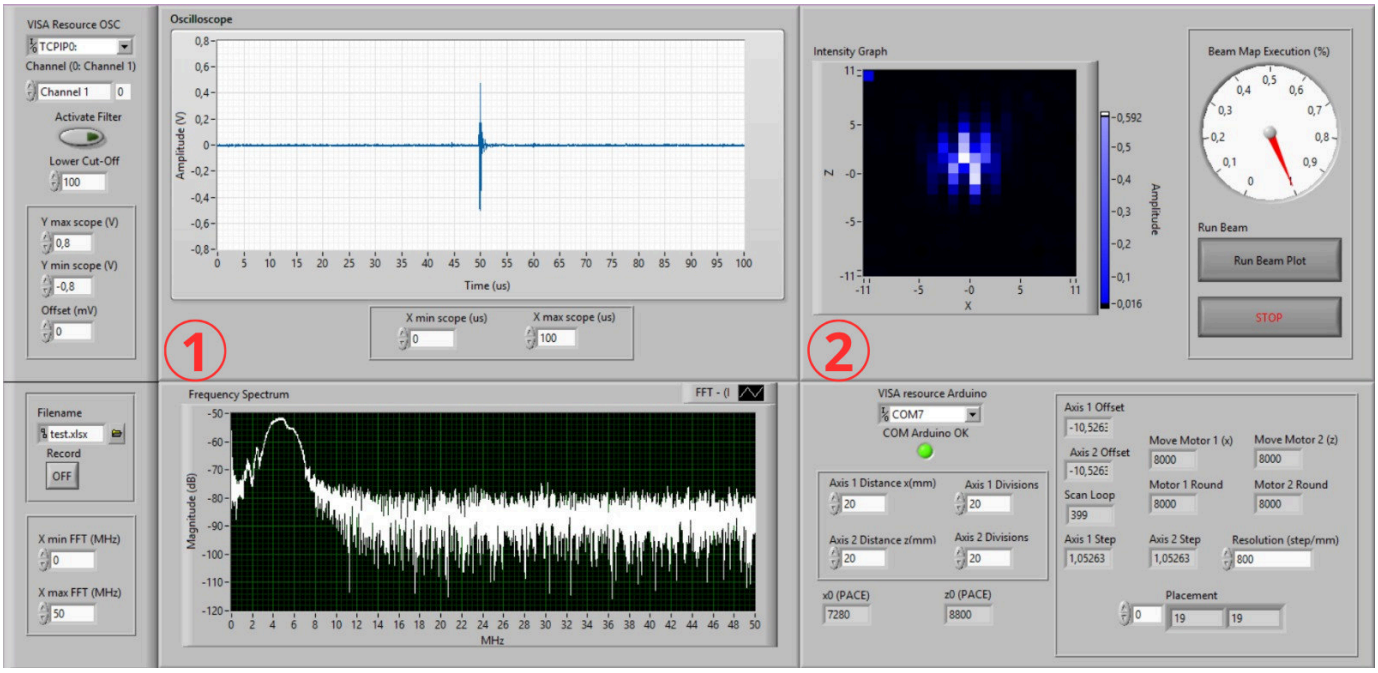

Figura 8. Interface desenvolvida no LabVIEW para visualização e armazenamento das formas de onda ultrassônicas.

Tabela I
PRINCIPAIS CARACTERÍSTICAS DA INTERFACE GRÁFICA DE USUÁRIO DESENVOLVIDA

Módulo	**Funcionalidade**
Aquisição	Visualização da forma de onda e da respectiva FFT Ajuste das escalas de tensão [V], *offset* [V] e tempo [μs] Habilitação do filtro passa-baixa (FPB) Ajuste da faixa de frequência da FFT [MHz] Salvamento do mapa de tensão negativa de pico
Mapa	Ajuste do número de divisões nos eixos x e z Ajuste das dimensões de varredura nos eixos x e z Salvamento do mapa da tensão negativa de pico

O ciclo de aquisição de dados inicia-se com a configuração da interface de comunicação com o instrumento de medição por meio do campo (i) *VISA Resource Osc* (ilustrado operando via protocolo TCP/IP), seguida da seleção do canal analógico do osciloscópio (CH1, CH2, CH3 ou CH4) por meio do controle (ii) *Channel*. Para garantir a integridade dos dados e atenuar componentes de baixa frequência indesejadas, o sistema dispõe de um estágio de condicionamento digital. O operador pode habilitar essa função por meio do botão (iii) *Activate Filter*, definindo a frequência de corte do filtro passa-alta no campo (iv) *Lower Cut-Off*.

Para facilitar a descrição das funcionalidades da interface, a tela apresentada na Fig. 8 foi subdividida em dois painéis. O primeiro painel reúne os recursos destinados ao monitoramento do sinal, realizado simultaneamente nos domínios do tempo e da frequência. No domínio do tempo, a forma de onda adquirida é exibida no gráfico superior, denominado (v) *Oscilloscope*. A janela de visualização pode ser ajustada dinamicamente pelo usuário por meio da configuração dos limites de amplitude nos campos (vi) *Y max scope (V)* e *Y min scope (V)*, bem como da inserção de um *Offset DC*. A base de tempo da aquisição é definida pelos campos (vii) *X min scope (μs)* e *X max scope (μs)*. Em seguida, o software aplica a FFT ao sinal e apresenta seu espectro no domínio da frequência no gráfico inferior (viii) *Frequency Spectrum*. Essa ferramenta permite a análise espectral e a visualização das componentes harmônicas do sinal, sendo a faixa de frequência de interesse ajustável por meio dos limites (ix) *X min FFT (MHz)* e *X max FFT (MHz)*. Por fim, o sistema permite a exportação do sinal adquirido. O usuário define o diretório e o nome do arquivo de saída (no formato de planilha) por meio do campo (x) *Filename* (por exemplo, *teste.xlsx*). A gravação dos dados para posterior análise *offline* é iniciada por meio do botão (xi) *Record*.

No segundo painel, o ciclo operacional inicia-se com a configuração da porta serial no campo (i) *VISA Resource Arduino*, cuja comunicação é confirmada pelo indicador luminoso (ii) *COM Arduino OK*. Inicialmente, o sistema opera no modo manual para o ajuste da posição do hidrofone. Ao pressionar a tecla *S* no LCD Keypad *Shield* 16×2, as coordenadas são transmitidas via USB e preenchidas nos campos (iii) *X inicial (PACE)* e *Z inicial (PACE)*, sendo então assumidas como a origem (x_0, z_0) da malha de varredura automatizada. Com a comunicação estabelecida, os limites geométricos do experimento são definidos pelo usuário por meio dos campos de configuração da área de varredura: (iv) *Axis 1 Distance x (mm)* e *Axis 2 Distance z (mm)*, que especificam as distâncias máximas de translação do hidrofone nos eixos x e z, respectivamente; (v) *Axis 1 Divisions* e

Axis 2 Divisions, que determinam o nível de discretização da malha ao subdividir a área de varredura em intervalos de aquisição; e (vi) *Resolution (steps/mm)*, no qual o usuário informa a resolução de deslocamento, utilizada para calcular a quantidade equivalente de passos dos motores necessária para percorrer a malha.

Após a configuração de todos os parâmetros, o operador aciona o botão (vii) *Run Beam Plot*, alterando o estado do sistema para o modo autônomo de varredura. A partir desse instante, o software inicia a execução da malha de varredura automatizada, enquanto o indicador *Beam Map Execution* exibe seu progresso em percentual.

E. Demonstração Experimental do Sistema de Aquisição

Para a avaliação do funcionamento do sistema de aquisição desenvolvido, foram utilizados dois transdutores ultrassônicos monoelemento, ambos da FUNBEC, com frequências nominais de 1,6 MHz e 5 MHz e diâmetros de 19 mm e 6,35 mm, respectivamente, além de um hidrofone do tipo agulha com diâmetro de 1 mm (modelo 1730, Precision Acoustics). O hidrofone apresenta sensibilidade típica de 991,4 mV/MPa quando utilizado em conjunto com o pré-amplificador submersível PA11029 (Precision Acoustics), cuja saída foi conectada ao sistema de aquisição. O sinal proveniente do hidrofone foi condicionado pelo pré-amplificador e pelo DC Coupler (modelo DCPS180, Precision Acoustics), responsável pela alimentação do pré-amplificador e pelo acoplamento do sinal ao sistema de aquisição. Os transdutores ultrassônicos são apresentados na Fig. 9, enquanto o hidrofone de agulha com o pré-amplificador é apresentado na Fig. 10.

(a) **(b)**

Figura 9. Transdutores ultrassônicos de 1,6 MHz e 5 MHz utilizados nos ensaios: (a) vista lateral e (b) vista frontal.

Figura 10. Hidrofone do tipo agulha de 1 mm de diâmetro, modelo 1730 (Precision Acoustics), utilizado nos ensaios experimentais.

O desempenho do sistema foi inicialmente avaliado por meio da comparação entre a resposta ultrassônica captada pelo hidrofone, adquirida pelo osciloscópio, e o sinal correspondente exportado pelo LabVIEW e processado no MATLAB R2024a. Foram avaliados os parâmetros espectrais do transdutor, bem como a similaridade entre os sinais. A frequência de pico (f_p) foi determinada experimentalmente a partir do espectro de frequência, correspondendo à frequência associada ao valor máximo do espectro. A frequência central (f_c) foi calculada como a média aritmética das frequências de corte inferior (f_L) e superior (f_H), ambas determinadas em -6 dB. As larguras de banda absoluta (BWabs) e relativa (BWrel) foram calculadas pelas Equações (1) e (2), respectivamente.

$$\mathrm{BW}_{\mathrm{abs}} = f_H - f_L \tag{1}$$

$$\mathrm{BW}_{\mathrm{rel}} = \frac{\mathrm{BW}_{\mathrm{abs}}}{f_c} \times 100\% \tag{2}$$

O coeficiente de correlação de Pearson (PCC) foi utilizado para quantificar a similaridade entre os sinais, enquanto o erro quadrático médio normalizado (NRMSE) foi empregado para mensurar o erro entre eles [9], [10]. Valores de NRMSE próximos de 0 (%) e de PCC próximos de 1 (adimensional) indicam elevada concordância entre os resultados. As métricas NRMSE e PCC são definidas, respectivamente, como:

$$\mathrm{PCC} = \frac{\sum_{i=1}^{N} (x_i - \bar{x})\,(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{N} (x_i - \bar{x})^2}\sqrt{\sum_{i=1}^{N} (y_i - \bar{y})^2}}, \tag{3}$$

$$\mathrm{NRMSE} = \frac{\sqrt{\frac{1}{N}\sum_{i=1}^{N} (x_i - y_i)^2}}{x_{\max} - x_{\min}} \times 100, \tag{4}$$

em que x_i e y_i representam as amostras dos sinais comparados, $x_{\max}$ e $x_{\min}$ correspondem aos valores máximo e mínimo do sinal de referência, $\bar{x}$ e $\bar{y}$ representam as médias dos respectivos sinais, e N é o número total de amostras.

F. Avaliação Preliminar de Desempenho do Sistema de Varredura

Com o objetivo de avaliar o desempenho e a repetibilidade do sistema de varredura, foram realizadas cinco varreduras mecânicas independentes em uma região de 20×20 mm, utilizando uma malha de 20×20 posições nos eixos x e z. Em cada posição, foi registrada a tensão correspondente ao pico negativo da resposta ultrassônica medida pelo hidrofone, permitindo a construção de um mapa 2D da distribuição espacial. Essa grandeza pode ser posteriormente convertida em pressão por meio da sensibilidade calibrada do hidrofone, possibilitando a determinação da pressão negativa de pico (*Peak Negative Pressure* – PNP) [1], [5].

A repetibilidade espacial do sistema foi avaliada por meio da comparação entre os mapas 2D de pressão acústica negativa de pico obtidos em varreduras sucessivas. Para esse ensaio, o hidrofone foi inicialmente posicionado na região de máxima amplitude acústica gerada pelo transdutor de 5 MHz, a uma

distância de aproximadamente 1 cm de sua superfície. O mesmo transdutor foi então submetido a cinco varreduras independentes, sendo realizado o procedimento de *homing* dos eixos x e z antes do início de cada aquisição. Essa abordagem permite avaliar a consistência do posicionamento do sistema a partir de uma característica espacial do próprio campo acústico, considerando conjuntamente o sistema de translação, o posicionamento do hidrofone e o procedimento de aquisição.

III. Resultados

A Fig. 11 ilustra o arranjo experimental utilizado na demonstração de funcionamento do sistema e na caracterização do transdutor. O arranjo é composto pela estrutura mecânica desenvolvida, um recipiente plástico contendo água e o hidrofone com pré-amplificador, posicionado a 5 mm da face do transdutor. A porção inferior da figura apresenta uma ampliação da região interna do recipiente, destacando o posicionamento relativo entre o hidrofone e o transdutor. O custo total dos componentes para a construção da plataforma de varredura 2D foi de aproximadamente R$ 2.200,00 (USD 425,00, cotação de agosto de 2026), desconsiderando o transdutor ultrassônico, o hidrofone e os equipamentos de instrumentação. A discriminação detalhada dos itens e seus respectivos valores está disponível no repositório do projeto no GitHub, indicado na Seção II-B.

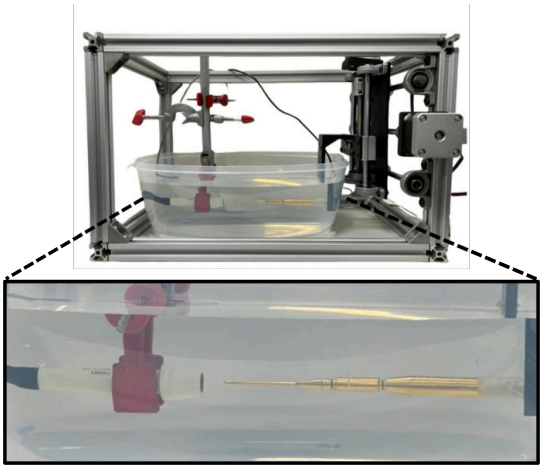

Figura 11. Arranjo experimental utilizado na avaliação do sistema e na caracterização do transdutor. A ampliação na porção inferior da figura destaca o posicionamento do hidrofone a 5 mm da face do transdutor ultrassônico.

A comparação entre os sinais adquiridos pelo osciloscópio e os sinais correspondentes exportados pelo LabVIEW é apresentada na Fig. 12. Para o processamento no MATLAB, os sinais exportados pelo LabVIEW foram submetidos à janela de Hanning antes do cálculo da FFT. As Fig. 12(a) e 12(b) apresentam, respectivamente, os sinais no domínio do tempo e os respectivos espectros de frequência para o transdutor de 1,6 MHz. Observa-se elevada concordância entre os sinais no domínio do tempo, bem como entre os respectivos espectros de frequência, indicando que o procedimento de aquisição e exportação preserva adequadamente as características do sinal ultrassônico. De forma semelhante, as Fig. 12(c) e 12(d) apresentam os resultados no domínio do tempo e da frequência, respectivamente, para o transdutor de 5 MHz, também evidenciando boa concordância entre os sinais obtidos pelo osciloscópio e aqueles exportados pelo LabVIEW.

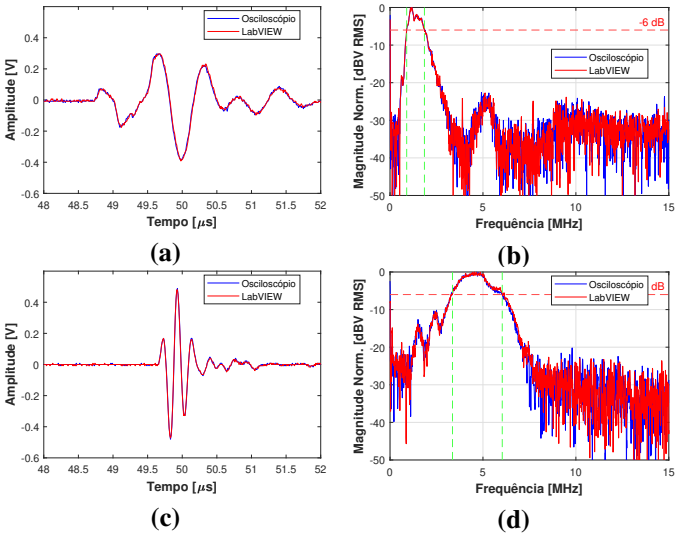

Figura 12. Comparação entre os sinais ultrassônicos adquiridos pelo osciloscópio e os sinais exportados pelo LabVIEW. (a) e (b) Sinais no domínio do tempo e respectivos espectros em frequência para o transdutor de 1,6 MHz, respectivamente. (c) e (d) Sinais no domínio do tempo e respectivos espectros em frequência para o transdutor de 5 MHz, respectivamente.

A Tabela II reúne os resultados quantitativos obtidos nos ensaios experimentais, incluindo as métricas de comparação entre os sinais nos domínios do tempo e os parâmetros espectrais determinados em -6 dB para os dois transdutores apresentados na Fig. 12. Os elevados valores de PCC indicam forte correlação e preservação das características temporais dos sinais. Os valores de NRMSE também indicam boa concordância, sendo influenciados pelas diferenças de amplitude, pois os sinais não foram normalizados.

A Fig. 13 apresenta o mapa 2D da pressão acústica negativa de pico, obtido no modo autônomo e reconstruído por interpolação cúbica com fator de 5. A tensão medida pelo hidrofone foi convertida em pressão utilizando sua sensibilidade calibrada, e o mapa de pressão foi interpolado para melhorar a visualização da distribuição espacial. A tensão negativa de pico máxima medida foi utilizada para estimar a PNP. Observa-se que o sistema foi capaz de reconstruir o perfil espacial da resposta ultrassônica na região avaliada, evidenciando o funcionamento integrado do posicionamento mecânico, da aquisição automática de sinais e do processamento de dados. Considerando a tensão negativa de pico máxima de 0,592 V, medida na saída do pré-amplificador, a PNP máxima estimada foi de 597,14 kPa.

Como complemento à caracterização do sistema, foi realizado um segundo ensaio para avaliar sua repetibilidade espacial, sendo obtidos, em sucessivas varreduras, os respectivos mapas 2D de pressão acústica negativa de pico e

Figura 13. Mapa 2D da pressão acústica negativa de pico obtido pelo hidrofone em uma região de varredura de 20 × 20 mm com 20 × 20 posições de aquisição, após conversão da tensão e interpolação cúbica com fator 5.

as coordenadas $(x_{\max}, z_{\max})$ correspondentes aos pontos de máxima pressão. Entre as cinco varreduras, foram observadas variações máximas de 20 μm nos eixos x e z, caracterizando a repetibilidade espacial do sistema de posicionamento.

Como referência comercial, foi considerado um sistema de varredura de campo acústico da GAMPT Ultrasonic Solutions, composto pelo SF620 (*Sound field scanner 3 dimensions*), SF630 (*Sound field scanning drive with DLL*) e um tanque para medições em água, com custos de €4.201,00, €1.387,00 e €320,00, respectivamente, totalizando €5.908,00. Embora a solução comercial permita varreduras 3D, a plataforma desenvolvida foi projetada para varreduras 2D, atendendo às necessidades deste estudo. A solução proposta apresenta menor custo e integra a movimentação, a aquisição e o processamento de sinais, proporcionando maior flexibilidade para adaptações experimentais. Ressalta-se, contudo, que a comparação considera apenas os custos dos equipamentos, não abrangendo diferenças de precisão, velocidade de varredura e repetibilidade entre as soluções.

IV. CONCLUSÃO

Este trabalho apresentou o desenvolvimento e a avaliação preliminar de uma plataforma de baixo custo para caracterização de transdutores ultrassônicos, integrando um sistema de posicionamento mecânico controlado por microcontrolador, uma interface supervisória em LabVIEW e rotinas de processamento em MATLAB. Os resultados demonstraram o funcionamento adequado dos modos manual e autônomo, bem como a capacidade de aquisição, análise e mapeamento bidimensional da resposta acústica de transdutores ultrassônicos. Como trabalhos futuros, pretende-se aprofundar a avaliação da repetibilidade e da reprodutibilidade das medições nos campos próximo e distante, bem como implementar métricas de intensidade acústica, como a intensidade espacial de pico e temporal média (*Spatial Peak Temporal Average Intensity* – ISPTA), a intensidade espacial de pico e de pulso médio (*Spatial Peak Pulse Average Intensity* – ISPPA) e o índice mecânico (*Mechanical Index* – MI), ampliando as funcionalidades da plataforma para a caracterização de campos ultrassônicos [1]. Adicionalmente, está prevista a extensão da plataforma para uma configuração de varredura 3D, possibilitando a caracterização espacial completa do campo acústico e ampliando sua aplicabilidade.

***Abstract*—This work investigates the feasibility of identifying four distinct hand movements — wrist opening, wrist closing, wrist flexion, and wrist extension — from surface electromyographic (sEMG) signals acquired using only two channels positioned on the forearm. The signals were collected with surface sensors connected to an ESP32 microcontroller operating at a sampling rate of 1000 Hz, and subjected to a pre-processing pipeline based on moving average smoothing with window sizes of 5, 10, and 20 samples. A window of 10 samples provided the best trade-off between noise attenuation and preservation of muscular activation patterns. For feature extraction, an interval detection algorithm based on a two-threshold state machine was applied to isolate the contraction segments, after which the mean energy of each channel was computed, yielding a two-dimensional feature vector per repetition. The resulting scatter plot reveals well-separated clusters for wrist flexion and extension, while wrist opening and closing exhibit greater intra-class variability and cluster overlap. Overall, the proposed approach provides preliminary evidence of separability among the analyzed movements using a single time-domain feature and minimal hardware, highlighting its potential for low-cost myoelectric interfaces while leaving automatic classification for future evaluation.**

***Index Terms*—Electromyography, sEMG, Wrist Movement Recognition, Time-Domain Features, Low-Cost Myoelectric Interface, ESP32.**

I. Introduction

The functional loss of the upper limb, whether resulting from amputation, neuromuscular injuries, or degenerative diseases, significantly compromises the autonomy and quality of life of affected individuals, driving growing demand for myoelectric prostheses and human–machine interfaces capable of restoring hand movements in a natural and intuitive manner [1]–[3]. In this context, surface electromyography (sEMG) signals stand out as a non-invasive source of information about the user's motor intention, enabling the control of assistive devices from the electrical activity of the forearm muscles [4], [5].

Despite this potential, the widespread adoption of myoelectric interfaces still faces challenges related to the cost of acquisition systems, the computational complexity of classification algorithms, and the robustness against noise, physiological variability, and embedded hardware constraints [6], [7]. Most high-performance solutions available in the literature assume the use of multiple sEMG channels, specialized hardware, and advanced processing pipelines, which limits their applicability in low-cost scenarios.

Recent studies indicate that the number of acquisition channels directly influences gesture recognition performance: configurations with 8 to 16 channels tend to achieve high accuracy across large movement vocabularies, but at the expense of greater cost and complexity [8]. Conversely, reduced-channel arrangements can maintain competitive performance on smaller gesture sets, provided they are combined with appropriate electrode placement strategies, pre-processing, and feature extraction [9]. In parallel, there is a strong trend toward machine learning and deep learning techniques, including convolutional neural networks, hybrid CNN–LSTM models, and attention mechanisms, which typically demand higher computational resources [10], [11].

In this scenario, approaches based on simple time-domain features — such as mean absolute value (MAV), root mean square (RMS), signal amplitude, and moving average — remain relevant due to their low computational cost and ease of implementation on microcontrollers [12], [13].

Motivated by these considerations, this work investigates the separability of four distinct hand movements — wrist opening, wrist closing, wrist extension, and wrist flexion — from sEMG signals acquired using only two channels positioned on the forearm, relying exclusively on time-domain processing. The main contributions are: (i) the implementation of an analog acquisition and conditioning chain based on sEMG sensors and an ESP32 microcontroller; (ii) the evaluation of the effect of moving average smoothing (with window sizes of 5, 10, and 20 samples) on signal quality; and (iii) the exploratory analysis of mean energy from the two channels as a compact two-dimensional representation of the analyzed movements, supporting the feasibility of simple, replicable, and low-cost myoelectric interfaces.

The authors want to thank Fapemig for partial funding of this research.

II. Background

A. Electromyography (EMG)

Electromyography (EMG) is a well-established technique for assessing the electrical activity associated with skeletal muscle contraction, enabling the inference of motor behavior from the detection of action potentials generated by muscle fibers when activated by the central nervous system [4], [14], [15]. From this perspective, the electromyographic signal constitutes an indirect measure of the neural drive, allowing the study of motor unit recruitment strategies during voluntary and involuntary movements, as well as the functional analysis of muscle groups in dynamic or isometric tasks [4], [16].

EMG signals can be obtained through invasive approaches, such as needle electrodes inserted directly into the muscle, or through non-invasive techniques using electrodes placed on the skin surface [14]. In applications related to rehabilitation, myoelectric prosthesis control, and human–machine interfaces, surface electromyography (sEMG) is the preferred modality due to its safety, reduced user discomfort, and lower cost, making it widely employed in both clinical and research settings [4], [14].

Although a correlation exists between the EMG signal amplitude and the level of muscular activation, this relationship is influenced by multiple factors, including muscle fatigue, subcutaneous tissue thickness, electrode placement and orientation, contact impedance, and inter- and intra-individual variability [4], [16]. Consequently, the quantitative interpretation of the signal requires careful acquisition and processing procedures, particularly in systems that aim to recognize movement patterns from a limited number of channels.

The electromyographic signal is also highly susceptible to noise from various sources, including power line interference, motion artifacts, capacitive coupling with cables and adjacent devices, as well as thermal noise and external electromagnetic interference [6], [17]. Under these conditions, the adoption of analog conditioning and digital filtering strategies to attenuate unwanted signal components while preserving the physiologically relevant frequency band becomes indispensable.

The quality of the acquired sEMG signal critically depends on aspects such as the choice of muscle group, standardization of the inter-electrode distance, skin preparation, and repeatability of electrode placement across sessions [14], [18]. Inadequate placement may result in a low signal-to-noise ratio or in crosstalk — that is, the inadvertent capture of signals from neighboring muscles — thereby compromising physiological interpretation and reducing gesture discriminability [14], [18]. In systems employing few acquisition channels, such as the one proposed in this work, these issues become even more critical, as the amount of information available for movement differentiation is inherently limited [19].

1) Time-domain features: In the context of sEMG-based movement recognition, numerous feature extraction techniques have been proposed, spanning the time domain, frequency domain, and time–frequency representations [12], [20]. Time-domain features such as mean absolute value (MAV), root mean square (RMS), signal amplitude, and waveform length are widely used due to their low computational cost and their ability to effectively represent the intensity of muscular contraction, even in hardware-constrained systems [12], [13].

2) Challenges with a reduced number of channels: The use of a reduced number of sEMG channels introduces specific challenges related to the spatial limitation of the available information and to the overlap of electric fields generated by different muscles [3]. Even small variations in electrode placement between sessions or across users can significantly alter the observed activation patterns, hindering classifier generalization and the stability of amplitude-based decision thresholds [21]. Furthermore, muscle fatigue, variations in applied effort, and task context can modify signal amplitude and morphology, introducing relevant intra-class variability.

On the other hand, recent studies indicate that, when combined with appropriate placement strategies, pre-processing, and feature selection, reduced-channel configurations can maintain competitive performance on limited gesture vocabularies while simultaneously reducing cost, instrumentation complexity, and energy consumption [7]–[9], [22]. This approach is particularly attractive in resource-constrained scenarios, such as low-cost embedded systems.

III. Methodology

The goal of this work is to investigate whether the electromyographic patterns associated with four distinct hand movements (wrist opening, wrist closing, wrist flexion, and wrist extension) exhibit separable activation patterns when represented in a low-dimensional feature space. The analysis is exploratory and is intended to assess the feasibility of using the resulting representation as a basis for future movement classification and myoelectric interface applications. To this end, acquisition and pre-processing procedures were defined to assess the separability of the analyzed movements within a low-dimensional feature space.

This section describes the developed system, justifying the choices made at each stage. The acquisition protocol is presented first, followed by the signal acquisition and conditioning chain and, finally, the feature extraction procedure.

A. System Overview

The overall architecture of the proposed system is presented in Figure 1, which illustrates the complete flow from the acquisition of surface electromyography (sEMG) signals to computational processing and organization of the resulting data. The system is structured into functional blocks comprising: signal acquisition through surface electrodes; analog conditioning and amplification, including filtering for noise and interference reduction; digitization; and processing for digital filtering, feature extraction, and movement analysis.

Each of these stages is described in detail in the following subsections.

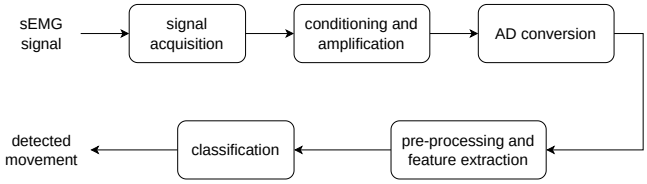

Fig. 1: Block diagram of the developed system.

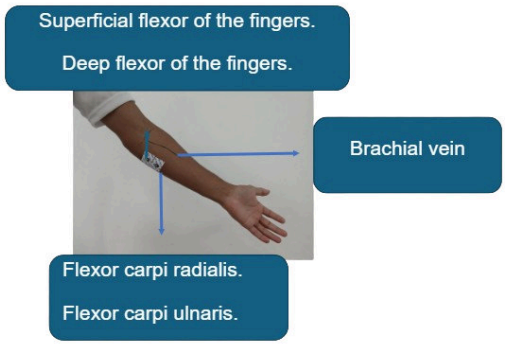
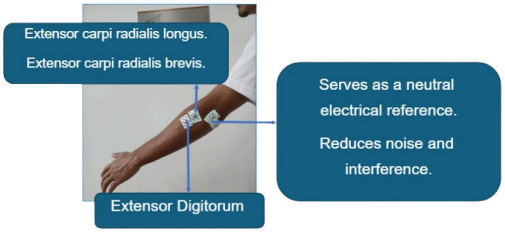
B. Experimental Protocol

The experiment was conducted with the authors themselves, two healthy male volunteers, both 23 years old, right-handed and physically active (regular physical exercise approximately five times per week), with body mass between 65 kg and 75 kg and no history of fractures or muscular injuries in the upper limbs. Participation was voluntary, and the procedures were explained to the participants prior to the data collection.



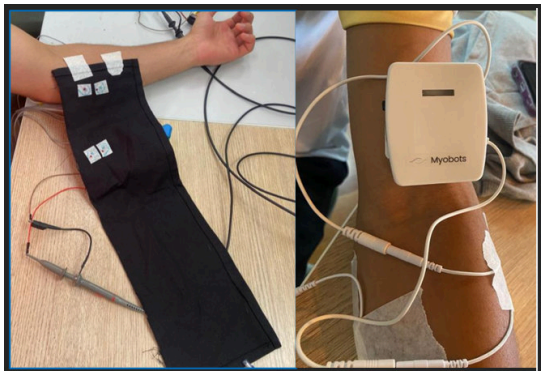
During the experiments, the volunteers remained seated, with the dominant arm supported and relaxed at the beginning of each acquisition. The experimental environment was kept as controlled as possible in order to minimize external interference, postural variations, and muscle fatigue effects over the repetitions.

The surface electrodes were positioned on two specific regions of the forearm, selected based on the muscles predominantly activated during the analyzed movements. Placement was standardized using a previously defined template, ensuring repeatability across acquisitions and across volunteers. Figure 2 presents the adopted positioning from different perspectives, along with the template used to define the electrode fixation points and the distribution of the anatomical references employed.



Four distinct forearm and hand movements were analyzed, selected for their functional relevance and because they involve the activation of different muscle groups:

- Wrist opening, associated primarily with the activation of the finger extensor muscles;
- Wrist closing, associated with the activation of the finger flexor muscles;
- Wrist flexion, related predominantly to the flexor carpi radialis muscle;
- Wrist extension, related to the wrist extensor muscles.



For each movement, 50 repetitions were performed per volunteer, providing a set of samples suitable for the exploratory analysis carried out in this study. Each repetition followed a standardized temporal cycle consisting of 2 seconds of active muscular contraction, corresponding to the execution of the movement, followed by 2 seconds of rest, allowing the return to the baseline state, for a total duration of 4 seconds per repetition. Each acquisition began with the muscle at rest, followed by the execution of the movement during the established contraction time, and ended with the relaxation period. This standardization was adopted to ensure reproducibility of the collections and comparability among the sEMG signals acquired for different movements and volunteers.

(b) Sensor 2 placement.

(c) Template for sensor placement.

Fig. 2: Placement details for each of the sensors.

C. Signal Acquisition and Conditioning

1) Signal acquisition: The sEMG signals were acquired using surface sensors designed to capture the electrical activity generated by muscle fibers during contraction. These sensors perform the initial amplification and conditioning of the signal, providing an analog output compatible with the ADC available in the microcontroller.

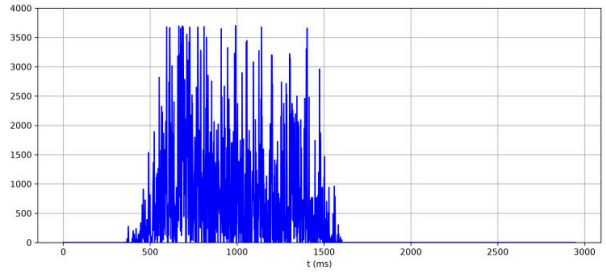
The system was configured with two acquisition channels, corresponding to two sensors positioned on different regions of the forearm. The use of a reduced number of channels makes it possible to assess the feasibility of distinguishing hand movements from a simplified architecture, aligned with low-cost applications and embedded systems with limited computational resources. The details of the sensor placement are described and justified in Section III-B.

2) Amplification and conditioning: The analog signals from the sensors are routed to a signal conditioning board, responsible for reducing external interference, adjusting the amplitude level, and matching the dynamic range of the signals to the input of the microcontroller's analog-to-digital converter (ADC). This stage contributes to improving the signal-to-noise ratio and to preventing saturation during digitization.

Since sEMG signals are highly susceptible to electrical noise, environmental interference, and amplitude variations arising both from muscular activity and from the limitations of the acquisition system, and considering the restricted dynamic range of the ADC integrated into the ESP32, an analog pre-processing stage was required prior to digitization. For this purpose, a dedicated acquisition board was developed to condition the analog signals, limiting the signal amplitude to a range compatible with the input of the microcontroller's ADC while improving the signal-to-noise ratio.

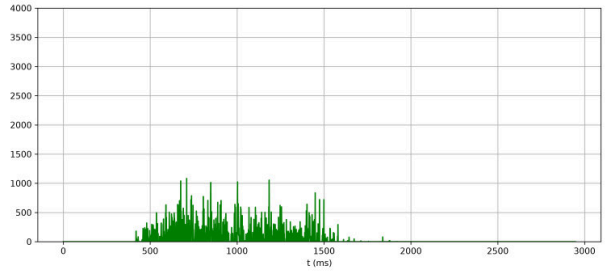
3) A/D conversion: After analog conditioning, the signals are sent to an ESP32 microcontroller, which performs the analog-to-digital conversion. This device was selected for its processing capability, the availability of multiple ADC channels, and the ease of communication with external computing systems — characteristics suitable for near-real-time biomedical signal acquisition applications.

The sEMG signals were acquired at a sampling rate of 1000 Hz, as this value preserves information relevant to time-domain analysis, to the visualization of contractions, and to the differentiation among the executed movements, while keeping the data volume compatible with near-real-time processing. The acquired data were stored in Comma-Separated Values (CSV) files, which facilitates subsequent organization and processing.



D. Feature Extraction

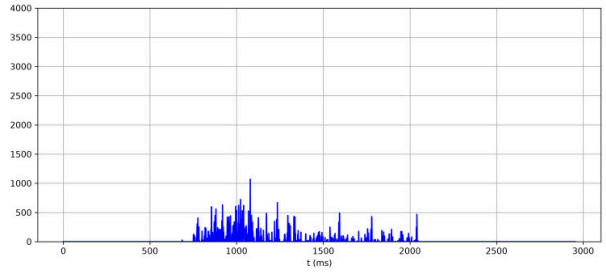
The objective is to differentiate the four movements described above. Figures 3 to 6 below show the sensor readings for the wrist flexion and extension movements. During wrist extension, the signal from Sensor 1 is considerably larger than the one read by Sensor 2, whereas during wrist flexion the readings are reversed: the signal from Sensor 1 is smaller than the one from Sensor 2. For the wrist opening and closing movements, the signals from the two sensors exhibit approximately the same amplitude.



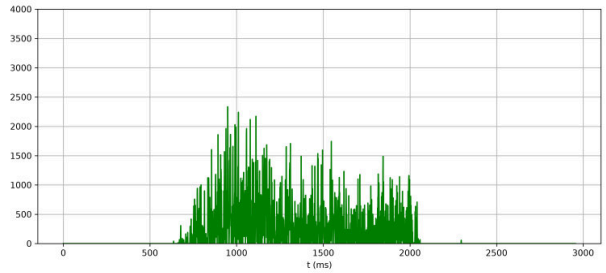
This behavior suggests that the relative activation patterns captured by the two sensors may provide information for distinguishing the analyzed movements. Accordingly, the mean energy calculated independently for each sensor is used to construct a compact two-dimensional feature representation of each repetition.

The computation of this parameter follows the procedure described in Figure 7, detailed below: moving average filtering, analysis interval detection, and mean energy calculation.

1) Moving average filtering: The noisy nature of the signal hinders the detection of the onset and offset instants of muscular activation. To facilitate this task, a moving average filter was applied to smooth the signal:

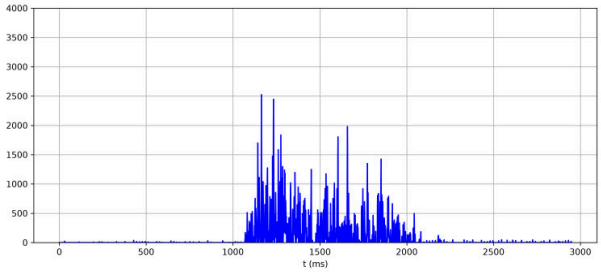


(a) Sensor 1.

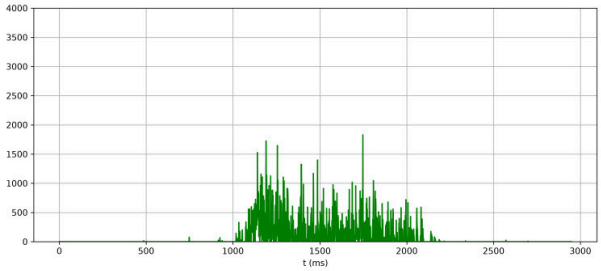


(b) Sensor 2.

Fig. 3: Sensor signals during the wrist flexion movement.

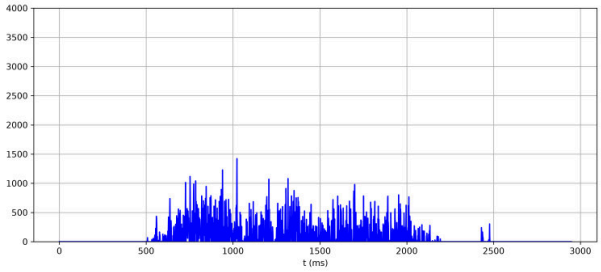


(a) Sensor 1.

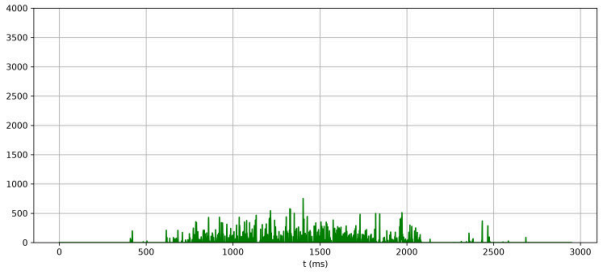


(b) Sensor 2.

Fig. 4: Sensor signals during the wrist extension movement.



(a) Sensor 1.



(b) Sensor 2.

Fig. 5: Sensor signals during the wrist opening movement.

(a) Sensor 1.

(b) Sensor 2.

Fig. 6: Sensor signals during the wrist closing movement.

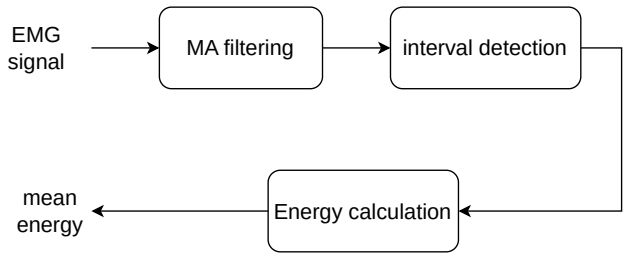


Fig. 7: Block diagram of the feature extraction procedure.

$$y[n] = \frac{1}{N} \sum_{k=0}^{N-1} x[n-k] \tag{1}$$

where:

- $x[n]$ is the original sEMG signal at the discrete time instant n;
- $y[n]$ is the smoothed signal after applying the filter;
- N is the moving average window size (the number of samples considered in the computation);
- k is the summation index, which iterates over the preceding samples within the window;
- n is the discrete time index of the signal.

Moving average windows of 5, 10, and 20 samples were tested in order to evaluate the impact of the window size on the degree of signal smoothing. The 10-sample window provided the best trade-off between noise reduction and preservation of the signal characteristics, maintaining the integrity of the muscular activation peaks while significantly reducing undesired fluctuations. Figure 8 shows the effect of this filter on the signal.

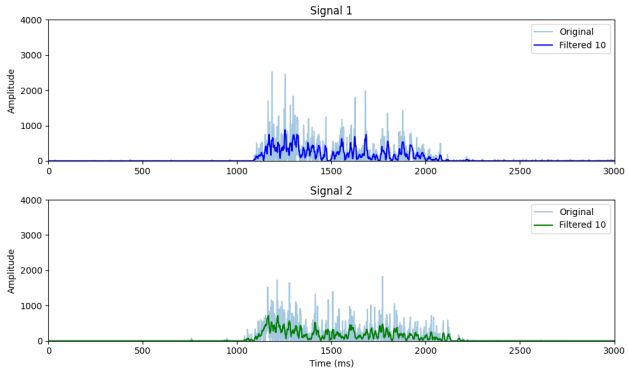

Fig. 8: sEMG signal of the wrist extension movement after appl:ying the moving average filter with a 10-sample window.

2) Analysis interval detection: Defining the analysis interval is important because it discards the regions of the signal where there is no muscular activity (rest regions), thereby allowing an accurate reading of the activation levels for each sensor. The algorithm used for this purpose consists of the following steps:

a) Each signal is divided into 10 ms windows, with 50% overlap between adjacent windows.
b) The energy of each window is computed as the sum of the squared samples of the smoothed signal within that window:

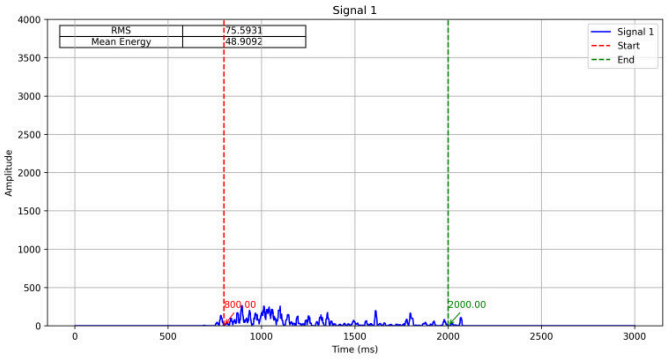
$$E_i = \sum_{n \in W_i} y[n]^2 \tag{2}$$

where E_i is the energy of the i-th window W_i and $y[n]$ is the smoothed signal. The largest value among all windows (E_{max}) is taken as a reference.
c) Two thresholds k_1 and k_2 are defined: k_1 corresponds to 10% of E_{max} and k_2 to 20% of E_{max}.
d) To determine the onset of the interval, a three-state machine is used: 0 (no signal), 1 (onset candidate), and 2 (onset). The system starts in state 0. Beginning at the start of the signal, the energy of each window is monitored. When the energy of a window exceeds k_1, the system transitions to state 1 (onset candidate). From there, two scenarios are possible: if the energy in the subsequent windows remains above k_1 and later exceeds k_2, the onset is set as the first window in which k_2 was reached; if the energy drops below k_1, the system returns to state 0. This mechanism minimizes the occurrence of false positives.
e) The detection of the offset instant is performed analogously, using the same thresholds k_1 and k_2.

For each signal, the onset and offset points of the interval of interest were determined. Figure 9 illustrates this procedure for the wrist extension movement, showing Channel 1 and Channel 2 of the same contraction separately and highlighting the limits used in the mean computation. It can be observed that, although both signals correspond to the same movement, the onset and offset instants may differ between channels, evidencing variations in the intensity of the signal captured by each sensor.

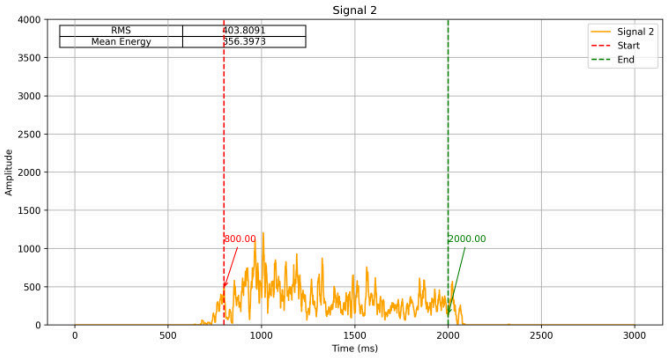
3) Mean energy calculation: Within the interval selected for each acquisition, the mean energy of the signal was computed, resulting in a single scalar value per channel. It is obtained using the following equation:

$$\overline{E} = \frac{1}{M} \sum_{i=1}^{M} E_i \tag{3}$$



where:

- $\overline{E}$ is the mean energy;
- M is the number of windows within the analysis interval;
- E_i is the energy of the i-th window, as defined in Equation (2).



As a result, each executed movement is represented by only two scalar values.

IV. Results and Discussion

To explore the separability of the analyzed movements, the mean energy values obtained in each repetition were arranged in a two-dimensional scatter plot, with Channel 1 on the horizontal axis and Channel 2 on the vertical axis, as shown in Figure 10. The analysis is based on visual inspection of the resulting feature-space distribution and does not constitute a quantitative classification evaluation.

(a) Sensor 1.

(b) Sensor 2.

Fig. 9: Onset and offset instants of the interval of interest produced by the interval detection algorithm for the wrist extension movement.

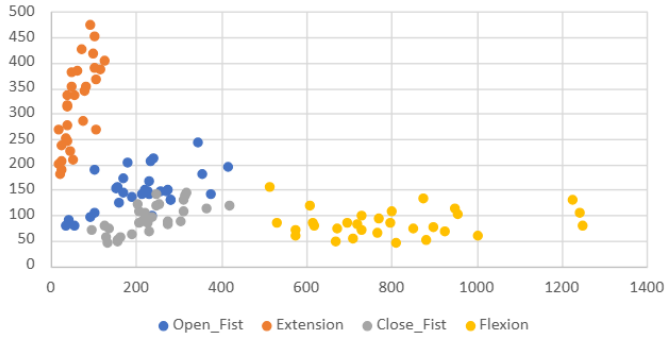


Fig. 10: Scatter plot of the mean energy values of the EMG signals for the four analyzed movements. Each point represents an individual repetition. The colors indicate the different movements: extension (orange), wrist opening (blue), wrist closing (gray), and flexion (yellow).

The formation of clusters associated with each movement can be observed. Extension and flexion occupy weakly

overlapping regions, indicating good separation when both channels are considered. In contrast, wrist opening and wrist closing form closer clusters with a greater tendency to overlap, suggesting more similar mean activation patterns or higher intra-class variability.

Using only two channels and a single time-domain feature (mean energy), the scatter plot provides preliminary evidence of separability among the analyzed movements based on their characteristic activation patterns. Wrist flexion and extension exhibit comparatively distinct regions in the feature space, whereas wrist opening and closing show greater overlap. These observations support the feasibility of the proposed low-dimensional representation as a basis for future automatic classification, but they should not be interpreted as a quantitative measure of classification performance.

These findings should nonetheless be regarded as preliminary, since they were obtained from a small and homogeneous sample of two healthy male volunteers of similar age and build. Consequently, the observed separability cannot be assumed to generalize to a broader population. In particular, no quantitative classification performance was evaluated in the present study. Validation with a larger and more diverse group of participants, together with quantitative classification experiments, is required before drawing more general conclusions.

V. Conclusion

This work addressed the difficulty of acquiring, processing, and interpreting EMG signals in an accessible and reliable manner, with a focus on exploring the separability of different muscular movements using a low-dimensional representation, particularly in applications related to the analysis of upper-limb movements. The variability of EMG signals, the presence of noise, and the need for appropriate processing techniques represent relevant challenges for the correct identification of the muscular patterns associated with each movement.

In this context, an EMG signal acquisition system was developed using the ESP32 microcontroller, operating at the sampling rate defined for the experiment, with the acquired signals stored in CSV files and subsequently processed on a computer. The system incorporated moving average smoothing with windows of different sizes, aimed at reducing noise and improving the representation of muscular activation patterns. The mean energy of each channel was then extracted as the feature used to characterize and compare the signals.

The obtained results showed that the adopted processing techniques provided a clearer representation of the muscular activation patterns. The graphical analysis based on the two-channel feature space revealed that wrist extension and flexion form comparatively well-separated clusters, while wrist opening and closing exhibit greater overlap. Thus, the results provide preliminary evidence that the proposed two-dimensional representation captures movement-dependent activation patterns, while quantitative classification performance remains to be evaluated.

As its main contribution, this work presents a low-cost and relatively simple approach for the acquisition and processing of EMG signals, integrating accessible hardware and efficient computational methods. The resulting two-dimensional feature representation provides an exploratory basis for studying movement-dependent activation patterns and can serve as a starting point for future classification studies and applications in device control, assistive rehabilitation, human–machine interfaces, and academic studies focused on biomedical signals.

As future work, quantitative classification experiments using the existing feature representation are suggested, including the evaluation of suitable classifiers and performance metrics such as accuracy, sensitivity, and confusion matrices. Comparisons with established time-domain features such as mean absolute value (MAV), root mean square (RMS), and waveform length would also help to position the proposed representation relative to classical sEMG descriptors. In addition, increasing the number and diversity of volunteers and the number of analyzed movements is necessary to enhance the robustness and generalizability of the findings. Furthermore, the investigation of additional filtering and feature extraction techniques, along with the integration of the system into real-time actuation devices, could significantly broaden the scope and applications of the project.

***Abstract*—Brain-Computer Interfaces (BCIs) based on electroencephalography (EEG) are expected to become an important solution for extreme cases of neuromotor rehabilitation. To do so, it is key to comprehend the characteristics of brain signals elicited in typical BCI paradigms. One of the most popular paradigms for BCI studies is cue-based with visual stimulus indicating the motor imagery (MI) task to be performed. This paradigm is widely adopted to study MI signals and calibrate BCI systems before usage. An important challenge for EEG decoding is the variability of the signal, which is caused, among other reasons, by the inappropriate reference electrode choice. Despite some alternatives to minimize the problem, it remains as an unsolved issue. Recently, a new promising approach to this issue called Inverted Perspective Reference Electrode (IPRE) was proposed. In this paper, we use the IPRE to investigate EEG signals from a publicly available MI-cue-based dataset to find which cortical information dominates the recordings in this paradigm. An IPRE-based score metric is proposed to rank the channels according to the amount of information they contain. Then the 10 channels with highest scores are analyzed along with their signals. Our hypothesis is that either visual or motor cortical activities are more likely triggered by the task paradigm. Therefore, the procedures were applied to α band energy signals corresponding to the trials of left-hand MI. Results showed notable agreement among the channels selected across different subjects, especially the presence of O2 occupying the reference position and the other electrodes distributed over the parieto-occipital cortex, slightly tending to the right motor cortex. The event-related desynchronization (ERD) time-linked to the cue appearance was identified for all subjects and channels, although presenting subject-specificities. The channels and the time-energy features suggest that the ERD corresponds mostly to visual processing with some contribution of the motor cortex due to MI performance.**

***Index Terms*—Electroencephalogrphy (EEG), Motor-Imagery, IPRE, Reference electrode**

I. Introduction

Brain-Computer Interfaces (BCIs) are systems designed to provide a direct communication pathway between the brain and external devices, translating neural signals into computer commands. In the past decades, they have gained attention as a promising alternative for motor rehabilitation due to their encouraging results in such applications [1], [2]. BCIs have become an even more appealing subject when considering the limitations of current therapies towards severely impaired people, such as when a person has only residual motor control over a limb or no control at all [3], [4]. Electroencephalography (EEG) based BCIs are the most popular type of BCI, especially for safety (it is a non-invasive technique) and practical reasons, such as the high temporal resolution of EEG measurements [5]. In this scenario, the analysis of motor imagery (MI) EEG signals is key, given that even in extreme situations patients may still be able to activate their motor cortex by using imagery.

The EEG analysis, however, presents some major challenges, which have been limiting the use of BCIs in actual rehabilitation therapies. Motor imagery signals, in fact, increase these challenges compared to motor execution, for instance. The intra-subject variability of EEG signals is perhaps the major difficulty to assess and has been a research topic from pioneering works related to EEG-based BCIs [6], [7] till the current state-of-the-art [8], [9]. A major part of such variability is caused by the inappropriate choice of the reference electrode [10], [11]. Despite the existence of classical techniques to reduce the reference electrode influence, such as common average reference [12], REST [13], and surface Laplacian [14], [15], there is still no golden standard, and each of these approaches introduces other sources of uncertainties [8]. A different approach is to assume the impossibility to eliminate the reference issue and look at any channel as a bipolar derivation [8]. However, this approach generates a large amount of data, requiring the definition of specific criteria to select subset of channels. A recent approach called Inverted Perspective Reference Electrode (IPRE) [16] suggests that a monopolar set of channels should be viewed as a collection of information from the reference site, and uses PCA to extract the first principal component (PC), in order to maximize the information about the reference in just one signal. In IPRE, the location of interest should be set as the reference and the multi-channel monopolar signals are substituted by the PC.

This research was supported by Coordination for the Improvement of Higher Education Personnel (CAPES), Finance code 001; São Paulo Research Foundation (FAPESP), Grants 2013/07559-3 (BRAINN), 2023/12422-9 and 2024/00998-6 (CRISQuaM); Brazilian National Council for Scientific and Technological Development (CNPq), Grants 306255/2024-3 and 408389/2024-9 (INCT-NeuroComp); Funding Authority for Studies and Projects (FINEP), Grant 2140/22 (DReANNs); and Brazilian Coordination for the Improvement of Higher Education Personnel (CAPES) - Finance Code 001.

In the BCI literature, the offline investigation of MI signals plays an important role in improving the understanding of task-related features [17]. The underlying mechanisms of the brain are complex even during a simple task, such as MI performance. This complexity is due, among other factors, to the variety of stimuli inherent to any experimental setup. These stimuli can originate from the clinical or laboratory environment or from the BCI paradigm itself. When it comes to the BCI paradigm, the use of virtual scenarios with visual cue-based trials is probably the most common strategy for signal acquisition [17]. Therefore, it is important to identify brain activities present in EEG signals in this paradigm, regardless of whether they are directly related to MI or to other stimuli.

In this paper we explored the IPRE approach to rank the channels according to their contribution to the task-related information captured by the IPRE approach in a cue-based paradigm. To rank the channels, we adapted the IPRE strategy to quantify how much each channel (combination of two electrodes) influenced the PCs. To do so, a score was proposed to account for the importance of each component and how much each channel influenced it. With this score, we could rank the channels for each subject. A publicly available dataset [18] with MI signals was used. Because the signal acquisition paradigm was MI cue-based, it was hypothesized that visual potentials related to the cue and motor-related potentials associated with the MI task would be elicited more than other EEG signatures. In both cases, it has been shown that the event-related desynchronization (ERD), which is a band-specific energy reduction time-locked to cortical activation, occurs as an indication of visual processing or motor-imagery execution. The ERDs for these cortical activities have been reported to occur mainly in the α band ($8-12$ Hz) over the occipital cortex for visual processing and over the motor cortex for motor-imagery [19]–[22].

II. Methods

A. EEG Dataset

The publicly available data set from BCI Competition IV (dataset 1, calibration data) [18] has EEG related to MI tasks from seven subjects labeled as A through G. However, subjects C, D, and E correspond to artificially generated signals, so they were not considered in this work. Data were recorded with 59 electrodes according to the $10-20$ extended system distributed over the scalp and more concentrated on the motor cortex. In this work, only MI for the left hand was considered, although the dataset also contained right-hand MI trials. Subjects were oriented to look at a computer screen and execute the MI according to the cues appearing on the screen (arrow pointing left indicated left hand MI). It was a permanent process consisting of 2s of blank screen, 2s with a cross in the center of the screen, 4s with the cross and the cue, and the same sequence repeated multiple times. By the end of data acquisition there were 75 left-hand MI trials. The trial interval with the starting point after the first 1 s of blank screen is schematically shown in Fig. 1.

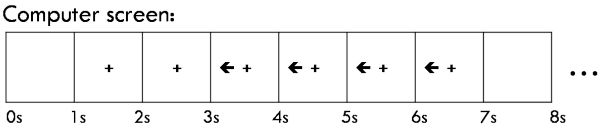

Fig. 1. Sequence of one trial 8s long.

B. EEG Pre-processing

For the entire channel selection procedure and results presentation, only the 4-second interval from $t = 1s$ to $t = 5s$ was considered (see Fig. 1). This 4-second interval was chosen because it contains the most relevant events of the task, which are the cross appearing on the screen as an attention signal, the cue presentation indicating the MI to be executed, and the initiation of the MI activity itself, which likely occurs within two seconds post cue appearance. Because the focus was to find channels with ERD in the α band, signals were band-pass filtered in the $8-12$ Hz range with a 6^{th} order Butterworth filter in both directions.

C. Channel Scoring Pipeline

To perform the channel selection, a procedure consisting of 7 steps took place repeatedly and separately for each subject: 1) Definition of an electrode to be set as the reference; 2) Data re-referencing to the new reference; 3) Transformation of the signals into energy by squaring the samples; 4) Smoothing of the energy signals with a 100 ms sliding window; 5) Trial average calculation separately for each channel; 6) PCA transformation; 7) Score calculation for each combination of channel (pair of electrodes) and PC, which was designated as Total Score.

The procedure was repeated so that all available electrodes were eventually set as the reference in step 1. After all 59 electrodes were used as the reference, all channels (pairs of electrodes) along with their corresponding PC were ranked according to their score. For each subject, the top 10 scores were analyzed to select the channels.

D. IPRE, Channel Impact and Total Score

The IPRE core, as presented in [16], is a way to approach a multichannel monopolar dataset to reduce the issue of the active reference electrode. It consists of setting the electrode of interest as the reference for all the others, opposed to the traditional approach, and calculating the first PC which supposedly contains the maximum information about the reference. In the IPRE, the first PC would then be used as the signal to be analyzed. However, the method proposed in this work does not use the first PC as a substitute for the signals, but instead it quantifies how much each channel contributed to the PC. This channel contribution, called Channel Impact, and the amount of information (variance) of the corresponding PC are used to generate the Total Score for each channel. In the following, details on how the PCA, Channel Impact and Total Score were calculated are presented. Although PCA is a well-known multivariate technique that has been applied

to EEG signals for decades [23]–[28], a brief explanation is given here to provide a more intuitive reasoning for the proposed scoring. Given the EEG data matrix X_{np}, where each row is a time sample and each column is an EEG channel,

$$X = \begin{bmatrix} x_{11} & x_{12} & x_{13} & \dots & x_{1p} \\ x_{21} & x_{22} & x_{23} & \dots & x_{2p} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ x_{n1} & x_{n2} & x_{n3} & \dots & x_{np} \end{bmatrix}$$

we calculate the correlation matrix R_{pp} where each element r_{jk} is given by

$$r_{jk} = \frac{\sum_{i=1}^{n}(x_{ij} - \bar{X_j})(x_{ik} - \bar{X_k})}{\sqrt{\sum_{i=1}^{n}(x_{ij} - \bar{X_j})^2}\sqrt{\sum_{i=1}^{n}(x_{ik} - \bar{X_k})^2}} \quad (1)$$

where $\bar{X_j}$ and $\bar{X_k}$ are the mean values of columns (channels) j and k, respectively. Next, the eigenvalue problem must be solved for R and the eigenvector $\tilde{a}_i$ must be calculated.

$$|R - \lambda I| = 0 \quad (2)$$

$$\tilde{a}_i = \begin{bmatrix} a_{i1} \\ a_{i2} \\ \vdots \\ a_{ip} \end{bmatrix} \quad (3)$$

Finally, the $i-th$ component can be determined with the $i-th$ eigenvector as

$$Y_i = a_{i1}X_1 + a_{i2}X_2 + \dots + a_{ip}X_p \quad (4)$$

where $X_1, ..., X_p$ are columns (channels) of a particular re-referenced EEG matrix. The contribution C_i of the $i-th$ PC to the original multichannel data is usually calculated as the percentage of its variance compared to the total variance. However, because we were to compare values from different sets of re-referenced multichannel EEG, the total variance could be seen as an attribute of that reference. Thus, we considered the absolute value of the variance of the first PC instead of its percentage relative to the corresponding total variance. In this case, the contribution was given by:

$$C_i = Var(Y_i) \quad (5)$$

With Y_i, it was possible to quantify the influence of the channel X_j (Channel Impact) on the $i-th$ PC using:

$$Corr(X_jY_i) = r_{X_j.Y_i} = a_{ij}\frac{\sqrt{Var(Y_i)}}{\sqrt{Var(X_j)}} \quad (6)$$

The proposed concept of Total Score TS_{jki} for a channel X_j (which is a combination of electrode j and reference electrode k) associated to a component Y_i was given by Eq. (7):

$$TS_{jki} = C_i r_{X_j.Y_i} \quad (7)$$

Because only the first PC was considered, $i = 1$ for any j and k. Finally, all channels (pairs of electrodes) were ranked according to their TS_{jki} values. The top 10 channels for each subject were selected for analysis.

III. Results

Fig. 2 shows a visual representation of the top 10 channels' positions for each subject. Tab. I informs the 10-20 positions of these same channels, indicating which electrode is used as the reference. With Fig. 3 and Tab. I it can be seen that O2 was the reference electrode in all cases and all the other electrodes were placed in the posterior part of the coronal plane, which means $10-20$ positions between C line (not included) and O line (included). Also, for all four subjects, the closest electrodes to the C line occurred at the right hemisphere.

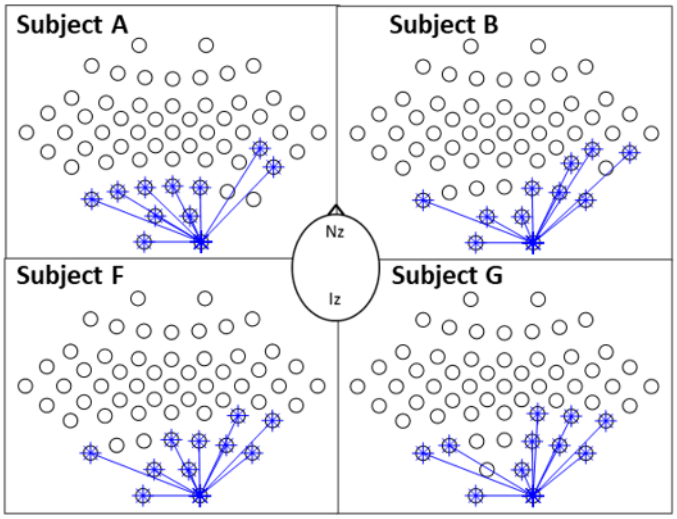

Fig. 2. Visual representations of the top 10 channels for each subject. The lines connect both electrodes within a channel.

Fig. 3 shows the trial-average of the smoothed energy in the α band of all top 10 channels from each subject. A visual inspection allows to find, within each subject, relevant similarities among the signals in the entire interval, given that most of the positive and negative peaks are fairly synchronized, despite magnitude differences. However, only some specific similarities were found among different subjects, which contrasts with the inter-subject similarities between the areas corresponding to the selected channels. For instance, Subjects A and F had similar behaviour in their signals, although for Subject F there was a clear tendency of energy reduction between $t = 2s$ and $t = 3s$ that was not found for Subject A. Subjects B and G, on the other hand, had more unique behaviour and energy levels as well. The time evolution of the energy for Subject G showed a more typical

ERD following the cue-appearance, because prior to that there was a 1-second interval with reasonably stable energy levels, matching the requirement for a good ERD baseline [20]. One temporal mark common to all subjects was the negative peak between $t = 3s$ and $t = 4s$, right after the movement cue appearance ($t = 3s$). Moreover, in general there was an event-related desynchronization (ERD) for all subjects, despite their different intensities, initiating approximately at $t = 2s$ (except for Subject G which initiated at $t = 3s$) associated with the negative peak in between $t = 3s$ and $t = 4s$.

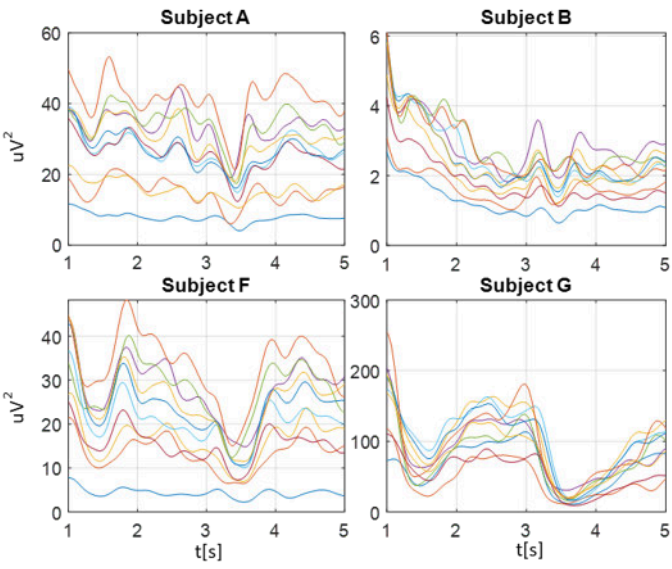

Fig. 3. The trial-average signals from each of the 10 channels of each subject.

IV. DISCUSSION

In this work we proposed a metric using the IPRE to maximize the task-related information in an MI task based on a visual cue paradigm. The procedure allowed to identify channels that carried α band energy changes synchronized to important task events, notably the cue appearance. The selected channels across the four subjects presented notable similarities concerning the cortical regions and shared the same reference electrode.

PCA is a multivariate statistical approach that transforms the original data into uncorrelated components in descending order of variance, i.e., amount of information of the original data. When applied to a multichannel EEG data, this means that these components carry most of the overall information from all channels in the corresponding interval and frequency band. Each set of data in this case is a monopolar set, which means that there are 58 electrodes referenced to the same electrode, making it 58 monopolar channels. In this sense, the IPRE approach [16] argues that the PCA is actually an analysis of the one electrode being used as the reference. In a simple analogy, it relates to 58 points-of-view of one single object (the reference electrode, in this case). This is particularly suitable in this work because the voltage signals are transformed into energy prior to the analysis, therefore their samples are squared, nullifying the effect of which electrode occupies the reference position. The results here presented seem to corroborate this hypothesis, mainly because for each subject all channels had the same reference and at the same time there were notable similarities among the signals.

It has been reported that a simple reference electrode test for the analysis of a certain null-reference candidate location is to change the reference and see if it will produce significant changes in the signal, and if the signals do not change, it is an indication that the locations are adequate for a "silent" reference [11]. This is similar to what was observed in the results if we designated the reference as the "main" electrode and the others as different references for the given "main" electrode. Taking into consideration the presented hypothesis and the results, it seems that the scalp location O2 was the one with most EEG information for all subjects in the MI task protocol in the α band ($8 - 12$ Hz) during the analyzed interval lying in between cross appearance on the screen and 2s post movement cue appearance indicating the left hand MI. This well-founded test and its agreement with the presented results reinforces the validity of these findings.

The similarity regarding the channels selected for the different subjects also deserves great attention, especially because the subject specificity in terms of spatial and temporal features of EEG is well known [8]. It could be expected to find the channels in some large scalp area common to all subjects, but in the presented results they share some very specific similarities that go beyond this. For instance, the electrode O2 was the reference in all 40 channels (10 per subject), and all the other electrodes were in the posterior part of the coronal plane as well. Moreover, whenever an electrode beyond the P line (towards Nz) was selected, it was necessarily at the right hemisphere, in agreement with the contra-lateral activation for left-hand motor tasks. Furthermore, there were 4 channels in common for all subjects (O1-O2, PO2-O2, P5-O2, and P2-O2). Despite these similarities regarding the channels, and some similarities across the signals of the different subjects (e.g. negative peak between $t = 3s$ and $t = 4s$), the signals showed notable subject-specific features, such as different energy range

and overall waveforms. This suggests that even if the cortical processes are similar for all subjects and if they are detected at the same scalp locations, the way they appear in the EEG signals can be considerably different.

Another point that deserves to be noted is the fact that the results suggest that the main information in the selected channels is probably related to visual processing in the occipital cortex. This is in conformity with the experimental paradigm and with the scientific literature [21], [22]. However, we also expected to find movement-related components, which did not seem to be the case. It could be argued that O2 is actually performing the role of a "silent" reference and the other electrodes, closer the the motor cortex and slightly shifted to the contra-lateral hemisphere, are the ones really providing the signals. This is a seductive hypothesis, especially because of the negative peak time-related to the probable initiation of the MI by the subjects, and because it would be a better result at a first sight aiming at a motor rehabilitation BCI. Nevertheless, we believe this is not the case for two reasons: 1) the reference electrode test previously mentioned [11] that puts O2 in the "main" electrode position, and 2) despite the electrodes being slightly closer to the motor cortex, only 10 electrodes out of the top 10 channels for all subjects are actually beyond line P towards the motor cortex. In fact, these 10 electrodes might contain motor-related signals contributing to generate the negative peak in the signals after the cue presentation. This does not mean that there was no significant motor ERD, but only that the visual processing by the occipital cortex carried more information in terms of variance. For instance, maybe it would be possible to find principal components with less variance and with their most relevant channels concentrated in the motor cortex, thus reflecting the motor ERD more purely.

V. Conclusion

In this work we proposed a strategy to find channels that maximize the information from EEG in an MI cue-based paradigm using the IPRE approach. A publicly available dataset was used, with data from four subjects, from which only the left-hand imagery trials were analyzed. A Total Score metric was presented as a criterion to rank the channels separately for each subject. All combinations of pairs of electrodes were considered. Our findings suggested that the electrode position O2 is the one with most task-related information, probably due to visual processing of the stimuli on the computer screen, instead of motor cortex activity. The latter, however, also seems to contribute with ERD information in the hemisphere contra-lateral to the MI. This holds for all subjects. However, although results are interesting, they must be considered with caution due to the limited subject sample. Future studies are needed with a larger group of subjects and diverse paradigms to confirm the presented hypothesis.

Abstract*—Wearable photoplethysmography (PPG) has enabled continuous cardiovascular monitoring outside clinical environments; however, motion artifacts remain a major source of signal degradation, particularly in consumer-grade earable devices. This study presents a signal-level characterization of in-ear photoplethysmography (earPPG) acquired from a commercial earable and evaluates a lightweight motion-artifact rejection strategy to improve heart rate (HR) estimation. EarPPG and reference electrocardiogram (ECG) signals were simultaneously acquired in a controlled single-subject protocol comprising resting conditions and four motion scenarios: walking, horizontal head movement, vertical head movement, and mastication. Signals were synchronized, filtered, and segmented into analysis windows, while motion contamination was quantified using a moving standard deviation metric with a threshold derived from resting-condition variability. Heart rate estimation performance was evaluated before and after rejecting motion-contaminated windows using mean absolute error (MAE), root mean square error (RMSE), Bland-Altman analysis, and Pearson correlation. The proposed strategy reduced global MAE from 11.67 BPM to 5.97 BPM and RMSE from 19.41 BPM to 10.78 BPM, while reducing estimation bias from -10.11 BPM to -4.87 BPM. The largest improvements were observed during head-motion conditions, with error reductions of 58.47% and 69.89% for horizontal and vertical movements, respectively. These findings demonstrate that lightweight signal-quality screening can substantially improve HR estimation from commercial earPPG recordings acquired under motion, providing a practical foundation for future validation studies involving larger and more diverse populations.

***Index Terms*— earable, photoplethysmography, heart rate estimation, motion artifacts.**

I. Introduction

The increasing adoption of wearable technologies has expanded the possibilities for continuous physiological monitoring beyond conventional clinical environments [1], [2]. Among the sensing modalities employed in wearable systems, photoplethysmography (PPG) has become one of the most widely adopted techniques due to its low cost, non-invasive operation, and suitability for compact devices [3]. By measuring optical variations associated with pulsatile blood volume changes, PPG enables the estimation of cardiovascular parameters such as heart rate (HR), heart rate variability (HRV), and peripheral vascular dynamics [4], [5].

Despite its widespread use, wearable PPG acquisition remains susceptible to motion artifacts, variations in sensor placement, changes in optical coupling, low perfusion, and environmental interference [6]. These disturbances may distort the waveform morphology, introduce false pulse detections, and degrade the accuracy of downstream physiological estimations. Consequently, robust signal-quality assessment and computationally efficient motion-aware processing remain important challenges in wearable biomedical signal processing.

Recently, earable devices have emerged as a promising platform for physiological sensing by integrating optical and multimodal sensors into consumer electronics such as wireless earbuds and hearing aids [7]. Compared with conventional wrist-worn devices, the auricular region provides a mechanically stable measurement location while remaining comfortable for prolonged daily use. In addition, the widespread adoption of consumer earbuds and hearing aids creates opportunities for

unobtrusive and continuous physiological monitoring using devices that are already incorporated into everyday routines [8]. These characteristics have motivated increasing interest in in-ear photoplethysmography (earPPG) as a practical sensing modality for wearable cardiovascular monitoring.

Although the availability of commercial earable platforms has increased considerably [9], the characteristics of the raw physiological signals provided by these devices remain comparatively less explored than those obtained from dedicated research prototypes. A better understanding of signal behavior under representative operating conditions is essential for the development of reliable signal-processing algorithms and wearable health applications.

A. Related Works on EarPPG and Motion Artifact Assessment

The feasibility of in-ear physiological monitoring has been demonstrated by several studies using dedicated research prototypes and custom-designed sensing platforms. Bubb et al. [10] investigated earable-based physiological sensing and highlighted the suitability of the ear canal for unobtrusive cardiovascular monitoring, emphasizing its mechanical stability and reduced susceptibility to upper-limb motion. Benkert et al. [11] evaluated the influence of different motion conditions on earPPG acquisition, demonstrating that head movements substantially affect signal morphology and heart-rate estimation accuracy.

More recently, research has shifted toward commercially available earable devices. Liu et al. [12] proposed EarFusion, a quality-aware framework that combines in-ear audio and photoplethysmography signals to improve heart-rate estimation by exploiting complementary sensing modalities available in earables. In parallel, Doherty et al. [13] validated the heart-rate measurements provided by AirPods Pro 3 during graded treadmill exercise, demonstrating the growing potential of consumer-grade earbuds as physiological monitoring platforms.

Beyond earable-specific research, motion artifact mitigation has been extensively investigated in wearable PPG systems. Previous studies have proposed adaptive filtering, machine-learning algorithms, and signal-quality assessment techniques to detect or suppress motion-related distortions in photoplethysmographic signals [14], [15]. Among these approaches, lightweight quality assessment methods are particularly attractive for wearable and edge-computing applications because they require limited computational resources while allowing unreliable signal segments to be identified before physiological estimation [16].

Although previous investigations have demonstrated the feasibility of earPPG acquisition, most studies have focused on prototype platforms or on the final performance of physiological estimation algorithms. Comparatively fewer studies have characterized the raw signals provided by commercially available earables under controlled but representative motion conditions. Likewise, the effectiveness of simple signal-quality metrics for identifying motion-contaminated earPPG segments remains insufficiently explored.

In this context, this work presents an exploratory case study based on a single healthy volunteer to characterize raw earPPG signals acquired from a commercially available earable. Rather than providing population-level validation, the objective is to investigate the signal behavior obtained from a consumer-grade platform under controlled motion scenarios. Specifically, this study aims to: (i) characterize raw earPPG signal behavior during different motion conditions; (ii) quantify the impact of motion artifacts on heart-rate estimation; and (iii) evaluate a lightweight motion-aware rejection strategy based on temporal signal variability. The proposed framework provides an initial signal-level assessment that may support the development of more robust physiological monitoring algorithms for future earable applications.

The remainder of this article is organized as follows. Section II introduces the fundamentals of in-ear photoplethysmography, while Section III describes the experimental protocol, data acquisition procedures, signal processing pipeline, motion artifact detection strategy, and evaluation methods. Section IV presents the experimental results obtained under different motion conditions. Section V discusses the implications and limitations of the proposed approach. Finally, Section VI summarizes the main conclusions and future research directions.

II. In-ear Photoplethysmography (earPPG)

Photoplethysmography is a non-invasive optical sensing technique widely used for cardiovascular monitoring by measuring temporal variations in light intensity associated with pulsatile blood volume changes in microvascular tissue [4], [17]. In a typical PPG system, a light-emitting diode (LED) illuminates the tissue while a photodetector measures the intensity of the reflected or transmitted light. The acquired waveform consists of a pulsatile alternating component (AC), produced by cardiac-driven blood volume variations, superimposed on a slowly varying direct component (DC), associated with static tissue properties, venous blood, and sensor-tissue coupling [5].

In earable devices, the PPG sensor is positioned inside the external auditory canal, where the surrounding tissue exhibits favorable vascularization and relatively stable mechanical coupling [18]. Compared with conventional wrist-based configurations, this anatomical location is less affected by upper-limb movements and may provide improved signal stability during daily activities [7], [10]. In the present study, the green optical channel (530 nm) was employed, as this wavelength is widely adopted in wearable PPG systems due to its high sensitivity to pulsatile blood volume variations.

Despite these anatomical advantages, earPPG acquisition remains susceptible to motion-induced disturbances. Head rotations, mastication, variations in insertion depth, changes in contact pressure, and tissue deformation may alter the optical coupling between the sensor and surrounding tissue, producing amplitude fluctuations, baseline variations, and waveform distortions. Such artifacts may compromise pulse detection and, consequently, the estimation of cardiovascular parameters.

For these reasons, reliable physiological monitoring using earPPG requires appropriate signal preprocessing, quality assessment, and artifact mitigation strategies. The methodology adopted in this work focuses on evaluating raw earPPG signals acquired from a commercial earable and investigating whether a lightweight signal-quality metric can identify motion-contaminated segments before heart-rate estimation.

III. Methodology

Figure 1 summarizes the complete processing workflow adopted in this study. Starting from raw signal acquisition, the proposed pipeline performs preprocessing, motion-aware quality assessment, heart rate estimation, and quantitative performance evaluation. Each stage is detailed in the following subsections.

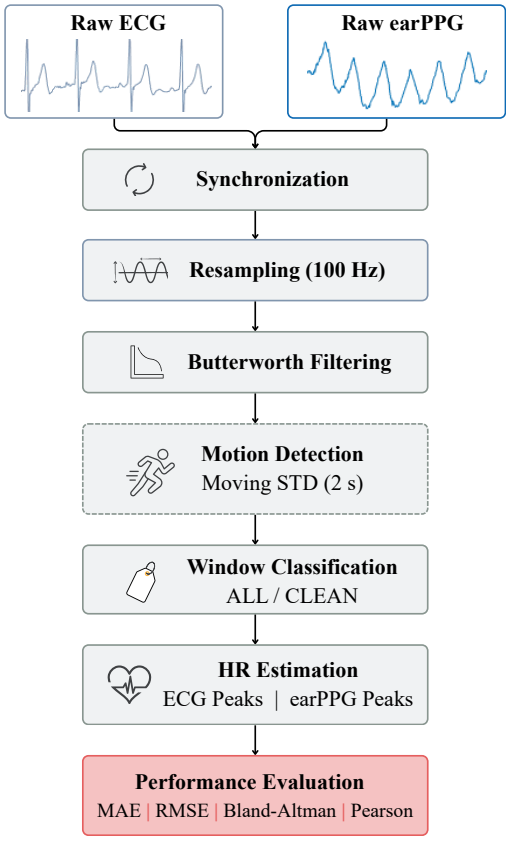

Fig. 1: Overview of the proposed signal processing pipeline for motion-aware heart rate estimation from earPPG signals.

A. Earable Platform

The experimental acquisitions were performed using the OmniBuds Research Platform (OmniBuds Ltd., Cambridge, UK; Figure 2), a sensory earable designed for physiological monitoring and research applications [19]. Originating from Nokia Bell Labs [20], OmniBuds is a commercially available research platform for in-ear physiological monitoring. The device integrates kinetic, acoustic, thermal, and optical sensing modalities, enabling continuous real-time monitoring of multiple vital signs with up to six hours of battery life. For research applications, the platform provides access to raw sensor streams via a dedicated Python API over Bluetooth Low Energy (BLE), allowing unprocessed data to be exported to an external host for offline analysis. This capability was the primary feature exploited in this study.

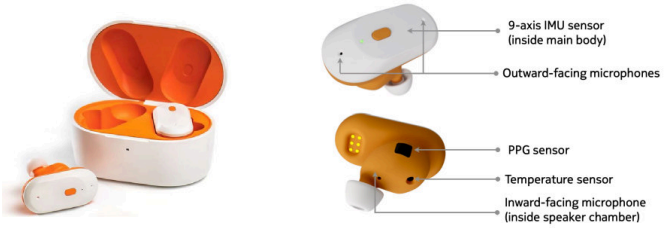

Fig. 2: The OmniBuds Research Platform [20].

B. Participant and Data Acquisition

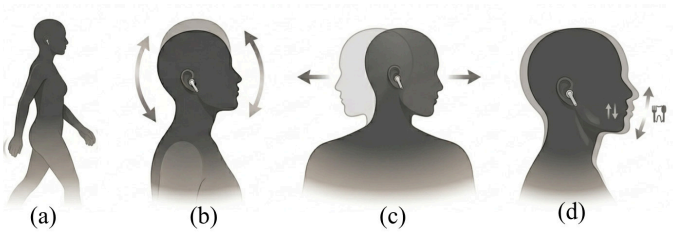
The acquisitions were conducted with a single healthy adult volunteer in a controlled laboratory environment under constant artificial light. The wearable device was positioned in the right external auditory canal according to manufacturer instructions. Raw PPG signals were exported directly from the device at a sampling frequency of 100 Hz and streamed in real time to a desktop computer for continuous data logging. The green LED channel (530 nm) was employed in this study, and the LED drive current was set to 31 mA, which controls the optical emission intensity.

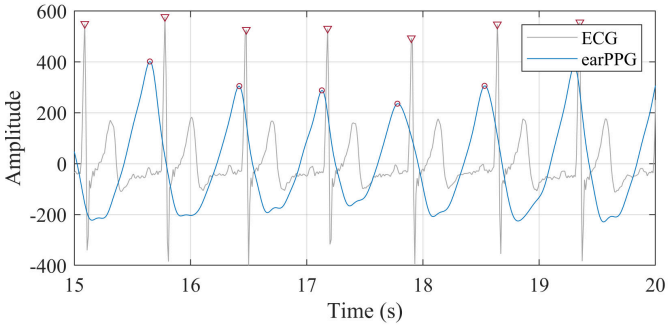
Recording sessions followed a structured 80-second protocol, divided into a tri-phasic sequence: an initial 30 s rest period, a 20 s movement interval, and a final 30 s recovery rest. This design captured natural variability alongside motion-induced perturbations. The volunteer performed four motion tasks (Figure 3), representing distinct profiles relevant to everyday auricular wearable use:

- Scenario (a): walking at 100 steps per minute (daily physical activity);
- Scenario (b): horizontal head shaking at 70 repetitions per minute (axial head rotation);
- Scenario (c): vertical head shaking at 70 repetitions per minute (sagittal head rotation);
- Scenario (d): mastication through chewing gum (repetitive facial muscle activity).

To ensure temporal consistency and standardized task execution, a metronome was used to pace Scenarios (b)-(d). In total, 20 motion recordings were acquired in addition to baseline resting recordings. Each motion scenario was repeated five times. Simultaneously, a chest-worn heart rate monitor (Polar H10, Polar Electro Oy) was used as a cardiac reference signal [21]. No physiological manipulation, calibration procedures, or signal conditioning were applied during acquisition. The study focused exclusively on signal-level characterization rather than physiological intervention or diagnostic evaluation.

An additional acquisition was performed entirely at rest to validate the earPPG measurements, as illustrated in Figure 4. Figure 4(a) shows synchronized ECG and earPPG recordings





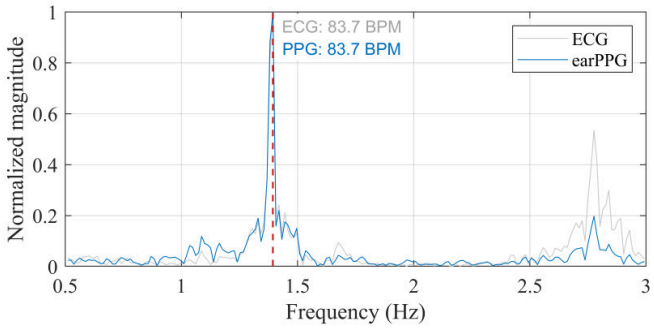


Fig. 3: Representative acquisition scenarios used for structured characterization of in-ear multimodal signals. (a) walking; (b) horizontal head motion; (c) vertical head motion; and (d) chewing.

in the time domain, where the pulsatile earPPG waveform follows the cardiac cycles identified by the ECG R-peaks, despite the expected temporal delay associated with pulse transit time. Figure 4(b) presents the corresponding normalized frequency spectra, showing that both signals exhibit the same dominant frequency component (83.7 BPM), confirming preservation of the cardiac pulsatility in the earPPG signal.

(a) Time-domain ECG and earPPG waveforms.

(b) Corresponding frequency-domain spectra demonstrate preservation of cardiac pulsatility in the in-ear PPG signal.

Fig. 4: Representative synchronized ECG and earPPG recordings acquired during the resting condition.

C. Signal Processing

The raw ECG and earPPG signals were independently acquired and exported as timestamped data streams. Since both sensors operated with distinct internal clocks and potentially different native sampling frequencies, all signals were temporally synchronized prior to analysis. Duplicated timestamps were removed to avoid interpolation inconsistencies. Occasional discontinuities in the earPPG stream caused by Bluetooth packet losses were automatically identified through temporal gap detection. A gap was defined whenever the interval between consecutive PPG timestamps exceeded 1.5 times the nominal sampling interval. Missing segments were reconstructed through linear interpolation using neighboring valid samples.

The common valid time interval between ECG and earPPG recordings was then determined by selecting the overlapping acquisition period shared by both modalities. Subsequently, both signals were resampled onto a uniform temporal grid at 100 Hz using piecewise cubic Hermite interpolation (PCHIP), ensuring synchronized sample-wise alignment while preserving waveform morphology. To eliminate unstable acquisition periods commonly observed at recording initialization and termination, the first and last 10 seconds of each recording were discarded prior to analysis.

Digital filtering was then applied independently to each modality. ECG signals were processed using a fourth-order Butterworth bandpass filter with cutoff frequencies between 0.5 Hz and 40 Hz to preserve the cardiac QRS complex while attenuating baseline wander and high-frequency noise. EarPPG signals were filtered using a fourth-order Butterworth bandpass filter between 0.5 Hz and 8 Hz, preserving pulsatile cardiovascular components while suppressing attenuating baseline fluctuations and high-frequency noise [22].

D. PPG Signal-Quality Screening

Motion contamination was quantified by computing a moving standard deviation (STD) over a 2-second sliding window across the filtered earPPG signal. Let $x[n]$ denote the earPPG signal and L the number of samples corresponding to the 2-second window. The local STD sequence is computed as

$$s[n] = \sqrt{\frac{1}{L-1}\sum_{k=0}^{L-1}\left(x[n-k]-\bar{x}_n\right)^2}, \tag{1}$$

where $\bar{x}_n$ denotes the local mean over the same window. The moving STD characterizes short-term temporal variability in the earPPG waveform, allowing localized increases in signal variance associated with motion artifacts to be identified [23].

The filtered earPPG signal was subsequently segmented into 10-second analysis windows with 50% overlap (i.e., a 5-second hop size). For each analysis window W_i, a scalar motion metric was defined as the average value of the moving STD,

$$M_i = \frac{1}{N}\sum_{n\in W_i} s[n], \tag{2}$$

where N is the number of samples contained in the corresponding analysis window.

The decision threshold was estimated exclusively from the resting-condition recordings as

$$T = \text{median}(M_{\text{rest}}) + 3\ \text{MAD}(M_{\text{rest}}), \tag{3}$$

where M_{rest} denotes the set of motion metric values obtained from resting recordings and MAD is the median absolute deviation [23].

Each analysis window was then classified according to

$$C_i = \begin{cases} \text{CLEAN}, & M_i < T, \\ \text{MOTION}, & M_i \geq T, \end{cases} \tag{4}$$

where C_i denotes the quality label assigned to the i-th analysis window.

Thus, the short-term variability quantified over successive 2-second windows is summarized into a single motion metric for each 10-second analysis window, enabling motion-contaminated segments to be identified prior to heart-rate estimation.

E. Heart Rate Estimation

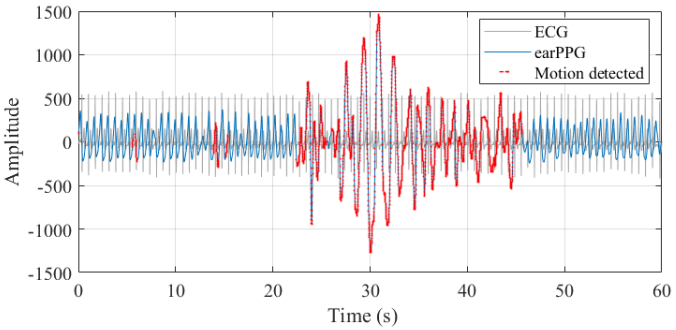
Heart rate (HR) was independently estimated from both ECG and earPPG signals using peak interval analysis applied within each 10-second analysis window. For ECG processing, cardiac peaks were detected using a peak-finding algorithm based on local prominence, with a minimum peak distance of 0.4 seconds (corresponding to a maximum detectable heart rate of 150 BPM). The prominence threshold was defined as the standard deviation of the ECG signal within each analysis window. RR intervals were computed as the time differences between consecutive detected peaks, and heart rate was then estimated from the average RR interval within each window.

Similarly, systolic peaks were detected in the earPPG signal using the same minimum peak distance criterion, with a prominence threshold defined as the standard deviation of the earPPG signal within each window. Pulse-to-pulse intervals were obtained from consecutive detected peaks and used to compute the corresponding heart rate estimate.

The heart rate estimation error (HRE) for each window was defined as the absolute difference between the earPPG-derived and ECG-derived heart rate values, computed independently for each analysis segment.

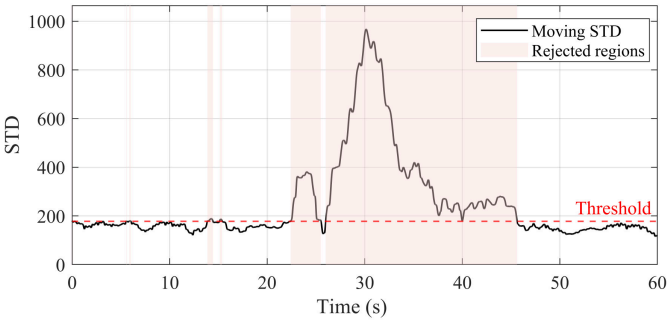
F. Performance Evaluation

The accuracy of the earPPG heart rate estimation was evaluated against the reference cardiac signal acquired using a Polar H10 chest strap both before (ALL windows) and after (CLEAN windows) the application of the proposed motion-aware rejection strategy. Performance was quantified using the Mean Absolute Error (MAE), Root Mean Square Error (RMSE), bias, and standard deviation (SD) of the estimation error. While MAE reflects the average absolute difference between earPPGand ECG-derived heart rates, RMSE emphasizes larger deviations associated with motion-induced artifacts. Bias and SD were used to characterize the central tendency and dispersion of the estimation error distribution, respectively. Because all recordings were obtained from a single participant and the analysis windows overlapped, these metrics were treated as descriptive measures of within-session and within-subject performance rather than as population-level estimates.



Agreement between both measurement modalities was further assessed through Bland-Altman analysis and the corresponding limits of agreement (LoA) [24]. In addition, the Pearson correlation coefficient was computed between the proposed motion metric and the absolute heart rate estimation error across all analysis windows in order to investigate the relationship between motion intensity and estimation degradation.

G. Ethical Considerations



This study was conducted as a self-experiment involving a single participant. The protocol consisted of non-invasive physiological signal acquisition using a commercial earable device and a reference ECG system.

IV. Results

In the evaluated recordings, application of the proposed signal-quality screening reduced the descriptive earPPG heart rate estimation error across the investigated conditions. Figure 5 shows a representative segment containing motion artifacts (Scenario (b)), where increased motion intensity induces substantial amplitude fluctuations in the earPPG waveform, successfully captured by the moving standard deviation metric.

(a) ECG and earPPG signals with motion artifact segments.

(b) Moving STD with rejected regions above the threshold.

Fig. 5: Motion artifact detection in physiological signals.

Table I summarizes the heart rate estimation error obtained before (ALL windows) and after (CLEAN windows) motion-based rejection, together with the percentage of rejected analysis windows. Error reduction was observed for all evaluated

motion conditions. The largest improvements were obtained during head movement conditions, with relative error reductions of 58.47% and 69.89% for horizontal and vertical head motion, respectively. Walking also presented a measurable improvement of 21.98%, while chewing-related motion produced a smaller but consistent reduction of 12.24%. Resting segments already exhibited low estimation error, resulting in only minor improvement after rejection.

TABLE I: Heart rate estimation error before (ALL windows – AW) and after (CLEAN windows – CW) motion rejection.

Condition	AW Error (BPM)	CW Error (BPM)	Improvement (%)	Removed Windows (%)
Baseline	1.79	1.75	2.14	4
Scenario a	13.27	10.36	21.98	20
Scenario b	22.11	9.19	58.47	48
Scenario c	16.89	5.09	69.89	42
Scenario d	4.28	3.76	12.24	44

The percentage of removed windows varied according to the motion profile. Walking produced the lowest rejection rate among dynamic conditions (20%), whereas repetitive head movements and chewing generated higher rejection rates ranging from 42% to 48%. Interestingly, chewing resulted in a relatively high rejection rate (44%) despite a modest reduction in HR estimation error, suggesting that facial movements affect waveform morphology without proportionally degrading pulse interval estimation. These findings indicate that the proposed variability-based metric is sensitive to distinct motion-induced perturbation patterns affecting earPPG acquisition.

Figure 6 presents the distribution of heart rate estimation errors across all motion conditions for both the original (No Rejection) and motion-filtered (Motion-Rejected) cases. Beyond the reduction in average error reported in Table I, the boxplot reveals a consistent decrease in variability, interquartile range, and outlier occurrence after motion rejection. These results indicate that, within the evaluated recordings, the screening strategy was associated with lower descriptive error and reduced error variability after exclusion of low-quality windows.

Global performance metrics demonstrated improved HR estimation performance after motion-aware screening. As summarized in Table II, the Mean Absolute Error (MAE) decreased from 11.67 BPM to 5.97 BPM, while the Root Mean Square Error (RMSE) was reduced from 19.41 BPM to 10.78 BPM after excluding motion-contaminated windows. Likewise, the estimation bias decreased from -10.11 BPM to -4.87 BPM, and the standard deviation of the error decreased from 16.60 BPM to 9.64 BPM. These improvements indicate not only greater accuracy but also a more consistent HR estimation process, with fewer large deviations caused by motion artifacts.

Bland–Altman analysis showed narrower descriptive limits of agreement after motion-aware rejection (Figure 7). The distribution of the differences between earPPG-derived and reference ECG heart rates became more concentrated around the mean bias, with visibly narrower limits of agreement.

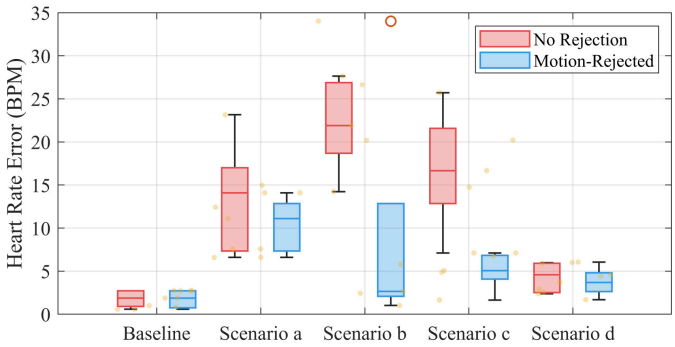


Fig. 6: Distribution of heart rate estimation error across motion conditions for No Rejection and Motion-Rejected cases. Points represent individual analysis windows; markers outside whiskers indicate outliers.

Consistent with the values reported in Table II, the limits of agreement were reduced from -42.65 to 22.43 BPM in the ALL windows condition to -23.77 to 14.03 BPM after rejection. Moreover, the number of extreme disagreement points was substantially reduced, indicating that the proposed screening strategy effectively removed the windows most affected by motion artifacts while preserving the remaining physiological information.

Pearson correlation analysis presented a moderate positive association between the proposed motion metric and absolute heart rate estimation error ($r = 0.342$). Given the single-subject design and overlapping analysis windows, this correlation is interpreted descriptively rather than as population-level statistical evidence. This result suggests that increased temporal variability is associated with higher HR estimation errors, supporting the use of the proposed metric for motion-aware window screening.

V. Discussion

This exploratory study demonstrated that motion-induced variability substantially affects in-ear PPG signals and downstream heart-rate estimation performance in consumer-grade earables. The findings provide an initial feasibility-oriented assessment of a lightweight signal-quality strategy and establish a methodological basis for future validation in larger and more heterogeneous populations.

Motion artifacts substantially degraded earPPG-based heart rate estimation, consistent with previous studies reporting that wearable PPG signals are highly susceptible to motion-induced corruption during ambulatory conditions [14], [15], particularly during dynamic activities such as walking and repetitive head movements. Despite its simplicity, the proposed moving-STD approach was effective in identifying segments associated with increased estimation error without requiring auxiliary inertial sensors or computationally intensive artifact-removal techniques. Because the method relies exclusively on short-term temporal variability, it may offer a computationally lightweight alternative for signal-quality assessment in

TABLE II: Global performance metrics for earPPG-based heart rate estimation (BPM) before and after motion-aware rejection.

Condition	Bias	SD	LoA Lower	LoA Upper	RMSE	MAE
ALL windows	-10.11	16.60	-42.65	22.43	19.41	11.67
CLEAN windows	-4.87	9.64	-23.77	14.03	10.78	5.97

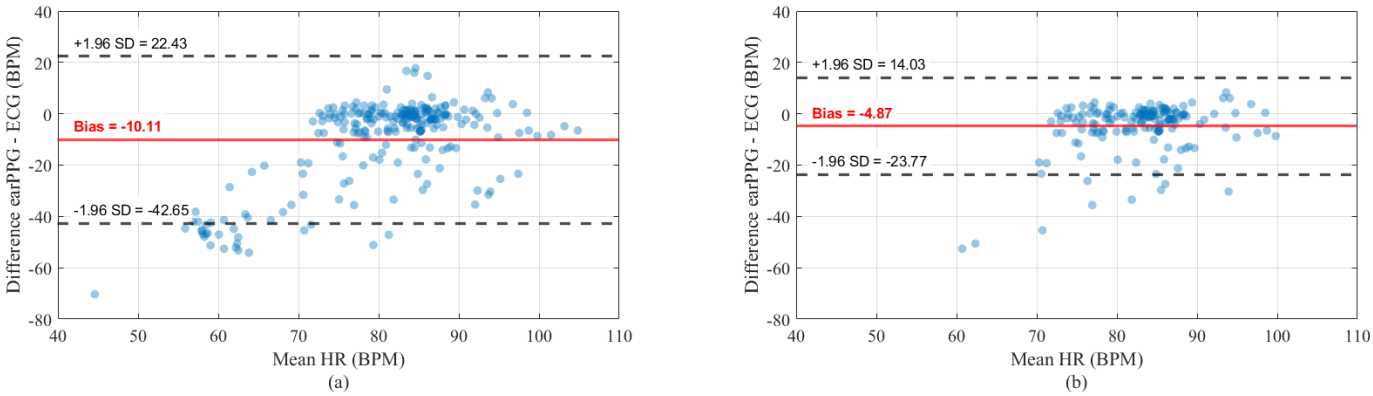

Fig. 7: Bland-Altman analysis comparing earPPG-derived and reference heart rate estimates before (a) and after motion-aware rejection (b).

resource-constrained wearable systems [16]. However, its generalizability and robustness to inter-subject variability remain to be established.

A relevant aspect of the proposed rejection strategy is the trade-off between signal quality improvement and temporal data coverage. Conditions associated with stronger motion contamination, such as repetitive head movements, achieved the largest reductions in heart rate estimation error but also required rejecting a substantial proportion of analysis windows (up to 48%). In contrast, walking exhibited more moderate rejection rates while still producing meaningful error reduction. This behavior suggests that the proposed approach can adaptively preserve reliable physiological segments while discarding highly unstable intervals, which may be advantageous for edge-based remote monitoring systems prioritizing data reliability over continuous transmission.

Interestingly, mastication produced relatively high rejection rates despite comparatively small heart rate estimation errors, suggesting that certain facial-motion patterns substantially alter waveform morphology without fully compromising cardiac periodicity estimation. This behavior is consistent with prior evidence that facial and jaw movements introduce significant biomechanical disturbances in in-ear sensing modalities [25]. This observation reinforces the complexity of motion-related interference in earPPG acquisition and highlights the need for motion-specific artifact characterization strategies.

Considering the growing intersection between audiological care and cognitive health, embedding lightweight physiological-monitoring algorithms directly into hearing aids or consumer-grade true wireless stereo earbuds may enable diverse digital health applications. For the general and working-age population, continuous earPPG monitoring during daily routines could support longitudinal stress assessment and autonomic function monitoring through heart rate variability analytics [26]. For elderly populations, this framework could potentially extend cardiovascular safety monitoring, such as opportunistic screening for asymptomatic atrial fibrillation associated with ischemic stroke risk, without requiring adherence to additional dedicated medical devices.

Although the proposed approach significantly improved agreement with the reference cardiac signal, several limitations must be acknowledged. First, the study was conducted using recordings from a single healthy volunteer, limiting generalizability across different anatomical ear canal structures, skin properties, and cardiovascular conditions. Second, the proposed method performs artifact rejection rather than true artifact correction, meaning that highly corrupted segments are discarded instead of reconstructed. Consequently, excessive rejection rates may reduce temporal data coverage during highly dynamic physical activities. Future work should include validation in larger and more heterogeneous populations, direct comparison with IMU-based artifact-detection strategies, and investigation of interoperability with standardized health data frameworks, further bridging the gap between consumer earables and scalable digital health systems.

VI. Conclusion

This study presented an initial evaluation of a computationally efficient, motion-aware framework for improving heart rate (HR) estimation from consumer-grade earPPG signals. By identifying motion-contaminated segments through temporal variability analysis, the proposed strategy demonstrated, within this single-subject setting, that a lightweight algorithm can substantially improve HR estimation accuracy relative to a ref-

erence cardiac signal without introducing significant computational overhead. The proposed framework additionally reduced the amount of motion-corrupted data requiring downstream transmission and processing, supporting its suitability for low-power edge deployment in wearable telemonitoring systems.

Although restricted to basic HR extraction, these findings highlight the feasibility of performing signal-quality screening directly on resource-constrained wearable devices. Because the current approach relies on rejecting corrupted segments rather than correcting them, future implementations may benefit from integrating the device's embedded inertial sensors (IMU), which were acquired but not fully exploited in the present analysis, to automatically identify and classify specific motion profiles such as walking or mastication.

The combination of optical and inertial sensing modalities provides a promising pathway for adaptive signal-quality assessment and future heart rate variability (HRV) analysis in auricular wearables. The observed signal-quality screening behavior also suggests potential applicability to remote monitoring scenarios; however, computational cost, energy consumption, data-transmission requirements, and clinical performance were not evaluated in the present study. Therefore, broader studies involving multiple participants, independent recording sessions, and real-world monitoring conditions are required to establish the generalizability and practical applicability of the proposed approach.

***Abstract*—Accurate recognition of movement intentions using surface electromyography (sEMG) is crucial for the development of intuitive and functional myoelectric prostheses. This paper presents a comparative study of Multi-Class and Multi-Label classification approaches for recognizing these intentions. Using the NinaPro DB3 database, the performance of the Random Forest algorithm for identifying 8 functional gestures was evaluated. Notably, this study utilizes data from upper-limb amputees, which presents a significantly harder challenge for classification algorithms compared to intact subjects due to altered muscular anatomy and signal variability. The methodology was based on extracting time-domain features from muscular contraction windows. The results indicated the superiority of the holistic Multi-Class approach, which achieved an average accuracy of 66.5%, compared with the anatomical Multi-Label approach. To mitigate spurious posture predictions in the Multi-Label model, which analyzes 7 joint groups in isolation, a biomechanical restriction algorithm based on the Hamming Distance was implemented, raising the system's accuracy from 47.9% (exact match) to 59.3%. The analysis revealed high performance variability among subjects, attributable to physiological factors and inherent sEMG signal degradation, reinforcing the need for locally customized training models for each volunteer. It is concluded that the Multi-Class model presents greater predictive robustness due to its simplified logic.**

***Index Terms*—sEMG, Gesture Classification, Upper Limb Prosthetics, Machine Learning, Random Forest, Multi-Class, Multi-Label.**

I. Introduction

Surface electromyography (sEMG) is used to record muscle electrical activity in clinical and research applications, such as controlling prostheses, exoskeletons, and other assistive devices, primarily due to its non-invasive nature [1] [2] [3]. However, the accuracy and robustness of myoelectric control systems are often impaired by factors such as muscle fatigue, sweating, and electrode placement [4].

To improve integration with prosthetic hardware, Machine Learning algorithms have been employed as powerful alternatives for multichannel sEMG control [5]. Machine Learning is a branch of Artificial Intelligence in which the model is trained to make decisions [6].

Recent comprehensive reviews have mapped the evolution of these algorithms in sEMG pattern recognition, highlighting a significant transition from classical feature engineering to advanced Deep Learning architectures [7], [8]. These surveys emphasize that while traditional shallow classifiers, such as Support Vector Machines (SVMs) and Linear Discriminant Analysis (LDAs), established the foundation for myoelectric control, contemporary research focuses heavily on Convolutional Neural Networks (CNNs) and hybrid models.

However, beyond the choice of the underlying algorithm, the fundamental way the classification problem is structured plays a critical role in prosthesis control. Traditionally, pattern recognition relies on a single-label, or Multi-Class, approach. Previous studies have widely utilized this formulation with sEMG and EEG data [9], [10], treating each movement as a single, holistic entity. While straightforward, this paradigm forces the system to operate within a closed set of predefined gestures, meaning every sample must belong to one unique, isolated class.

In contrast, the Multi-Label approach recognizes that natural hand gestures require the simultaneous activation of multiple muscle groups and motor units. In this paradigm, a single sEMG sample can be associated with a set of independent labels [11]. By decomposing muscle activity into independent, joint-level components, this approach aims for a composite decoding representation that more closely reflects natural biomechanics [12], [13]. For prosthetic control, this offers a significant advantage: the system is not locked into a rigid dictionary of gestures, and if a single target joint is misclassified, the execution of the overall movement is not entirely compromised [11].

To evaluate the practical implications of these structural differences, this work presents a comparative analysis between

This work was supported by a scholarship from Fundação Araucária.

the holistic Multi-Class approach and the anatomically inspired Multi-Label approach for the recognition of movement intentions.

II. Materials and Methods

To effectively evaluate and compare the Multi-Class and Multi-Label classification approaches for movement intention recognition, a structured experimental pipeline, illustrated in Figure 1, was developed. The methodology encompasses four main stages. First, a suitable sEMG database containing data from upper-limb amputees was selected to ensure the study addresses a realistic and challenging clinical scenario. Following data selection, signal processing and the extraction of time-domain features from muscular contraction windows were performed. The functional gestures were then mapped into both the holistic single-label representation and the anatomical multi-label representation. Finally, the Random Forest algorithm was implemented to train both classification models, followed by the application of a biomechanical restriction algorithm to refine the Multi-Label predictions. The following subsections detail each phase of this procedure.

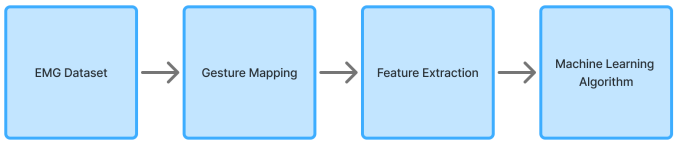

Fig. 1. Methodology flowchart, from the dataset acquisition to the implementation of the Machine Learning Algorithm.

A. Data

The data used in this study were extracted from the NinaPro DB3 database, widely recognized in the literature on myoelectric prosthesis control. This database contains labelled sEMG signals collected from individuals with amputation, in contrast to other databases that include only able-bodied-person data. The samples have diverse characteristics in age, years since amputation, and percentage of remaining forearm [14]. During the acquisition procedure, the subject moved in response to the displayed gesture, while 12 Delsys electrodes recorded sEMG data at 2 kHz [14]. The relevant characteristics of the selected data for our analysis are:

- 11 subjects with upper limb amputation;
- 8 sEMG electrode channels positioned on the forearm. Although DB3 contains 12 electrodes, only the first 8 were selected because they form an equally spaced dense array around the radio-humeral joint, which is the standard configuration for capturing the main synergistic muscle activation patterns while optimizing computational cost and avoiding redundant features from the remaining sparse electrodes;
- 17 total movements recorded in the protocol, of which 8 functional gestures were selected for classification (Figure 2); and
- 6 physical repetitions for each movement, interleaved by neutral rest periods.

In addition to the raw sEMG signals, the original annotation vectors from the database, referred to as *restimulus* (ranging from 0 to 17, indicating the gesture) and *rerepetition* (ranging from 0 to 6, indicating the repetition number), were used as reference to temporally map the onset and offset of each executed muscle contraction.

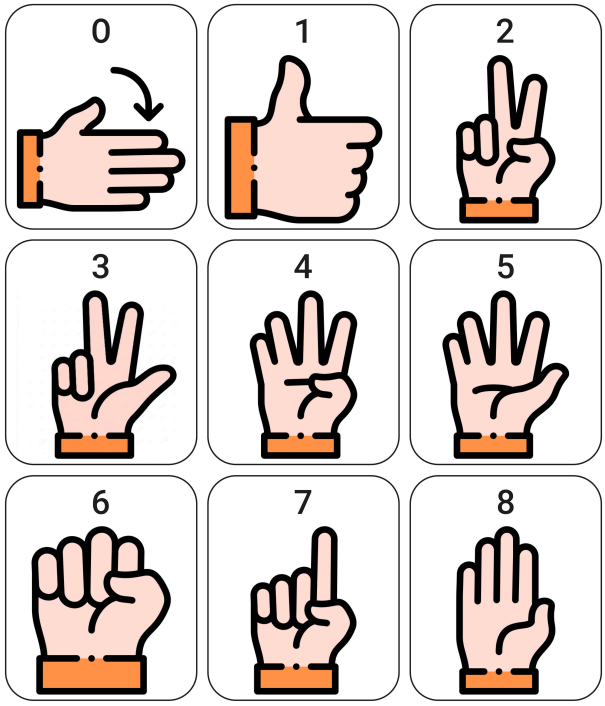

Fig. 2. Gestures of the first eight movements in the Ninapro DB3 and the rest of the gestures labelled.

B. Gesture Mapping

For implementing the Multi-Label classifier, the eight movements extracted from the database were decomposed into discrete joint states. Instead of handling the gesture as a single class, the adopted anatomical model divided the hand into seven independent joint groups: Thumb, Index, Middle, Ring, Little, Fingers, representing combined abduction and adduction, and Carpal, for the carpo-metacarpal movement of the thumb.

Each of these seven joints was mapped to three possible kinematic states for movement execution: Extension (E), Flexion (F), or Neutral (N), as shown in Table I. Thus, the subject's final movement intention is mathematically represented by the simultaneous vector combination of these isolated joints.

C. Feature Extraction

The raw sEMG signal is not directly fed into the classification algorithm. To reduce data size and optimize the

TABLE I
HAND GESTURE CLASSIFICATION, WHERE E IS RELATED TO FINGER EXTENSION, F TO FINGER FLEXION, AND N THE FINGER MAINTAINING AS NEUTRAL POSITION.

Gesture	Description	Thumb	Index	Middle	Ring	Little	Fingers	Carpal
0	Hand at rest	N	N	N	N	N	N	N
1	Thumb extended	E	F	F	F	F	N	E
2	Index and middle extended	F	E	E	F	F	E	F
3	Index, middle and ring extended	E	E	E	F	F	E	E
4	Fingers extended, thumb in palm	F	E	E	E	E	E	E
5	Hand fully open	E	E	E	E	E	E	E
6	Closed fist	F	F	F	F	F	N	N
7	Index finger pointing	E	E	F	F	F	N	F
8	All fingers extended and adducted	E	E	E	E	E	N	E

recognition of muscle activation patterns, the signal is segmented to extract time-domain mathematical features. Instead of using highly redundant overlapping sliding windows, a single continuous processing window was extracted per physical contraction. To ensure temporal consistency and avoid zero-padding, the window size was dynamically defined for each subject based on the duration of their shortest valid contraction execution. From these tailored windows, time-domain mathematical features were extracted. Previous studies [15]–[17] established that features such as Mean Absolute Value (MAV), Root Mean Square (RMS), Waveform Length (WL), and Zero Crossing (ZC) perform robustly with sEMG signals, while other reviews [18] highlight the Teager-Kaiser Energy Operator (TKEO) as a method to enhance gesture classification.

Considering x_i as the amplitude of the sEMG signal at the i-th sample and N as the total number of samples in the analysis window, the following features were extracted individually for each of the eight channels:

- **Mean Absolute Value (MAV):** Provides an estimate of the average muscle contraction amplitude over the time window.

$$MAV = \frac{1}{N}\sum_{i=1}^{N}|x_i|. \tag{1}$$

- **Root Mean Square (RMS):** Models the continuous power of the signal, serving as a robust indicator of motor activation force.

$$RMS = \sqrt{\frac{1}{N}\sum_{i=1}^{N}x_i^2}. \tag{2}$$

- **Waveform Length (WL):** Measures the complexity and cumulative amplitude variation of the signal, capturing information from both amplitude and frequency.

$$WL = \sum_{i=1}^{N-1}|x_{i+1} - x_i|. \tag{3}$$

- **Zero Crossing (ZC):** Counts the number of times the signal amplitude crosses the zero axis (algebraic sign change), serving as an indirect estimate of the signal's frequency properties in the time domain.

$$ZC = \sum_{i=1}^{N-1}\mathbb{I}\{sgn(x_i) \neq sgn(x_{i+1})\}. \tag{4}$$

- **Teager-Kaiser Energy Operator (TKEO):** Computes the instantaneous energy of the signal, highlighting rapid contraction peaks and increasing the distinction between active signal and noise.

$$TKEO = \frac{1}{N-2}\sum_{i=2}^{N-1}(x_i^2 - x_{i-1}\cdot x_{i+1}). \tag{5}$$

By applying these five equations to the eight electrodes, each movement window is mathematically described by a 40-dimensional feature vector (five features $\times$ eight channels), which serves as the definitive input to the Machine Learning model. Although features such as RMS and TKEO have intrinsically different amplitude scales compared to ZC, feature normalization (e.g., Z-score) was deliberately bypassed. This is because the selected classification algorithm, Random Forest, relies on independent threshold-based recursive partitioning, making it strictly scale-invariant and immune to feature magnitude disparities.

D. Multi-Class Classification

The Multi-Class approach represents the traditional method of pattern recognition in myoelectric prostheses, in which each movement intention is treated as a single and global class. In this architecture, the model's objective is to correlate the synergistic muscle activation pattern captured by the electrodes with a single gesture identifier.

The feature matrix X, with dimensions 48×40, acts as the system input. The corresponding target variable is the column vector y, with dimensions 48×1, containing integer labels from one to eight, representing the exact ID of the executed functional gesture.

Among the possible Machine Learning models, Random Forest was chosen due to its robust performance in processing sEMG signals [19]–[21]. As an ensemble classifier, Random Forest operates by constructing a multitude of decision trees during training. This architecture is particularly advantageous for biological signals because it inherently mitigates the

overfitting commonly associated with noisy, high-dimensional data—such as the 40-dimensional feature vectors used in this study.

The algorithm was implemented via *TreeBagger* in MATLAB, configured with an ensemble of 100 decision trees. To ensure reproducibility, default hyperparameters for classification were maintained: the minimum leaf size was set to 1, and the number of predictors sampled at each node split was set to the square root of the total number of features (approximately 6). No artificial data balancing techniques (e.g., SMOTE) were required, as the experimental protocol inherently ensures a balanced class distribution through an equal number of physical repetitions per gesture. The model evaluates all trees simultaneously and uses majority voting to select the final class. This approach has the implicit advantage of learning forearm muscle synergies, as it evaluates the total context of the sEMG signal to determine hand movement as a single block.

E. Multi-Label Classification

In contrast to the holistic Multi-Class model, the Multi-Label approach proposes the isolated prediction of the anatomical states that compose the hand. As defined in the gesture mapping, the desired output is no longer a single scalar identifier but rather a matrix Y with dimensions 48×7. Each of the seven columns of this matrix represents a joint group (Thumb, Index, Middle, Ring, Little, Fingers, and Carpal), and the values contained therein indicate the kinematic state of the joint: extension, flexion, or neutral.

Instead of training a single global classifier, seven independent Random Forest models were instantiated, one for each joint group, all receiving the same normalized input matrix X (48×40) and sharing the same hyperparameters defined in the Multi-Class model.

During the testing phase, the seven models analyze the same time window of the sEMG signal and emit their predictions in parallel, without any communication or weight sharing between them. The final result is a prediction matrix of dimension 1×7, which reconstructs the estimated state of the entire hand at that instant.

F. Error Correction via Hamming Distance

The main limitation of the Multi-Label approach with independent models is the absence of biomechanical constraints. Since there is no communication between the joint classifiers, the system is susceptible to predicting spurious combinations of joint states that do not correspond to any of the eight real gestures mapped in the protocol.

To mitigate this issue and force the model to converge toward anatomically valid postures, a fallback algorithm based on Hamming Distance was implemented. When the system composes the 1×7 prediction vector from the individual model outputs, it simultaneously compares it against a reference lookup table containing the perfect definitions of the eight functional gestures.

The Hamming Distance (D_H) is calculated as the number of positions at which the predicted vector (v_p) differs from the vector of a valid gesture (v_g), expressed by:

$$D_H(v_p, v_g) = \sum_{j=1}^{7} \mathbb{I}\{v_p(j) \neq v_g(j)\} \tag{6}$$

where j represents the joint index and $\mathbb{I}$ is the indicator function that returns "1" in the case of divergence (error) and "0" in the case of agreement.

The algorithm counts the total number of joint errors for each prediction relative to the known classes and replaces the spurious combination with the identifier of the real gesture that presents the smallest D_H, which is the closest gesture. In tie cases, where the predicted vector is equally distant from two or more valid gestures, the algorithm adopts the first-ranked class as a tiebreaker criterion.

G. Model Training and Validation Protocol

To ensure a robust and unbiased evaluation of the classifiers, an intra-subject analysis was adopted. Due to the high inter-subject variability inherent to sEMG signals—caused by differences in muscle anatomy, sensor positioning, and varying levels of amputation—a generalized global model is often ineffective. Therefore, independent Machine Learning models were trained and tested specifically for each of the 11 subjects.

The evaluation procedure followed a Leave-One-Repetition-Out Cross-Validation (LORO-CV) methodology. Because the experimental protocol consists of six independent repetitions per functional gesture, a 6-fold cross-validation strategy was implemented based strictly on these physical repetitions rather than random data splitting.

In each iteration of the cross-validation cycle, five repetitions were aggregated to construct the training set, while the remaining unseen repetition was isolated to form the testing set. This loop was iterated six times until every repetition had served as the test set exactly once. Structuring the validation around full physical repetitions, rather than shuffled time windows, is crucial in sEMG pattern recognition; it actively prevents data leakage between highly correlated adjacent temporal samples and guarantees that the reported accuracy reflects the model's true generalization capacity on novel motor executions.

III. Results and Discussion

This section presents the empirical results obtained from the comparative analysis between the Multi-Class and Multi-Label classification approaches. First, the overall predictive performance of both models is evaluated, highlighting the critical impact of the biomechanical constraint algorithm. Subsequent discussions analyze the underlying causes of the observed accuracy metrics, addressing the inherent biological challenges of myoelectric pattern recognition in the target demographic.

A. Overall Performance: Multi-Class vs. Multi-Label

The model evaluation demonstrated that the traditional Multi-Class approach achieved a higher average accuracy of 66.5%, with a standard deviation of 17.3%. As illustrated in Figure 3, the Multi-Label model in its pure form—which requires an exact match of all seven joint states simultaneously—achieved a lower average accuracy of 47.9%.

The application of biomechanical constraints via the Hamming Distance algorithm proved strictly necessary for the viability of the anatomical approach. Correcting spurious postures raised the average accuracy of the Multi-Label system to 59.3%, with a standard deviation of 16.2%, representing an absolute performance gain of 11.4 percentage points (a 23.8% relative gain) (Figure 3).

To formally evaluate this performance difference, a paired statistical test was conducted. Given the sample size ($n = 11$) and the lack of guaranteed normality, a Wilcoxon signed-rank test was utilized. The test confirmed that the performance difference between the Multi-Class approach and the Multi-Label approach with Hamming distance was statistically significant ($p = 0.007$, effect size $r = 0.81$), substantiating the superiority of the holistic model.

The lower performance of the Multi-Label method compared to the Multi-Class method is primarily justified by the greater mathematical complexity of the problem, which requires the simultaneous convergence of seven independent classifiers rather than predicting a single global label. Furthermore, it is critical to contextualize these absolute accuracy values within the clinical reality of the dataset. Because the signals were acquired from upper-limb amputees, the classification algorithms faced significantly degraded sEMG inputs. Factors such as muscle atrophy, altered anatomical synergies, and variable electrode contact due to residual limb anatomy inherently limit the maximum achievable accuracy when compared to controlled studies conducted on intact subjects. This highlights the severe challenge of translating standard pattern recognition algorithms to realistic clinical scenarios.

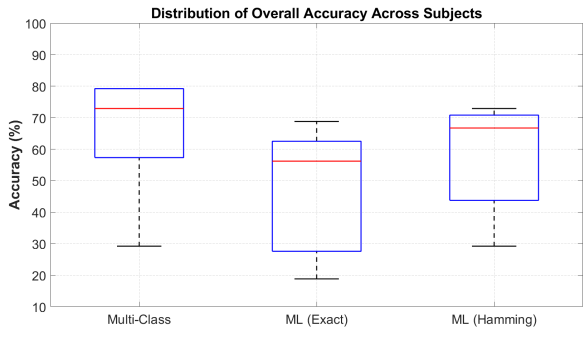

Fig. 3. Distribution of overall sample accuracy. The boxplot highlights the superior performance of the Multi-Class method and the significant performance gain of the Multi-Label model after applying the Hamming Distance correction algorithm.

B. sEMG Signal Variability

A notable characteristic in the results of both approaches is the high standard deviation, driven by a sharp accuracy drop in subjects 05, 07, and 10, as illustrated in Figure 5. In the Multi-Class model, for example, subject 07 recorded only 29.2% accuracy, in stark contrast to subjects that reached nearly 80%.

However, evaluating myoelectric pattern recognition in amputees solely through global accuracy can mask the system's true functional viability. An overall accuracy of 29.2% does not necessarily imply a complete failure of the classifier; rather, it often reflects a severe biological inability to separate specific synergistic patterns due to missing musculature. To properly diagnose the source of these errors, it is necessary to move beyond global accuracy and analyze the specific error distribution. Confusion matrices provide this transparency, allowing for the identification of exactly which gestures lack separable feature representations and which remain functionally robust despite the amputation (Figure 4).

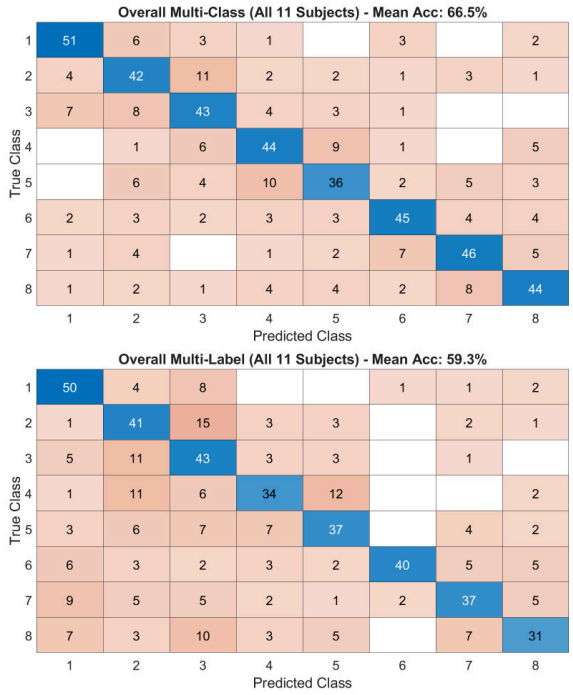

Fig. 4. Overall confusion matrices comparing the Multi-Class and Multi-Label classification approaches. The matrices illustrate the global error distribution across all evaluated subjects.

A direct investigation of the data confirmed that this performance degradation does not stem from flaws in the mapping or algorithm parameterization, but is an inherent consequence of the quality of the sEMG signal captured from these specific individuals. Physiological factors common in amputee databases, such as variations in residual limb volume, skin impedance, or muscle fatigue during the protocol, are reflected in signals with lower SNR, hindering pattern recognition regardless of the classifier architecture.

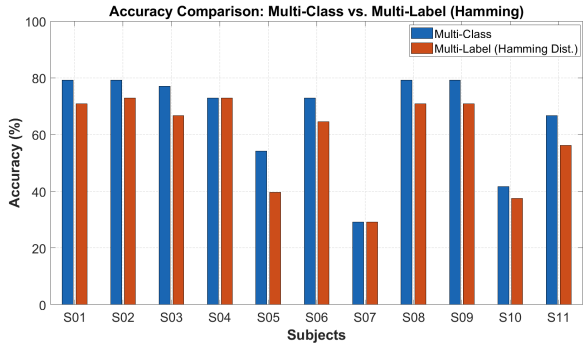

Fig. 5. Direct per-subject accuracy comparison between the Multi-Class and Multi-Label approaches, highlighting the pronounced performance degradation in subjects S05, S07, and S10.

C. Performance Analysis by Joint Group

The main methodological advantage of the Multi-Label approach is the ability to isolate the accuracy rate per anatomical joint. The detailed analysis of the prediction matrix revealed significant discrepancies in the model's ability to identify different components of the hand.

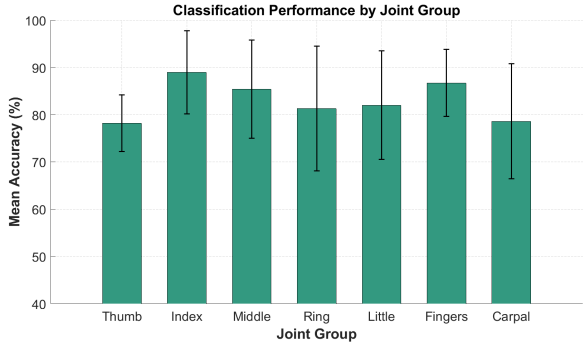

Fig. 6. Average individualized classification accuracy per joint group in the Multi-Label model. Error bars represent the standard deviation across the 11 evaluated subjects.

The movements associated with the Index and Middle fingers presented the highest recognition rates, with average accuracies of 89.0% and 85.4%, respectively. In contrast, the joints that most contributed to the system's overall error were the Thumb and Carpal. The Thumb achieved an average accuracy of 78.2% (with an average of 10.5 errors on incorrectly classified instances), while the Carpal reached 78.6% (with an average of 10.3 errors).

This behavior has biomechanical foundations. Thumb kinematics and radiocarpal movements involve more complex or deep muscle bundles. Surface electrodes positioned along the forearm readily capture the activation of the long flexor and extensor muscles of the central fingers, but present technical limitations in isolating the intricate synergies responsible for carpal rotation and thumb abduction/opposition.

IV. Conclusion

This study presented a comparative analysis between Multi-Class and Multi-Label approaches for classifying movement intentions using sEMG signals from amputee subjects. The results demonstrated that the Multi-Class model achieved better overall performance, benefiting from a simpler, more straightforward predictive architecture. In contrast, the Multi-Label approach, although offering more detailed anatomical mapping, showed greater susceptibility to failures. The requirement to predict multiple joint states in an isolated and simultaneous manner created a broader margin for cumulative errors, which penalized the system's final accuracy even with the application of biomechanical constraint algorithms.

The analysis also highlighted the strong impact of biological and anatomical differences between subjects. Three specific subjects exhibited severe degradation in signal recognition, significantly reducing the study's overall average. This variability, inherent in sEMG data, supports the premise that local classification approaches, where the model is customized and trained individually for each user, make more sense and yield more reliable results than adopting a single global classifier.

Despite the theoretical consistency of the evaluated models, the current methodology presents practical limitations. The deployment of the developed technique in commercial myoelectric prostheses is not ideal due to the extensive processing window required for gesture recognition (which equaled the full duration of the shortest contraction), which introduces unacceptable delays in natural motor control.

Therefore, as proposals for future work, it is suggested to optimize the selection and extraction of mathematical features within the algorithms, as well as the transition to reduced and overlapping time windows. Such improvements are fundamental to balancing the classifier's accuracy with the stringent latency requirements of real-time control of bionic limbs.

***Abstract*—Skin cancer is a prevalent and potentially deadly disease that requires early detection for effective treatment. In this study, we propose a multiclass skin cancer classification model using convolutional neural networks (CNNs) and Grad-CAM-based explainability. We utilize the HAM10000 dataset, which contains 10,015 dermatoscopic images of skin lesions categorized into seven classes: melanocytic nevi, melanoma, benign keratosis-like lesions, basal cell carcinoma, actinic keratoses and intraepithelial carcinoma, vascular lesions, and dermatofibroma. The proposed model achieves an accuracy of 88.42% in classifying these skin lesions, while the Grad-CAM technique provides visual explanations for the model's predictions.**

***Index Terms*—Skin Cancer Classification, Convolutional Neural Networks, Grad-CAM, Explainable AI.**

I. Introduction

Skin cancer is one of the most common types of cancer worldwide, with millions of new cases diagnosed each year [1]. Early detection and accurate classification of skin lesions are crucial for effective treatment and improved patient outcomes [2], [3]. Traditional methods for skin cancer diagnosis rely on visual examination by dermatologists, which can be subjective and prone to errors [4], [5].

Many people suffer from skin cancer, and the number of cases is expected to rise in the coming years due to factors such as increased sun exposure and aging populations [6], [7]. The World Health Organization (WHO) classifies skin cancer into three main types: basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and melanoma [8]. Melanoma is the most aggressive form of skin cancer and is responsible for the majority of skin cancer-related deaths [8]. Therefore, accurate classification of skin lesions into these categories is essential for guiding treatment decisions and improving patient prognosis.

Previous studies have focused on binary classification, particularly distinguishing between melanoma and non-melanoma [9]–[12]. However, a multiclass classification approach that can differentiate among various types of skin lesions is more clinically relevant and provides more comprehensive diagnostic information.

Artificial intelligence (AI) and machine learning techniques have shown potential in improving the accuracy and efficiency of skin cancer diagnosis [13]–[16]. Convolutional neural networks (CNNs), a class of deep learning models, have been particularly successful in image classification tasks, including medical image analysis [17]. However, the lack of interpretability of CNNs has raised concerns about their adoption in clinical settings. To address this issue, we incorporate the Gradient-weighted Class Activation Mapping (Grad-CAM) technique to provide visual explanations for the model's predictions [18], enhancing the interpretability of the skin cancer classification model.

Motivated by the need for accurate and interpretable skin cancer classification, this study aims to develop a multiclass classification model using CNNs and Grad-CAM-based explainability. We evaluate the performance of the proposed model on the HAM10000 dataset, which contains a diverse set of dermatoscopic images of skin lesions. Moreover, to mitigate the class imbalance present in the dataset, we apply the Deep SMOTE technique [19] to generate synthetic samples for underrepresented classes. The results demonstrate the effectiveness of the model in classifying skin lesions into multiple categories while providing insights into the decision-making process through visual explanations. The main contributions of this study are summarized as follows:

i) Development of a CNN for the multiclass classification of seven skin lesion types using dermoscopic images from the HAM10000 dataset.
ii) Comprehensive evaluation of different data balancing strategies, including conventional oversampling and DeepSMOTE, in combination with DenseNet169, DenseNet201, EfficientNetB4, ensemble learning, and test-time augmentation (TTA) to assess their impact on classification performance.
iii) Integration of the Grad-CAM explainability technique to provide visual interpretations of the CNN predictions.

The rest of the paper is organized as follows: Section II reviews related work in skin cancer classification using machine

learning and deep learning techniques. Section III describes the dataset. Section IV presents the proposed deep learning models and the Grad-CAM explainability technique. Section V presents the results and discussion of the model's performance, while Section VI concludes the study and outlines future research directions.

II. Related Work

Some recent studies have used the HAM10000 dataset for skin cancer classification [20]–[26]. Different approaches have been proposed, including deep learning models, hybrid models, and ensemble methods. Table I summarizes the performance of various models in terms of accuracy, precision, recall, and F1-score, along with their corresponding references.

In [26], the authors proposed a computer-aided diagnosis framework for binary skin lesion classification by combining image preprocessing, data augmentation, transfer learning, and SVM-based classification. The approach employs median filtering, contrast enhancement, and edge detection, followed by fine-tuning of ResNet50 and VGG16 models. To improve performance, the final fully connected layer was replaced with an SVM classifier. In the same way, in [25], the authors proposed a stacked convolutional neural network for binary melanoma classification. The model was trained on the HAM10000 dataset and externally validated on ISIC-2020. Its performance was compared with VGG16, InceptionV3, ResNet50, EfficientNetB0, and traditional machine learning classifiers. The proposed model achieved 96% accuracy and 96% F1-score on HAM10000.

In [23], the networks AlexNet, InceptionV3, and RegNetY-320 were evaluated. RegNetY-320 achieved the best performance, reaching 91% accuracy and 88.1% F1-score, demonstrating the effectiveness of class balancing and deep architectures for skin lesion classification. In a different approach, the authors in [22] applied the DenseNet169 architecture with hair removal using the Dull Razor algorithm. The best performance was achieved by DenseNet169 with undersampling, obtaining 91.2% accuracy and 91.7% F1-score.

In the work [20], the authors proposed a novel deep learning framework called the Dual Optimization Deep Learning Network (DODL net) for skin cancer detection. Dermoscopic images are initially processed using a U-net architecture to segment the specific region of the skin lesion. Dual optimization algorithms, specifically Bacterial Foraging Optimization (BFO) and Particle Swarm Optimization (PSO), are employed to extract features from the segmented images. The DODL net is then trained on the extracted features to classify skin lesions into different categories. The model achieved an accuracy of 98.76%, demonstrating its effectiveness in skin cancer detection.

Differently, in [21], the authors proposed a novel deep learning model called SkinLesNet for the classification of skin lesions and melanoma detection. The model was trained using the Adam optimizer with a learning rate of 0.001 and evaluated on the PAD-UFES-20-Modified, HAM10000, and ISIC2017 datasets. To validate its effectiveness, the authors compared SkinLesNet with well-established architectures such as ResNet50 and VGG16. The proposed model outperformed both reference networks across all evaluated datasets, achieving an accuracy of 96% on PAD-UFES-20-Modified, 90% on HAM10000, and 92% on ISIC2017.

More recently, in [24], the authors proposed SkinWiseNet (SWNet), a deep convolutional neural network designed for binary skin cancer classification. The framework combines feature fusion across multiple datasets, including HAM10000, ISIC2019, ISIC2020, and Melanoma Skin Cancer, to improve generalization and reduce dataset-related bias.

TABLE I
Comparison of Deep Learning Approaches for Skin Cancer Classification

Model	Accuracy	Precision	Recall	F1-Score	Ref.
DODL-Net	98.76	96.02	95.37	95.32	[20]
Multi-layer CNN	90.00	89.00	87.00	85.00	[21]
DenseNet169	91.20	–	–	91.70	[22]
RegNetY-320	91.00	–	–	88.10	[23]
SkinWiseNet (SWNet)	81.93	36.00	55.73	43.79	[24]
Stacked CNN	96.00	97.00	95.00	96.00	[25]
ResNet50 and SVM	98.43	96.31	–	96.98	[26]

Based on the review of related work, it is evident that while significant progress has been made in skin cancer classification using deep learning techniques, there is still a need for models that can effectively handle multiclass classification tasks and provide interpretability. The works [24]–[26] focus primarily on binary classification. The proposed study aims to address these gaps by developing a CNN-based model for multiclass skin cancer classification and integrating Grad-CAM for explainability.

III. Dataset

The dataset used in this study is the HAM10000 dataset, which consists of 10,015 dermatoscopic images of skin lesions [27]. Fig. 1 shows sample images from the dataset. Each image is labeled with its corresponding class.

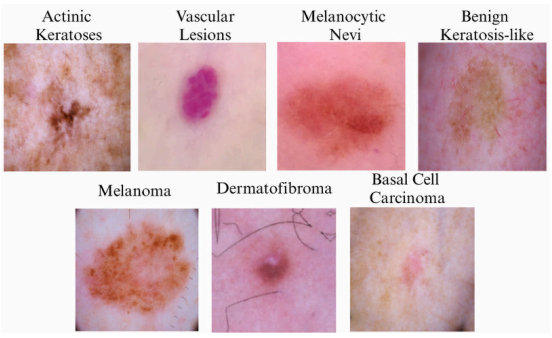

Fig. 1. Sample images from the HAM10000 dataset, showcasing the seven classes of skin lesions.

The dataset includes seven classes of skin lesions: melanocytic nevi (NV), melanoma (MEL), benign keratosis-like lesions (BKL), basal cell carcinoma (BCC), actinic keratoses and intraepithelial carcinoma (AKIEC), vascular lesions (VASC), and dermatofibroma (DF).

The class distribution is imbalanced, with 6,705 images of melanocytic nevi representing the majority class, followed by melanoma with 1,113 images and benign keratosis-like lesions with 1,099 images. The remaining classes are considerably smaller, comprising 514 basal cell carcinoma images, 327 actinic keratoses and intraepithelial carcinoma images, 142 vascular lesion images, and only 115 dermatofibroma images. This pronounced class imbalance poses a significant challenge for multiclass classification, as learning algorithms tend to become biased toward the majority classes, leading to reduced performance on underrepresented categories.

A. Data preprocessing

To mitigate class imbalance, random oversampling [28] and Deep SMOTE (Synthetic Minority Over-sampling Technique) [19] were investigated. Data augmentation strategies, including random rotations, horizontal and vertical flips, were also employed to increase the diversity of the training data and improve the model's generalization capabilities. Fig. 2 presents examples of synthetic images generated using Deep SMOTE through interpolation in the latent space learned by the autoencoder. The generated samples preserve the overall morphological characteristics of the original lesions, including their general shape, size, and color distribution.

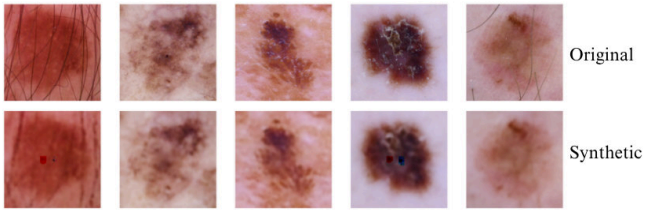

Fig. 2. Samples generated by the Deep SMOTE technique.

Before training and balancing, all images were preprocessed to reduce artifacts and highlight lesion regions. Hair removal was performed using the Dull Razor algorithm [22], which detects hair structures through morphological operations and restores the affected pixels using image inpainting. Fig. 3 illustrates the hair removal results.

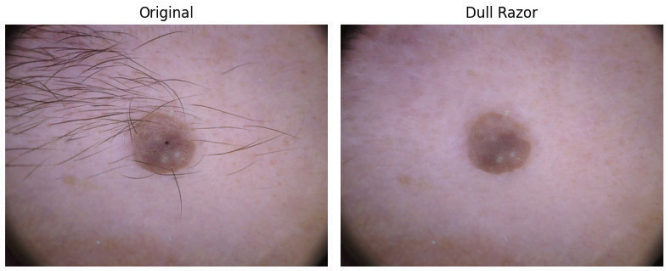

Fig. 3. Example of hair removal algorithm. The left image shows the original input, while the right image illustrates the result after hair removal and cropping around the lesion.

After the Dull Razor algorithm, the images were cropped around the lesion using the provided segmentation masks. The masks were used to localize the lesion region and perform lesion-centered cropping. For each image, the lesion boundaries were identified from the binary mask, and a bounding box with an additional 20-pixel margin was extracted.

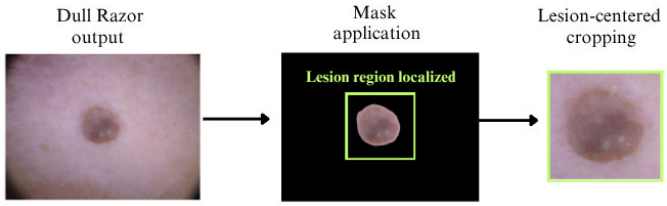

Fig. 4. Preprocessing for lesion-focused classification. The left image shows the Dull Razor result, while the right image illustrates the result after cropping around the lesion using the segmentation mask.

IV. Deep Learning Models

Different CNN architectures were evaluated for multiclass skin lesion classification, including DenseNet169, DenseNet201, and EfficientNetB4. These architectures were selected based on their proven performance in the previous work [22], [25]. The models were initialized with ImageNet pretrained weights and fine-tuned on the HAM10000 dataset. Moreover, to explain the model's predictions, the Grad-CAM technique was applied to generate class activation maps that highlight the regions of the input image that are most influential for the classification decision.

Fig. 5 illustrates the overview of the proposed experimental pipeline for multiclass skin lesion classification. The pipeline consists of five main stages: dataset collection, preprocessing, data handling and balancing, model training, and evaluation with grad-CAM-based explainability. The dataset collection stage involves acquiring dermatoscopic images from the HAM10000 dataset, which contains a diverse set of skin lesions. The preprocessing stage includes hair removal using the Dull Razor algorithm and lesion-focused cropping based on segmentation masks. The data balancing stage explores some strategies, such as oversampling and Deep SMOTE. Finally, the classification stage evaluates three CNN architectures: DenseNet169, DenseNet201, and EfficientNetB4. Ensemble learning and TTA are also explored to improve model robustness and generalization.

The following subsections provide a detailed description of each architecture and the Grad-CAM method.

A. DenseNet169 and DenseNet201

DenseNet169 and DenseNet201 were employed as the primary classification architectures due to their efficient feature reuse and dense connectivity mechanism [29]. Unlike traditional convolutional neural networks, where each layer receives input only from the previous layer, DenseNet connects each layer to all preceding layers, enabling improved gradient propagation and reducing the number of trainable parameters. The output of the (l)-th layer is given by

$$x_l = H_l([x_0, x_1, \ldots, x_{l-1}]), \tag{1}$$

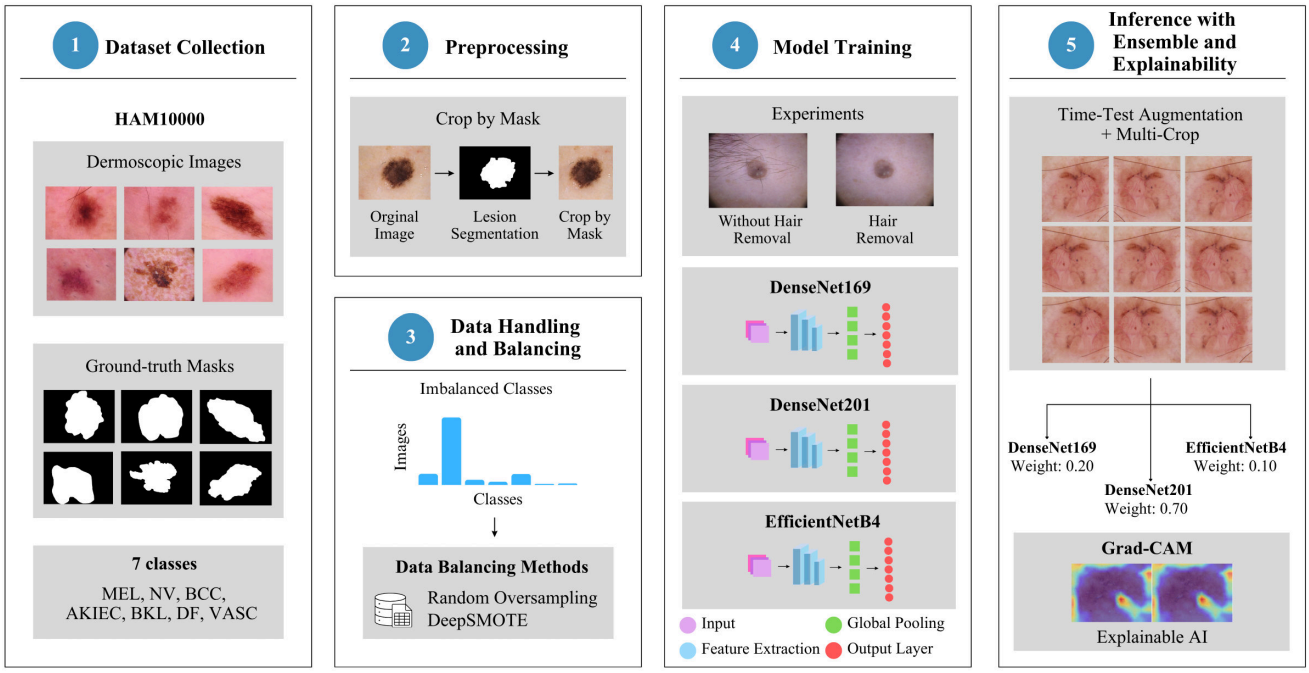

Fig. 5. Overview of the proposed experimental pipeline for multiclass skin lesion classification. The pipeline consists of five main stages: dataset collection, preprocessing, data handling and balancing, model training, and evaluation with grad-CAM-based explainability.

where $[\cdot]$ denotes feature-map concatenation and $H_l(\cdot)$ represents the composite operation of batch normalization, ReLU activation, and convolution.

After the final dense block, global average pooling is applied to obtain a feature vector z, which is passed to a fully connected layer producing the logits

$$o = Wz + b. \tag{2}$$

The class probabilities are computed using the Softmax function

$$P(y = i|X) = \frac{\exp(o_i)}{\sum_{j=1}^{K} \exp(o_j)}, \tag{3}$$

where K is the number of lesion classes. Model training is performed by minimizing the categorical cross-entropy loss

$$L = -\sum_{i=1}^{K} y_i \log\left(P(y = i|X)\right), \tag{4}$$

where y_i is the one-hot encoded ground-truth label. In this work, DenseNet169 and DenseNet201 differ primarily in network depth, containing 169 and 201 layers, respectively. In this work, both models were initialized with ImageNet pretrained weights and fine-tuned for multiclass skin lesion classification.

B. *EfficientNet*

EfficientNetB4 was evaluated as an alternative backbone architecture based on compound scaling [30]. Unlike DenseNet, which emphasizes feature reuse through dense connections, EfficientNet systematically scales network depth, width, and input resolution using a compound coefficient. EfficientNetB4 employs mobile inverted bottleneck convolution (MBConv) blocks combined with squeeze-and-excitation modules to enhance feature representation. The model was initialized with ImageNet pretrained weights and fine-tuned for multiclass skin lesion classification.

C. *Grad-CAM*

The Grad-CAM technique is used to provide visual explanations for the predictions made by the CNN model [18]. Let A^k denote the k-th feature map of the last convolutional layer and y^c the score for class c before the softmax activation. The importance weight of each feature map is obtained by globally averaging the gradients of the target class score with respect to the feature map activations:

$$\alpha_k^c = \frac{1}{Z} \sum_i \sum_j \frac{\partial y^c}{\partial A_{ij}^k}, \tag{5}$$

where A_{ij}^k represents the activation at spatial location (i, j) of feature map k, and Z corresponds to the total number of spatial locations in the feature map. The Grad-CAM localization map

is then computed as a weighted combination of the feature maps, followed by a ReLU activation:

$$L^c_{\text{Grad-CAM}} = \text{ReLU}\left(\sum_k \alpha^c_k A^k\right), \tag{6}$$

where $L^c_{\text{Grad-CAM}}$ denotes the class activation map associated with class c. The ReLU function removes negative contributions, preserving only the features that positively influence the prediction. The resulting heatmap is subsequently upsampled to the original image size and overlaid on the input image to provide a visual explanation of the model's decision [18].

V. Results and Discussion

The simulation was conducted on a workstation equipped with an NVIDIA GeForce GTX 1660 Ti, 6 GB of VRAM, and 128 GB of RAM. The models were implemented using the TensorFlow and Keras libraries. The training process utilized the Adam optimizer with a learning rate of $1e^{-4}$, a batch size of 32, and early stopping based on validation loss to prevent overfitting.

Experiments were conducted to evaluate different preprocessing, data balancing, and classification strategies for multiclass skin lesion recognition. Fig. 6 illustrates the experimental pipeline, which includes three main stages: preprocessing, data balancing, and classification. The preprocessing stage involved hair removal using the Dull Razor algorithm and lesion-focused cropping based on segmentation masks. The data balancing stage explored three strategies: oversampling, oversampling with the Dull Razor algorithm, and Deep SMOTE. Finally, the classification stage evaluated three CNN architectures: DenseNet169, DenseNet201, and EfficientNetB4. In addition, ensemble learning and TTA were explored to improve model robustness and generalization.

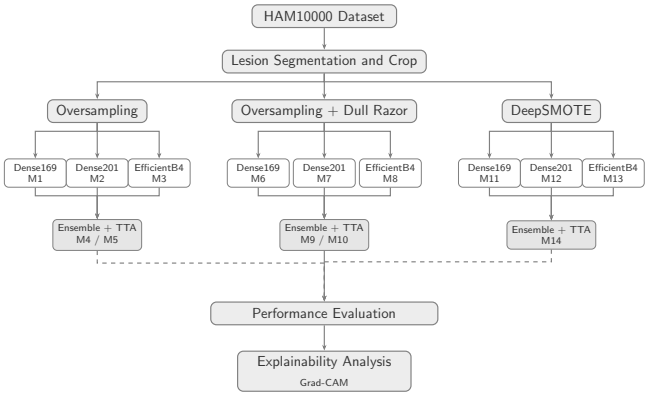

Fig. 6. Experimental pipeline for skin lesion classification, comparing three data augmentation strategies.

Deep SMOTE was implemented using lesion-cropped images resized to (256×256) pixels. The autoencoder was trained to learn a 512-dimensional latent representation of the lesions. The encoded training samples were then balanced by generating synthetic latent vectors through SMOTE-based interpolation between k-nearest neighbors ($k = 5$) within the same class. Finally, the synthetic latent vectors were decoded into dermoscopic images and added to the training set to improve the representation of minority classes.

Fig. 7 illustrates the class distribution of the original training set compared to the distribution after applying Deep SMOTE/Oversampling. The complete Deep SMOTE pipeline, including autoencoder training, latent-space interpolation, image reconstruction, and storage of synthetic samples, required approximately 1,271 minutes of execution time. The generated images were subsequently incorporated into the training set to improve the representation of minority classes.

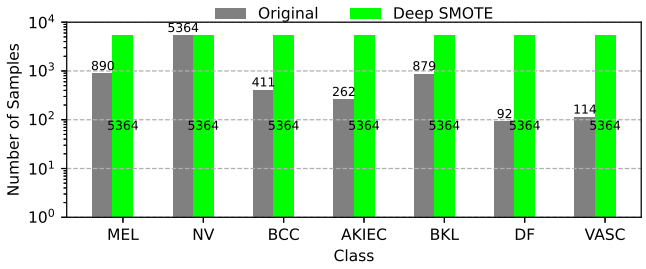

Fig. 7. Class distribution of the original and Deep SMOTE-augmented training sets.

Table II presents the performance comparison of the evaluated models. The results indicate that the ensemble model

M14: M11 + M12 + M13 + TTA.

M5, which combines DenseNet169, DenseNet201, and Effi-

cientNetB4 with oversampling and TTA, achieved the highest accuracy of 88.42% and an F1-score of 88.15%. In contrast, the ensemble model M14, which incorporates Deep SMOTE for data balancing, exhibited a lower accuracy of 82.28% and an F1-score of 81.35%. These findings suggest that conventional oversampling outperformed Deep SMOTE in this multiclass skin lesion classification task.

Moreover, contrary to expectations, the application of hair removal did not improve classification performance. Across all evaluated architectures, the Dull Razor preprocessing step resulted in either negligible gains or a reduction in accuracy and F1-score. One possible explanation is that lesion cropping already minimized the influence of background artifacts, making hair removal redundant. Furthermore, the inpainting procedure used to reconstruct hair-covered regions may have altered subtle dermoscopic structures relevant to lesion discrimination.

Tables III and IV demonstrate that the ensemble composed of DenseNet201, DenseNet169, and EfficientNetB4 trained using conventional oversampling (M5) achieved the best overall performance, reaching an accuracy of 88.42% and an F1-score of 88.15%.

TABLE III
CLASS-WISE PERFORMANCE METRICS FOR M5 MODEL.

Class	Precision	Recall	F1-Score
MEL	0.7853	0.6726	0.7246
NV	0.9302	0.9635	0.9465
BCC	0.7727	0.8252	0.7981

BKL	0.7761	0.7091	0.7411
DF	0.9524	0.8696	0.9091
VASC	0.8966	0.9286	0.9123

TABLE IV
CLASS-WISE PERFORMANCE METRICS FOR MODEL M14.

Class	Precision	Recall	F1-Score
MEL	0.7101	0.4395	0.5429
NV	0.8847	0.9500	0.9162
BCC	0.5620	0.7476	0.6417
AKIEC	0.5119	0.6615	0.5772
BKL	0.7394	0.5545	0.6338
DF	0.8000	0.3478	0.4848
VASC	0.8966	0.9286	0.9123

In contrast, replacing conventional oversampling with Deep SMOTE (M14) reduced the accuracy to 82.28% and the F1-score to 81.35%. The class-wise analysis confirms this trend, as M5 consistently outperformed M14 for most lesion categories, particularly MEL, BCC, AKIEC, BKL, and DF, while both approaches achieved similar performance for VASC. These findings suggest that the synthetic images generated by DeepSMOTE did not provide additional discriminative information for the ensemble. The reason may be that the latent-space interpolation performed by Deep SMOTE introduced samples that did not fully preserve the fine-grained texture, color distribution, and morphological characteristics of real skin lesions. Consequently, the generated samples may have reduced the generalization capability of the network. Conversely, conventional oversampling preserves the original image distribution by replicating authentic training samples, allowing the ensemble to learn more representative visual features and resulting in superior classification performance.

For a more comprehensive evaluation of the model's performance, the confusion matrices were computed for both M5 and M14 models. Fig. 8 presents the normalized confusion matrix for M15, while Fig. 9 shows the normalized confusion matrix for M14.

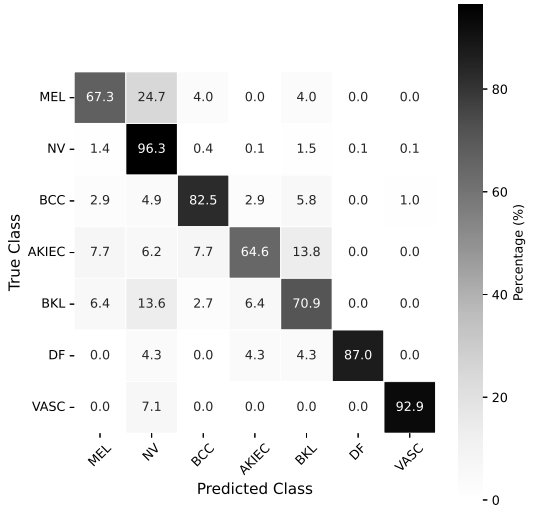

Fig. 8. Normalized confusion matrix for M5 model.

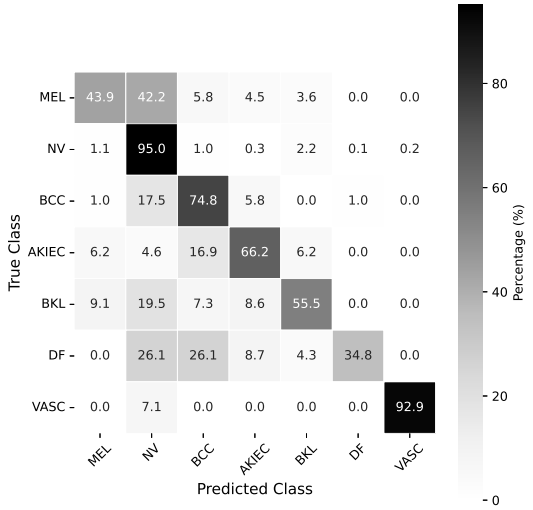

Fig. 9. Normalized confusion matrix for M14 model.

The confusion matrices reveal that M5 achieved higher true positive rates across most classes, particularly for MEL, BCC, AKIEC, and DF, compared to M14. The improved performance of M5 can be attributed to the use of conventional oversampling.

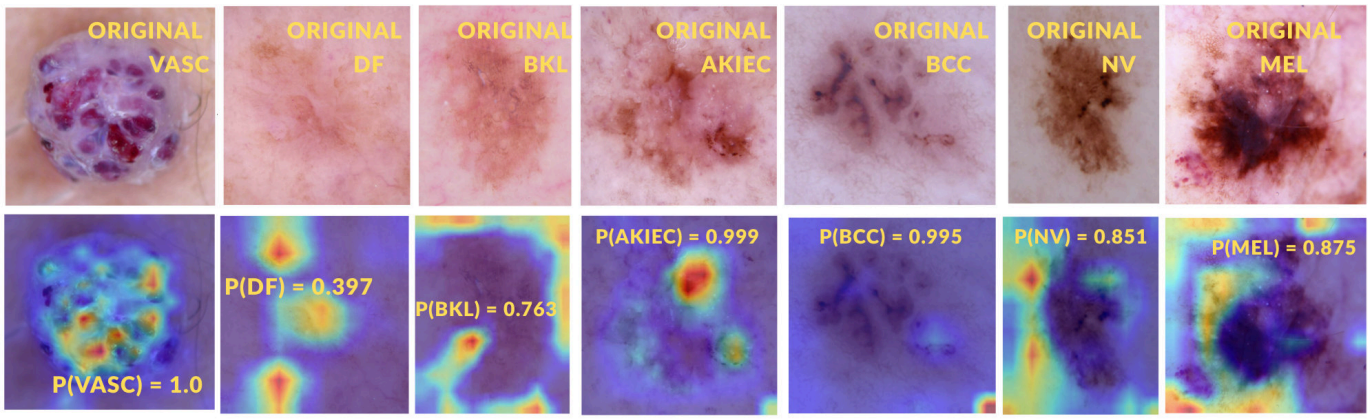

Fig. 10. Grad-CAM visualizations for selected test images. The first column shows the original dermatoscopic images, while the second column presents the corresponding Grad-CAM heatmaps overlaid on the input images.

Fig. 10 presents Grad-CAM visualizations for selected test images with M5. The heatmaps highlight the regions of the lesions that contributed most to the model's predictions.

The Grad-CAM indicates that the model generally focuses on localized image regions that contribute most strongly to the prediction of each skin lesion class. However, the quality of the explanations varies among classes, reflecting differences in lesion morphology and classification confidence. For the VASC example, the model achieved the highest confidence ($P(VASC) = 1.0$), and the activation map concentrated on the vascular structures inside the lesion. This suggests that the network successfully identified the characteristic vascular patterns associated with vascular lesions.

For the DF lesion, the prediction confidence was considerably lower ($P(DF) = 0.397$). The Grad-CAM highlighted only a limited central region, while substantial portions of the lesion received little attention. The BKL case ($P(BKL) = 0.763$) shows activations distributed over several portions of the lesion rather than a single focal region.

For AKIEC ($P(AKIEC) = 0.999$), the activation map is highly localized, with the strongest response centered on the most atypical region of the lesion. Similarly, the BCC example ($P(BCC) = 0.995$) exhibits concentrated activation around irregular pigmented structures, suggesting that the model primarily relied on clinically relevant morphological characteristics instead of background skin regions.

In the NV example ($P(NV) = 0.851$), the network focused mainly on the central pigmented area of the nevus while assigning little importance to the surrounding healthy skin. Finally, for the MEL lesion ($P(MEL) = 0.875$), the activation map covers a large portion of the lesion with stronger emphasis on darker and more irregular regions.

Comparing the best model (M5) with the related works presented in Table I, it is observed that M5 achieved competitive performance; however, it did not surpass the accuracy of the DODL-Net model [20], which achieved 98.76% accuracy. It is important to note that DODL-Net employed a different approach, including dual optimization algorithms and feature extraction techniques, which may have contributed to its superior performance. Nevertheless, the proposed M5 model demonstrated strong performance in multiclass skin lesion classification, achieving an accuracy of 88.42% and an F1-score of 88.15%, while also providing interpretability through Grad-CAM visualizations. The main goal of this study was to develop a multiclass classification with analysis of the impact of different preprocessing, data balancing, and classification strategies, rather than achieving the highest possible accuracy. The results highlight the importance of considering various factors in the design of skin lesion classification models and provide insights for future research in this area.

VI. Conclusion

In this study, we developed a multiclass skin lesion classification model using CNN architectures, including DenseNet169, DenseNet201, and EfficientNetB4. The model was trained and evaluated on the HAM10000 dataset. To address the class imbalance in the dataset, we explored different data balancing strategies, including conventional oversampling and Deep SMOTE. Additionally, we incorporated the Grad-CAM technique to provide visual explanations for the model's predictions, enhancing interpretability.

The experimental results demonstrated that the ensemble model combining DenseNet169, DenseNet201, and EfficientNetB4 with conventional oversampling and TTA achieved the best performance, with an accuracy of 88.42% and an F1-score of 88.15%. In contrast, the use of Deep SMOTE for data balancing resulted in lower performance, suggesting that conventional oversampling was more effective in this multiclass classification task. Furthermore, the application of hair removal using the Dull Razor algorithm did not improve classification performance, indicating that lesion cropping was sufficient to minimize background artifacts. Overall, this study highlights the importance of considering various factors, such as data balancing strategies and preprocessing techniques, in the design of skin lesion classification models. The integration of Grad-CAM provided valuable insights into the model's

decision-making process, contributing to the interpretability of the predictions.

Future research could investigate alternative data augmentation and class-balancing strategies, including more advanced generative approaches, given the inferior performance observed with Deep SMOTE. The removal of the DullRazor step from the pipeline could also be considered, particularly in light of the lack of performance gains and the possibility that the inpainting process may alter or obscure subtle dermatoscopic structures. Furthermore, the development of multimodal models that integrate dermatoscopic images with additional clinical information, such as patient metadata, could be explored to improve the performance and generalization of skin lesion classification models.

ACKNOWLEDGMENT

The authors would like to thank the Federal University of Rural Semi-Arid (UFERSA) for providing the necessary resources and infrastructure to conduct this research.

Abstract*—Monitoring brain activity in comatose patients is a critical challenge in Intensive Care Units (ICUs), particularly within the Brazilian Unified Health System (SUS), where access to advanced neuroimaging is limited. This study proposes a quantitative electroencephalographic (EEG) analysis in 21 comatose patients (Glasgow Coma Scale score = 3) admitted to the ICU of the Hospital de Clínicas of the Federal University of Uberlândia, comparing silence and musical stimulation with Mozart's Sonata K.144 using two power spectral density-based quantifiers: Percentage Power Contribution (PCP) and interhemispheric Coherence (Wilcoxon Signed-Rank Test, = 0.05). Significant differences were identified in 8 of 120 PCP electrode-rhythm combinations (6.67%), predominantly at electrode P3 (left parietal region), and in 24 of 48 Coherence combinations (50.0%), with reductions predominating in both quantifiers. In PCP, the Theta band showed the highest Variation in Percentage (VAP) values (up to 22.73%); in Coherence, Delta showed the highest VAP (up to 23.51%) and Gamma reached significance in 7 of the 8 analyzed electrode pairs. Notably, 11 of the 24 significant Coherence combinations (45.8%) involved high-frequency bands above 30 Hz (Gamma and Super Gamma), with Super Gamma VAP values reaching up to 15.34%, a frequency range rarely investigated in this clinical context. Electrode P3 and the P3–P4 pair exhibited the highest concentration of significant combinations across both quantifiers. These findings suggest that interhemispheric synchrony is more sensitive to structured musical stimulation than local spectral power in this population, and that Coherence may serve as a potential marker of residual cortical responsiveness. The multiparametric, low-cost approach adopted is aligned with the resource constraints of the Brazilian public healthcare context.

***Index Terms*—coma, disorders of consciousness, electroencephalography, interhemispheric coherence, music therapy, power spectral density, quantitative EEG, intensive care unit**

I. Introduction

Monitoring brain activity in critically ill patients is one of the major challenges of clinical practice in Intensive Care Units (ICUs). In this context, Electroencephalography (EEG) stands out as a low-cost, non-invasive, and bedside-applicable tool capable of recording cortical electrical patterns in real-time [1]. Its sensitivity to variations in cerebral metabolism gives EEG an essential role in the stratification of levels of consciousness, especially in cases of profound unconsciousness in which comatose patients remain with closed eyes and without perceptible interaction with the environment [2].

The assessment of the state of consciousness in comatose patients is often performed using clinical scales, such as the Glasgow Coma Scale (GCS). However, these instruments present limitations, particularly in the detection of residual consciousness in apparently unresponsive individuals, and recent studies estimate that approximately 15% of patients clinically classified as unresponsive exhibit patterns of brain activation compatible with some level of consciousness, identifiable only through neurophysiological methods [3]. In this context, the prognostic value of EEG has been consistently demonstrated: Hofmeijer et al. [4] showed that unfavorable EEG patterns within 24 hours predicted poor neurological outcome with 100% specificity in 277 comatose patients after cardiac arrest, while early recovery toward continuous patterns within 12 hours was strongly associated with good outcome; machine learning approaches applied to EEG have further reinforced its value for outcome prediction in comatose patients [5], [6]. Such evidence reinforces the clinical value of EEG in critical care and motivates the investigation of strategies capable of modulating cortical activity in ways detectable by this tool.

In this scenario, music therapy has emerged as a promising non-pharmacological approach for the stimulation of patients with disorders of consciousness (DoC) [7]. Music therapy is particularly suited to this population due to its ability to activate distributed neural circuits, including regions associated with emotion, memory, and attention [8], [9], and

has been shown to modulate functional brain connectivity even in severely impaired states [10]. Studies conducted in clinical settings have demonstrated that musical exposure can induce measurable changes in electroencephalographic activity, with potential effects on clinical prognosis [11]–[14]. Therefore, the combination of quantitative EEG and musical stimulation protocols represents a strategy situated at the intersection of neurophysiology and music therapy, exploring the impact of sound on neurological recovery as a complement to conventional approaches focused on the stabilization of vital systems. This strategy is particularly relevant within the context of the Brazilian Unified Health System (SUS), where access to advanced neuroimaging technologies is often limited by structural and financial constraints, and where rapid and efficient diagnostic approaches are essential due to high patient demand and hospital bed overcrowding. Despite the growing international scientific production in this field, studies employing quantitative EEG analysis under musical stimulation in comatose patients admitted to Brazilian public ICUs remain scarce in the national literature.

In light of this scenario, the present study proposes a quantitative analysis of EEG signals from comatose patients admitted to the Intensive Care Unit of the Hospital de Clínicas of the Federal University of Uberlândia (HC-UFU), with the aim of comparing periods of silence and musical stimulation using Mozart's Sonata K.144. For this purpose, two power spectral density (PSD)-based quantifiers were simultaneously employed: the Percentage Power Contribution (PCP) and interhemispheric Coherence. To the best of our knowledge, this combined approach has not yet been explored in a Brazilian population with this clinical profile.

II. Literature Review

Quantitative EEG (qEEG) spectral analysis stands out as the most widely used approach to measure neural responses to musical stimulation. The index $(\delta + \theta)/(\alpha + \beta)$, defined as the ratio between slow and fast brain waves, has been used as a marker of cerebral alertness, since its reduction indicates a transition from unconscious states to higher cortical activation [11], [15]. In this context, Sun and Chen [15] evaluated 40 patients with traumatic brain injury (TBI) in a coma, exposing the experimental group to music therapy sessions for four weeks. At the end of the intervention, the qEEG index was significantly reduced in the music group compared to the control group ($p = 0.038$), with a significant negative correlation between this index and Glasgow Coma Scale scores, both before ($r = -0.482$, $p = 0.002$) and after treatment ($r = -0.493$, $p = 0.005$). These findings showed that the relative reduction of Delta and Theta waves, accompanied by an increase in Alpha and Beta activity, reflects improved functional brain activity. While this ratio aggregates spectral bands into a single index, the Percentage Power Contribution (PCP) quantifier extends this concept by quantifying the relative contribution of each individual rhythm per electrode, thereby enabling spatially resolved analysis of spectral changes across the entire scalp [16].

A related pattern, linking frequency spectrum reorganization to consciousness recovery, was also reported by Keller and Garbacenkaite [17], who applied neurofeedback based on the θ/β ratio in three patients with unresponsive wakefulness syndrome (UWS) [18], using preferred music as a positive reinforcement stimulus within the neurofeedback protocol. Two of the three patients showed a statistically significant reduction in this ratio over 15 sessions, accompanied by improvements in CRS-R scores in the auditory, motor, and arousal subscales. The authors interpret this decrease as a reflection of a reorganization of the dominant rhythm toward the Alpha band, consistent with partial restoration of cortical circuits.

Beyond the power spectrum, the effect of music on cognitive processing has been investigated through evoked potentials. Castro et al. [19] exposed 13 patients with disorders of consciousness (DoC) to sequences of their own name preceded either by excerpts of preferred music or by neutral spectrally matched noise. The N2/P3 discriminatory response to the subject's own name emerged significantly more frequently in the musical condition, indicating that music promoted a pre-activation of mid-anterior cortical structures that enhanced residual auditory responsiveness. This contextual potentiation effect (in which music acts as a cognitive primer rather than merely an isolated stimulus) suggests that different auditory conditions modulate the organization of brain electrical activity in distinct ways.

The regional distribution of these responses also revealed patterns of functional asymmetry between hemispheres and across brain lobes. Wu et al. [11] analyzed 14 patients with DoC using qEEG during exposure to three auditory stimuli: music, the subject's own name, and white noise, and found that, during musical stimulation, the $(\delta + \theta)/(\alpha + \beta)$ index was consistently higher in parietal and occipital regions than in frontal and temporal regions, in both the DoC and control groups. This topographic gradient suggests that music exerts a preferential influence on areas involved in sensory integration, spatial perception, and higher-order auditory processing. Additionally, in the TBI subgroup, the authors identified a negative correlation between the qEEG index and CRS-R scores ($R = -0.785$, $p = 0.012$), with a positive predictive value of 66.7% for favorable outcomes.

While spectral power indices provide a measure of regional cortical activation, Hu et al. [20] extended this investigation to evoked potentials, evaluating mismatch negativity (MMN, an electrophysiological component associated with automatic auditory discrimination and short-term sensory memory) before and after five minutes of exposure to a symphony with positive emotional associations. Before music exposure, MMN amplitude in patients with DoC was significantly lower than in the control group ($p < 0.001$); after stimulation, this difference was no longer statistically significant, indicating that music increased cortical responsiveness to a level close to that of healthy individuals. Post-musical MMN retesting yielded a negative predictive value of 100%, suggesting that its absence after musical exposure was associated with unfavorable

outcomes in all cases of the study, although this result did not reach statistical significance ($p > 0.05$), likely owing to the limited sample size ($n = 14$). Such evidence reinforces that musical stimulation can reorganize neural synchronization patterns, a process that can be captured not only by power spectrum analysis but also by inter-regional synchrony.

Although the reviewed studies consistently demonstrate that musical stimulation induces measurable changes in the electroencephalographic activity of comatose patients, most are limited to the use of a single spectral quantifier, predominantly indices derived from frequency-band ratios. Complementarily, Ramos et al. [16] and Ramos [21] have documented that interhemispheric Coherence (a measure of the degree of functional coupling between homologous regions of the two hemispheres) shows significant variations across different states of consciousness in Brazilian patients, with reduced values associated with impaired consciousness and potential trajectories of neurological recovery. Furthermore, classical music has been shown to produce measurable behavioral responses in unconscious ICU patients, with Rahgoi et al. [22] reporting significant reductions in pain observational and behavioral scales following exposure to classical music (including Mozart) in 30 unconscious patients ($p < 0.05$), further motivating its use as a structured auditory stimulus in this clinical context. The simultaneous analysis of two independent quantifiers, namely the spectral power distribution per electrode (PCP) and interhemispheric synchrony (Coherence), remains unexplored in this context, as does the application of these methodologies in Brazilian patients admitted to public ICUs. The present study seeks to address this gap by investigating neural responses to musical stimulation through a multiparametric and low-cost approach, suitable for the clinical and healthcare constraints of the Brazilian Unified Health System (SUS).

III. Methodology

A. Data Collection

Electroencephalographic recordings were performed in the Adult ICU of HC-UFU, approved by the UFU Research Ethics Committee (protocol no. 82824017.5.0000.5152). Data were collected during routine care, without interference in therapeutic procedures. The sample consisted of 21 adult patients with Glasgow Coma Scale score = 3. Inclusion criteria were age over 18 years, hemodynamic stability, a clinical indication for EEG, and written informed consent from the legal guardian. Patients requiring high-dose vasopressors or lacking consent were excluded. One additional patient was excluded due to excessive signal artifact. Approximately 62% of participants were male, aged 21–86 years, with predominant diagnoses of traumatic brain injury, hemorrhagic stroke, and subarachnoid hemorrhage. Coma was classified as induced when sedative agents were administered at the time of EEG recording, and as natural otherwise; 5 of 21 patients (24%) met this criterion. All but one patient were under mechanical ventilation (endotracheal tube or tracheostomy); the remaining patient received supplemental oxygen via tracheostomy. Regarding outcome, 8 patients (38%) died (3 due to brain death), 6 (29%) were discharged, 3 (14%) remained hospitalized, and outcome was not registered for 4 (19%).

EEG signals were acquired using the BrainNet BNT-EEG amplifier, with 20 active electrodes positioned according to the international 10-20 system, two auricular reference electrodes, and one cardiac-signal electrode. The sampling frequency was 400 Hz, defined after six months of testing at the Adult ICU of HC-UFU, where higher frequencies resulted in excessive environmental noise, precluding quantitative analysis [16].

The experimental protocol consisted of six auditory stimuli presented sequentially: silence (0–3 min), preferred music (3–6 min), the note A (440 Hz; 6.5–8 min), white noise (10–13 min), Gregorian chant (13.5–16.5 min), and Mozart's Sonata K.144 (17–20 min), interspersed with brief intervals of human conversation. Recordings were performed with patients supine and eyes closed. Stimuli were reproduced through speakers positioned near the patient's head, at intensity adjusted for adequate perception without disturbing other patients. Speakers were used instead of headphones to reduce infection risk from shared devices and avoid additional discomfort in patients already connected to multiple therapeutic devices. The protocol and data processing pipeline are shown in Fig. 1.

B. Data Processing

Following acquisition, two neurologists from the Clinical Neurophysiology unit of HC-UFU selected ten two-second artifact-free epochs by visual inspection, one evaluator per patient across all stimulation conditions; inter-rater agreement could therefore not be calculated. Analyses were conducted on the initial silence period (0–3 min) and the final three minutes of Mozart's Sonata K.144 (17–20 min), the condition established in the group's research protocol [16]. Signals were analyzed using two PSD-based quantifiers: PCP and interhemispheric Coherence.

PCP quantifies the relative contribution of each cerebral rhythm to the total power of the EEG signal at a given electrode [16], calculated according to (1):

$$PCP^{a}_{rhythm,i} = \frac{\displaystyle\int_{f=f_{in}^{rhythm}}^{f_{out}^{rhythm}} |S_{x_{ia}}(f)|^2 \, df}{P_i}, \qquad (1)$$

$$P_i = \int |S_{x_{ia}}(f)|^2 \, df,$$

where i denotes the analyzed epoch; f_{in}^{rhythm} and f_{out}^{rhythm} are the lower and upper frequency boundaries of the rhythm of interest [Hz]; $S_{x_{ia}}(f)$ is the PSD of the EEG signal at electrode x [μV^2/Hz]; and P_i is the total signal power. Both quantifiers were computed using the bilateral auricular reference adopted during acquisition, without re-referencing. The notch filter was applied in the frequency domain, after the Fourier transform and before the power calculation.

The following frequency bands were analyzed: Delta (1–3.5 Hz), Theta (3.5–7.5 Hz), Alpha (7.5–12 Hz), Beta (12–30 Hz), Gamma (30–80 Hz), and Super Gamma (80–100 Hz),

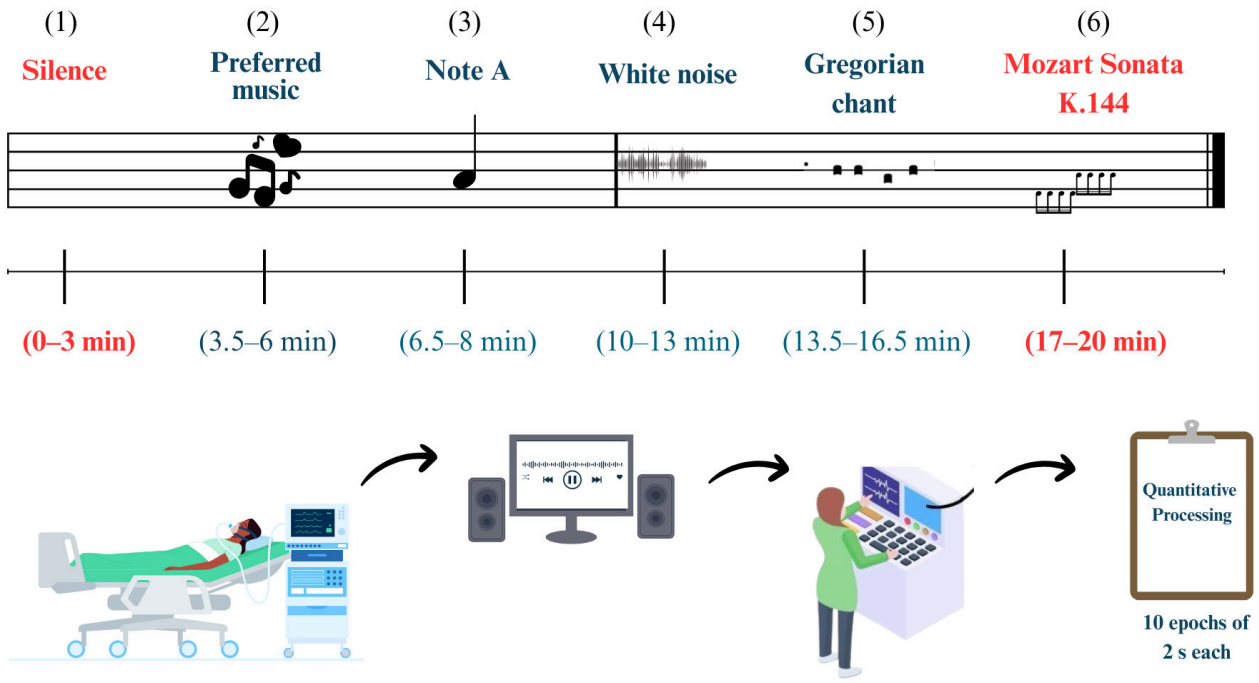

Fig. 1. Stimulation protocol and data processing pipeline. Six auditory conditions were applied sequentially over a total duration of 20 min, separated by 30-second intervals of human conversation sounds: (1) Silence (0–3 min), (2) Preferred music (3.5–6 min), (3) Note A, 440 Hz (6.5–8 min), (4) White noise (10–13 min), (5) Gregorian chant (13.5–16.5 min), and (6) Mozart's Sonata K.144 (17–20 min). Conditions highlighted in red were selected for quantitative analysis. The lower panel illustrates the data processing pipeline: EEG acquisition, auditory stimulation via speakers, visual selection of 10 artifact-free epochs of 2 s each, and quantitative analysis (PCP and Coherence).

across 20 electrodes distributed according to the 10-20 system, yielding a total of $20 \times 6 = 120$ electrode-rhythm combinations.

Coherence assesses the degree of coupling between signals from homologous regions of the right and left hemispheres [1], [16], calculated according to (2):

$$\left|\Gamma_{xy}(e^{j\omega})_i\right|^2 = \frac{\left|S_{xy}(e^{j\omega})\right|^2}{S_x(e^{j\omega}) \cdot S_y(e^{j\omega})}, \quad 0 \leq \left|\Gamma_{xy}(e^{j\omega})_i\right|^2 \leq 1, \tag{2}$$

where S_{xy} is the cross-PSD; S_x and S_y are the individual PSDs of the signals; and i denotes the segment under consideration. Values close to 1 indicate strong interhemispheric synchrony; values close to 0 indicate low coupling between signals.

Eight pairs of homologous electrodes were analyzed: FP1–FP2, F7–F8, F3–F4, T3–T4, C3–C4, T5–T6, P3–P4, and O1–O2, yielding a total of $8 \times 6 = 48$ electrode pair-rhythm combinations.

C. Statistical Analysis

PCP and Coherence results were expressed as median per condition. Comparison between silence and musical stimulation was performed using the Wilcoxon Signed-Rank Test [23], adopting a significance level of 5%. This test was chosen for being appropriate for paired samples from continuous distributions, without assuming data normality, a condition not guaranteed in EEG signals from comatose patients with reduced sample sizes. As each patient served as their own control, this design accounts for inter-subject variability but does not establish whether the observed responses are specific to the comatose state, which would require a non-comatose reference group.

For combinations with statistically significant differences ($p < 0.05$), the Percentage Variation (VAP) was calculated from the medians, according to (3):

$$VAP = \frac{|Md_{music} - Md_{silence}|}{\max(Md_{music}, Md_{silence})} \times 100\%, \tag{3}$$

where Md_{music} and $Md_{silence}$ correspond to the medians obtained under musical stimulation and silence, respectively. As VAP was computed only for combinations already identified as significant, it should be read as a descriptive measure of effect magnitude, not as an independent significance criterion.

IV. Results

A. Percentage Power Contribution (PCP)

The statistical analysis of PCP identified significant differences ($p < 0.05$) in 8 of the 120 electrode-rhythm combinations (6.67%), concentrated in five electrodes: P3, CZ, T5, PZ,

and O2. The P3 electrode, located in the left parietal region, accounted for half of the significant combinations (4 out of 8), with changes observed in the Theta, Alpha, Beta, and Gamma bands. The remaining electrodes (CZ, T5, PZ, and O2) showed significance in only one rhythm each, as detailed in Table I. Of the 8 significant combinations, 6 corresponded to reductions in the median PCP during musical stimulation. Among the significant combinations, the Theta band showed the highest concentration of changes in PCP, appearing in three of the eight significant electrode-rhythm combinations (CZ, P3, and PZ), with VAP values reaching up to 22.73%, the largest observed in this quantifier.

TABLE I
SIGNIFICANT PCP RESULTS ($p < 0.05$; $n = 8/120$; 6.67%)

Electrode	Rhythm	VAP (%)
CZ	Theta	−22.73
T5	Delta	+3.88
P3	Theta	−13.64
P3	Alpha	−17.40
P3	Beta	−15.85
P3	Gamma	−7.80
PZ	Theta	−15.86
O2	Gamma	+9.27

VAP – Percentage variation of the median between silence and music; negative values indicate reduction, positive values indicate increase under musical stimulation.

Fig. 2 illustrates the topographic distribution of the median differences in PCP (ΔPCP = Music − Silence) for the six evaluated brain rhythms. Each map uses its own color scale, allowing identification of the spatial pattern of intra-rhythm variation; comparisons of magnitude between different rhythms should be made based on the absolute values reported in Table I, rather than by the visual intensity of the colors.

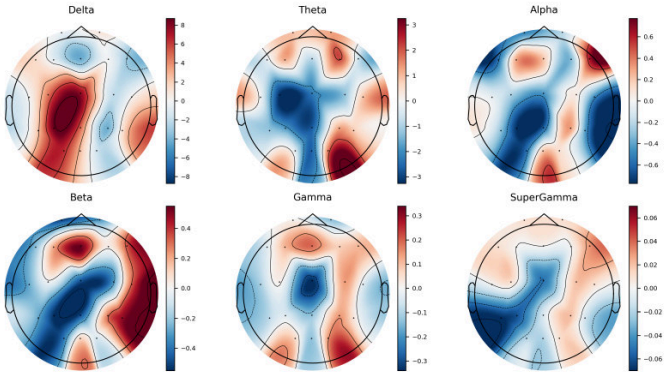

Fig. 2. Topographic distribution of median PCP differences (ΔPCP = Music − Silence) for the six evaluated brain rhythms. Independent color scale per rhythm; red: increase ($\Delta > 0$); blue: decrease ($\Delta < 0$).

B. Interhemispheric Coherence

The statistical analysis of Coherence identified significant differences ($p < 0.05$) in 24 of the 48 electrode-rhythm pair combinations (50.0%). The F7–F8, T3–T4, and P3–P4 electrode pairs concentrated the highest number of significant rhythms, with significance observed in 5 of the 6 evaluated rhythms for each pair. The F3–F4 pair showed significance in 1 rhythm, the FP1–FP2 pair in 1 rhythm, and the C3–C4 and T5–T6 pairs in 2 rhythms each, as detailed in Table II. Of the 24 statistically significant combinations, 16 (66.7%) corresponded to reductions in the median Coherence during musical stimulation, while 8 (33.3%) corresponded to increases. Among the evaluated frequency bands, Gamma showed the broadest spatial distribution, reaching significance in 7 of the 8 analyzed electrode pairs, while Delta exhibited the highest individual VAP value (23.51% in the T3–T4 pair). Of the 24 significant combinations, 11 (45.8%) involved high-frequency bands above 30 Hz, comprising 7 Gamma and 4 Super Gamma combinations, with Super Gamma VAP values reaching up to 15.34% in the O1–O2 pair.

TABLE II
SIGNIFICANT COHERENCE RESULTS ($p < 0.05$; $n = 24/48$; 50.0%)

Pair	Rhythm	VAP (%)
FP1–FP2	Beta	+10.41
F7–F8	Delta	−13.19
F7–F8	Alpha	−20.09
F7–F8	Beta	−8.67
F7–F8	Gamma	−3.92
F7–F8	SG	+11.35
F3–F4	Gamma	−5.58
T3–T4	Delta	+23.51
T3–T4	Theta	−13.45
T3–T4	Beta	−7.75
T3–T4	Gamma	+6.08
T3–T4	SG	+4.67
C3–C4	Beta	−9.36
C3–C4	Gamma	−5.34
T5–T6	Theta	−10.69
T5–T6	Beta	−8.72
P3–P4	Delta	−5.18
P3–P4	Theta	−11.77
P3–P4	Beta	−14.53
P3–P4	Gamma	−10.65
P3–P4	SG	−13.53
O1–O2	Delta	+15.33
O1–O2	Gamma	+12.06
O1–O2	SG	+15.34

SG – Super Gamma. VAP – Percentage variation of the median between silence and music; negative values indicate reduction, positive values indicate increase under musical stimulation.

Fig. 3 presents the spatial distribution of Coherence differences (ΔCoherence = Music − Silence) between electrode pairs for the six evaluated brain rhythms, represented as connection lines whose thickness is proportional to the magnitude of the variation and whose color indicates the direction of the difference.

C. Comparative Analysis

Coherence showed a higher proportion of significant combinations than PCP (50.0% vs. 6.67%), with reductions predominating in both quantifiers: 6 of the 8 significant PCP

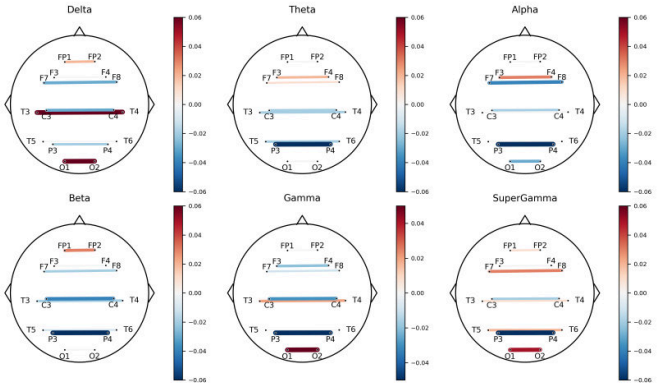

Fig. 3. Interhemispheric Coherence Differences (ΔCoherence = Music − Silence) between electrode pairs for the six evaluated brain rhythms. Color: direction of the difference (red, $\Delta > 0$; blue, $\Delta < 0$). Line thickness: proportional to $|\Delta$Coherence$|$, increasing from the smallest to the largest observed magnitude within each rhythm. Independent color scale for each rhythm.

combinations and 16 of the 24 Coherence combinations. The parietal region emerged as a common point between the two measures, with electrode P3 concentrating most of the significant PCP results and the P3–P4 pair showing significance across five rhythms, all reduced. High-frequency bands above 30 Hz (Gamma and Super Gamma) accounted for 45.8% of the significant Coherence combinations (11 of 24), with Gamma reaching significance in 7 of the 8 electrode pairs and Super Gamma VAP values up to 15.34%.

V. Discussion

The results indicate that musical stimulation with Mozart's Sonata K.144 induced measurable changes in the electroencephalographic activity of comatose patients, detectable through two independent spectral quantifiers. The low proportion of significant combinations in PCP (6.67%), against the high proportion observed in Coherence (50.0%), constitutes the central finding of the present study.

This higher sensitivity of Coherence relative to PCP suggests that musical stimulation preferentially modulates interhemispheric functional organization rather than local spectral power, consistent with the hypothesis that music recruits distributed circuits connecting homologous regions across hemispheres rather than isolated cortical activation [24], [25]. Accordingly, the predominance of Coherence reductions (16 of 24 significant combinations, 66.7%) aligns with Ramos and Destro-Filho [21], who reported that lower interhemispheric coherence characterizes impaired consciousness states in Brazilian patients, and that variations in this parameter during hospitalization may track neurological evolution [16]. Taken together, these results suggest Coherence as a candidate marker of residual cortical responsiveness to structured auditory stimuli, to be further examined in longitudinal designs.

The parietal region was also a spatial point of convergence between the two quantifiers: electrode P3 concentrated four of the eight significant PCP combinations, and the P3–P4 pair showed the most extensive and consistent Coherence reduction, across five rhythms. This converges with Wu et al. [11], who identified the parietal lobe as most influenced by musical stimulation in DOC patients due to its role in multimodal sensory integration and spatial perception, and with Heine et al. [25], who reported increased connectivity in the temporoparietal junction and supramarginal gyrus during music exposure in DOC patients, regions anatomically close to electrodes P3 and P4. As both quantifiers were computed independently, this convergence reduces the likelihood that the pattern reflects a methodological artifact.

In contrast, the low proportion of significant PCP combinations (6.67%) is best read as evidence that local spectral power changes are less sensitive to musical stimulation than interhemispheric synchrony in this population, rather than as an absence of response. Sun and Chen [15] and Wu et al. [11] similarly reported reductions in the $(\delta + \theta)/(\alpha + \beta)$ index under musical stimulation in DOC patients, a pattern partially consistent with the PCP reductions observed here in the Theta band at P3, CZ, and PZ, which further reinforces the spatial specificity of these responses in the parietal region.

Beyond the conventional bands, Gamma activity reached significance in 7 of the 8 analyzed electrode pairs, and Super Gamma combinations showed VAP values up to 15.34%, indicating that musical stimulation also modulates interhemispheric coupling at frequencies rarely investigated in this clinical context. Most studies on musical stimulation in disorders of consciousness restrict spectral analysis to conventional bands below 30 Hz, leaving Gamma and Super Gamma activity largely unexplored [8], [12]. However, the 80–100 Hz range is particularly susceptible to electrical, myogenic, and ventilator-related artifacts in the ICU environment, and no artifact control specific to this frequency range (e.g., line-noise assessment, imaginary coherence, or surrogate data analysis) was applied in the present study; these Gamma and Super Gamma findings should therefore be interpreted with caution until confirmed through such controls.

The F7–F8, T3–T4 and O1–O2 pairs also showed distinct patterns across frequency bands, with predominant Coherence reductions at F7–F8 and T3–T4 and increases at O1–O2, broadly consistent with frontotemporal and occipital connectivity changes reported during music exposure in DOC patients [16], [19], [25]. Nonetheless, these pair-specific patterns should be read as exploratory, given the sample size and the absence of correction for multiple comparisons.

These findings should be interpreted alongside the study's design constraints. The etiological heterogeneity of the sample (traumatic brain injury, stroke, and subarachnoid hemorrhage) and the wide age range (21–86 years), combined with the sample size ($n = 21$), limit generalization beyond the population studied and precluded diagnosis-stratified analysis; future work should confirm these patterns in etiology-stratified cohorts. Likewise, no correlation was tested between EEG findings and clinical outcome or neurological evolution, and the absence of a healthy control group precludes attributing the observed patterns specifically to the comatose state; both aspects were

outside the scope of the present exploratory analysis. The fixed order of stimulus presentation shown in Fig. 1, with silence always first and Mozart's Sonata K.144 last, is a further consideration: the observed differences may partly reflect time-dependent factors such as arousal drift, sedation accumulation, or intervening ICU events, in addition to the auditory content of the stimulus. Randomized or counterbalanced designs with matched non-musical controls would help isolate stimulus-specific effects in future work. Sedation is an additional factor to consider: 5 of the 21 patients received sedative agents at the time of recording, known to alter spectral EEG activity and interhemispheric coupling, and this variability was not statistically controlled for. Exact p-values, effect sizes, and confidence intervals are not reported for individual comparisons; significance is indicated only categorically ($p < 0.05$). Moreover, no correction for multiple comparisons was applied across the 120 PCP and 48 Coherence tests, so the reported significant combinations should not be read as independent evidence, and the present findings are considered exploratory pending replication with corrected significance thresholds and complete reporting of test statistics. Additionally, body temperature, formal auditory assessment, standardized prognostic examinations, and time from injury onset to EEG were not systematically recorded in the original protocol and are noted here rather than treated as covariates. Finally, the analysis was restricted to silence and Mozart's Sonata K.144; incorporating the remaining stimuli from the protocol (preferred music, the note A, white noise, Gregorian chant) will clarify whether the response is specific to structured music or reflects a general auditory response.

Despite these constraints, the multiparametric combination of PCP and Coherence proved feasible using low-cost, bedside-compatible equipment without disrupting routine ICU care, supporting its applicability within SUS-based intensive care units. Also, the convergence of both quantifiers on the parietal region, despite being computed independently, indicates that combining spectral and connectivity measures adds diagnostic value beyond either metric alone. Building on these results, replication in larger, etiology-stratified samples, using randomized or counterbalanced stimulus designs and longitudinal follow-up, would help establish the prognostic value of interhemispheric coherence as a biomarker of cortical responsiveness to musical stimulation in comatose patients.

VI. Conclusion

This study investigated the neural response to musical stimulation with Mozart's Sonata K.144 in comatose ICU patients, through the simultaneous analysis of PCP and interhemispheric Coherence. The sample consisted exclusively of patients with profound coma (Glasgow Coma Scale score of 3), a population that remains underrepresented in the quantitative EEG literature on musical stimulation, particularly in Brazilian public ICUs. Coherence proved substantially more sensitive to musical stimulation than PCP (50.0% vs. 6.67% of significant combinations), suggesting that structured auditory stimuli preferentially modulate interhemispheric functional organization rather than local spectral power. This pattern was reinforced by the predominance of reductions in both quantifiers and by their spatial convergence at the parietal region, particularly at electrode P3 and the P3–P4 pair. Delta and Gamma showed the most pronounced Coherence changes, while Theta showed the highest VAP values in PCP; notably, Coherence also revealed significant Super Gamma-band changes in four homologous electrode pairs, extending the analysis beyond the frequency range typically investigated in this clinical context. Given the sample size and the absence of correction for multiple comparisons, these findings are best regarded as exploratory, warranting confirmation in larger, etiology-stratified cohorts.

Even with these constraints, the approach adopted requires only standard, low-cost EEG equipment and non-pharmacological stimulation, making it directly compatible with the operational and financial constraints of Brazilian public ICUs within the SUS framework. As one of the few studies to jointly apply PCP and Coherence in this population, and the first, to our knowledge, to extend this analysis into the Gamma and Super Gamma bands, it contributes a methodological reference for future quantitative EEG research in resource-constrained critical care settings. Building on these results, future work should incorporate the remaining stimuli from the experimental protocol (preferred music, the note A, white noise, and Gregorian chant) to assess the specificity of the observed responses relative to non-musical auditory controls, and evaluate the prognostic value of Coherence modulation as a biomarker of neurological evolution through longitudinal designs with larger, etiology-stratified samples.

Abstract*— Obstructive Sleep Apnea Syndrome (OSA) is a severe respiratory disorder, frequently underdiagnosed due to the high cost and complexity of polysomnography, the current diagnostic gold standard. This study aims to develop and evaluate the functional integration and signal processing capability of acoustic, accelerometric, and oximetric data in a multisensory prototype designed to investigate sleep-related respiratory events. The system consists of an electroacoustic transducer (MAX9814), synchronized with wearable accelerometry (MPU-6050) and oximetry (PPG) modules, with MATLAB-based processing for digital filtering and feature extraction (RMS, Spectral Centroid, LF/HF ratio). The proof-of-concept trial, conducted in a laboratory environment (LIHOM-UFPE) through simulated bench tests, demonstrated a pre-configured temporal alignment among the three sensors: a prolonged period of acoustic silence (200–280 s) was followed by a rescue sound of -19 dBFS and by the nadir of simulated desaturation (SpO2 = 91%, t = 291 s), with a delay parameterized according to the lung-to-finger circulation time described in the literature.Spectral analysis via FFT revealed a predominance of energy at 38.82 Hz, within the frequency range reported in the literature for low-frequency snoring components. However, as a single spectral peak from a synthesized stimulus, this result reflects the system's spectral analysis capability rather than obstruction-site classification. The accelerometry module correctly captured the programmed postural transition from supine to lateral decubitus, confirming the sensor's ability to register movement patterns relevant to positional monitoring, without constituting evidence of POSA-related physiological coupling. Built from commercial, low-cost electronic components, the prototype demonstrated technical feasibility as a multisensory acquisition and synchronization platform for future sleep-related respiratory-event research.

Keywords*— *Sleep Apnea Obstructive, Snoring, Accelerometry, Oximetry, Monitoring Physiologic.

I. INTRODUCTION

Sleep-disordered breathing, notably snoring and obstructive sleep apnea syndrome (OSA), represents a growing public health challenge and affects a significant portion of the adult population [1], [2]. Frequently viewed merely as a social nuisance, snoring is the result of airway vibration and acts as an important pathophysiological marker of increased upper airway resistance and changes in the breathing pattern [1], [2]. Apnea, in turn, is a severe chronic condition characterized by repeated interruptions in breathing. Although snoring is relevant to the obstructive pattern, its sensitivity and specificity are limited. Its isolated presence does not necessarily define the diagnosis of OSA [1]-[3].

Studies indicate that snorers undergo changes in respiratory mechanics and airway musculature, especially during Non-Rapid Eye Movement (NREM) sleep. This elevated airway resistance increases the tendency for pharyngeal collapse, which prevents the maintenance of deep sleep stages and results in shorter, poorer-quality rest [1]-[3]. The early detection of obstructive events is clinically crucial, as OSA is associated with severe cardiovascular, metabolic, and neurocognitive complications. Although polysomnography is the diagnostic gold standard, its high operational cost and the requirement for specialized infrastructure limit population access. Consequently, there is a growing demand for alternative, portable, and less invasive methods for screening and nocturnal monitoring, using snoring as a clinical predictor [3], [4].

In the context of developing a prototype based on sensor integration, a wearable device, and IoT (Internet of Things) technology, the acoustic analysis of snoring serves as a useful tool in the functional assessment of the upper airways, especially when analyzing the associations between sound frequencies and specific sites of obstruction, providing support for functional evaluation [5]-[7]. In order to identify obstructive apneic events non-invasively and in a manner adaptable to the home environment, the simultaneous implementation of body movement and peripheral oxygenation sensors expands the possibilities of respiratory monitoring [8], whereby accelerometry applied to the thoracic and abdominal region assists in estimating respiratory dynamics [9]. Additionally, pulse oximetry detects drops in oxygen saturation resulting from reduced airflow, and its integration with acoustic signals can significantly improve the automated identification of obstructive events, reducing dependence on complex laboratory exams such as polysomnography [10], [11].

Therefore, the development of a technology that integrates acoustics, oximetry, and accelerometry emerges as a promising strategy [11]. The fusion of these signals provides a broad view of respiratory dynamics, enabling the detection of obstructive events with high analytical robustness [10] and democratizing the early diagnosis of OSA, especially in regions lacking specialized exams [12].

In this context, this study aims to develop and evaluate the functional integration and signal processing capability of acoustic, accelerometric, and oximetric data in a multisensory prototype designed to investigate sleep-related respiratory events.

II. Material and methods

The proposed device is characterized as a benchtop prototype in the proof-of-concept phase for the continuous and non-invasive monitoring of parameters indicative of Obstructive Sleep Apnea (OSA). Structurally, the system consists of three independent physical modules: acoustic (sound), oximetry (optical plethysmography), and accelerometry (mechanical). The device embodies the IoT technology approach, aiming to minimize the use of wires and integrate the sensors responsible for sound and biomechanical analysis. Its internal structure comprises an independent power supply (battery) with USB cable charging and an SD memory card for data storage, which are later processed and analyzed with the aid of the SISMO UFPE web portal (Sistema de Monitoramento Fisioterapêutico de Pacientes) and MATLAB software, for integrated visualization of the results [13], [14].

A. Processing Unit and Sensors

- *Electroacoustic transducer (ESP32-S3 Super Mini and MAX9814)***:** The module is controlled by the ESP32-S3 Super Mini microcontroller. The choice is due to the presence of internal 12-bit analog-to-digital converters (ADCs), which allow for the precise reading of multiple simultaneous analog channels and high data encapsulation capacity for IoT. Additionally, its compact size, versatility, and high energy efficiency are essential characteristics for continuous monitoring devices [15]. The MAX9814 sensor, responsible for detecting snoring sound episodes, was chosen mainly based on its internal automatic gain control (AGC), which ensures that abrupt variations in acoustic amplitude are properly adjusted and conditioned for the ESP32-S3 analog input, ensuring data integrity by preventing signal saturation [16]. It is important to note that the AGC continuously adjusts the input gain in response to signal amplitude; consequently, the dBFS, RMS, Leq, and threshold-based measurements reported in this study reflect the sensor's post-AGC output and should be interpreted as relative indicators of the processing pipeline's behavior, rather than calibrated sound pressure measurements against a fixed acoustic reference. A calibration procedure was not performed at this stage and is identified as a requirement for future quantitative comparisons;
- *Wearable Peripheral Oximetry Module:* Oxygen saturation is measured non-invasively using a sensor positioned at the fingertip. Its functionality operates through photoplethysmography (PPG), analyzing the difference in red and infrared light absorption by deoxygenated hemoglobin (Hb) and oxyhemoglobin (HbO2), allowing for the continuous calculation of oxygen saturation (SpO2) [14];
- *Wearable Accelerometry Module (MPU-6050):* The sensor captures linear acceleration and angular velocity data. Positioning this sensor on the trunk allows for the evaluation of decubitus (posture) in orthogonal axes (X, Y, Z) and the identification of thoracoabdominal effort associated with respiratory pauses based on chest wall biomechanics [13].

B. Data Processing

- *Hybrid acquisition (Table I):* The acoustic signal is sampled by the ESP32-S3 module via Direct Memory Access (DMA). In the firmware itself, an oversampling technique was implemented, with an initial high-frequency collection rate (20 kHz) followed by a decimation step by a factor of 20. This procedure acts as a moving average digital low-pass filter, attenuating high-frequency noise and adjusting the effective sampling rate to 1 kHz, optimizing the data flow for subsequent export and saving in a .csv file. Simultaneously, the numerical matrices of accelerometry and oximetry are exported from the SISMO cloud platform.

  Each channel was acquired using an independent microcontroller of the same model (ESP32-S3), governed by its own onboard crystal oscillator, with no shared clock or synchronization trigger implemented between channels. Temporal correspondence across channels was instead achieved by manually matching the pre-configured simulated event sequence during data visualization in MATLAB. Accordingly, the reported temporal correlation among channels reflects the precision of this manual matching process rather than a measured synchronization error between independent oscillators. Formal quantification of this error is identified as a requirement for future implementations employing a shared clock reference or hardware-level triggering.
- *Data processing and parameter extraction:* For data processing, the chosen tool was the MATLAB software by MathWorks (WEB version). The raw signals are processed by importing the numerical matrices from the three sources. In MATLAB, the algorithm is programmed to apply low-pass and high-pass filters to identify and attenuate noise, such as sudden movement artifacts and power line interference. This cleaning step is fundamental to enable the temporal alignment of events, allowing the correlation between peaks in the accelerometer signal with drops in the SpO2 curve and variations in snoring amplitude;

TABLE I. Acquisition Parameters and Signal Ranges by Channel

Channel	Signal Type / Origin	Sampling Rate	Range / Units	Applied Filter
Electroacoustic Transducer	Simulated signal (pre-configured sound stimulus), read via MAX9814	20 kHz (initial acquisition), 1 kHz (effective, after decimation by a factor of 20)	dBFS (e.g., -19 dBFS rescue sound; -18 dBFS isolated peak)	DC offset removal; 20–300 Hz band-pass; notch filter; 100-sample windowing with 50% overlap
Wearable Accelerometry Module	Postural movement mechanically reproduced on the bench, read via MPU-6050/ESP32-S3	50 samples per second (Hz) on both axes	Dimensionless amplitude on the X, Y, Z axes (Hz)	Digital moving average filter, 10-sample window
Wearable Peripheral Oximetry Module	Simulated saturation (programmed nadir), obtained via PPG module, exported from the SISMO platform	50 samples per second (Hz)	SpO2 in 80–110% (sensor operating range) Simulated event values ranged from 91% to 97.2% within this scale	Artifact-rejection filter via retention of the last valid value below 90%

- *Filtering of biomechanical signals:* In MATLAB, a digital moving average filter with a 10-sample window is applied to the three orthogonal axes of accelerometry, acting as a linear low-pass filter to attenuate high-frequency noise and tremors. Given the accelerometry sampling rate of 50 Hz, this filter configuration yields an approximate cutoff frequency of 2.2 Hz, effectively attenuating high-frequency artifacts while preserving the lower-frequency postural and thoracoabdominal movement signals of physiological interest;
- *Filtering of oximetry signals:* A logical conditional artifact rejection filter is applied, which retains the last valid physiological value if the reading suddenly drops to values below 90% (characteristic of sensor failure), stabilizing the saturation curve.

  It should be noted that this retention strategy, while stabilizing the visual continuity of the saturation curve, does not distinguish between an artifact-induced drop and a genuine desaturation event below the 90% threshold. As currently implemented, the filter does not generate an explicit flag or annotation when a value is being carried forward rather than newly acquired, which represents a limitation for downstream event detection. A future implementation should log each occurrence of value retention as a distinct output flag rather than allowing it to appear as an unbroken physiological trace;
- *Acoustic signal filtering:* The raw data initially undergo DC offset (continuous level) removal. Filters are implemented for the frequencies of interest. The band-pass filter retains only frequencies between 20 and 300 Hz, eliminating excessively low- or high-frequency noise that does not belong to snoring. The notch filter is used to mitigate electromagnetic interference and artifacts. The resulting signal is normalized and segmented by a 100-sample windowing with 50% overlap;
- *Feature extraction and acoustic analysis:* Through the Fast Fourier Transform (FFT), the frequency spectrum of the entire audio is calculated, allowing the identification of the predominant frequency components. The spectral analysis, illustrated by the FFT, shows that the highest concentration of respiratory sound energy is located in the band below 300 Hz, justifying the digital filter choices. From each window, the algorithm extracts features in the time domain (Respiratory Energy, RMS, Zero-Crossing Rate) and in the frequency domain via Welch's Power Spectral Density (Centroid, Entropy, Rolloff, LF/HF ratio). The detection of apnea/snoring events is based on dynamic thresholds using the signal's median to define the silence baseline, stratifying the intensity of the events into statistical percentile levels (L1, L5, L10) and Equivalent Noise Level (Leq).

C. Operational Protocol

This stage was characterized by the development and verification of the prototype. Given the preliminary nature of the research, experimental validation was conducted in a laboratory environment, through bench tests with simulated sound stimuli, without collecting human biological data, focusing exclusively on the technical functioning of the hardware and the response of the acoustic sensor, with no clinical diagnostic objective. The experimentation was carried out at the Human-Machine Interface Laboratory of the Electronics and Systems Department at UFPE (LIHOM-UFPE). It is noteworthy that the oximetry and accelerometry devices have been previously validated and are functioning, communicating with the monitoring platform [14], [15]. Therefore, the procedure consisted of the functional validation and integration of the MAX9814 sensor into the pre-existing system.

a) Metrics

The metrics analyzed covered the performance of the instrumentation hardware and the accuracy of the detection algorithms. The evaluated parameters included:

1. Hardware and network metrics: Effective sampling frequency, which is the microcontroller's ability to maintain the programmed reading rate (Hz) when integrating the A/D conversion of the audio signal;

2. Acoustic signal quality: Evaluation of the Signal-to-Noise Ratio (SNR) guaranteed by the acoustic sensor's AGC in relation to background environmental noise;

3. Digital processing validation: Accuracy in identifying snoring peaks was ensured by applying an event detection algorithm, which uses dynamic thresholds calculated from the median of the signal baseline. Additionally, the acoustic intensity of the events was stratified in decibels (dBFS) through the Equivalent Noise Level (Leq) and statistical percentiles (L1, L5, and L10).

b) Usage Guidelines

Before starting the test, the responsible technical team considered the main prior precautions necessary to avoid data inadequacy, performing the following instrumental, environmental, and technical checks, respectively:

- *Observation of equipment integrity:* inspecting for possible signs of breakage or mechanical shocks. If there was any damage, the use of the device was to be interrupted until laboratory repair was completed;
- *Minimal use of external sources:* that could cause electromagnetic and light interference during collection, aiming to reduce artifacts in the acquired data;
- *Data verification and formatting:* It is strictly necessary to pay attention to .csv formatting and file-nomenclature standardization, following the model used in the SISMO portal during data acquisition (e.g., proc_20260507170129_(device)_.csv), ensuring compatibility for signal processing in the MATLAB software.

III. Results and Discussion

The interpretation and systematization of the data obtained in the laboratory testing of the device were structured to validate the integrated technical functioning of its modules and fulfill its main purpose: investigating the influence of snoring on obstructive events through the direct correlation between sound characteristics (acoustic module), thoracoabdominal breathing pattern (accelerometry module), and peripheral oxygenation responses (SpO2). For functional and analytical evaluation of the multimodal prototype, the topic was divided into five complementary sections.

A. Validation of the Biomechanical Module in Decubitus Change and Interaction with Oximetry

The prototype's ability to register a controlled simulation of decubitus change and correlate it with ventilatory responses was initially evaluated using the accelerometer module. The reproduction of the postural transition from supine to lateral decubitus was captured by the z-axis of the accelerometer (Fig. 1), through a steep decline in amplitude (t = 0.78 - 1.25 s | max amp = -1.04 | min amp = -0.93). Conversely, a brief reduction (amp = -0.49) was observed around 2 s of testing (t = 1.89 s), which may represent a movement artifact associated with the controlled mechanical movement of the sensor.

As described in the Methods section, a moving average digital filter (10-sample window) was applied in MATLAB over the accelerometry axes to attenuate high-frequency noise and tremors. Fig. 2 shows the difference between raw and filtered data, with a reduction of 0.09 in the maximum amplitude and 0.01 in the minimum (t = 0.78 - 1.25 s | max amp = -0.95 | min amp = -0.92). In the brief reduction period, the filtering effect was slightly more pronounced than in the estimated period for decubitus change, with a difference of 0.14 (t = 1.9 s | amp = -0.35).

.

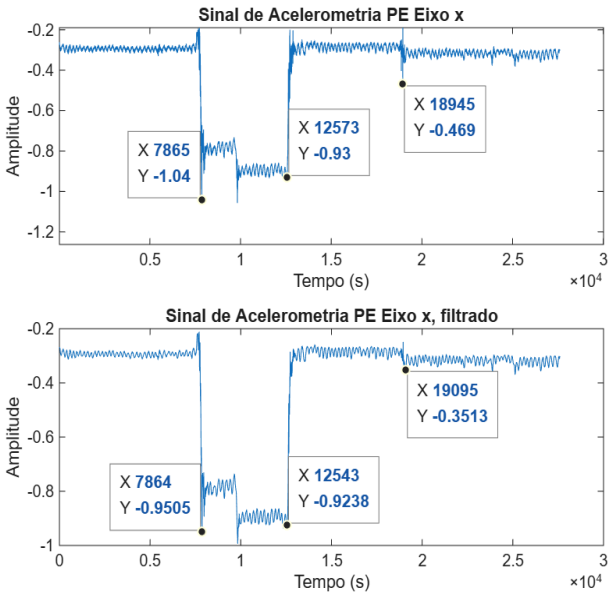

Fig. 2. Raw data versus filtered data on the accelerometry x-axis. Source: Data obtained from a bench test with simulated stimuli, processed and statistically analyzed on the MATLAB web portal.

In Fig. 3, referring to the oximetry signal, an oscillating pattern generated by the oximetry signal during the simulated decubitus trial is demonstrated, evidenced in the demarcated range in the three axes (x-axis: t = 0.78-1.25 s | max amp = -0.95 | min amp = -0.92; y-axis: t = 0.77-1.27 s | max amp = -0.08 | min amp = -0.06) and in the SpO2 curve (z-axis: t = 162-291 s | max SpO2 = 97.2% | min SpO2 = 91%).

This amplitude redistribution pattern falls within the range of postural signatures described in the literature for positional obstructive sleep apnea (POSA), in which supine decubitus favors upper airway collapse due to the action of gravity on the tongue and soft palate, while lateral decubitus tends to reduce airway resistance and the frequency of obstructive events [17]. As the postural transition was mechanically reproduced on the bench rather than performed by a patients, this result demonstrates the accelerometry module's capability to register and temporally align postural changes with the other sensor channels, reinforcing its role as a complementary sensor in multimodal OSA monitoring [9]. However, it does not

constitute physiological evidence of POSA-related airway behavior, which would require validation in human participants.

B. *Spectral Characterization of Snoring - Fast Fourier Transform (FFT)*

The analysis of energy concentration in the frequency domain, via FFT, revealed a predominance around 38.82 Hz (Fig. 4), characterizing the acoustic signal as low-frequency and compatible with the spectral profile described as a breathing pattern without relevant upper airway alterations in this segment of the recording [18]. This instrumental performance of the prototype aligns with the literature on the acoustic classification of snoring, according to which lower frequency components tend to be associated with higher levels of obstruction (retropalatal/oropharyngeal), while higher frequencies usually reflect obstructions at lower levels of the airway (retrolingual/hypopharyngeal) [18], [7].

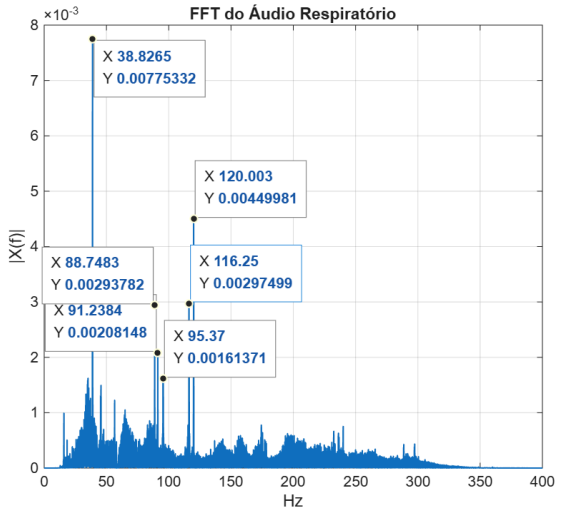

Fig. 4. Fast Fourier Transform (FFT) of Snoring. Source: Data obtained from a bench test with simulated stimuli, processed and statistically analyzed on the MATLAB web portal.

Subsequently, the system demonstrated sensitivity by registering the emergence of irregular frequencies delimited up to the 120 Hz range, showing compatibility with possible superposition of vibration sites.

C. *Extraction of Acoustic Features and Mapping of Obstructive Events*

The evaluation of the prototype over a continuous 665-second window (Fig. 5) certified its capability to extract longitudinal acoustic attributes to identify obstructive breathing disorders. In the interval between 50 s and 440 s, the device's algorithm discriminated a basal, rhythmic, and chronic snoring pattern, evidenced by the persistent RMS amplitude and sharp, cyclic drops in spectral entropy, which mark the periodic transition from chaotic respiratory noise to well-structured and predictable harmonic waves.

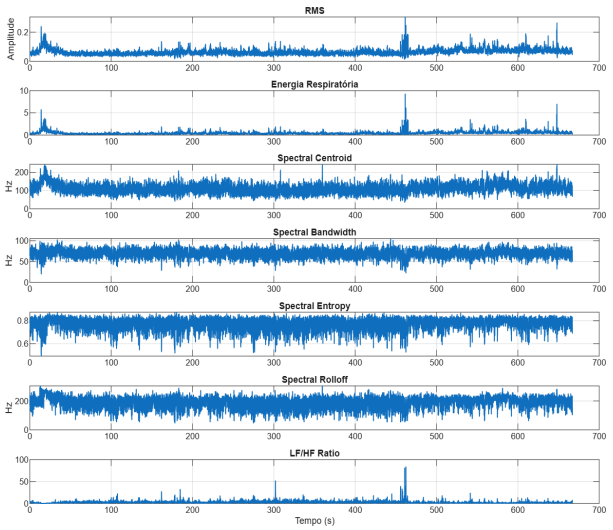

Fig. 5. Respiratory Features regarding snoring amplitude, vibration site, and gravity. Source: Data obtained from a bench test with simulated stimuli, processed and statistically analyzed on the MATLAB web portal.

D. *Stratification of Obstructive Events and Postural Influence Metrics*

The accuracy of the digital processing concerning the detection of respiratory events was evaluated via frequency peaks with a minimum amplitude validation of 35% (Fig. 6). The algorithm identified an outlier in the first 20 seconds of the recording, which artificially elevated the sound frequency ceiling (RMS = 0.21).

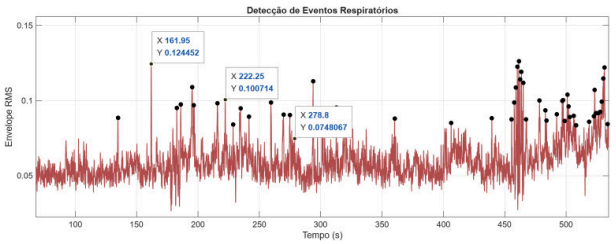

Fig. 6. Detection of Respiratory Events, via frequency peaks based on a minimum amplitude validation of 35%. Source: Data obtained from a bench test with simulated stimuli, processed and statistically analyzed on the MATLAB web portal.

The most critical behavior of the recording was captured abruptly around 450 s, characterized by a significant surge in the RMS envelope and respiratory energy, consistent with the sharp peak in the LF/HF ratio (close to 80). This surge falls within the low-frequency band (20 – 120 Hz) described in the literature as characteristic of gasping/arousal acoustic signatures [19], [20]. As this event was part of the pre-configured simulated sequence, this result demonstrates that the signal-processing pipeline reliably detects programmed amplitude and spectral-ratio transitions. It does not, by itself, validate the acoustic signature of airway

collapse and reopening in a physiological sense, which would require testing with real recordings from human participants.

Highlighting the purpose of integration, the gyroscope analysis in the z-axis (Fig. 7) associated the amplitude limitations and SpO2 oscillations with specific postural changes. The initial RMS peak of 0.12 demarcates the period of transition to lateral decubitus (150 - 250 s). In this interval, a consistent variation of high-pitched sound peaks during the inspiratory phase was recorded (mean RMS = 0.10; t = 222 s), which physiologically show an association with saturation oscillations. The oxygen decline was captured by the plethysmographic module approximately 20 seconds after the acoustic event was captured—an interval compatible with the lung-to-finger circulation time already described in the pulse oximetry literature on sleep apnea [21]. These findings generated by the device suggest the ability to capture patterns compatible with the influence of lateralization, stated in the pathophysiology of POSA [17].

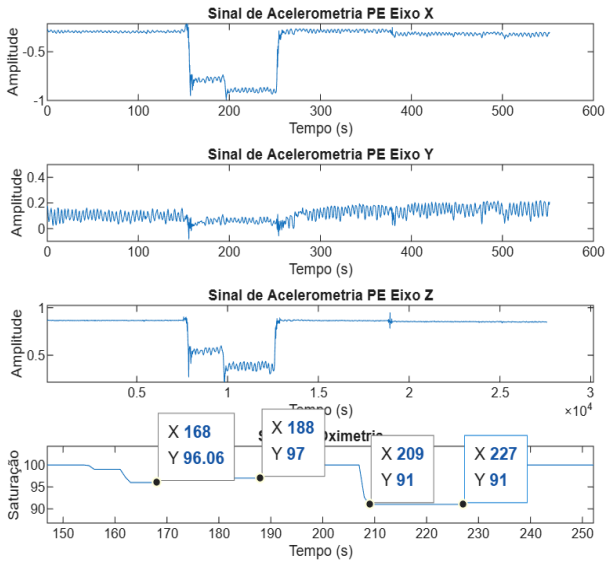

Fig. 7. Postural Alteration Captured by Gyroscope and Associated with Respiratory Events. Source: Data obtained from a bench test with simulated stimuli, processed and statistically analyzed on the MATLAB web portal.

E. Sound Intensity Weighting (Leq) and Synchronization with Oximetric Profile

To consolidate the validation of the simultaneous and correlated functioning of the sensors, the chronological agreement between the acoustic data and the oximetry profile was evaluated (Fig. 8).

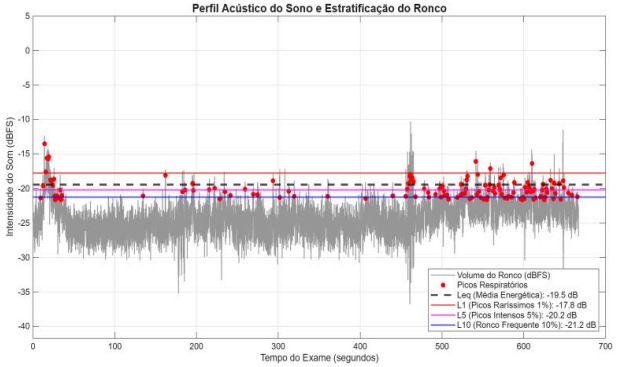

Fig. 8. Peripheral Oximetry Signal and Equivalent Noise Level (Leq) and statistical percentiles (L1, L5 and L10). Source: Data obtained from a bench test with simulated stimuli, processed and statistically analyzed on the MATLAB web portal.

In the first highlighted event, at instant t = 162 s, the emergence of an isolated respiratory peak in the acoustic envelope (approx. -18 dBFS) is observed, coinciding with an oxygen saturation still stable at 97.2%. This record demonstrates the adequate functioning of the transducer in capturing a brief respiratory manifestation, which occurred before there was sufficient time for a relevant drop in peripheral oxygenation. The most relevant instrumental finding regarding the prototype's purpose occurs at time t = 291 s, after a prolonged period of low amplitude in the acoustic signal (t = 200 - 280 s). The device recorded a rescue sound of -19 dBFS, emitted precisely at the moment the oximetry model showed the nadir of a significant desaturation, dropping to 91%.

This temporal agreement was intentionally parameterized in the simulated sequence, based on the physiological delay of approximately 10 to 20 seconds described in the literature between the end of a respiratory event and the detection of desaturation at the peripheral extremity, resulting from the lung-to-finger circulation time and the instrumental latency of the pulse oximeter [21]. Accordingly, this result verifies that the acquisition and visualization pipeline correctly preserved this programmed inter-channel delay - a synchronization and plotting-logic outcome - rather than demonstrating detection of the physiological delay itself, which was not measured but reproduced as a fixed, pre-defined parameter. This integration pattern reflects the timeline structure defined in the pre-configured simulation and demonstrates that the acquisition and synchronization pipeline can reproduce the type of multi-channel event sequence reported in acoustic-oximetric fusion approaches for OSA screening [19], [20]. This result supports the technical viability of the synchronization pipeline, providing a basis for future validation against real physiological delays. Establishing screening or diagnostic performance, however, would require dedicated studies with human participants.

IV. Conclusion

The developed prototype demonstrated satisfactory preliminary functioning during the integration of acoustic, mechanical, and oximetry signals. The system's efficiency was significant due to the precise temporal correlation between the acoustic silence valleys (200 to 280 s), the subsequent rescue sounds with low-frequency signatures and LF/HF ratio peaks close to 80, and the subsequent oxygen desaturations (nadir of 91% | t = 291 s), synchronized to decubitus changes reproduced on the bench and captured by the accelerometer. However, the susceptibility to artifacts in the first 20 seconds - which generated a biased RMS ceiling of 0.21 - evidences the critical need to improve digital filtering algorithms beyond the 10-sample moving average utilized.

From a technical applicability standpoint, it is noteworthy that the prototype was built entirely from commercial, compact, and relatively low-cost electronic components, avoiding the need for the specialized infrastructure and high operational investment required by polysomnography, the diagnostic gold standard [3]. This

characteristic, combined with the simplified operation enabled by IoT technology, supports the technical feasibility of a low-cost, synchronized multisensory acquisition platform as a foundation for future respiratory-event research. Clinical or outpatient applicability, however, has not been demonstrated at this stage and would require validation with human participants and comparison against the diagnostic gold standard.

***Abstract*—As doenças cardiovasculares lideram a mortalidade global, e o monitoramento eletrocardiográfico (ECG) contínuo é essencial para a detecção precoce de arritmias. Contudo, exames de longa duração, como o Holter, geram volumes de dados que desafiam a capacidade de armazenamento dos dispositivos e sobrecarregam a transmissão sem fio. Este trabalho propõe um algoritmo de compressão de ECG com perdas controladas, baseado na variação do conteúdo espectral obtido por Transformada Rápida de Fourier (FFT), com limiares de tolerância exponenciais adaptativos por componente harmônica, seguido de compressão sem perdas pelo algoritmo LZW. O método foi validado com sinais do banco de arritmias MIT-BIH e avaliado por um cardiologista em protocolo cego, alcançando taxa de compressão média de 154,2 e índices gerais de sensibilidade e especificidade de 91,71% e 99,97%. Nos registros avaliados, o algoritmo reduziu substancialmente o espaço de armazenamento necessário, preservando as características morfológicas e temporais associadas às arritmias estudadas.**

***Keywords*—Compressão de dados, ECG, Variação Espectral**

I. Introdução

Segundo a Organização Mundial da Saúde (OMS), as Doenças Cardiovasculares (DCV) permanecem como a principal causa de morte no mundo, tendo sido associadas a 19,2 milhões de óbitos em 2023 [1, 2], sem perspectiva de melhoria nas projeções para os próximos anos [3]. Sua prevalência cresce acentuadamente com a idade, atingindo mais de 80% da população acima de 80 anos nos Estados Unidos [4]. A elevada incidência está fortemente associada a fatores comportamentais cada vez mais presentes na sociedade contemporânea, tais como sedentarismo, obesidade, tabagismo, consumo excessivo de álcool e má alimentação [5, 6].

Entre as patologias do sistema cardiovascular destacam-se as arritmias cardíacas [7], caracterizadas por alterações na atividade elétrica do coração que modificam o ritmo e a eficácia dos batimentos [8]. Dependendo de sua natureza e gravidade, podem desencadear complicações severas, como acidente vascular cerebral (AVC), infarto agudo do miocárdio, embolia sistêmica e em casos extremos, a morte [9, 10]. Dessa forma, a detecção precoce das arritmias torna-se essencial para possibilitar intervenções antecipadas e reduzir os riscos associados à progressão dessas enfermidades [11].

A identificação das arritmias é realizada por meio do monitoramento dos sinais eletrocardiográficos, utilizando dispositivos como monitores cardíacos, eletrocardiógrafos e sistemas Holter. O Holter é um equipamento usado para registrar continuamente a atividade elétrica do coração por períodos superiores aos exames convencionais, permitindo a detecção de arritmias intermitentes que podem não ser observadas em registros de curta duração. Em geral, o dispositivo armazena os sinais de Eletrocardiograma (ECG) em cartões de memória SD durante intervalos que variam de 2 a 5 dias.

Entretanto, determinadas arritmias podem ocorrer de forma esporádica, apresentando longos intervalos entre os episódios, frequentemente superiores a 120 horas [12, 13]. Nesses casos, torna-se necessário prolongar o período de monitoramento para garantir o registro adequado das alterações rítmicas e morfológicas presentes no traçado eletrocardiográfico. Contudo, a capacidade limitada de memória dos dispositivos pode comprometer a captura e o armazenamento dessas informações de interesse. Além disso, em aplicações que envolvem transmissão sem fio dos sinais, é desejável que os arquivos possuam tamanho reduzido, minimizando o tempo de transmissão e o consumo de recursos do sistema [14].

Para mitigar essas restrições de armazenamento e transmissão, diferentes abordagens de compressão de sinais de ECG têm sido propostas na literatura. Em [15], foram integradas a Transformada Discreta de Fourier (DFT), a transformada *wavelet* e o *Run-Length Encoding* (Código *Run-Length*) (RLE), utilizando a mesma base de dados avaliada no presente estudo, a qual será detalhada na Seção II. Já em [16], o método de compressão sem perdas de sinais eletrocardiográficos proposto, combina um autoencoder convolucional binário (*Binary Convolutional Auto-Encoder*, BCAE) com uma rede de compensação do erro residual (*Residual Error Compensation*, REC). O BCAE converte o sinal em códigos binários, permitindo aumentar a capacidade da camada latente

sem reduzir a taxa de compressão, enquanto a REC corrige as diferenças entre o sinal original e o sinal reconstruído. O trabalho também foi avaliado com a mesma base de dados utilizada no presente projeto. Apesar desses avanços em hibridização e automação de parâmetros, o equilíbrio ideal entre altas taxas de compressão e preservação da morfologia clínica em registros de ultra-longa duração permanece um desafio em aberto.

Diante desse contexto, este trabalho tem como objetivo apresentar um algoritmo capaz de comprimir sinais de ECG de longa duração, focado em minimizar o espaço de armazenamento e, ao mesmo tempo, mantendo uma reconstrução de alta fidelidade. Busca-se preservar as principais características morfológicas e temporais do traçado, de modo a garantir uma análise visual limpa e confiável por parte dos cardiologistas, viabilizando um diagnóstico preciso.

O restante do trabalho está dividido da seguinte forma: a Seção II detalha a arquitetura do sistema de compressão proposto e as métricas de avaliação; a Seção III apresenta a análise de desempenho do algoritmo e a validação clínica; por fim, a Seção IV reúne as conclusões do estudo.

II. Materiais e métodos

A. Sistema de compressão

O método de compressão desenvolvido neste trabalho utiliza a Transformada Rápida de Fourier (FFT) para obter o conteúdo espectral de cada ciclo do sinal de entrada. Cada componente espectral (real e imaginária) de um ciclo é comparada sequencialmente com cada componente correspondente do ciclo subsequente, com o objetivo de armazenar apenas informações relevantes relacionadas às arritmias cardíacas que o paciente possa apresentar, além de reduzir o tamanho do arquivo utilizado para o armazenamento dos dados.

O fluxograma de funcionamento do algoritmo pode ser visto na Figura 1 e os diversos estágios desse sistema são descritos a seguir.

1) Filtragem: Para a remoção dos harmônicos da rede, foram projetados dois filtros digitais *notch* do tipo *butterworth* Resposta ao Impulso Infinita (IIR) de ordem 2, com as frequências de corte localizadas em 60 Hz e 120 Hz, respectivamente. Para a eliminação das variações da linha de base do sinal, um filtro digital IIR passa altas de ordem 2 do tipo *butterworth*, com frequência de corte igual a 0,5 Hz foi projetado.

2) Estimação da frequência cardíaca: A estimação da frequência cardíaca usada neste trabalho foi baseada no Intervalo RR do sinal amostrado [17]. As frequências de cada ciclo do ECG foram utilizadas no processo de Interpolação/Subamostragem do sinal. Inicialmente, para destacar a onda R, foi implementado um filtro digital IIR *butterworth* de ordem 2, com banda passante de 0,5 a 25 Hz, seguido de um filtro digital derivativo de primeira ordem, seguido de um amplificador quadrático, que eleva ao quadrado o valor de todas as amostras da saída do filtro derivativo. Por fim, os valores resultantes de todo o processo, que superaram um limiar pré-estabelecido, foram candidatos a serem pontos do ápice das ondas R. Para garantir a seleção de somente um ponto por ciclo, o estimador foi programado para eleger

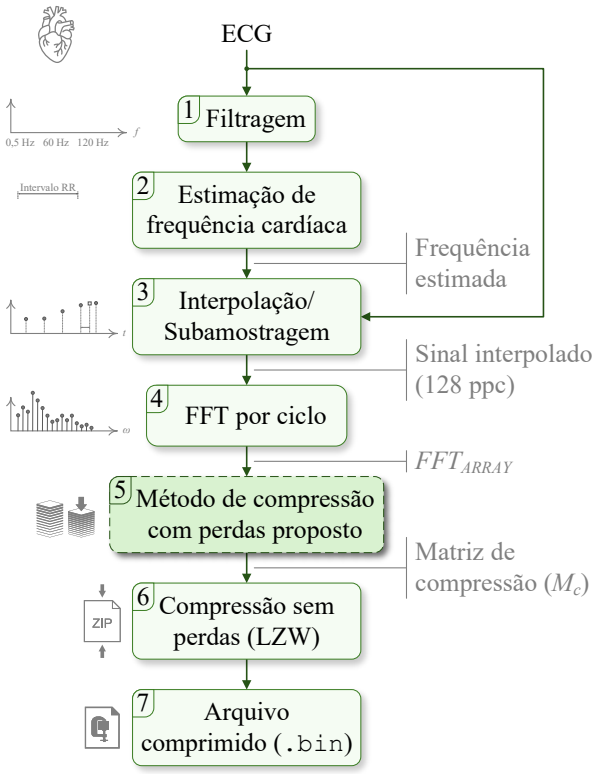

Fig. 1. Fluxograma geral do sistema de compressão de sinais de ECG proposto, ilustrando as etapas sequenciais de pré-processamento, análise espectral e codificação.

apenas um ponto a cada 300 ms. Esse valor foi definido empiricamente, assegurando uma detecção robusta.

3) Interpolação/Subamostragem: O estágio de reamostragem tem a função de normalizar temporalmente os ciclos cardíacos, assegurando que cada ciclo tenha $N = 128$ amostras igualmente espaçadas. Essa padronização dimensional é um requisito matemático e estrutural para garantir o cálculo eficiente da FFT na etapa subsequente. Com base na frequência cardíaca previamente estimada, o algoritmo ajusta dinamicamente a resolução de cada ciclo. Caso o ciclo original contenha mais de 128 amostras, o sinal passa por um processo de subamostragem. Em contrapartida, se o ciclo for mais curto, novos pontos são gerados (interpolação). O método de reamostragem adotado foi a interpolação com polinômio de Lagrange de grau três no domínio do tempo [18]. Essa técnica foi implementada empregando a estrutura de Farrow [19, 20].

4) FFT por ciclo: Após o estágio de reamostragem, o sistema aplica a FFT a cada ciclo. O resultado dessa operação é um conjunto de $K = 128$ números complexos, cada um com sua parte real e imaginária correspondente a cada componente espectral do ciclo em análise. Dessa forma, a saída da FFT, denominada $X[k], k = 0, 1, \ldots, K-1$ contém os K bins resultantes da transformada. Como o sinal de entrada é real, os coeficientes da FFT apresentam simetria conjugada, isto é, $X[k] = X^*[K-k], k = 1, \ldots, K-1$, onde $(\cdot)^*$ denota o conjugado complexo. Consequentemente, o módulo do espectro possui simetria par e a fase possui simetria ímpar, tornando redundante a segunda metade dos coeficientes espectrais [21, 22].

Além disso, na ordenação convencional da FFT, os coefi-

cientes são dispostos iniciando pelo componente de frequência nula (DC), seguido pelas frequências positivas até a frequência de Nyquist e, posteriormente, pelas frequências negativas em ordem decrescente [23]. Dessa forma, toda a informação espectral de um sinal real pode ser preservada utilizando apenas os primeiros $K/2 + 1$ coeficientes complexos da FFT.

Para a FFT de 128 pontos empregada neste trabalho, isso corresponde a $\frac{K}{2} + 1 = \frac{128}{2} + 1 = 65$ coeficientes complexos. Esses coeficientes são organizados num vetor denominado FFT_{ARRAY} mediante o armazenamento sequencial e intercalado de suas partes real e imaginária. Como resultado, obtém-se um vetor de comprimento $L = 130$, composto por 65 partes reais e 65 partes imaginárias.

O vetor FFT_{ARRAY} atua como o elo de transição dos dados do sistema, sendo transferido para o estágio subsequente, servindo como base para o método de compressão com perdas proposto.

5) Método de compressão com perdas proposto: O diagrama de funcionamento desse método de compressão pode ser visto na Figura 2.

Inicialmente, o conteúdo do vetor FFT_{ARRAY} relativo ao primeiro ciclo é copiado para os vetores MAX, MIN e SUM. Estes, por sua vez, possuem o mesmo comprimento de FFT_{ARRAY}, isto é, $L = 130$ posições, e servem para armazenar, respectivamente, o valor máximo, o valor mínimo e o valor acumulado de cada posição ao longo do tempo. Um quarto vetor, denominado vetor CNT, também de mesmo tamanho, recebe o valor unitário em todas as suas posições. A notação adotada para se referir ao índice destes vetores é l, que varia de 1 a 130.

Com os vetores inicializados, o sistema aguarda um novo FFT_{ARRAY}, correspondente ao próximo ciclo do sinal. A partir disso, todas as amostras desse novo vetor são comparadas com os valores de MIN e MAX, previamente armazenados. Caso o valor presente em alguma posição de índice l do FFT_{ARRAY} seja maior que o valor daquela mesma posição do vetor MAX ou menor que o da posição correspondente do vetor MIN, o MIN ou o MAX é atualizado naquela posição l. Com esses vetores atualizados, é feita uma comparação, para cada posição, do valor absoluto da diferença entre $MIN[l]$ e $MAX[l]$ com um valor de limiar (ou tolerância) específico para cada posição denominado γ. Se essa diferença for menor que a tolerância, o sistema interpreta que não há diferença entre os valores naquela posição e os vetores SUM e CNT sofrem as seguintes alterações: ao vetor SUM, é acumulado o valor do resultado da FFT e ao vetor CNT ocorre o incremento do valor unitário, ambos na posição l em análise. Portanto, SUM armazena o valor acumulado para cada posição dos vetores contendo os espectros dos ciclos do ECG (FFT_{ARRAY}) e o vetor CNT armazena o número de vezes que esse processo se repetiu. Dessa maneira, é possível calcular o valor médio de cada posição l dividindo SUM por CNT, elemento por elemento.

Se o valor absoluto da diferença entre MAX e MIN for

maior que a tolerância, o sistema entende que existe uma variação relevante para aquela posição l do vetor e salva todas as informações necessárias à reconstrução do sinal adquiridas até aquele momento. São elas: a posição em análise l o valor médio daquela posição ($SUM[l]/CNT[l]$) e o valor de CNT. Esses dados formam a matriz de compressão (M_c). Em seguida, o sistema é reiniciado na mesma posição em análise.

Quando todas as posições forem analisadas, o sistema recebe o próximo FFT_{ARRAY} contendo o espectro do próximo ciclo do sinal, repetindo-se todos os passos. O processo se encerra quando todos os ciclos de interesse do sinal de ECG em análise forem processados.

A matriz M_c possui três linhas e J colunas. A primeira linha contém as posições l. A segunda linha contém os valores de CNT de cada posição l da primeira linha. A terceira contém os valores médios também para as mesmas posições.

Em boa parte dos ECGs, as amplitudes das componentes harmônicas diminuem à medida que a ordem harmônica aumenta [24]. Esse comportamento pode ser visto no domínio da frequência. Portanto, para se realizar uma justa comparação, é necessário usar um valor de tolerância γ diferente para cada componente espectral da FFT em vez de um valor único para todas elas. Essa estratégia aumenta a eficácia do método e a qualidade da reconstrução do sinal. A variação dos valores de γ segue uma distribuição exponencial decrescente, pois essa é a função matemática que mais se assemelha ao comportamento dos espectros da maioria dos ECGs. Sua expressão matemática pode ser descrita pela seguinte função:

$$\gamma[m] = T\, m^{-\beta}, \quad 1 \leq m \leq 65, \tag{1}$$

onde T é um fator de ganho, m é o índice da posição do vetor função de limiares $\gamma[m]$ e β é o expoente responsável pela variação exponencial dos valores de tolerância. É importante salientar que uma posição m relaciona-se com a parte real e imaginária de um bin do espectro juntas, enquanto uma posição l corresponde a uma única componente, real ou imaginária. Dessa forma, m varia de 1 a 65, enquanto l varia de 1 a 130. Por causa disso, o mesmo valor de tolerância é aplicado a ambas as partes, real e imaginária, de cada bin do espectro.

6) Compressão sem perdas (Algoritmo LZW): A última etapa do processo de compressão consistiu na aplicação de um método de compressão sem perdas na matriz M_c. Quando todo espaço de memória destinado a M_c é preenchido após sua construção, esses dados passam pelo processo de compressão sem perdas (Algoritmo Lempel-Ziv-Welch (LZW)), disponibilizando um arquivo `.bin`. Por fim, a matriz é reinicializada para uma próxima execução. O algoritmo LZW foi escolhido para esse estágio, pois ele oferece altas taxas de compressão e existem versões *opensource* desse algoritmo disponíveis para os desenvolvedores [25].

7) Arquivo comprimido: Ao final, tem-se um arquivo comprimido no formato `.bin`, que otimiza o espaço de armazenamento. Este arquivo pode ser transmitido para um servidor remoto ou pode ser armazenado em algum dispositivo de memória para posterior reconstrução e investigação de patologias.

B. Reconstrução do sinal

Para reconstruir o sinal, é necessário, primeiramente, realizar a descompressão do arquivo (formato `.bin`), usando o algoritmo LZW e assim, recuperar M_c, a qual possui 3 linhas e J colunas.
