Across the acoustic-radiation-force measurements, the non-irradiated portions of each phantom remained comparatively homogeneous, while the irradiated zones displayed higher shear-wave velocities. For the optimized formulation, the 40-Gy region reached approximately 4.6 m/s compared with values below about 3.4 m/s outside the irradiated region; at 20 Gy the irradiated region was approximately 4.4 m/s. For the original formulation, representative irradiated-region values were approximately 4.3 m/s at 20 Gy and 5.0 m/s at 40 Gy. These values should be interpreted as representative regional measurements rather than a definitive calibration because the present study used one phantom per formulation and spatially localized regions of interest.

Comparison of the two ultrasound modalities showed that both excitation strategies were sensitive to the radiation- induced mechanical changes, although the absolute shear- wave velocities differed because the acquisitions were not performed at the same time after irradiation. This timing difference should be considered when directly comparing SWE and shaker-based mechanical-perturbation measurements.

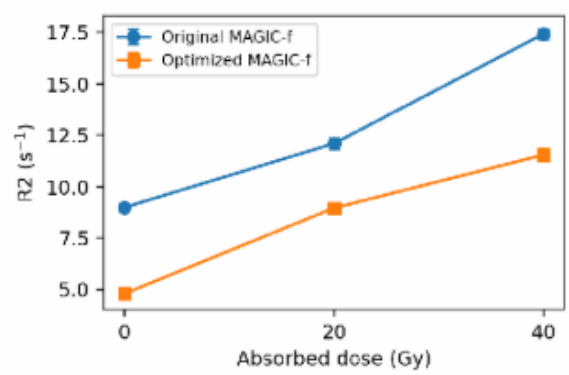

Fig. 11. Mean transverse relaxation rate R2 as a function of absorbed dose for the original and optimized MAGIC-f formulations. Error bars indicate the SD reported across analyzed frames.

V. Discussion

The ultrasound and MRI measurements probe different consequences of the same radiation-induced polymerization process. MRI R2 reflects changes in molecular spin-spin interactions, whereas shear-wave velocity is sensitive to changes in the mechanical stiffness of the polymer network. The dose-dependent increase observed with both readout mechanisms therefore provides complementary evidence that the irradiated gel can be spatially distinguished from non-irradiated material.

The optimized formulation improved thermal stability and produced clearer spatial stiffness contrast in the ultrasound maps. Both SWE and shaker-based mechanical perturbation detected mechanical differences associated with irradiation, demonstrating that the dosimetric information can be interrogated using distinct shear-wave excitation mechanisms. However, absolute shear-wave velocity differed between the two modalities, and the mechanical-perturbation experiment was performed after a delay that allowed partial phantom drying. These results should therefore be interpreted primarily as a feasibility demonstration of spatial dose discrimination rather than as a finalized calibration curve for quantitative

dosimetry. The MRI results provide the strongest quantitative dose dependence in the present dataset. The monotonic increase in R2 at 0, 20, and 40 Gy is consistent with increasing polymerization. In future experiments, a larger number of dose levels and repeated independent phantoms should be used to establish calibration equations, uncertainty, sensitivity, and reproducibility. Quantitative co-registration between R2 and shear-wave-velocity maps would also allow direct voxel-wise comparison of magnetic and mechanical dose surrogates. The present magnetoacoustic configuration was limited by excitation geometry. A coil with a lateral field-of-view matched to the phantom should improve the ability to detect the curvature and propagation of magnetically induced shear waves. Despite this limitation, the ultrasound-based 3D reconstruction pipeline itself was successfully implemented and produced interpretable volumetric maps across the investigated regions. The main limitations are the small number of independent phantoms, the use of only two irradiated dose levels, the lack of synchronized MRI and ultrasound acquisitions, and the time-dependent changes observed in the gel. Accordingly, the present data establish feasibility and dose sensitivity but do not yet define metrological accuracy. A future calibration study should include repeated phantom preparation, denser dose sampling, blinded region selection, uncertainty propagation, and direct registration of R2 and shear-wave-velocity volumes.

VI. Conclusions

Radiation-induced changes in MAGIC-f gel were detected by two ultrasound elastography modalities: SWE using acoustic-radiation-force excitation and mechanical perturbation generated by a shaker; as well as by MRI transverse relaxometry. The optimized formulation containing 6 percent gelatin and 2.5 percent agar improved thermal stability and supported volumetric ultrasound reconstruction. Representative shear-wave velocities increased in irradiated regions with both ultrasound excitation approaches, while mean R2 increased monotonically from 0 to 20 and 40 Gy in both formulations. These results support the feasibility of ultrasound-based 3D mapping of radiation-induced mechanical changes in MAGIC-f gel, with MRI relaxometry providing an independent quantitative reference. Further work should establish multi-dose calibration curves, repeatability, uncertainty, and spatial co-registration between the modalities.

***Abstract*—This paper presents a pipeline to indicate the increase in signal power during High Density Electromyography (HD-EMG) experiments in comparison with a resting baseline. It is designed to provide a real-time per-electrode visualization of signal quality, enabling relative identification of noise levels and faulty contacts during acquisition, which is done by displaying an 8x8 heatmap. The proposed pipeline was implemented in Python and tested by applying synthetic signals on real HD-EMG acquisition hardware.**

I. Introduction

Evaluation of motor unit recruitment strategies in humans has long been constrained by the spatial limitations of conventional surface electromyography. Classical configurations rely on a limited number of channels, capturing only a spatially averaged representation of the electrical activity over a broad area. Thus, the rich spatial heterogeneity of motor unit recruitment recorded across the muscle surface is lost [1]. High-Density Electromyography (HD-EMG) overcomes this limitation by using a two-dimensional electrode array with tiny contacts. This tool has opened new possibilities in the study of motor control, fatigue, and neuromuscular pathologies [2]. However, the lack of real-time signal quality feedback remains a critical weakness, as poor electrode contact or excessive noise often goes undetected until post-processing, potentially compromising an entire experimental session. Signal contamination in EMG recordings can arise from multiple sources, including baseline noise, power-line interference, motion artifacts, and electrocardiographic crosstalk, each requiring distinct detection and reduction strategies [3]. This issue is particularly severe in muscles with lower EMG signal amplitudes, such as the *soleus* — a primary component of the *triceps surae*, with a key role in postural control [4] [5]. Although online signal quality assessment for multichannel surface electromyography was previously addressed [6], estimation of the power per channel with an ready to use software is still not available. Besides, related work on HD-EMG quality assessment remains predominantly offline. Rojas-Martínez et al. [7] developed algorithms to suppress low-quality signals based on the comparison of adjacent channels. Even real-time decomposition methods rely on parameters learned in a prior offline session [8]. Thus, the development of a dedicated software pipeline capable of providing tools with a real-time visual feedback on signal-to-noise ratio and channel-by-channel quality allows acquisition issues to be identified and corrected during the experiment. The proposed software monitors signal quality directly during acquisition, with real-time per-channel signal power and noise power estimation and a heat map with the information of the muscle activation.

The outline of this paper is organized as follows. Section II describes the acquisition hardware and the estimation pipeline. Section III presents the validation results and Section IV discusses the platform's results, robustness, limitations, and future improvements.

II. Materials and methods

A. Acquisition Hardware and Software

A typical acquisition setup with all its components is illustrated in Fig. 1. In this article, only the red dotted-line area is of interest. The main steps involved in the acquisition of

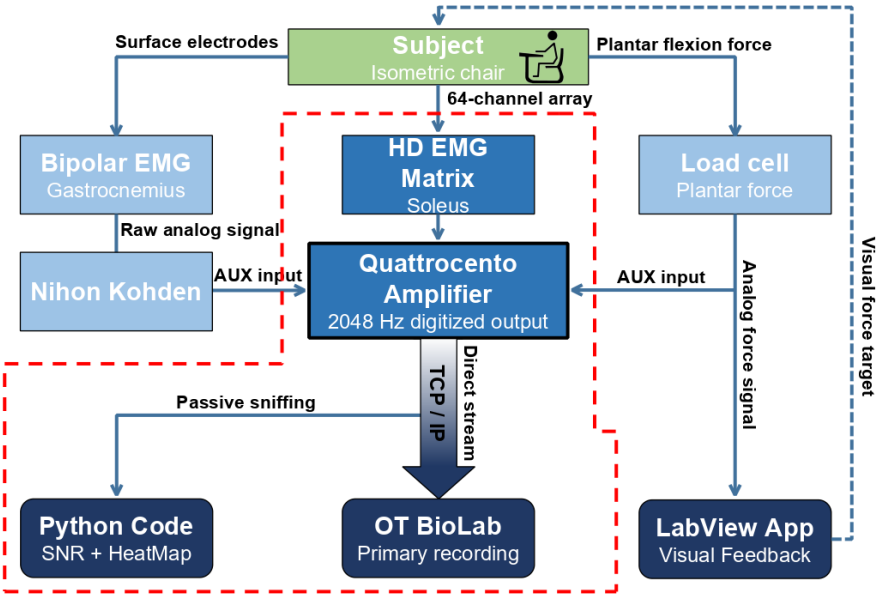

Fig. 1. Block diagram of the real-time HD-EMG acquisition and signal quality monitoring pipeline.

soleus muscle signals are summarized below. Before electrode placement, the skin must be prepared by gentle abrasion to remove dead skin cells, followed by the application of conductive paste to the electrode array to improve electrical contact. The electrode array and reference electrodes must then be positioned according to the SENIAM recommendations to ensure accurate anatomical placement and a standardized acquisition procedure [9].

To elicit the maximal voluntary contraction (MVC), verbal encouragement should be provided during trials to incentivize the subject and maximize force production [10]. During these trials, a specific joint alignment must be maintained to ensure the isolation of the target muscle group. The signals are acquired at a sampling frequency (f_s) of 2048 Hz. In the digital processing stage, a band-pass filter at 10 Hz and 500 Hz with 3-dB cutoff frequencies is applied.

For signal acquisition, a 64-channel gold-coated electrode matrix is connected to a Quattrocento amplification system (OT Bioelettronica) via a flat cable and an AD64 adapter. The adapter enables a monopolar configuration with an auxiliary reference electrode, providing an instrumentation gain of 5 and a hardware-level high-pass filter (cutoff frequency of approximately 0.7 Hz) to eliminate the DC component.

Due to the multiple steps involved in the preparation process, identifying setup-related issues and their underlying causes can be challenging. Therefore, a software tool capable of displaying the noise power of each channel is essential for assessing the quality of the experimental setup.

B. Signal Modeling and SNR Formulation

The average power P_{x_i} of a real-valued signal in a finite window is expressed as [11]

$$P_{x_i} = \frac{1}{N}\sum_{n=0}^{N-1} x_i^2[n], \tag{1}$$

where x_i denotes the discrete-time signal acquired in channel $i = 1, 2, \cdots, C$ in which C denotes the total number of channels in HD-EMG. Furthermore, $n = 0, 1, \cdots, N-1$ represents the sample index, where N is the total number of time instants.

The acquired signal $x_i[n]$ is modeled as the sum of the physiological signal $s_i[n]$ and a term $r_i[n]$ that incorporates all artifacts, including electronic noise, power line interference (PLI), low-frequency motion artifacts, and electrocardiographic crosstalk [3]. For simplicity, henceforth we shall refer to $r_i[n]$ as "noise". Thus, we may write

$$x_i[n] = s_i[n] + r_i[n]. \tag{2}$$

Substituting the signal composition model from (2) into the average power definition in (1) yields

$$P_{x_i} = P_{s_i} + \frac{2}{N}\sum_{n=0}^{N-1}(s_i[n]\cdot r_i[n]) + P_{r_i}. \tag{3}$$

The theoretical SNR in decibels in channel i is defined as the ratio of signal power to noise power:

$$\mathrm{SNR}_{i_{\mathrm{dB}}} = 10\cdot\log_{10}\left(\frac{P_{s_i}}{P_{r_i}}\right). \tag{4}$$

By defining the term $R_{sr_i} = \frac{2}{N}\sum_{n=0}^{N-1}(s_i[n]\cdot r_i[n])$ as an indicator of cross-correlation between the signal and the noise,

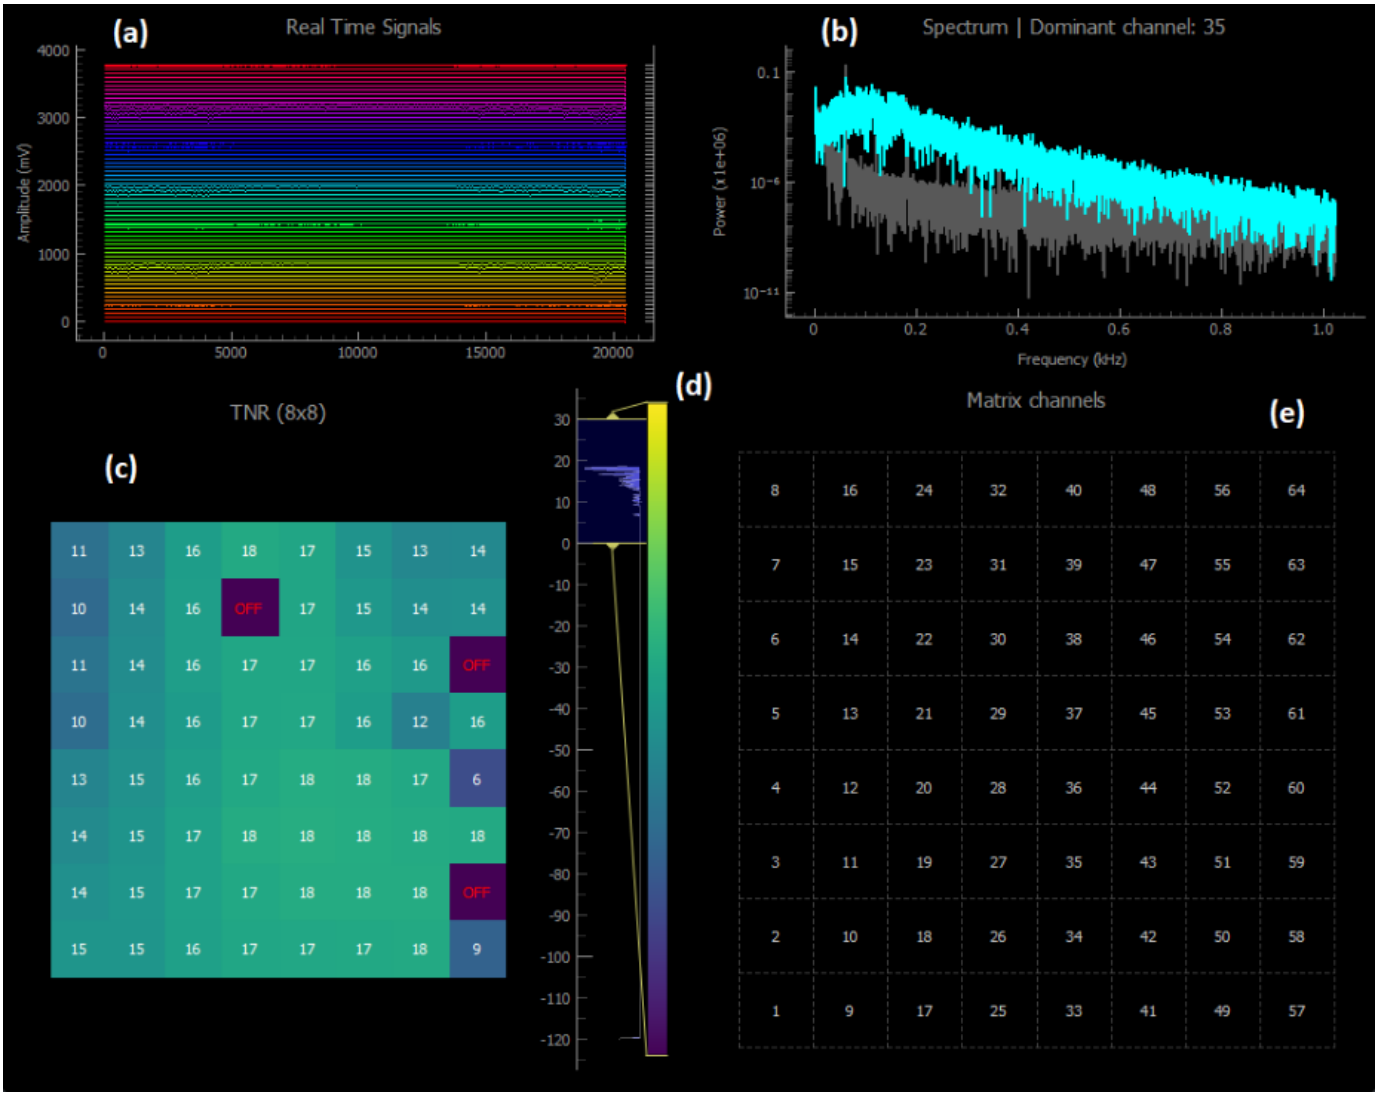

Fig. 2. The dashboard comprises five panels: (top-left: a) real-time oscillograms of all 64 channels; (top-right: b) the power spectral density of the dominant channel, identified as the electrode with higher TNR; (bottom-left: c) an 8×8 TNR heatmap of the electrode matrix, in each square the TNR value is displayed, if a channel is considered faulty, the word OFF is displayed; (bottom-center: d) a draggable colorbar, allowing the operator to manually adjust the min/max range of the TNR(dB)-to-color mapping displayed in the heatmap (c) ; and (bottom-right: e) the channel mapping layout of the matrix for spatial reference.

and combining expressions (3) and (4), the theoretical SNR is expressed as

$$\mathrm{SNR}_{i_{\mathrm{dB}}} = 10 \cdot \log_{10}\left(\frac{P_{x_i} - P_{r_i} - R_{sr_i}}{P_{r_i}}\right). \tag{5}$$

To evaluate the absolute power increase between the resting and active states without assuming any uncorrelation, we introduce the Total-to-Noise Ratio (TNR). This metric computes the ratio of the total short-time windowed power to the estimated noise:

$$\mathrm{TNR}_{i_{\mathrm{dB}}} = 10 \cdot \log_{10}\left(\frac{P_{x_i} - P_{r_i}}{P_{r_i}}\right). \tag{6}$$

By comparing (5) and (6), we note that $\mathrm{SNR}_{i_{\mathrm{dB}}} \approx \mathrm{TNR}_{i_{\mathrm{dB}}}$ if $R_{sr_i} \approx 0$. Thus, if there is little correlation between the physiological signal s_i and the noise r_i, the TNR given by (6) can be viewed as an accurate approximation for the SNR. However, it may be difficult to evaluate the validity of this assumption due to the many components in r_i. Furthermore, it is not straightforward to estimate the cross-correlation. For this reason, we do not take into account and for rigor we use the term TNR instead of SNR.

C. TNR and Power Noise estimation

Before the start of any muscle activation protocol, a mandatory period of resting baseline is recorded with the subject fully relaxed, allowing the software to estimate the per-channel noise used for subsequent TNR computation.

Assuming that the noise $r_i[n]$ is wide-sense stationary (WSS) [12] and that $s_i[n] \approx 0$ during the resting baseline phase, the noise power P_{r_i} remains constant throughout the

experimental session. Therefore, the power noise can be estimated as:

$$\widehat{P}_{r_i} = \frac{1}{K} \sum_{n=0}^{K-1} x_i^2[n], \tag{7}$$

where K is the number of samples in the resting phase.

The total short-time power P_{x_i} during the active contraction phase is continuously tracked over time using a sliding window with L samples for each channel. This result is updated every H samples for better visualization, with $H \ll L$. For the m-th frame, the total measured power in channel i is estimated as:

$$\widehat{P}_{x_i}[m] = \frac{1}{L} \sum_{n=K+mH}^{K+mH+L-1} x_i^2[n], \tag{8}$$

where $m = 0, 1, 2, \ldots$ represents the sequential frame (update) index processed by the real-time thread. In the proposed pipeline, we consider a sliding window with 1 s duration and a 64 ms update interval for the display, corresponding to $L = 2048$ ($L = f_s \cdot \Delta t = 2048 \cdot 1$) and $H = 131$ ($H = f_s \cdot \Delta t \approx 2048 \times 0.064 \approx 131$). Consequently, the practical, time-varying SNR estimator for each frame m is formulated as:

$$\widehat{\mathrm{TNR}}_{i_{\mathrm{dB}}}[m] = 10 \cdot \log_{10} \left(\frac{\max\left\{\varepsilon, \widehat{P}_{x_i}[m] - \widehat{P}_{r_i}\right\}}{\widehat{P}_{r_i}} \right). \tag{9}$$

where ε represents a small positive threshold implemented to prevent computational underflow or negative arguments within the logarithmic function when the estimated noise power exceeds the total power measured in the current frame (e.g., $\varepsilon = 10^{-10}$).

D. Software organization and presentation

As illustrated in Fig. 1 (red dotted area), once the incoming data stream described in Section II-A is captured, parsed, and organized into the 64-channel buffer, the custom software exhibits a real-time visual interface for the operator, which is refreshed at an update rate of approximately 64 ms throughout the acquisition session.

During the mandatory resting baseline phase, the interface remains blank while the proposed pipeline estimates the per-channel noise power according to (7). In this stage, $K = 20480$ samples are accumulated per channel, corresponding to 10 s of resting baseline at the 2048 Hz sampling rate, and the noise power ($\widehat{P}_{r_i}$) is calculated for each channel. Only after this calibration stage is complete does the interface begins displaying data to the operator.

Once the muscle activation protocol starts, the three main graphical elements are presented in Fig. 2: (a) the real-time raw signal traces for all 64 channels; (b) the power spectral density of the channel presenting the highest instantaneous TNR, i.e., the dominant channel; and (c) an 8×8 heatmap displaying the per-channel TNR, computed according to (9).

The spectrum shown in panel (b) is computed via the Fast Fourier Transform (FFT) of the dominant channel over a 5 s sliding window (10240 samples), weighted by a Hamming window prior to the transform to reduce spectral leakage, and updated every 64 ms.

Additionally, during the calibration phase, a channel i is classified as faulty and displayed as "OFF" on the heatmap when its estimated noise power ($\widehat{P}_{r_i}$) exceeds the median noise power across all channels by more than F times their standard deviation. In this work, F was set to 3 without empirical

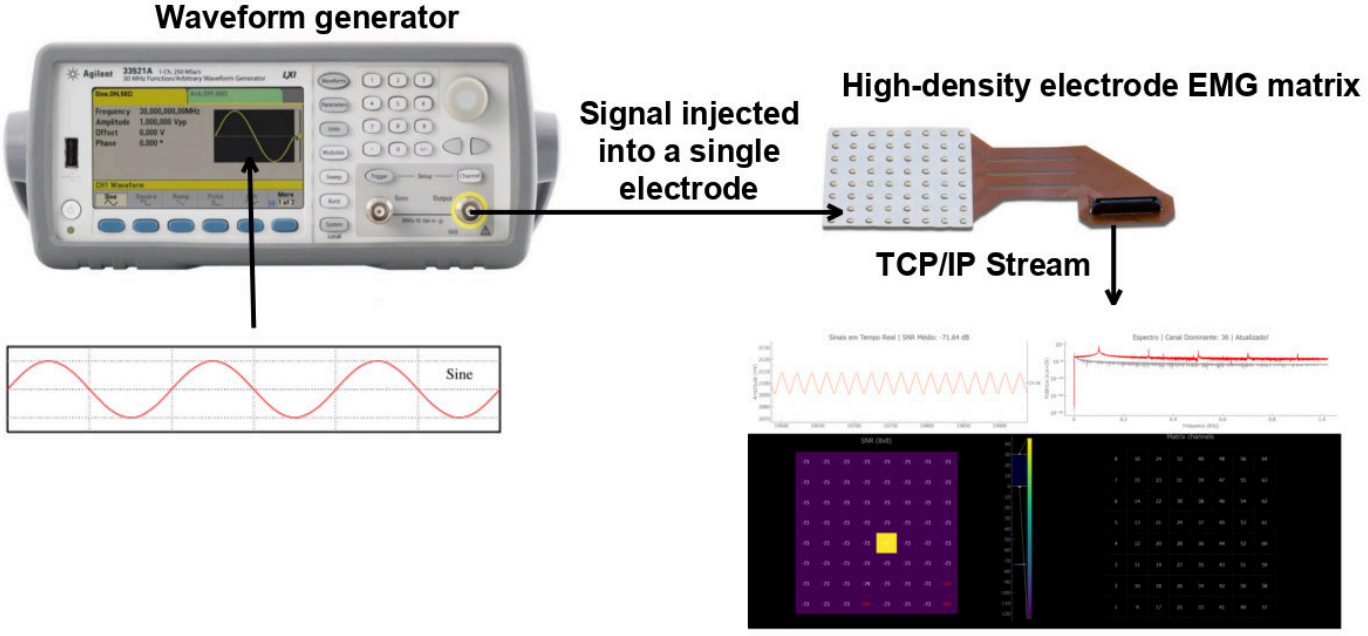

Fig. 3. Experimental setup used for validation of the signal processing pipeline. A deterministic signal was injected into a single channel of the matrix with the waveform generator and the results are displayed in real time.

TABLE I
TNR ERROR AND VPP ERROR BY CHANNEL AND AMPLITUDE

Channel	Amplitude	Mean Abs. Vpp Error	TNR Error (MAE ± SD)	Max Abs. TNR Error
1	10 mV	5.17%	0.46 ± 0.10	0.62
1	1 mV	4.79%	0.52 ± 0.22	0.83
1	20 mV	5.38%	0.47 ± 0.11	0.64
2	10 mV	27.97%	2.97 ± 0.02	2.98
2	1 mV	7.89%	0.96 ± 0.89	1.89
2	20 mV	5.78%	0.67 ± 0.57	1.00
12	10 mV	22.51%	2.12 ± 0.02	2.13
12	1 mV	41.46%	1.99 ± 0.96	2.96
12	20 mV	4.28%	0.48 ± 0.58	1.15
57	10 mV	4.97%	0.44 ± 0.10	0.61
57	1 mV	3.73%	0.36 ± 0.17	0.56
57	20 mV	4.93%	0.44 ± 0.11	0.62
64	10 mV	5.11%	0.18 ± 0.11	0.36
64	1 mV	3.56%	0.14 ± 0.11	0.31
64	20 mV	7.69%	0.44 ± 0.32	1.05

MAE = Mean Absolute Error (dB); SD = Standard Deviation (dB).

validation (see Section IV). This classification is intended as an initial approach for detecting potentially faulty channels and was not further investigated or validated in this work.

E. Pipeline validation

The signal processing pipeline was validated as illustrated in Fig. 3. A waveform generator (Agilent 33521A) was used to inject a sinusoidal signal directly into a single electrode of the 64-channel HD-EMG matrix. During the validation, the remaining electrodes were kept open (high-impedance state), i.e., without electrode-skin contact. A sine wave with peak-to-peak amplitudes of 1, 10, and 20 mVpp and frequencies of 40, 60, 80, 100, 120, and 160 Hz was sequentially injected. For simplicity, rather than detailing all 64 channels, a random subset of five channels (1, 2, 12, 57, and 64) was selected from the matrix for detailed analysis.

For each test, the amplitude and TNR estimated by the real-time processing pipeline were compared with their theoretical values. Since all tested frequencies lie within the passband of the acquisition system, no attenuation due to the acquisition filter was assumed. For a sinusoidal signal with peak-to-peak amplitude $V_{pp} = 2A$, the theoretical signal power was calculated as $P_s = A^2/2$, with $A = V_{pp}/2$. A single resting calibration period was performed before the tests, such that the estimated noise power $\widehat{P}_{r_i}$ remained unchanged throughout the experiments. The theoretical TNR was then calculated from the known signal and noise powers and compared with the value estimated by the pipeline.

III. RESULTS

Table I and Fig. 4 summarize the results obtained during the validation tests. The TNR estimation error is defined as the difference between the pipeline's estimated value and the theoretical expected value.

For most channels, the error remains stable across the dynamic range. Channels 1, 57, and 64 demonstrated close agreement, with a Mean Absolute Error (MAE) for the TNR consistently below 0.5 dB and Vpp relative errors around 4–7%, with their error curves in Fig. 4 following a similar bounded pattern across frequencies. Conversely, channels 2 and 12 exhibited the largest deviations among all tested channels, reaching Vpp and TNR errors of 27.97% and 2.98 dB (channel 2, 10 mV) and 41.46% and 2.96 dB (channel 12, 1 mV), respectively.

IV. DISCUSSION

The proposed pipeline provides real-time calculation of per-channel signal power and noise power and, combined with a qualitative analysis, it helps to detect faulty electrodes.

As shown in Table I, the TNR estimation error is highly channel-dependent: channels 1, 57, and 64 remained close to the theoretical values across the whole tested range, while channels 2 and 12 showed considerably larger errors at the lower amplitudes. However, this gap narrows at the highest amplitude tested (20 mVpp); this suggests that, for these two channels, the estimation becomes more reliable as the injected signal amplitude increases. Indeed, these channels exhibited visible waveform distortion and increased visual noise at lower amplitudes compared to the others.

Although only five channels were tested, no clear dependence of the TNR error on the signal frequency was observed within the 40–160 Hz range. Overall, the results agree with the expected values for the well-behaved channels, and the larger errors observed in channels 2 and 12 are more likely attributable to an intrinsic error of the acquisition hardware itself, specific to those channels, than to a limitation of the proposed TNR estimator. However, since the validation only compared the injected input with the pipeline's final output, without an independent characterization of the Quattrocento amplifier, cables, adapters, and electrode matrices, it is not possible to attribute this discrepancy specifically to the acquisition hardware. Such a characterization is necessary before the software can be validated in more detail under other acquisition conditions.

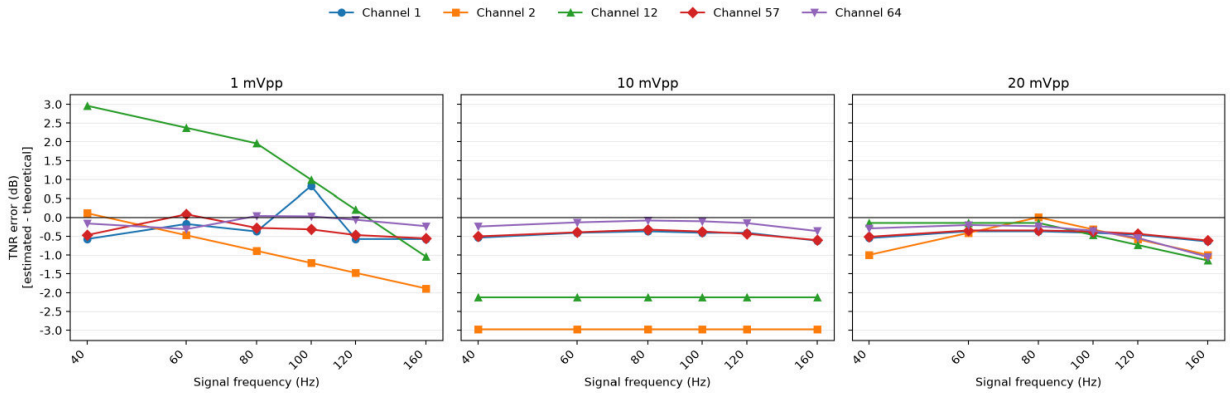

Fig. 4. Total-to-Noise Ratio (TNR) error in dB (estimated minus theoretical value) across different signal frequencies (Hz) for five randomly selected channels (1, 2, 12, 57, and 64) out of the 64-channel matrix. The three panels represent tests performed with peak-to-peak signal amplitudes of 1 mVpp, 10 mVpp, and 20 mVpp, respectively.

Despite its many features, several aspects of the solution presented in this paper can be improved. For example, the robustness of the communication with the Quattrocento still has to be fully evaluated. Moreover, the criterion adopted to classify inactive channels ("OFF") can be further improved to increase its robustness under different acquisition conditions and to indicate the failure mode. Finally, the proposed TNR estimator relies on a calibration stage to estimate the residual noise power. Consequently, variations in background noise after calibration may affect the estimated TNR, suggesting that adaptive noise estimation strategies should be investigated in future work.

V. Conclusion

This work presented a real-time HD-EMG signal quality assessment software capable of estimating channel-by-channel signal power and noise power while simultaneously providing waveform, spectrum, and visual feedback during data acquisition. The experimental results obtained with deterministic test signals revel a dependency on the acquisition system, particularly in the matrix channels.

The current implementation still presents some limitations as discussed in the previous section. Those limitations will be addressed by the development of a validation protocol for the communication and channel classification, a more precise characterization of the noise, and through validation sessions with real subjects and different software users. Nevertheless, in its current form, the proposed pipeline already provides useful feedback on signal quality during HD-EMG acquisition, allowing acquisition issues to be identified before offline processing.

Acknowledgments

***Resumo*—O estudo avaliou comprimidos acondicionados em organizadores plásticos utilizados por pacientes idosos em regime de atenção domiciliar, incluindo anti-hipertensivos, hipolipemiantes e antidiabéticos. A espectroscopia no infravermelho próximo (NIRS), associada à análise de componentes principais (PCA) foi utilizada para caracterizar alterações espectrais induzidas pela exposição a diferentes condições de umidade. Para isso, as amostras foram acomodadas nos ambientes da cozinha e do banheiro, locais comumente utilizados para guarda de medicamentos por essa população. Os espectros NIR obtidos experimentalmente permitiram comparar as amostras mantidas em cada ambiente, evidenciando variações espectrais associadas às diferentes condições de umidade relativa. Os resultados demonstraram que a abordagem multivariada viabilizou a discriminação espectral entre os grupos expostos aos diferentes ambientes, evidenciando a sensibilidade da técnica às alterações decorrentes da absorção de umidade superficial pelos medicamentos (com os dois primeiros componentes principais explicando $(85,9\%)$ da variância total). Ressalta-se que, para o captopril e a sinvastatina, o uso de fabricantes distintos entre os ambientes introduziu variações na formulação que atuam como fator de confundimento na análise espectral. Em suma, o estudo contribui para a compreensão dos efeitos das condições de armazenamento domiciliar sobre formas farmacêuticas sólidas, explorando alterações espectrais no infravermelho próximo induzidas pela umidade e o potencial da NIRS como ferramenta de monitoramento não invasivo.**

***Palavras-chave*—Espectroscopia de infravermelho próximo, análise de componentes principais, umidade, armazenamento domiciliar de fármacos.**

I. Introdução

Na atenção domiciliar, especialmente para a população idosa, existe uma necessidade maior em combinar soluções que promovam o apoio à vida independente, sabendo que o gerenciamento da medicação é um grande desafio [1]. Nesse contexto, tornou-se comum o uso de organizadores semanais de comprimidos, dispositivos que auxiliam no consumo assertivo dos fármacos na gestão de regimes de farmacoterapia complexos. Contudo, o armazenamento de medicamentos fora de suas embalagens primárias em locais como cozinha e banheiro, motivados pela conveniência, os expõem a condições de temperatura e umidade relativa elevadas, que podem comprometer sua estabilidade [2].

Neste estudo, foram selecionados fármacos de uso comum entre a população idosa: captopril (anti-hipertensivo), sinvastatina (hipolipemiante) e metformina (antidiabético), cuja escolha justifica-se por serem comprimidos sem revestimento, apresentando elevada sensibilidade à degradação por absorção de umidade superficial.

Nesse contexto, a aplicação da espectroscopia no infravermelho próximo (NIRS), técnica analítica rápida, não destrutível e sensível às principais bandas de absorção de água, em conjunto com a PCA permite explorar de forma eficiente as matrizes de dados multivariados e identificar alterações espectrais induzidas pelo ambiente de armazenamento [3]–[5].

II. Metodologia

A seleção dos medicamentos foi baseada no perfil farmacológico característico da população idosa. Entre as condições crônicas mais prevalentes nessa faixa etária estão a hipertensão arterial, o diabetes mellitus tipo 2 e a dislipidemia [6], sendo escolhido um medicamento representativo para cada patologia. Como critério de inclusão, estabeleceu-se que os comprimidos não deveriam possuir revestimento, uma vez que este atua como barreira física à absorção de umidade pelo princípio ativo e pode introduzir bandas espectrais adicionais que interferem na análise por espectroscopia NIR [4], [7]. A escolha de comprimidos sem revestimento justifica-se pela alta sensibilidade que suas formulações apresentam à degradação por absorção de umidade ao longo do tempo. Com base nesses

critérios, foram selecionados: Captopril 25 mg (inibidor de ECA) [8]; Cloridrato de Metformina 850 mg (biguanida) [9]; e Sinvastatina 20 mg (estatina) [10].

Os experimentos foram conduzidos na cidade de Recife (PE), durante o mês de junho de 2026, período de alta umidade relativa do ar média ($\sim 82\%$) [11]. Os ambientes selecionados para a exposição foram o banheiro e a cozinha, por serem os locais do domicílio onde medicamentos são comumente armazenados pela população. Todos os comprimidos foram transferidos para organizadores plásticos compartimentados, não herméticos. As medições foram realizadas em oito pontos temporais ao longo de 20 dias: D0 (dia inicial), D1, D3, D6, D9, D12, D16 e D20, com 3 repetições por grupo, correspondentes a 3 comprimidos distintos.

As medidas espectroscópicas foram realizadas com um espectrômetro NIR miniaturizado DWARF-Star (StellarNet Inc., Tampa, FL, EUA) [5], acoplado a uma fibra óptica bifurcada em Y operada pelo software SpectraWiz Spectrometer OS v5.33 (StellarNet Inc.) [12]. Os parâmetros instrumentais foram: tempo de integração de 800 ms, média de varreduras (*scans to average*) igual a 1 e suavização (*boxcar smoothing*) igual a 1. A calibração foi realizada diariamente no início de cada sessão, utilizando um padrão de reflectância branca de cerâmica. Tanto na etapa de calibração quanto na etapa de medição das amostras, a fibra óptica foi mantida em contato físico direto com a superfície analisada.

Após a calibração dos espectros com o calibrador de cada dia experimental, foi feita a correção da linha de base, por meio do método de Mínimos Quadrados Assimétricos (*Asymmetric Least Squares* – ALS) [13]. Com a linha de base corrigida, os espectros foram submetidos à normalização por área, restritos à faixa espectral compreendida entre 1450 e 1700 nm. Esta região foi selecionada por conter a principal banda de absorção da água no infravermelho próximo, que está associada às vibrações das ligações O–H [4]. Para corrigir pequenas variações nos comprimentos de onda que podem surgir entre aquisições sucessivas, aplicou-se interpolação linear, alinhando todos os espectros em uma mesma grade espectral, garantindo a correspondência entre os pontos amostrados.

Por fim, realizou-se a Análise de Componentes Principais (PCA) [14], concentrando a interpretação nos dois primeiros componentes principais (PC1 e PC2). A análise foi conduzida por meio dos gráficos de Scores e Scree Plot, permitindo avaliar a distribuição das amostras, identificar as regiões espectrais de maior contribuição para a variabilidade observada e acompanhar a evolução temporal da absorção de umidade nos diferentes medicamentos e condições de armazenamento.

Na etapa final da análise, os scores do primeiro componente principal (PC1) obtidos a partir da PCA foram submetidos à análise estatística para verificar a existência de diferenças significativas entre os tempos de exposição para cada combinação medicamento–ambiente. Para essa avaliação, foi empregado o teste não paramétrico de Kruskal–Wallis [15], com nível de significância de 5

Para exclusão de medições discrepantes (*outliers*), adotou-se como critério a inspeção visual dos espectros brutos, descartando leituras que se apresentaram como anomalias evidentes ou com ruídos excessivos, gerando o descarte de 4 espectros antes das etapas de modelagem.

III. Resultados e Discussões

Para a caracterização inicial do sistema de medição, a Fig. 1 apresenta o espectro óptico típico da fonte de luz e do detector, obtido durante a calibração com o padrão de reflectância branca de cerâmica.

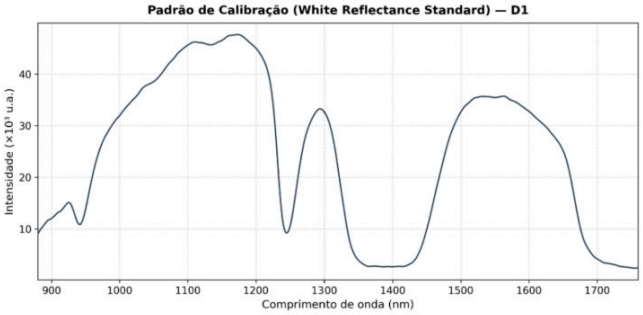

Figura 1. Espectro típico do padrão de calibração (*White Reflectance Standard*) obtido na região de 900 a 1700 nm.

A análise das alterações espectrais provenientes da exposição à umidade foi realizada com foco na faixa de 1450 a 1700 nm, região correspondente ao primeiro sobretom de absorção da ligação O–H. A Fig. 2 compara os espectros obtidos de D0 a D20 para o ambiente de maior variação de cada fármaco, permitindo avaliar o impacto do armazenamento nos organizadores plásticos. Os gráficos presentes nessa figura evidenciam a suavização dos vales característicos ao longo do período de armazenamento, um comportamento particularmente visível nos espectros da Metformina. No D0, o vale localizado próximo a 1500 nm é marcadamente mais pronunciado do que no D20.

A alteração observada na intensidade da banda em ~ 1450 nm entre D0 e D20 confirma a ocorrência de absorção de umidade pela superfície dos comprimidos sem revestimento armazenados nos organizadores plásticos não herméticos ao longo do período estudado.

Na região entre 1427 nm e 1709 nm, os espectros apresentaram comportamentos distintos entre os medicamentos, refletindo suas composições químicas específicas. O Cloridrato de Metformina exibiu comportamento espectral similar entre os ambientes de banheiro e cozinha (o que era esperado, uma vez que os comprimidos eram da mesma marca para ambos os ambientes), com picos bem definidos em 1480 nm, 1585 nm e 1644 nm, além de pequenos vales em 1508 nm e 1613 nm. É importante destacar que nesta região espectral encontra-se a primeira banda de sobretom do estiramento O–H da água em aproximadamente 1450 nm [4], que é de particular interesse para este estudo, pois permitirá monitorar a absorção de umidade ao longo do tempo. A presença de picos adicionais nesta região na metformina pode estar relacionada à sua estrutura molecular característica (biguanida) e aos excipientes presentes na formulação.

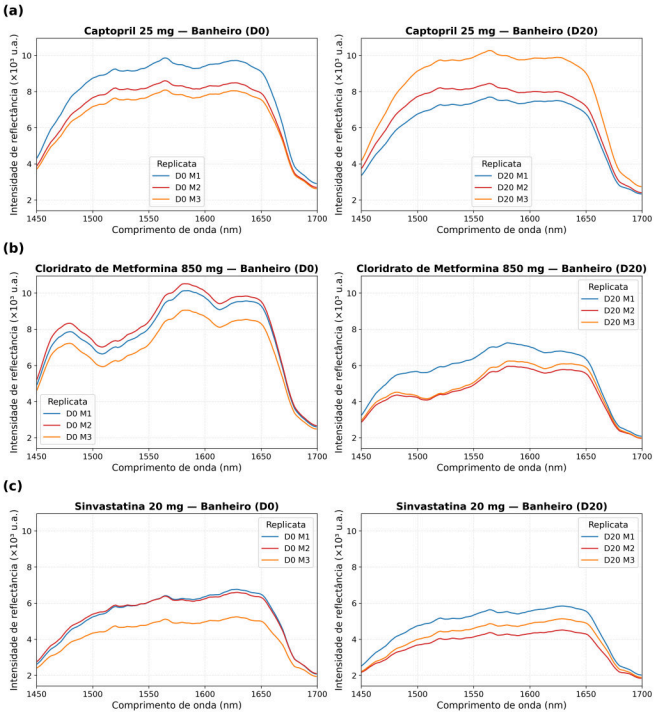

Figura 2. Comparação espectral ilustrativa (D0 vs. D20) na região de absorção de água (1450–1700 nm) para: (a) Captopril 25 mg; (b) Cloridrato de Metformina 850 mg; (c) Sinvastatina 20 mg no ambiente de maior variação.

A Sinvastatina armazenada no banheiro apresentou, na banda entre 1427 nm e 1709 nm, pequenos picos em 1520 nm, 1564 nm e 1629 nm, com uma leve inclinação crescente. Já a sinvastatina armazenada na cozinha exibiu uma banda majoritariamente plana nesta mesma região, com apenas um pico distinto em 1564 nm. O Captopril armazenado no banheiro apresentou comportamento espectral muito similar ao da sinvastatina no mesmo ambiente. Por sua vez, o Captopril da cozinha mostrou a banda entre 1427 nm e 1709 nm também relativamente plana, mas com pequenos picos observáveis em 1518 nm, 1564 nm e 1629 nm. As diferenças espectrais observadas entre os ambientes para captopril e sinvastatina são atribuídas ao uso de fabricantes distintos para cada ambiente, resultando em formulações com excipientes e processos de manufatura diferentes, que influenciam o perfil espectral na região do NIR [18].

Uma variação considerável nas intensidades absolutas foi observada nos espectros, inclusive entre replicatas do mesmo medicamento e ambiente. Esta variabilidade pode ser atribuída a múltiplos fatores: (i) flutuações na intensidade da fonte de luz durante as coletas; (ii) variações no posicionamento da fibra óptica sobre a superfície irregular dos comprimidos, afetando a geometria de iluminação e coleta; (iii) heterogeneidade da superfície dos comprimidos (rugosidade, porosidade, distribuição de partículas); e (iv) possíveis variações na pressão de contato entre a fibra e a amostra [19]. Estas fontes de variabilidade reforçam a importância da aplicação de pré-processamentos espectrais e da normalização dos dados antes das análises quantitativas.

Com o objetivo de investigar especificamente as alterações espectrais relacionadas à absorção de umidade, foi realizada uma PCA utilizando na região de 1450–1700 nm, correspondente ao primeiro sobretom das ligações O–H [4]. Os gráficos de Scree Plot (Fig. 3) demonstram que, em todas as combinações, os dois primeiros componentes principais concentram a maior parte da variabilidade de dados, com PC1 explicando entre 46.5

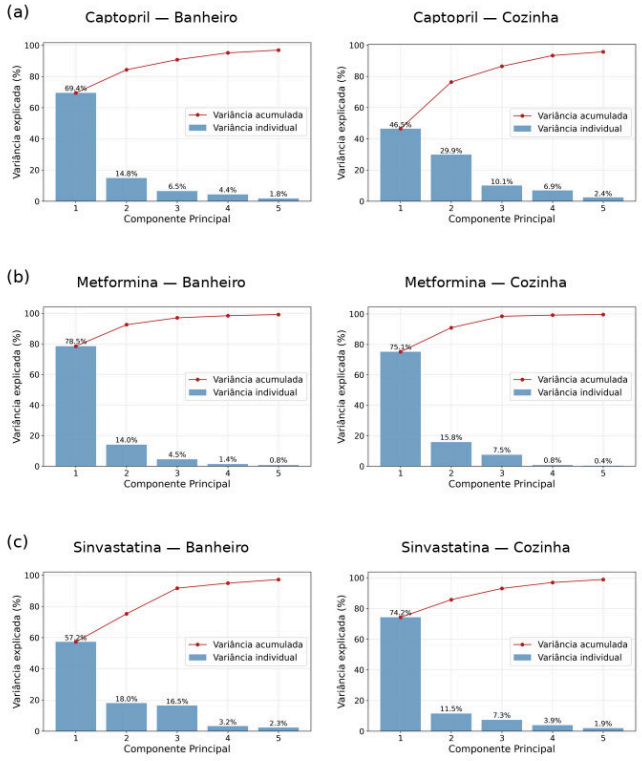

Figura 3. Gráficos de Scree Plot apresentando a porcentagem de variância explicada para: (a) Captopril; (b) Metformina; (c) Sinvastatina.

A Fig. 4 apresenta os gráficos de Scores (PC1 vs. PC2) para cada um dos medicamentos nos ambientes de cozinha e banheiro. PC1 esteve associado às variações globais de intensidade espectral, enquanto PC2 refletiu principalmente diferenças no teor de umidade. Os gráficos de scores não evidenciaram tendência temporal ao longo do armazenamento, embora T0 e T1 tenham apresentado maior dispersão. Além disso, as amostras armazenadas na cozinha exibiram maior variabilidade espectral que as do banheiro, sugerindo maior influência das condições ambientais sobre a região da água.

A análise estatística temporal dos scores de PC1 por meio do teste de Kruskal-Wallis [15] e dos gráficos de boxplots indicou comportamentos distintos entre os fármacos. Para o Captopril, a variação estatística ao longo dos dias foi significativa no banheiro ($p = 0,029$), em contrapartida na cozinha não se mostrou significativa ($p = 0,096$). Para a Sinvastatina, identificou-se alterações significativas em ambos os ambientes ($p = 0,014$ no banheiro e na cozinha). Por fim,

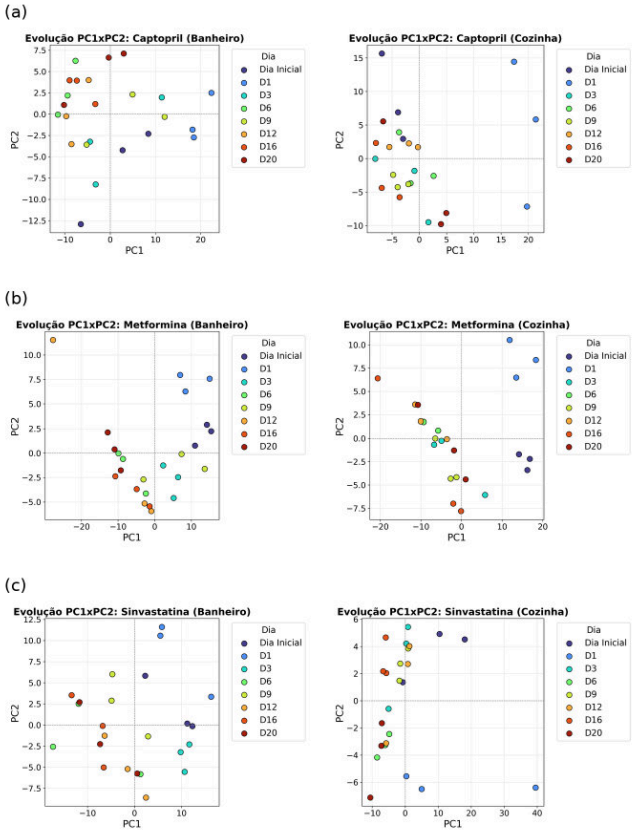

Figura 4. Gráficos de Scores da PCA (PC1 vs PC2) na faixa de 1450 a 1700 nm ao longo dos 20 dias para: (a) Captopril; (b) Metformina; (c) Sinvastatina.

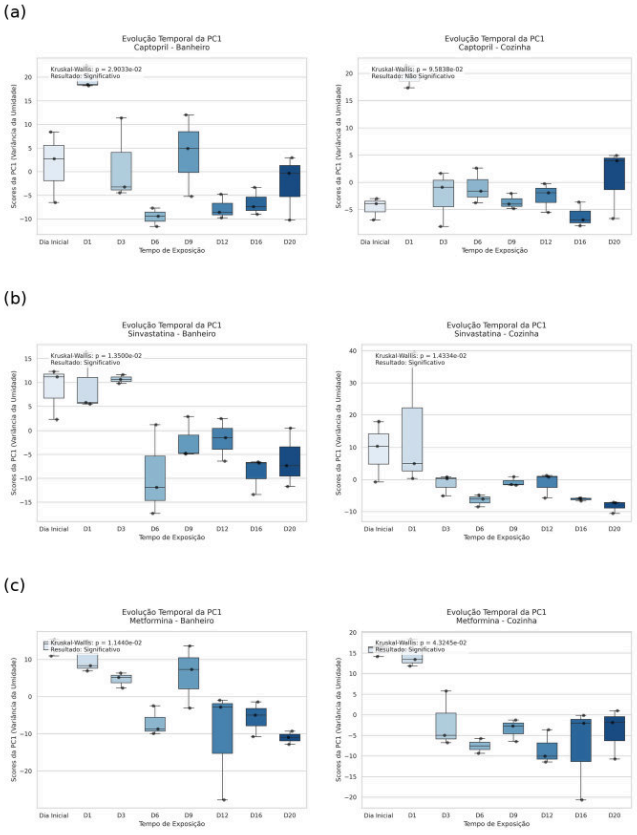

Figura 5. Boxplots da evolução temporal dos scores do primeiro componente principal (PC1) ao longo dos 20 dias para: (a) Captopril; (b) Metformina; (c) Sinvastatina.

a Metformina também apresentou variações significativas no banheiro ($p = 0,011$) e na cozinha ($p = 0,043$). No entanto, a análise conjunta dos boxplots mostra que tais variações refletem flutuações e dispersões pontuais entre as medições, não caracterizando uma tendência progressiva ao longo dos 20 dias.

No caso da metformina, os dois primeiros componentes principais concentraram a maior parte da variabilidade espectral, com PC2 associado a alterações mais localizadas relacionadas à água. Os gráficos de scores apresentaram maior dispersão das amostras, porém sem tendência temporal ao longo do armazenamento. Além disso, não foram observadas diferenças entre os ambientes de armazenamento, indicando maior estabilidade espectral da metformina frente às condições avaliadas.

A análise de PCA na região de absorção da água evidenciou diferenças marcantes entre os fármacos quanto à resposta às condições de armazenamento. A sinvastatina apresentou maior dispersão espectral na cozinha, o captopril mostrou separação entre os ambientes, enquanto a metformina exibiu ampla sobreposição e maior estabilidade espectral. Esses resultados indicam que a influência da umidade depende das características físico-químicas de cada fármaco.

A análise de componentes principais mostrou que a influência das condições de armazenamento sobre a resposta espectral depende da região espectral analisada e das características físico-químicas de cada princípio ativo. De modo geral, o ambiente de armazenamento exerceu maior influência do que o tempo de exposição, evidenciando o potencial da PCA para identificar as principais fontes de variabilidade em estudos de estabilidade farmacêutica [20].

Entre os fármacos, a sinvastatina apresentou maior sensibilidade às condições de armazenamento, com clara separação entre os ambientes, resultado compatível com sua conhecida suscetibilidade à degradação por temperatura e umidade. A metformina manteve elevada estabilidade espectral, sem diferenças consistentes relacionadas ao tempo ou ao ambiente. O captopril apresentou comportamento intermediário, com influência da umidade mais evidente na região da água, em concordância com sua susceptibilidade à degradação oxidativa.

IV. Conclusão

O estudo avaliou como os comprimidos de captopril, metformina e sinvastatina comportaram-se quando armazenados em organizadores semanais e expostos a diferentes ambientes, cozinha e banheiro, por meio da resposta espectral. Para essa avaliação, combinou-se a técnica NIRS com a PCA. Os resultados mostraram que a metformina, único fármaco de mesmo fabricante avaliado em ambos os locais, apresentou

elevada estabilidade espectral, sem diferenças temporais ou entre ambientes. Já para a sinvastatina e o captopril, observou-se uma clara separação espectral entre os ambientes, no entanto, este resultado pode ser reflexo das diferenças de formulação decorrentes do uso de fabricantes distintos entre os locais, não permitindo isolar apenas o efeito do ambiente.

A Análise de Componentes Principais (PCA) focada na faixa espectral de 1450 a 1700 nm permitiu separar as mudanças ligadas à absorção de água.

As descobertas reforçam a preocupação com a prática de guardar medicamentos em locais úmidos, algo frequente entre idosos que recebem cuidados em casa, a preocupação aumenta quando se trata de medicamentos mais sensíveis, como a sinvastatina. Nesse contexto, NIRS demonstrou potencial para monitorar a absorção de umidade pelos medicamentos, destacando-se por ser uma ferramenta rápida, não destrutiva e não invasiva.

Como limitações metodológicas, destacam-se a ausência de amostras controle mantidas em suas embalagens primárias originais [2] e o uso de dados de umidade relativa baseados na média climatológica local ($\sim 82\%$) [11]. Além disso, a metodologia e técnicas aplicadas não permitiram medir diretamente a degradação química dos fármacos. Para estudos futuros, pode-se considerar combinar a NIRS com técnicas de referência, como o HPLC.

Abstract*—Obstructive Sleep Apnea (OSA) is a highly prevalent sleep disorder linked to severe cardiovascular diseases and cognitive decline. Traditional diagnosis via manual polysomnography (PSG) is expensive, access-restricted, and labor-intensive. To enable scalable and less invasive screening, this study proposes an automated OSA detection pipeline utilizing a reduced subset of standard physiological channels from a real-world clinical dataset: nasal airflow (FLOW), pulse oximetry (SpO_2), thoracic effort (THX), and abdominal effort (ABD). We design and systematically evaluate three lightweight hybrid Deep Learning topologies that combine One-Dimensional Convolutional Neural Networks (1D-CNNs) and Bidirectional Long Short-Term Memory (BiLSTM) networks, contrasting expanding, contracting, and multi-scale/parallel spatial feature structures. Models are trained using a robust Focal Loss function and optimized via an independent patient-based cross-validation protocol to ensure true clinical generalizability. Our experimental results demonstrate that the multi-scale parallel architecture (Topology 3) achieved the highest overall performance, yielding a Cohen's Kappa of 0.5996, a Macro F1-score of 0.7996, and an AUC-ROC of 0.8843, while maintaining an accuracy of 81.03%. This parallel design offered the most compact alternative evaluated, reducing trainable parameters by up to 86% compared to deeper serial variations with no trade-off in diagnostic robustness. These findings suggest that integrating concurrent, multi-scale convolutional branches within lightweight networks represents an efficient alternative to over-parameterized structures, providing an accurate and computationally efficient mechanism for automated nocturnal diagnostic screening systems that use raw, multi-channel physiological streams.

I. Introduction

Obstructive sleep apnea (OSA) is a highly prevalent respiratory disorder characterized by recurrent partial or complete cessations of breathing during sleep. These episodes trigger systemic drops in blood oxygen saturation, frequent microarousals, and severe sleep fragmentation [1], [2]. Over time, these repetitive respiratory disruptions induce chronic inflammation and autonomic nervous system dysregulation, significantly compromising cardiovascular, metabolic, and cognitive functions [3]. It is estimated that approximately 23% of men and 17% of women suffer from OSA, though these figures may be substantially higher when considering undiagnosed cases [4]. Beyond degrading sleep quality and inducing profound daytime fatigue, OSA is strongly correlated with hypertension, cardiac arrhythmias, and an elevated risk of cardiovascular mortality, marking it as a critical global healthcare challenge [5].

Financially, OSA imposes a staggering macroeconomic and societal burden across direct, indirect, and intangible dimensions [6]– [8]. Direct costs encompass diagnostic polysomnography, continuous positive airway pressure (CPAP) therapies, and specialized clinical consultations, with severe cases requiring up to $5,186 annually per patient in Europe and over $32,500 in the United States [6], [7]. Indirect expenses are driven by profound workplace productivity losses—amounting to roughly $87 billion annually in the U.S., alongside $26 billion from traffic or occupational accidents and $30 billion from secondary comorbidities such as diabetes and stroke [9]. Furthermore, intangible costs reflecting diminished quality of life and psychological distress add an estimated $10 billion annually [7]. At the individual level, a patient can expect mean out-of-pocket expenses of approximately $2,100 per year, demonstrating that robust screening and early intervention possess immense potential to alleviate these global economic impacts [6]– [8].

To mitigate these systemic impacts, full nocturnal polysomnography (PSG) remains the diagnostic gold standard, capturing concurrent physiological signals including pulse oximetry (SpO_2), respiratory inductance plethysmography (RIP) for thoracic and abdominal effort, and nasal cannula airflow [10], [11]. However, manual visual scoring of these multi-channel recordings is labor-intensive, time-consuming, and subject to considerable inter-scorer variability [12]. Consequently, artificial intelligence (AI)-based automated screening systems have attracted increasing attention in recent years [13]. Early approaches relied primarily on handcrafted feature engineering combined with conventional machine learning algorithms [14], [15]. More recently, these approaches have progressively been replaced by end-to-end deep learning (DL) models capable of learning discriminative representations directly from raw physiological signals [16]– [18]. Current state-of-the-art solutions frequently employ convolutional neural networks (CNNs), recurrent neural networks (RNNs/LSTMs), and hybrid CNN-LSTM architectures to improve diagnostic performance while reducing manual preprocessing require-

ments [19]– [21].

Despite these advances, important physiological and architectural limitations remain. Most existing approaches either process each physiological channel independently or implicitly assume perfect temporal synchrony among respiratory signals [22], [23]. In practice, obstructive respiratory events are intrinsically asynchronous. Airflow cessation and thoracic or abdominal respiratory effort changes occur immediately after upper airway collapse, whereas peripheral oxygen desaturation (SpO_2) typically appears only after a physiological delay of approximately 10–40 seconds due to circulatory dynamics [24]. Ignoring these temporal offsets forces neural networks to analyze partially misaligned physiological events, potentially introducing spurious correlations, reducing predictive performance, and limiting physiological interpretability [25], [26].

Although hybrid CNN-LSTM and CNN-BiLSTM models have become increasingly popular for automated OSA detection, most reported architectures adopt a single serial convolutional feature extractor before temporal modeling [19]–[21], [34], [35]. Recurrent layers are naturally suited to capture long-term temporal dependencies and have therefore become the predominant choice for modeling respiratory dynamics in OSA detection. However, their effectiveness strongly depends on the quality of the representations extracted by the preceding convolutional stage. For example, Oh *et al.* [34] and Chang *et al.* [35] employ conventional serial CNN-BiLSTM pipelines composed of a single convolutional pathway, while Zhang *et al.* [19] similarly adopts a fixed convolutional hierarchy. Consequently, although recurrent modeling has received considerable attention, the influence of convolutional feature organization itself on the ability of BiLSTM networks to learn delayed physiological interactions has received comparatively little investigation. To the best of our knowledge, few studies have systematically compared expanding, contracting, and multi-scale parallel convolutional organizations under identical experimental conditions to isolate the effect of convolutional organization on respiratory representation learning.

From another perspective, another major challenge arises from the characteristics of real-world clinical datasets. Physiological recordings frequently contain sensor artifacts, motion disturbances, behavioral fluctuations, and instrumentation instabilities [31], [32]. Such variability may encourage neural networks to learn non-physiological patterns, reducing generalization capability and increasing false-positive detections [33]. Therefore, developing architectures capable of extracting robust physiological representations while maintaining computational efficiency remains an important research challenge.

Taken together, these limitations reveal three major gaps in current deep learning approaches for OSA detection. First, asynchronous temporal relationships among respiratory physiological signals remain insufficiently explored, despite the suitability of recurrent architectures for modeling long-range temporal dependencies. Second, although CNN-BiLSTM models have become widely adopted, previous studies typically employ only a single convolutional organization, leaving the influence of feature extraction strategy on temporal representation learning largely unexplored. Third, real-world clinical variability demands compact models capable of learning robust physiological representations without excessive computational complexity. Therefore, understanding how different convolutional organizations interact with recurrent temporal modeling represents an important step toward developing more reliable and physiologically consistent OSA detection systems.

To position this work against the state of the art in OSA detection and address the multi-signal processing limitations pointed out in the literature, we propose a topology that goes beyond isolated channel data processing. Historically, OSA detection approaches are divided into two groups: those based on hand-crafted features extracted statically and linearly from multiple signals, such as Tripathy (2018), who analyzes HRV and EDR using Fourier decomposition and KELM [43]; and deep learning models focused on single channels of raw ECG, such as the works of Banluesombatkul et al. (2018) [44] and Zhang et al. (2021) [45], which employ hybrid CNN-LSTM networks to map temporal characteristics [44], [45].

While the first group fails by assuming that the time windows of different physiological sources are strictly synchronized and processes them independently (discarding dynamic cross-correlations) [43], the second discards the rich information of multi-signal approaches by limiting itself to raw ECG signals [44], [45]. To mitigate these issues, the architecture proposed in this article introduces an early multi-channel feature concatenation mechanism. This architectural element directly addresses the synchronization premise by allowing asynchronous alignment and processing of data streams, capturing dynamic and non-linear interactions between signals without requiring identical sampling or perfectly static time windows. A comprehensive structural comparison of these methodologies is summarized in Table I.

TABLE I
COMPARATIVE ANALYSIS OF OSA DETECTION TOPOLOGIES.

Model / Ref.	Inputs	Approach / Sync	Limitations
Tripathy [43]	HRV, EDR	KELM / Independent processing. Assumes perfect sync.	Fails to capture cross-signal correlations; relies on R-peaks.
Banlues. [44]	Raw ECG (15s)	CNN-LSTM / Single-channel. No signal fusion.	Misses respiratory dynamics from other sources.
Zhang [45]	Raw ECG (10s)	Multi-scale CNN / Single-channel.	Highly sensitive to noise and motion artifacts.
Proposed	FLOW, SpO2 ABD, THX	CNN-BiLSTM / Active Asynchronous Fusion.	Higher training complexity and data requirements.

Consequently, the primary objective of this study is to investigate whether different convolutional feature organizations influence the ability of hybrid CNN-BiLSTM networks to learn asynchronous respiratory physiological patterns from reduced polysomnography signals. More specifically, three controlled architectural configurations were designed to evaluate

distinct hypotheses regarding convolutional feature extraction: an expanding serial organization, a contracting serial organization, and a multi-scale parallel organization. All remaining experimental conditions—including dataset composition, optimization strategy, loss function, preprocessing pipeline, and validation protocol—were intentionally kept unchanged, allowing convolutional organization to be isolated as the sole experimental variable. Therefore, beyond identifying the highest-performing architecture, this study aims to provide experimental evidence regarding the role of convolutional feature organization in hybrid CNN-BiLSTM models for automated OSA detection.

The remainder of this paper is organized as follows. Section II describes the materials and methods, including the clinical dataset, preprocessing procedures, evaluation metrics, and the proposed network topologies. Section III presents the experimental results together with their computational and physiological discussion. Finally, Section IV summarizes the principal conclusions and outlines future research directions.

II. Materials and Methods

This section details the comprehensive methodological framework and computational pipeline developed for the automated detection of OSA using a reduced configuration of polysomnography channels. First, the clinical dataset characterization and the data preprocessing strategy—including signal windowing, downsampling, and patient-wise normalization—are presented. Subsequently, the mathematical formulations of the evaluation metrics and the structural configurations of the three proposed hybrid 1D-CNN-BiLSTM network topologies are specified mathematically and architecturally. Finally, the section outlines the network optimization criteria, loss functions, and the strict patient-independent validation protocol employed to ensure model generalizability.

A. Dataset and computational description

The experimental evaluation in this study utilizes the publicly available PhysioNet Apnea-ECG Database (version 1.0.0) [46]. Although the full database comprises 70 overnight recordings, a specific sub-cohort of 8 recordings (*a01–a04*, *b01*, and *c01–c03*) provides continuous multi-parameter physiological streams alongside single-lead ECG. To construct a non-invasive, computationally efficient screening framework tailored specifically for OSA detection, this study isolates a reduced subset of four essential physiological channels from these 8 subjects: nasal airflow (*FLOW*, corresponding to *Resp N*), peripheral oxygen saturation (SpO_2), thoracic respiratory effort (*THX*, corresponding to *Resp C*), and abdominal respiratory effort (*ABD*, corresponding to *Resp A*). Expert clinical annotations indicating the presence or absence of obstructive sleep apnea on a minute-by-minute basis serve as the ground truth for model training and evaluation. Although restricted to 8 multi-parameter subjects, each overnight recording spans approximately 7–8 hours of continuous physiological monitoring. Under the 60-second windowing protocol with 75% overlap, this dataset yields a dense pool of approximately 14,500 temporal segments, providing a substantial continuous stream of apneic and non-apneic respiratory events for pattern extraction.

The computational workflow was developed in Python (v3.12.13). Signal preprocessing and EDF file handling relied on `MNE` [36] and `NumPy` [37]. Neural network architectures, tensor operations, and data loading pipelines were implemented in `PyTorch` [38]. Model evaluation, class balancing, and patient-independent cross-validation splitting (`GroupKFold` and `GroupShuffleSplit`) were executed using `Scikit-Learn` [39]. Visualizations were rendered via `Matplotlib` [40] and `Seaborn` [41], while hyperparameter tuning and experiment tracking were automated using `Optuna` [42] and `MLflow`. Preprocessing was conducted locally on an Intel Core i7-1255U processor (ASUS Vivobook 16), whereas deep neural network training was accelerated on Google Colab using an NVIDIA T4 GPU.

B. Data Preprocessing and Windowing

To transform the continuous multi-channel physiological recordings into an optimal format for deep learning, a structured preprocessing pipeline was implemented. The raw signals were segmented into fixed-length 60-second temporal windows with a 0.75 overlap factor, maximizing the density of training patterns. Given that human respiratory events and localized apneic anomalies manifest at significantly lower frequencies—typically well below 5 Hz—the signals were downsampled from 300 Hz to 16 Hz. This downsampling maintains the structural integrity of the physiological waves according to the Nyquist criterion while drastically reducing the data footprint and computational overhead. Ground truth labels were assigned using a thresholding rule: a 60-second window is classified as an OSA event if active apnea labels occupy at least 17% of its total duration. This threshold corresponds to approximately 10 seconds of continuous obstruction and strictly aligns with the clinical diagnostic criteria established by the American Academy of Sleep Medicine (AASM) [10]. To eliminate inter-patient physiological variance and remove signal outliers, patient-wise normalization was executed using the Z-score standardization method, defined as:

$$z = \frac{x - \mu}{\sigma} \tag{1}$$

where μ and σ represent the mean and standard deviation computed exclusively per individual channel per patient.

Normalization was performed independently for each patient's complete overnight PSG recording after preprocessing and before window segmentation. Since the proposed framework operates offline, the entire recording is available during inference. Consequently, the mean (μ) and standard deviation (σ) are estimated exclusively from the signals of the patient being analyzed, ensuring that no information from other subjects is incorporated into the normalization process.

C. Evaluation Metrics

The classification capability of the deep learning topologies was rigorously evaluated using three widely established met-

rics in biological time-series analysis: Area Under the Receiver Operating Characteristic Curve (AUC-ROC), F1-Score, and Cohen's Kappa (κ). These metrics are mathematically justified as optimal indicators for analyzing deep learning models under typical physiological class imbalances [27], [28]. The F1-Score represents the harmonic mean of precision and recall, ensuring that both false positives and false negatives are heavily penalized:

$$\text{F1-Score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{2}$$

Cohen's Kappa measures the level of agreement between the predicted labels and the true annotations while explicitly accounting for the possibility of agreement occurring by chance [29]:

$$\kappa = \frac{p_o - p_e}{1 - p_e} \tag{3}$$

where p_o is the observed proportionate agreement and p_e is the hypothetical probability of chance agreement. The AUC-ROC computes the integral of the True Positive Rate against the False Positive Rate across all possible classification thresholds, describing the model's discriminative threshold-agnostic capability. Additionally, standard classification performance indices, namely Accuracy, Sensitivity (Recall), and Specificity, were computed from the accumulated true positives, false positives, true negatives, and false negatives to provide a comprehensive clinical evaluation.

D. Model Topologies and Structural Comparison

This study evaluates and compares various structural variations of a hybrid deep neural network combining one-dimensional convolutional layers with bidirectional recurrent units. The base system relies on 1D-CNN layers to map localized morphological features from the four input streams, followed by a BiLSTM network designed to track long-term asynchronous interactions across time.

Each topology was designed to evaluate a distinct architectural hypothesis. The expanding topology investigates whether progressively increasing representational capacity improves respiratory pattern extraction. The contracting topology evaluates whether a reduced-depth architecture can preserve diagnostic performance while lowering computational complexity. Finally, the parallel multi-scale topology investigates whether simultaneous multi-resolution feature extraction better represents asynchronous physiological events prior to temporal modeling.

To determine the most efficient architecture for OSA prediction, three distinct topological variants were evaluated, as detailed below:

a) Topology 1 (Expanding Serial Structure): As illustrated in Fig. 1, this architecture employs a deep serial extraction pipeline composed of three sequential 1D-CNN layers with expanding channel dimensions (32, 64, and 128 filters, respectively) and decreasing kernel sizes ($k = 11$, $k = 7$, and $k = 5$). This spatial representation is then forwarded to a robust recurrent stage consisting of two stacked BiLSTM layers with 64 hidden units each, optimized to track deep sequential temporal dependencies.

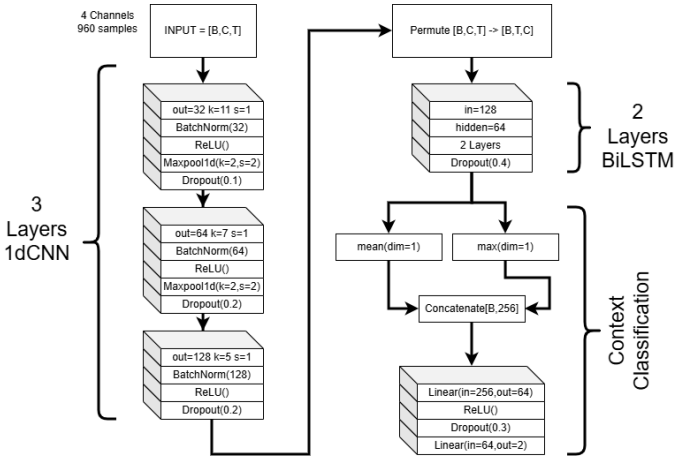

Fig. 1. Structural diagram of the first proposed 1D-CNN-BiLSTM network topology variation (Expanding Structure).

b) Topology 2 (Contracting Serial Structure): Shown in Fig. 2, this variation evaluates a shallower serial alternative, using two 1D-CNN layers configured with contracting channel configurations. It starts with a wide feature map of 128 filters ($k = 15$) and contracts to 64 filters ($k = 11$) in the second layer. The temporal tracking is performed by a more compact configuration of a single BiLSTM layer with 32 hidden units.

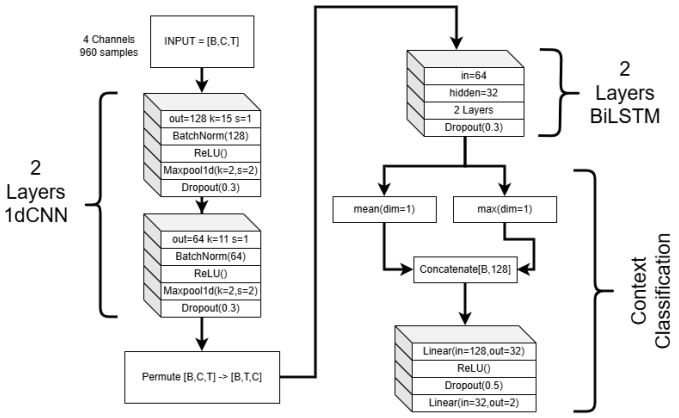

Fig. 2. Structural diagram of the second proposed 1D-CNN-BiLSTM network topology variation (Contracting Structure).

c) Topology 3 (Multi-Scale Parallel/Inception Structure): Presented in Fig. 3, this hybrid configuration introduces an Inception-inspired parallel processing mechanism. Instead of rigid sequential layers, the input streams are processed concurrently by two parallel 1D-CNN branches with heterogeneous receptive fields ($k = 11$ and $k = 21$, both with 32 filters). This allows the network to capture both rapid localized morphological anomalies and extended low-frequency respiratory trends simultaneously. The parallel features are concatenated and regularized via an intermediate reduction 1D-CNN layer

(64 filters, $k = 5$) before being fed into a lightweight single-layer BiLSTM network with 32 hidden units.

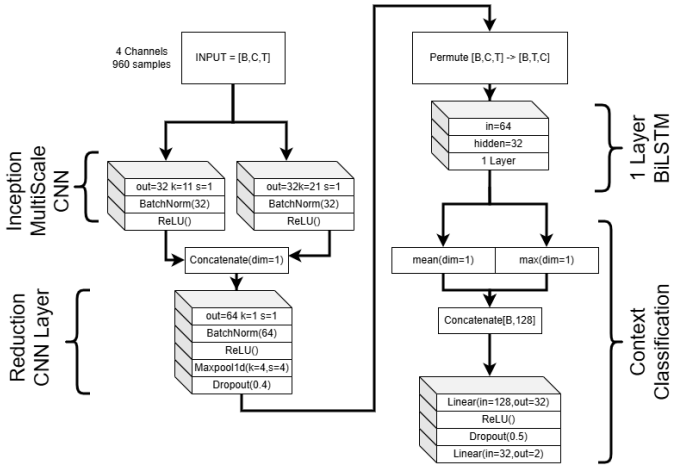

Fig. 3. Structural diagram of the third proposed 1D-CNN-BiLSTM network topology variation (Multi-Scale/Inception Parallel Structure).

These variants differ significantly in terms of layer depth, filter sizing, filter progression, and spatial feature extraction structures, directly affecting their abstraction capacities, operational layer configurations, and overall computational complexity. The specific structural complexities and memory footprints for each architectural variant are quantified through their total number of trainable parameters, as summarized in Table II.

TABLE II
TOTAL TRAINABLE PARAMETERS PER ARCHITECTURAL TOPOLOGY.

Architecture Variant	Trainable Parameters
Case I (Topology 1 — Expanding)	272,610
Case II (Topology 2 — Contracting)	152,738
Case III (Topology 3 — Multi-Scale)	37,858

A critical factor in this architectural comparison is the total number of trainable parameters within each network variation. Striking an optimal balance between parameter density and generalization is vital; overly complex networks risk overfitting the 8-patient training cohort, while shallow topologies may fail to track the subtle time lags between oximetry drops and airflow blockages. The specific parameter counts, operational layer structures, and comparative performance indicators for each topology are detailed comprehensively in the subsequent sections.

E. Training Specifications and Validation Strategy

To address the inherent class imbalance in natural sleep recordings, the networks were trained using the *Focal Loss* function [30]. This loss forces the optimization process to focus on hard-to-classify respiratory boundaries by down-weighting the loss contribution of easy, well-classified background sleep windows:

$$\mathrm{FL}(p_t) = -\alpha_t (1 - p_t)^{\gamma} \log(p_t) \tag{4}$$

where p_t represents the model's estimated probability for the correct class, α_t balances class prevalence, and γ is the focusing parameter that dynamically adjusts the down-weighting of easy examples.

The validation pipeline was strictly structured using a 4-fold cross-validation scheme via the `GroupKFold` algorithm. The cross-validation grouping was explicitly restricted by patient identifiers, ensuring that data windows belonging to a specific individual were never split between the training and validation sets simultaneously. This approach completely prevents data leakage and ensures that all reported evaluation metrics reflect true patient-wise generalization rather than memorized individual traits. Consequently, all performance metrics in this study are reported as the mean values computed across the independent verification folds.

Network optimization was driven by the AdamW algorithm, which incorporates decoupled weight decay to regularize connections. Furthermore, the learning rate was dynamically modulated via a schedule directly tied to the validation loss (`val_loss`). Specifically, a `ReduceLROnPlateau` policy was adopted with a reduction factor of 0.5 and a patience configuration of 4 epochs, ensuring fine-grained convergence whenever the optimization stalled. The specific hyperparameter settings assigned to each experimental case—including the initial learning rates, weight decay coefficients, batch sizes, and maximum epoch values are presented in Table III.

TABLE III
HYPERPARAMETER CONFIGURATIONS ACROSS THE THREE EXPERIMENTAL CASES

Hyperparameter	Case I	Case II	Case III
Learning Rate	1×10^{-3}	25×10^{-5}	1×10^{-4}
Weight Decay	1×10^{-1}	2×10^{-3}	15×10^{-2}
Batch Size	32	64	32
Epochs	20	30	15

III. RESULTS AND DISCUSSION

The computational efficiency and training runtime of the proposed architectures were evaluated based on the cloud-based execution framework utilizing an NVIDIA T4 GPU. The total training time across the complete 4-fold patient-independent cross-validation protocol varied significantly among the topologies due to their varying parameter densities. Case I (expanding serial topology) required 33 minutes to achieve convergence, whereas Case II (contracting serial topology) demanded the highest computational overhead, totaling 43 minutes of execution. In contrast, the multi-scale parallel architecture evaluated in Case III demonstrated lower computational cost, completing the entire training and verification pipeline in just 18 minutes. This represents a substantial runtime reduction, driven by its highly optimized, compact parameter footprint.

To guarantee rigorous clinical generalizability, the experimental lifecycle of each test case was systematically monitored using MLflow. Table IV summarizes the compiled cross-validation performance indices, reflecting the mean values and

standard deviations computed exclusively across the independent validation patient folds.

TABLE IV
CROSS-VALIDATION PERFORMANCE SUMMARY ACROSS TEST CASES.

Metric	Case I	Case II	Case III
Kappa	0.5686 ± 0.0431	0.5432 ± 0.0542	**0.5996 ± 0.0456**
F1-Score	0.7814 ± 0.0229	0.7692 ± 0.0282	**0.7996 ± 0.0233**
AUC-ROC	0.8694 ± 0.0221	0.8692 ± 0.0228	**0.8843 ± 0.0205**
Accuracy	79.28 ± 1.84%	78.65 ± 2.69%	**81.03 ± 2.10%**
Sens.	72.44 ± 4.39%	63.23 ± 5.62%	**72.70 ± 4.94%**
Spec.	83.87 ± 2.59%	**89.56 ± 3.15%**	86.44 ± 3.12%

Regarding structural efficiency, Case III (Topology 3) achieved the highest average performance among the evaluated architectures, consistently outperforming the deeper serial configurations across nearly all clinical assessment indices. It achieved a peak Cohen's Kappa of 0.5996, a Macro F1-score of 0.7996, and a discriminative threshold-agnostic capacity (AUC-ROC) of 0.8843. Additionally, this multi-scale parallel design achieved competitive validation performance while establishing a compact architectural footprint, reducing the total number of trainable parameters by up to 86% compared to deeper serial networks.

To evaluate Case III against baselines, paired Student's t-tests ($df = 3$) were conducted across the 4 validation folds (Table V). Case III significantly outperforms Case II across nearly all metrics, most notably delivering a $+9.47\%$ boost in Sensitivity ($p = 0.033$), AUC-ROC ($p < 0.001$), and Kappa ($p = 0.010$). Furthermore, Case III achieves statistical superiority over Case I in all global metrics, including Kappa ($p = 0.019$), F1-Score ($p = 0.016$), and AUC-ROC ($p = 0.045$), while remaining statistically equivalent in class-specific trade-offs ($p > 0.4$).

TABLE V
PAIRED STUDENT'S T-TEST RESULTS COMPARING CASE III AGAINST BASELINES (DF = 3).

Metric	Case III vs. Case I			Case III vs. Case II		
	Mean Diff.	t-stat	p-value	Mean Diff.	t-stat	p-value
Kappa	+0.0310	4.59	**0.019**	+0.0564	5.82	**0.010**
F1-Score	+0.0157	4.91	**0.016**	+0.0304	5.07	**0.015**
AUC-ROC	+0.0132	3.33	**0.045**	+0.0150	13.93	**0.001**
Accuracy	+1.75%	3.63	**0.036**	+2.38%	4.64	**0.019**
Sens.	+0.21%	0.07	0.949	+9.47%	3.75	**0.033**
Spec.	+2.09%	0.77	0.497	-3.12%	-1.83	0.164

Note: Bold p-values denote statistical significance at the $\alpha = 0.05$ level.

Furthermore, while paired t-tests confirmed statistically significant performance gains for Topology 3 over Cases I and II ($p < 0.05$), it is important to note that the small number of folds in the cross-validation setup ($df = 3$) constrains the statistical power of these tests. This represents a methodological limitation that should be addressed in future evaluations with expanded multi-center patient cohorts.

Regarding clinical relevance, achieving a specificity of 86.44% and a macro F1-score of 0.7996 on a reduced subset of standard respiratory channels (FLOW, SpO_2, THX, ABD) indicates strong potential for low-cost automated screening systems. High specificity is clinically crucial in primary screening to minimize false positives and prevent unnecessary, costly full-night polysomnography referrals. However, from an inferential perspective, the small cohort size ($n = 8$) and reduced degrees of freedom ($df = 3$) limit the statistical power of the hypothesis tests, meaning these statistical gains should be interpreted as preliminary architectural evidence. Consequently, while the multi-scale parallel design demonstrates superior representational efficiency under controlled conditions, extensive clinical validation on larger, multi-center cohorts remains necessary to confirm its diagnostic generalizability across broader patient demographics.

When analyzing the performance of models reported in the literature for OSA detection based on ECG signals, the highest values for the main evaluation metrics varied significantly depending on the adopted approach. The hybrid model based on deep learning by Zhang et al. (2021) obtained the highest overall performance indices in recent literature, achieving a total accuracy (TAC) of **96.1%**, sensitivity of **96.1%**, specificity of **96.2%**, and a Kappa coefficient of **0.92** on the Apnea-ECG test set [45]. In contrast, using traditional machine learning with hand-crafted features extracted by FDM from HRV and EDR signals, the KELM classifier by Tripathy (2018) reached a maximum accuracy of **76.37%** (with a specificity of **74.64%** using an RBF kernel in hold-out mode) [43] and a maximum sensitivity of **84.52%** (hold-out with linear KELM [43], reaching an average of **86.08%** in 10-fold cross-validation [43]). Lastly, the deep hybrid network for severity classification by Banluesombatkul et al. (2018), evaluated on the MrOS database, recorded an accuracy of **79.45%** [44] (with a sensitivity of **77.6%** and specificity of **80.1%** reported comparatively in the literature [45]).

Although these reference models report higher peak metrics, direct quantitative comparisons must be made with caution due to differences in dataset design and input modalities. While literature models primarily rely on clean, single-lead ECG segments, our proposed multi-scale network addresses the highly complex task of multi-signal fusion under a rigorous patient-independent cross-validation protocol. In this challenging and clinically realistic scenario, the proposed Case III topology demonstrates outstanding robustness, outperforming traditional multi-signal frameworks and offering superior generalizability.

Physiologically, this performance advantage stems from the asynchronous nature of multi-channel sleep signals. Upper airway collapse causes immediate high-frequency disruptions in nasal airflow (FLOW) and respiratory effort (THX/ABD), whereas peripheral oxygen desaturation (SpO_2) exhibits a circulatory lag of 10–40 seconds. While rigid serial structures (Cases I and II) struggle to isolate these heterogeneous temporal alignments without overfitting, Topology 3 uses concurrent parallel branches with varying kernel sizes. This multi-scale design extracts localized flow patterns with smaller kernels while simultaneously tracking delayed SpO_2 drops

with larger kernels, yielding compact, highly discriminative representations for the subsequent BiLSTM layers.

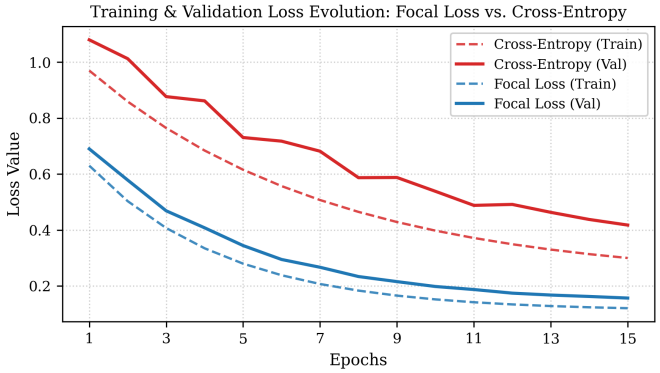

Fig. 4. Comparison of training and validation loss trajectories between Focal Loss ($\gamma = 2$) and standard Cross-Entropy Loss over 15 training epochs.

To empirically justify the selection of Focal Loss over standard Cross-Entropy (CE) loss, Fig. 4 illustrates the comparative evolution of training and validation loss trajectories across 15 epochs. Standard Cross-Entropy displays higher loss variance and slower convergence due to the overwhelming abundance of easy negative (non-apneic background sleep) windows, which dominate gradient updates during early optimization. In contrast, Focal Loss dynamically down-weights easy background samples through its focusing parameter ($\gamma = 2$), forcing the optimization process to prioritize hard-to-classify borderline respiratory transitions. Consequently, Focal Loss exhibits a smoother loss decay, substantially lower validation error, and faster stabilization, confirming its quantitative superiority for handling severe physiological class imbalances in automated sleep apnea detection.

Analysis of the learning trajectories revealed stable optimization curves when driving gradient descent via the custom Focal Loss module. Traditional cross-entropy functions frequently suffer from severe gradient oscillations in sleep-monitoring data due to extreme class imbalance, in which normal breathing periods far outnumber active apneic windows. This imbalance causes the algorithm to over-penalize minority-class errors or to fall into local minima. The Focal Loss formulation successfully suppressed the background gradient noise generated by easy-to-classify normal sleep windows by applying a dynamic down-weighting mechanism. This behavior allowed both the training and validation loss streams to converge synchronously, establishing stable diagnostic boundaries across independent patient domains without signs of premature divergence or over-parameterization.

IV. Conclusion

This study evaluated lightweight hybrid CNN-BiLSTM topologies optimized for automated OSA detection using a reduced set of standard polysomnography channels (FLOW, SpO_2, THX, ABD). By assessing structural feature map transitions, we show that carefully configured compact models can maintain robust diagnostic boundaries while avoiding the high computational cost of over-parameterized architectures. The integration of Focal Loss and patient-independent Group K-Fold validation proved essential to stabilizing gradient convergence and enhancing real-world clinical generalizability. The obtained results indicate that a reduced configuration of respiratory channels can feed compact deep learning architectures to support accessible sleep screening systems.

However, due to the highly subject-dependent nature of physiological signals, validating model generalization across unseen patients remains paramount. While this study utilized robust cross-validation techniques, a key limitation is the absence of a strict Leave-One-Subject-Out (LOSO) validation scheme. As immediate future work, we plan to evaluate the network using a completely isolated test set and implement LOSO validation to rigorously assess the model's performance in clinical, patient-independent settings.

Additionally, to build further on this work, we intend to introduce statistical feature-engineering stages prior to deep model input. Specifically, while the BiLSTM layers implicitly track cross-channel temporal relationships, explicitly mapping the physiological time delays (lags) via cross-correlation functions could further reduce the required input window lengths without sacrificing diagnostic accuracy. Finally, to overcome the limitations of cross-dataset comparison, future efforts will focus on implementing and benchmarking key baseline algorithms from the literature alongside our proposed architectures using a single, unified dataset.

***Abstract* — Although the ex vivo cardiac perfusion system based on the Langendorff model is widely used in studies of cardiac arrhythmias using isolated hearts, it still relies, in many cases, on the manual control of critical parameters such as pressure, temperature, and flow, compromising the reproducibility and accuracy of experiments. This project aims to implement, at the HEartLab Cardiac Electrophysiology Laboratory of the Federal University of ABC, which operates a Langendorff setup, high-precision digital sensors, electronic actuators, servo motors, microcontrollers (Arduino Nano and ESP32), and wireless communication modules (nRF24L01) to enable the real-time monitoring and control of physiological variables (flow, pressure, and temperature), thereby promoting greater experimental stability and reducing the need for human intervention. The expected outcomes include the development of configurable, and modular monitoring and control devices with potential applications in other areas of electrophysiology and biomedical engineering research.**

Keywords — cardiac arrhythmias, Langendorff system, automation, biomedical sensors, physiological control, biomedical instrumentation.

I. INTRODUCTION

Cardiovascular diseases remain the leading cause of morbidity and mortality worldwide, with cardiac arrhythmias accounting for a significant proportion of sudden cardiac death cases [1]. A detailed understanding of the electrophysiological mechanisms underlying these conditions is essential for the development of new therapeutic approaches, including pharmacological interventions and more effective ablation protocols [1]. In this context, ex vivo experimental models play a crucial role in cardiovascular research, as they enable the direct investigation of isolated myocardial tissue without the influence of systemic and hormonal factors [2].

Among the methodologies used to study the isolated heart, the Langendorff system is based on the technique of retrograde perfusion through a cannulated aorta. In this system, a heated and oxygenated nutrient solution is delivered in the direction opposite to the normal physiological blood flow through the aorta. This process forces the closure of the aortic valve and redirects the perfusate directly into the coronary arteries, thereby maintaining myocardial metabolism and contractile activity viable outside the organism [2].

However, the viability of the experiment and the reliability of the collected data are highly dependent on the strict maintenance of a homeostatic microenvironment within the experimental setup. Physical and chemical variables such as temperature, perfusion pressure, hydrodynamic flow, pH, and oxygenation levels directly influence cardiac cellular viability in isolated heart studies using the Langendorff system [3]. Accidental thermal deviations alter the electrical conduction velocity, whereas abrupt fluctuations in coronary flow may induce episodes of micro ischemia. From a physiological perspective, these disturbances affect the transmembrane resting potential and intracellular calcium homeostasis. From an experimental standpoint, the occurrence of such artifacts obscures the true physiological responses, compromises reproducibility, and may invalidate the conclusions drawn from the study.

With advances in microelectronics, high-precision digital sensors, and embedded automation platforms, the implementation of low-cost automated control systems for these experimental models has become increasingly feasible [4][5]. The use of microcontrollers, pressure, temperature, and flow sensors, as well as servo motors and electronically controlled on/off switches, enables the development of intelligent platforms capable of maintaining experimental parameters within predefined ranges while providing real-time monitoring of these critical variables [6][7].

This undergraduate research project was based on the Langendorff system developed by the HEartLab research group at the Federal University of ABC [8], which is dedicated to the study of cardiac arrhythmias in isolated animal hearts (CEUA No. 3947230519). The experimental setup consists of two fluidic circuits (see Figure 1A). In the perfusion circuit, Modified Krebs-Henseleit solution is pumped from a lower reservoir to an elevated reservoir, from which it flows by gravity through a heat exchanger heated by a water bath before perfusing the heart. In parallel, to mimic the transthoracic impedance between the heart and the thoracic surface, the heart is immersed in a tank containing a sucrose solution. This solution continuously circulates through the system, and its temperature is regulated by a second independent water bath. The lack of monitoring and control of critical variables—including pH, flow rate, perfusion pressure, and perfusate temperature—directly affected the quality of the data acquired by the optical and electrical mapping systems, reduced the duration of experiments due to the deterioration of cardiac viability, and compromised experimental reproducibility.

This work was supported by the São Paulo Research Foundation (FAPESP) through an Undergraduate Research Grant awarded to M. Santos (Grant No. 2025/22698-7) and a Young Investigator Grant awarded to J. Salinet (Grant No. 2018/25606-2)

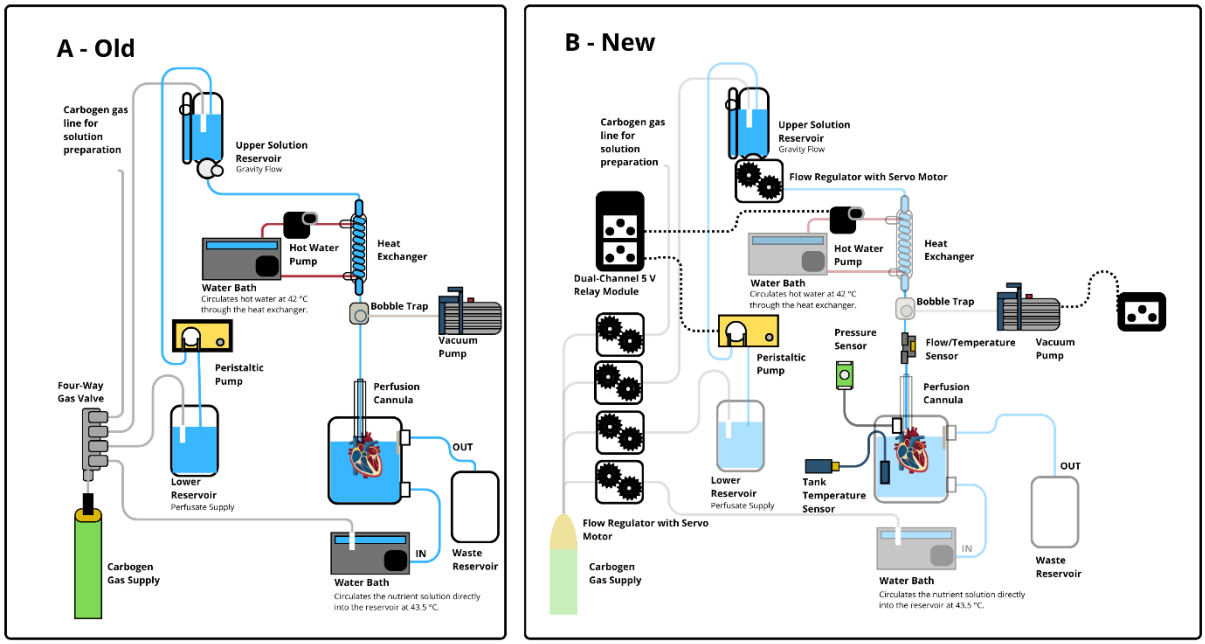

Figure 1. (A) Schematic representation of the HEartLab Langendorff system prior to the implementation of this project. (B) Updated system showing the locations of the integrated digital sensors, servo motors, and relays incorporated into the experimental setup.

II. Materials and Methods

The present project addresses the following limitations of the current HEartLab system: (1) the lack of monitoring of critical variables (flow rate, temperature, and perfusion pressure); (2) the absence of automated control and warning mechanisms when these variables fall outside the experimentally established ranges; and (3) the lack of continuous recording of these variables for subsequent analysis of their influence on experimental outcomes.

To address these limitations, the project proposes the integration of high-precision digital sensors for monitoring the following critical variables:

- **Carbogen gas pressure**, responsible for maintaining the pH of the nutrient solution at **7.4 ± 0.05** [8].
- **Perfusate flow rate** through the heart, maintained within the range of **20–40 mL/min** [8], ensuring the continuous supply of nutrients to the heart throughout the ex vivo experiment.
- **Temperature of the nutrient solution** perfused into the heart through the aorta, maintained at **37 °C** to replicate the rabbit's physiological core body temperature [2][9], as well as the **temperature of the sucrose solution** contained in the immersion tank, which simulates transthoracic impedance.
- **Perfusion pressure of the nutrient solution at the level of the heart,** maintained within the range of **40–60 mmHg** [2][8].

Figure 1B illustrates the original system together with the components added to the experimental setup, including: four carbogen gas flowmeters coupled to four servo motors, two power outlets connected to relay modules, one flow sensor, one pressure sensor, one temperature sensor, and one solution flow regulator coupled to a servo motor (see Figure 1B).

The project architecture was divided into four main components: **hardware design**, **mechanical integration**, **firmware development**, and **real-time visualization software**.

A. Hardware design

Initially, a comprehensive evaluation of the available technologies was conducted to specify the most portable and modular system capable of meeting the physiological monitoring and control requirements of the experimental setup.

At this stage, the Arduino Nano and ESP32 microcontrollers were evaluated in terms of their processing capability and data acquisition speed. For preliminary data transmission tests, Wi-Fi and Bluetooth modules, as well as nRF24L01 radio frequency communication modules, were investigated to better understand the advantages and limitations of each component, including noise susceptibility, data transmission rate, and support for multiple communication nodes. A literature review was also conducted to select the most suitable temperature sensors among the DS18B20, Type K thermocouples, and PT100 resistance temperature detectors (RTDs); Honeywell ABPD silicon piezoresistive pressure sensors, known for their high stability and low power consumption [11]; and Sensirion SLF series flow sensors, which are compact, high-precision liquid flow sensors designed to measure dynamic flow rates [12]. In addition, several communication protocols, including Serial, SPI, and I²C, were evaluated to support the design of the complete hardware architecture.

Based on this evaluation, the system was designed around three main modules (see Figure 2):

1. **Communication Central Module** – responsible for communication with the computer (Figure 2A);

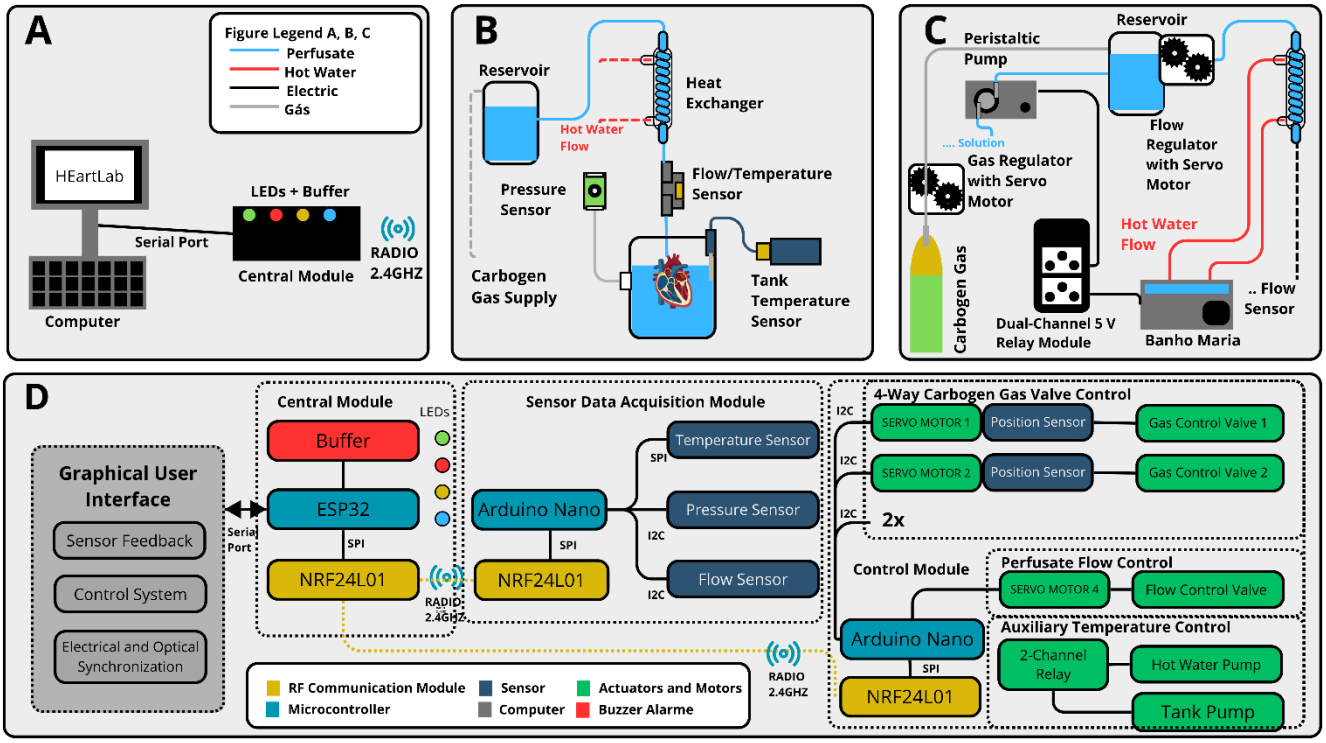

Figure 2. (A) Central Communication Module connected to the computer. (B) Location of the Sensor Data Acquisition Module for pressure, flow, and temperature measurements. (C) Location of the Control Module. (D) Flowchart providing an overview of the automation architecture of the Langendorff system

2. **Sensor Data Acquisition Module** – responsible for acquiring data from the sensors (Figure 2B);
3. **Control Module** – responsible for controlling the experimental variables (Figure 2C);

This modular architecture enables the monitoring and control functions proposed in this work while providing a flexible and scalable solution that can be adapted to the specific requirements of the Langendorff system without requiring major modifications to the existing experimental apparatus (Compare Figure 1A and 1B).

1) Central Communication Module

The Central Communication Module serves as the brain of the upgraded system. It is responsible for enabling the transmission and reception of radio-frequency data between the experimental setup and the computer. Through this module, data acquired from the flow, pressure, and temperature sensors are collected, commands for switching the peristaltic pump and water bath pump on and off are executed, and the flow control valves for both the heart perfusate and the carbogen gas supply are operated (see Figure 2). All of these functions are powered exclusively through the computer's USB connection.

The module consists of an ESP32-WROOM-32 microcontroller, a development board featuring a dual-core processor with integrated Wi-Fi and Bluetooth connectivity [13]. An nRF24L01 radio-frequency communication module, connected to the ESP32 via the SPI protocol, provides wireless communication with the other system modules (Sensor Data Acquisition Module and Control Module). In addition, a 1-µF decoupling capacitor is connected across the module's power supply pins to reduce electrical noise and prevent transmission interference, thereby ensuring stable wireless communication [14].

To facilitate system status monitoring, visual indicators were also incorporated into the module. A blue LED indicates successful reception of sensor data packets, a yellow LED signals the transmission of control commands, and an active buzzer together with a flashing red LED provides audible and visual alarms whenever the physiological variables exceed their predefined operating ranges: temperature between 37 and 40 °C, perfusion pressure between 40 and 60 mmHg, and flow rate between 20 and 40 mL/min [8].

2) Sensor Data Acquisition Module

The Sensor Data Acquisition Module is responsible for acquiring data from the digital temperature, pressure, and flow sensors used in the system. It was designed to minimize cable usage, allowing the module to be easily installed and removed after each experiment. In addition, the sensors can be quickly replaced through JST connectors, eliminating the need to desolder components from the printed circuit board (see Figure 2). The board features two interchangeable I²C interfaces and one SPI interface.

The module consists (see Figure 3) of an Arduino Nano (B), selected because of its more compact size compared with the ESP32, connected to an nRF24L01 radio-frequency communication module (A), which enables wireless communication with the Central Communication Module. The three sensors are connected to the board through JST connectors (G), forming the core of the physiological data acquisition system for the Langendorff setup.

The first sensor is a Honeywell ABPDANN005PG2A3 pressure sensor, positioned at the level of the perfused heart to measure the hydrostatic pressure at the heart level (see

Figures 1B and 2B). The sensor is factory-calibrated and temperature-compensated, and is designed for gauge pressure measurements over a range of 0 to 258 mmHg. Operating at 3.3 V, it provides a 14-bit digital output via the I²C protocol, corresponding to a theoretical resolution of approximately 0.016 mmHg per digital level. The digital interface eliminates the need for external signal-conditioning or amplification circuitry, thereby simplifying hardware integration and prototyping [11].

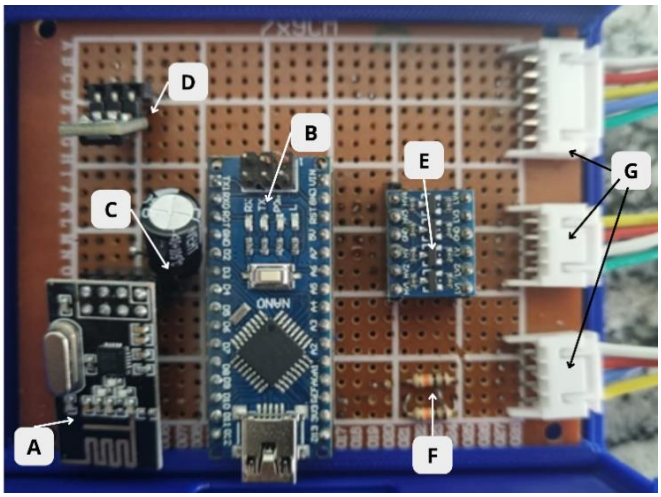

Figure 3. Circuit board developed for the Sensor Data Acquisition Module. (A) nRF24L01 module; (B) Arduino Nano; (C) filter capacitor; (D) 3.3 V voltage regulator; (E) logic level converter; (F) 220 Ω resistors; (G) JST connectors.

The second sensor is a Sensirion SLF3S-4000B, a high-precision liquid flow sensor with an operating range of 0 to 600 mL/min and a 16-bit digital output via the I²C interface [12]. The sensor provides a flow update rate of approximately 2 kHz. For water, the specified repeatability is ±0.5% of the measured value or ±0.3 mL/min, whichever is greater, while the specified accuracy is ±5% or ±0.5 mL/min for flow rates up to 300 mL/min. The sensor is installed in the nutrient-solution line near the perfused heart (see Figure 1B). It operates based on a thermal sensing principle, in which a central microheater and two symmetrically positioned temperature sensors detect the distortion of the thermal profile caused by fluid movement. To measure the absolute temperature of the liquid, the sensor incorporates an integrated thermal sensing element that continuously monitors the temperature of the perfusate. Owing to its fixed design, with no moving parts, and its 200 ms response time, the sensor is well suited for applications requiring continuous and reliable monitoring with minimal pressure drop. Consequently, it enables the simultaneous measurement of both the perfusate flow rate and temperature within the system.

The third sensing unit consists of a Type K thermocouple combined with a MAX6675 thermocouple-to-digital converter module, used for temperature measurements when the experiment employs the multi-electrode tank (see Figure 1B). The Type K thermocouple is capable of measuring temperatures over a wide range, from 0 °C to 1024 °C, with a 12-bit digital resolution (0.25 °C per bit) provided by the MAX6675 [15]. The MAX6675 functions as a digital converter, transmitting temperature data to the Arduino Nano via the SPI interface using a read-only SO (Slave Out) communication line.

The sensors used in this study are factory-calibrated, ensuring measurements within the accuracy specified by their manufacturers. The Sensirion SLF3S-4000B flow sensor is factory-calibrated for water, hydrocarbons (HC), and isopropyl alcohol (IPA), while the Honeywell ABPDANN005PG2A3 pressure sensor and the Type K thermocouple combined with the MAX6675 are also supplied pre-calibrated. To validate their performance in the proposed system, the measurements obtained from these sensors were compared with those from the reference instruments previously used in the experimental setup, namely a flowmeter, a pressure gauge, and a thermometer, allowing the agreement between the measurements to be evaluated.

3) Control Module

This module was designed using a modular architecture, allowing its components to be rapidly reconfigured on the printed circuit board by connecting or disconnecting servo motors and relay modules according to the experimental requirements. The module is structured as follows:

- **Central communication and control:** An Arduino Nano integrated with an nRF24L01 radio-frequency communication module establishes a wireless link for receiving and transmitting commands between this device and the Central Communication Module, as described for the other two modules.
- **Two relay-controlled power outlets:** These are used to switch a peristaltic pump, responsible for filling the upper reservoir, and a water circulation pump, which injects hot water into the heat exchanger to regulate the temperature of the nutrient solution delivered to the heart.
- **Four carbogen gas flowmeters coupled to four MG995 servo motors:** These provide automated control of the carbogen gas flow supplied through four independent lines connected to the upper reservoir, lower reservoir, immersion tank water bath, and nutrient solution preparation system.
- **Solution flow regulator coupled to an MG90S servo motor:** This regulator is connected to the upper reservoir and controls the flow rate of the nutrient solution delivered to the heart by gravity. Opening the regulator increases the flow rate, whereas closing it reduces the flow rate. The regulator operates in conjunction with the flow sensor to determine and maintain the appropriate valve position required to achieve the desired perfusate flow rate.

B. Mechanical Integration

Both the installation of the digital sensors into the experimental setup, according to the Sensor Data Acquisition Module described in the hardware design, and the mechanical coupling of the servo motors to the carbogen gas flow regulators and the nutrient solution flow regulator, described

in the Control Module, required the design and fabrication of custom 3D-printed components. Custom mounting brackets were designed to secure the pressure sensor, the immersion tank temperature sensor, and the flow sensor to the experimental apparatus; custom gears were manufactured to mechanically couple the flow control valves and the carbogen gas regulators to their respective actuating servo motors; and protective enclosures were developed to house the printed circuit boards of each module.

All components were designed using Autodesk Fusion 360 and sliced using Bambu Studio, and were subsequently fabricated on a Bambu Lab A1 3D printer using 1.75 mm Basic PLA filament. Basic PLA was chosen over the Lite, HT, and CF variants due to its favorable balance between cost, printability, and mechanical performance; this is because the fiber reinforcement in CF-PLA, while strengthening the X-Y plane, reduces interlayer strength along the Z-axis, a drawback for gear teeth subjected to cyclic bending [17]. The parts were printed with a nozzle temperature of 210 °C and a bed temperature of 60 °C, using a layer height of 0.2 mm; the gears and coupling components, subjected to higher mechanical loads, were printed with 4 wall perimeters and 100% infill density, while the enclosures used 2 wall perimeters and 20% infill, in accordance with infill density being the dominant parameter for tensile strength in FDM-printed PLA parts [18].

To dimension the coupling between the servo motors and the flow-regulating valves, two servo motor models with distinct torque ratings were tested: the MG90S, with a rated torque of 2.2 kg.cm [19], and the MG995R, with a rated torque of 11 kg.cm [20]. This comparison allowed the evaluation of which servo motor would provide sufficient torque to overcome the mechanical resistance of each regulator without compromising the integrity of the PLA-printed gears. As a result, both models were adopted, each applied to the component for which it performed best: the servo motor that offered sufficient torque combined with better compatibility with the available physical space in the assembly was used for the corresponding coupling, while the other model was employed in the regulator where its additional torque prevented gear tooth failures observed during preliminary testing.

C. Firmware Development

A The firmware for all three modules was developed using the Arduino IDE and follows the programming logic illustrated in Figure 3. The Sensor Data Acquisition Module acquires data from the immersion tank temperature sensor, the pressure sensor, and the flow sensor, including the temperature measured by the flow sensor. These measurements are compressed into a single data packet for wireless transmission.

The Central Communication Module receives and decodes these data packets at a sampling interval of 200 ms Each packet follows a predefined format, in which the identifier "SN1" specifies the transmitting module, while each subsequent "0000" field represents the value of a monitored physiological variable. Based on the real-time analysis of these data, the Central Communication Module transmits control commands to the Control Module. For example, it can deactivate the immersion tank water bath through a relay, perform PID control of the perfusate flow rate by actuating a servo motor coupled to the flow control valve (see Figure 4), or switch off the pump that circulates hot water through the heat exchanger (see Figure 2C) whenever the perfusate temperature exceeds 41 °C.

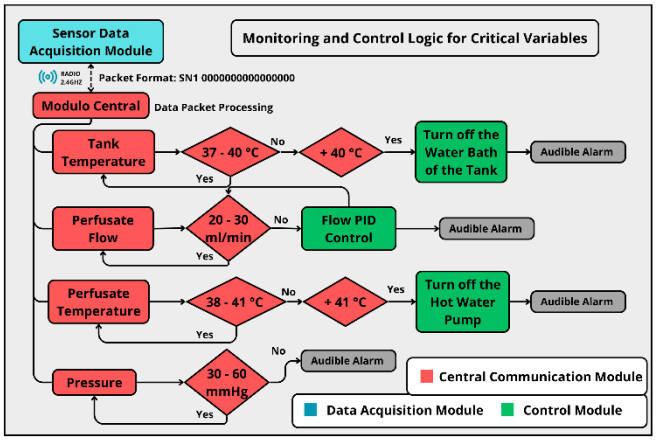

Figure 4. Firmware logic for the monitoring and control of the immersion tank temperature, perfusate flow rate, perfusate temperature, and coronary perfusion pressure.

D. Real-Time Visualization Software

The graphical user interface (GUI), developed in a Python environment through the integration of the Tkinter and PySerial libraries, constitutes the central platform for control and data acquisition of the perfusion system. Communication between the computational unit and the Central Communication Module is established bidirectionally via the UART serial protocol, enabling both the transmission of operational commands and the continuous reception of telemetric data from the digital sensors, operating at 200-millisecond sampling intervals.

During the execution of the experimental protocol, the software provides real-time monitoring of operational and hemodynamic variables, encompassing the immersion bath temperature, coronary perfusion pressure, flow rate, and perfusate temperature, through time-series plots and numerical indicators. To enable subsequent analyses, all measurements are automatically stored in timestamped CSV files, ensuring full traceability of the acquisition process and allowing for the subsequent synchronization and correlation of these parameters with the electrophysiological recordings obtained from the isolated heart model.

III. Results

The developed Central Communication Module is capable of transmitting and receiving data via 2.4 GHz radio-frequency communication, while interfacing with the computer through its serial port. This architecture enables the integration and communication of multiple modules added to the experimental setup. Figure 5 shows the components of the

Central Communication Module, identified according to the figure legend, assembled on the printed circuit board and housed within its custom 3D-printed enclosure.

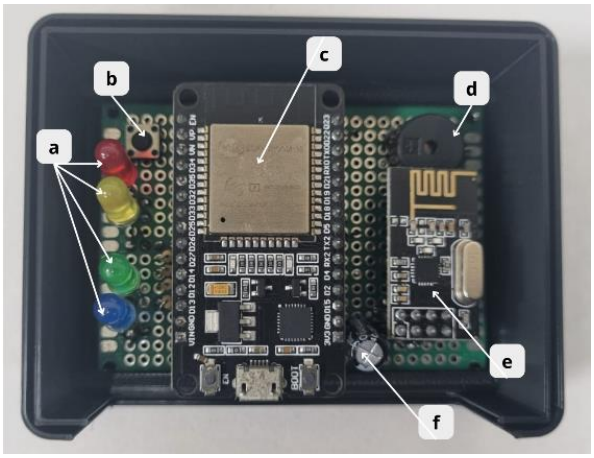

Figure 5. Printed circuit board (PCB) developed for the Central Communication Module connected to the computer. (A) Status indicator LEDs; (B) push button; (C) ESP32 microcontroller; (D) 3.3 V buffer; (E) nRF24L01 module; (F) 100 µF Capacitor.

The Sensor Data Acquisition Module was assembled (see Figure 6) and integrated into the experimental apparatus to enable real-time monitoring of the sensors through the visualization software described in the Materials and Methods section (see Figure 7). Figure 6 illustrates the locations of the perfusate flow sensor (A), the pressure sensor positioned at the level of the heart (B), and the immersion tank temperature sensor (C), Sensor Data Acquisition Module (D), together with their respective positions within the experimental setup. The right side of the figure shows the custom 3D-printed enclosures designed and fabricated to securely mount and protect each sensor.

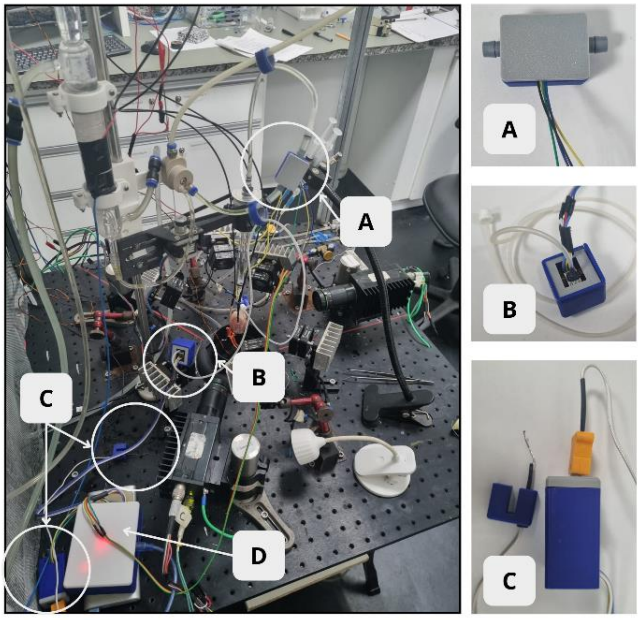

Figure 6. Left: Experimental setup showing the perfusate flow sensor and perfusate temperature sensor (A), the pressure sensor (B), the immersion tank temperature sensor (C), and the Sensor Data Acquisition Module (D). Right: Individual views of each sensor mounted in its respective custom 3D-printed enclosure and support bracket.

Figure 7 shows the GUI of the Real-Time Visualization Software running on the ‘for continuous monitoring of the physiological variables. The Sensor Data tab displays panels with the instantaneous values of the immersion tank temperature, coronary perfusion pressure, perfusate flow rate, and perfusate temperature. Adjacent to these numerical indicators, real-time time-series plots illustrate the behavior of each variable over the previous few seconds, enabling continuous assessment of the experimental conditions.

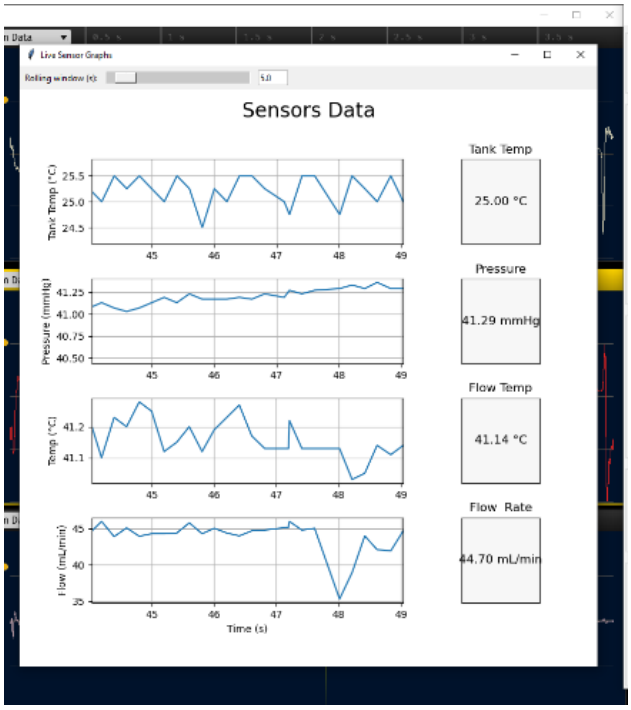

Figure 7. Computer interface of the Real-Time Sensor Monitoring Software. **Left:** Panels displaying the instantaneous values of the monitored physiological variables. **Right:** Real-time time-series plots showing the recent behavior of each monitored variable.

All sensor measurements are continuously acquired, logged, and stored in CSV files for offline analysis. Figure 8 illustrates the temporal profiles of the key physiological and system variables, including immersion bath temperature, perfusate flow rate, perfusate temperature, and coronary perfusion pressure, recorded during a isolated rabbit heart experiment using the proposed data acquisition system, with the acquisition and central communication modules connected to the computer-based GUI. The behavior observed in Figure 8 was consistently reproduced in seven additional experiments performed under the same experimental conditions. A gradual increase in coronary perfusion pressure was consistently observed as the experiments progressed. During the initial phase of perfusion, larger oscillations in the measured flow rate were detected, primarily due to spontaneous cardiac contractions that produced transient backflow of the perfusate through the coronary circulation. The flow signal also exhibited occasional sharp peaks caused by the presence of air bubbles trapped inside the flow sensor. This phenomenon is an inherent limitation of the sensor's measurement principle and

internal flow-channel geometry rather than a physiological event (see Figure 8). In contrast, both the perfusate temperature and the immersion bath temperature remained remarkably stable throughout the entire experiment, confirming the ability of the temperature regulation system to maintain the thermal conditions required for Langendorff heart perfusion.

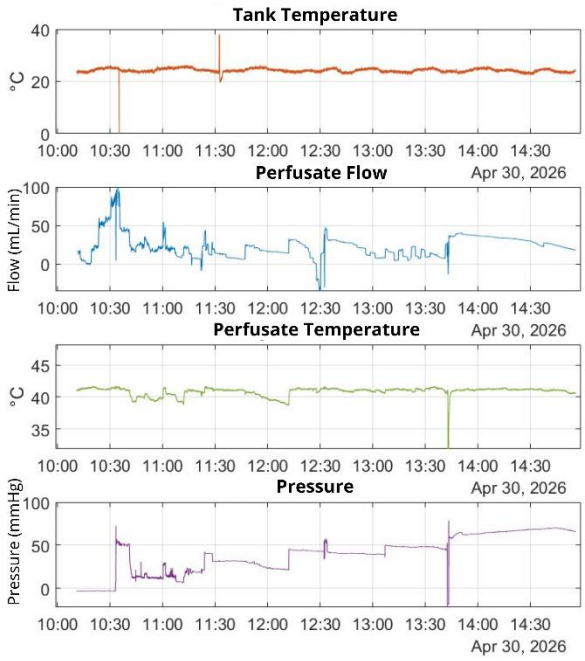

Figure 8. Temporal profiles of perfusate flow rate, perfusate temperature, and coronary perfusion pressure throughout the entire duration of a representative experiment.

The Control Module was assembled and subjected to preliminary validation tests using the Langendorff system without a perfused heart (see Figure 9). It is important to note that the automated control of the carbogen gas flow valves is still under development and remains in the prototyping stage. Therefore, this functionality was not included in the results presented in this study.

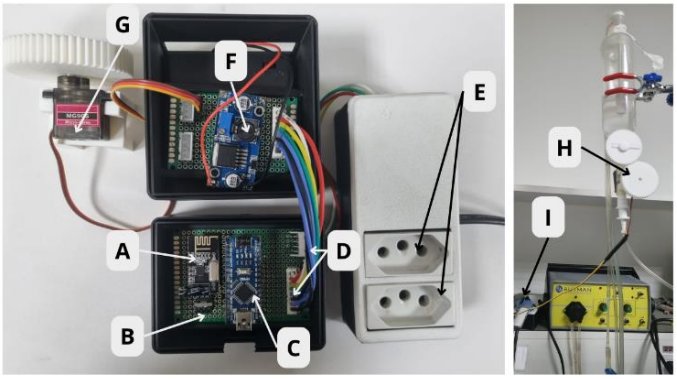

Figure 9. (A) nRF24L01 module; (B) 3.3 V voltage regulator; (C) Arduino Nano; (D) JST connectors; (E) dual-channel relay module connected to two power outlets; (F) servo motor power supply; (G) MG90S servo motor; (H) mechanical coupling between the servo motor and the flow control valve; (I) peristaltic pump and heat exchanger circulation pump connected to the Control Module.

The graph shown in Figure 10 demonstrates the effectiveness of the proportional–integral–derivative (PID) controller in regulating the perfusate flow rate through a servo motor coupled to the control valve, maintaining the variable at the predefined setpoint. In a control experiment performed without a perfused heart, a command to maintain the flow rate at 30 mL/min was issued at 16:36, and the system reached a stable steady state after approximately 2 minutes of minor oscillations. Subsequently, at 16:41, the flow setpoint was changed to 10 mL/min, again reaching stability after approximately two minutes. At 16:46, the flow rate was returned to 30 mL/min, and at 16:51, it was increased to 50 mL/min; in both cases, the controller stabilized the flow within approximately two minutes.

At 17:00, 17:01, and 17:02, successive forced closures of the flow path were performed to evaluate the system's response to potential obstructions in the perfusion line. Throughout the experiment, the fluid temperature remained between 37 °C and 41 °C, regulated by a relay connected to the hot-water circulation pump of the heat exchanger (Figure 5C). This relay automatically switched the pump on or off based on continuous temperature monitoring (Figure 3). Furthermore, when the monitored variables were intentionally driven beyond their predefined operating limits, the audible alarm was successfully activated.

A complementary analysis using the Pearson correlation coefficient ($r = 0.7251$) confirmed a positive relationship between the perfusate flow rate and fluid temperature, as illustrated in Figure 10. Under low-flow conditions (approximately 10 mL/min), a corresponding decrease in fluid temperature was observed. In contrast, at higher flow rates, the temperature stabilized at 41 °C, demonstrating the effectiveness of the thermal control system in compensating for the increased thermal demand imposed by higher perfusion flow rates.

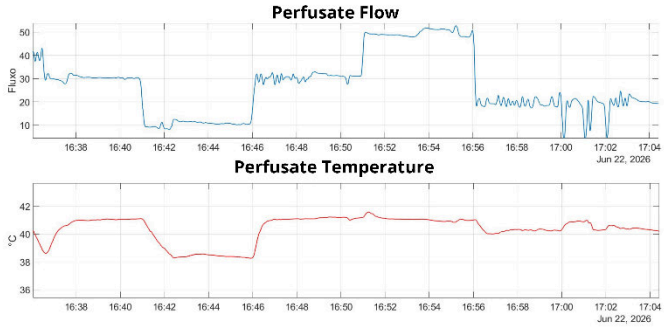

Figure 10. Temporal analysis of the relationship between perfusate flow rate and perfusate temperature during a control experiment performed without the perfused heart.

The results presented in this section demonstrate the development of a modular and configurable system capable of real-time monitoring of critical physiological variables, including coronary perfusion pressure, perfusate flow rate, and perfusate temperature. The monitoring system and its graphical user interface (GUI) were evaluated through a series of seven experiments using the Langendorff rabbit heart model. The control system is currently in the pre-experimental testing phase, regulating perfusate flow rate and

temperature without a perfused rabbit heart. Once fully integrated into the experimental setup, it will enable a more comprehensive analysis of the behavior and influence of these critical variables throughout each experiment.

IV. Conclusion

The results obtained demonstrate the feasibility of a scalable, and scientifically sound solution with direct application to an experimental setup for the study of cardiac arrhythmias in animal models. The proposed system enables the real-time monitoring and control of critical experimental variables, thereby reducing manual errors, improving the accuracy of experimental parameters, and increasing the efficiency of physiological control throughout the experiments.

Acknowledgments

This work was partially supported by the São Paulo Research Foundation (FAPESP) through grants awarded to M. Santos (Grant No. 2025/22698-7) and J. Salinet (Grant No. 2018/25606-2), as well as by CNPq INCT INTERAS (Call No. 58/2022). Additional support was provided by the Brazilian National Council for Scientific and Technological Development (CNPq) during the initial phase of the project.

The authors would like to thank all members of the HEartLab at the Federal University of ABC (UFABC) for developing the original experimental Langendorff setup that served as the foundation for this undergraduate research project.

***Abstract*—Wastewater-Based Epidemiology (WBE) is a complementary approach for population-level surveillance of biomarkers associated with illicit drug use. This exploratory cross-sectional study qualitatively screened raw sewage from three wastewater treatment plants (WWTPs) serving socioeconomically distinct areas of São Luís-Ma, for cocaine- and cannabis-related immunoassay signals associated with benzoylecgonine (BE) and THC-COOH. Grab samples collected over the course of one week at each wastewater treatment plant were used and analyzed using rapid lateral-flow immunoassays originally developed for human urine. The manufacturer decision thresholds were 150 ng/mL for the cocaine-related assay and 50 ng/mL for the cannabis-related assay. Because the assays were not analytically validated for raw wastewater, these thresholds were used only for qualitative classification and were not interpreted as measured wastewater concentrations. BE-associated positivity was observed in 71% of Vinhais samples and 100% of Anil and Bacanga samples, whereas THC-COOH-associated positivity was 14%, 43%, and 43%, respectively. Pairwise Fisher's Exact Tests showed no statistically significant differences among WWTPs ($p > 0.05$). Therefore, the data do not support quantitative estimates of community drug consumption or an association between socioeconomic conditions and consumption. The findings were interpreted as preliminary qualitative screening results and require confirmation using matrix-validated quantitative methods and representative 24-h composite sampling.**

***Index Terms*—Wastewater-Based Epidemiology; qualitative screening; benzoylecgonine; THC-COOH; raw sewage; immunoassay; Fisher's Exact Test.**

I. Introduction

Illicit drug use is an important public health issue in Brazil. National survey data indicate substantial lifetime exposure to illicit psychoactive substances, including cannabis [5], [17], while official seizure data in Maranhão reinforce the regional relevance of cocaine- and cannabis-related markets [12] . Conventional surveillance methods, including surveys, clinical records, and seizure statistics, are useful but may be affected by underreporting, response bias, delays, and limited temporal or spatial resolution [8], [15].

Wastewater-Based Epidemiology (WBE) has emerged as a non-invasive complementary strategy for monitoring population-level biomarkers in sewage [6], [8], [15]. Quantitative WBE typically relies on validated measurements of biomarker concentration, representative wastewater sampling, flow data, contributing population, biomarker stability, and appropriate excretion/correction factors [6], [15].

Benzoylecgonine (BE) is commonly used as a cocaine-related biomarker, whereas THC-COOH is used in cannabis-related wastewater studies [9], [15].

The present study examined raw sewage from the Vinhais, Anil, and Bacanga WWTPs, which serve urban areas with different socioeconomic characteristics. These contextual differences motivated an exploratory comparison of qualitative detection frequencies. However, socioeconomic characteristics were not treated as evidence of individual exposure or as a causal determinant of drug use.

The objective was therefore to evaluate, as an exploratory qualitative screening study, the occurrence of cocaine- and cannabis-related immunoassay signals associated with BE and THC-COOH in raw sewage from the three WWTPs and to compare their detection frequencies using Fisher's Exact Test.

II. Background

A. Wastewater-Based Epidemiology and Analytical Context

Domestic sewage contains urine, feces, suspended solids, organic matter, detergents, and numerous chemical constituents [7]. Biomarkers excreted after drug use may enter sewer networks and reach WWTP influents, where they can be investigated for public health surveillance. Nevertheless, raw wastewater is a complex analytical matrix, and biomarker measurements may be affected by dilution, degradation, adsorption to solids, sewer travel time, and matrix interferences [15].

Validated quantitative WBE studies generally use representative composite sampling and instrumental analytical methods. The literature emphasizes the importance of uncertainty control in sampling, analytical recovery, biomarker

stability, flow measurement, population estimation, and back-calculation [6], [15]. These requirements differ fundamentally from qualitative screening based on a decision threshold.

In Brazil, WBE investigations have been reported in Brasília and other regions [1], [2], [9], [13], [14]. The present work differs by evaluating the feasibility and limitations of an initial qualitative immunoassay screening approach in São Luís. Because the assay used here was originally designed for urine and was not validated for raw wastewater, its findings are treated as preliminary screening observations rather than validated quantitative WBE estimates.

B. Study Areas and Socioeconomic Context

The Vinhais, Anil, and Bacanga WWTPs serve areas with contrasting socioeconomic characteristics according to the contextual information compiled in the original study from IBGE, SNIS, CAEMA projects, and author synthesis. These characteristics were retained only to describe the study setting and were not used to infer individual drug use or causal socioeconomic effects.

TABLE I
CONTEXTUAL SOCIOECONOMIC CHARACTERISTICS OF THE AREAS SERVED BY THE WWTPS.

Variable	***Vinhaes***	***Anil***	***Bacanga***
Approx. household income	3–6 minimum wages	1–3 minimum wages	0.5–3 minimum wages
Predominant profile	Middle/upper	Middle/lower	Low
Estimated sewer coverage	$> 60\%$	$< 50\%$	100%
Occupation type	Planned/regular	Mixed	Planned/socialhousing

III. MATERIALS AND METHODS

A. Study Design and Sampling

The study had an exploratory, cross-sectional design. Raw sewage was collected at the inlets of the Vinhais, Anil, and Bacanga wastewater treatment plants over the course of a week during distinct periods. Seven grab samples were evaluated per WWTP. The sampling design was intended for initial qualitative pre-screening and did not constitute 24-h composite sampling or long-term temporal monitoring.

The possible influence of recreational, cultural, regional, or sporting events was not systematically controlled in the initial sampling design. Consequently, the data cannot be used to infer stable temporal patterns of drug use. A subsequent phase of the broader research project uses 24-h composite samples and instrumental quantitative analysis; because those analyses are still ongoing, those data are not included in this manuscript.

B. Qualitative Immunoassay Screening

Samples were collected in 250 mL PVC bottles, filtered, and applied to rapid visual lateral-flow immunoassays supplied by SABRE SAFETY LTDA. A critical methodological procedure was pH monitoring using colorimetric strips. It was observed that the pH of the raw sewage ranged from 6.0 to 8.0. Maintaining this near-neutral range is essential to ensure the integrity of the antibodies immobilized on the nitrocellulose strip, as extreme pH values can cause protein denaturation and compromise antigen-antibody affinity, leading to false-negative results [18]. According to the product labeling used in the study, the assays were intended for qualitative screening of cocaine-related (COC) and cannabis-related (THC) targets in human urine, with manufacturer decision thresholds of 150 ng/mL and 50 ng/mL, respectively.

The assays were not analytically validated in this study for raw wastewater. Therefore, the manufacturer cut-offs were not treated as measured concentrations of BE or THC-COOH and were not used to calculate mass loads or community consumption. Positive/negative results are interpreted as exploratory cocaine-related and cannabis-related immunoassay responses associated with the target biomarkers discussed in the study.

C. Statistical Analysis

Qualitative outcomes were coded as 0 (absence/negative) and 1 (presence/positive). Detection frequencies were summarized for each WWTP. Because the sample size was small and both variables were categorical, two-sided Fisher's Exact Tests were used for pairwise comparisons between Vinhais and Anil, Vinhais and Bacanga, and Anil and Bacanga [16]. The null hypothesis was that the detection frequency did not differ between the two WWTPs being compared. Statistical significance was set at 5% ($p < 0.05$).

IV. RESULTS AND DISCUSSION

The cocaine-related/BE-associated immunoassay was positive in 5 of 7 samples from Vinhais (71.4%) and in all 7 samples from both Anil and Bacanga (100%). The cannabis-related/THC-COOH-associated immunoassay was positive in 1 of 7 Vinhais samples (14.3%) and in 3 of 7 samples from both Anil and Bacanga (42.9%). Thus, Anil and Bacanga showed higher observed detection frequencies than Vinhais, particularly for the cannabis-related assay.

TABLE II
QUALITATIVE DETECTION FREQUENCIES BY WWTP.

WWTP	***BE-associated Positive***	***BE-associated Negative***	***THC-COOH-associated Positive***	***THC-COOH-associated Positive***
Vinhais	$5/7(71.4\%)$	$2/7(28.6\%)$	$1/7(14.3\%)$	$6/7(85.7\%)$
Anil	$7/7(100\%)$	$0/7(0\%)$	$3/7(42.9\%)$	$4/7(57.1\%)$
Bacanga	$7/7(100\%)$	$0/7(0\%)$	$3/7(42.9\%)$	$4/7(57.1\%)$

Autor.

However, all pairwise Fisher's Exact Test p-values were greater than 0.05. For the cocaine-related/BE-associated results, p = 0.462 for Vinhais versus Anil, p = 0.462 for Vinhais versus Bacanga, and p = 1.000 for Anil versus Bacanga. For the cannabis-related/THC-COOH-associated results, p = 0.559, p = 0.559, and p = 1.000, respectively. The null hypothesis was therefore not rejected for any comparison.

TABLE III
PAIRWISE FISHER'S EXACT TEST RESULTS

Target	***WWTP Comparison***	***p-value***	***Interpretation***
BE-associated	Vinhais × Anil	0.462	Not significant
BE-associated	Vinhais × Bacanga	0.462	Not significant
BE-associated	Anil × Bacanga	1.000	Not significant
THC-COOH-associated	Vinhais × Anil	0.559	Not significant
THC-COOH-associated	Vinhais × Bacanga	0.559	Not significant
THC-COOH-associated	Anil × Bacanga	1.000	Not significant

Autor.

The higher descriptive detection frequencies observed at Anil and Bacanga cannot be interpreted as evidence of higher drug consumption or as an effect of socioeconomic vulnerability. The qualitative design, small sample size, grab sampling, and lack of wastewater-specific analytical validation preclude such inference. The socioeconomic profile is therefore interpreted only as contextual information describing the areas served by each WWTP.

The higher detection frequency observed for the cocaine-related/BE-associated signal compared with the cannabis-related/THC-COOH-associated signal may reflect differences in biomarker excretion and physicochemical behavior. BE is widely used as a biomarker for cocaine monitoring in wastewater, whereas THC-COOH presents greater analytical challenges in wastewater-based surveillance. Its relatively low excretion, together with partitioning to suspended particulate matter and other matrix-related effects, may reduce its availability in the aqueous fraction and consequently affect detection. Therefore, the lower frequency of cannabis-related/THC-COOH-associated positive results observed in this study should not be interpreted as evidence of lower cannabis use in the populations investigated. Rather, it may partly reflect differences in excretion, wastewater partitioning, dilution, and the analytical characteristics of the qualitative immunoassay.

V. CONCLUSION

This exploratory study detected cocaine-related and cannabis-related immunoassay signals in raw sewage from the three investigated WWTPs in São Luís. The observed positivity frequencies differed descriptively among WWTPs, but Fisher's Exact Tests did not identify statistically significant pairwise differences.

Because the immunoassays were originally designed for urine, were not validated for raw wastewater, and were applied to grab samples collected week periods, the findings must be interpreted strictly as preliminary qualitative screening results.

The study nevertheless provides an initial feasibility assessment for qualitative wastewater screening in a setting with limited analytical infrastructure. More representative sampling and validated quantitative methods, preferably incorporating SPE and LC-MS/MS, are required to confirm biomarker identity, quantify concentrations, and support robust WBE estimates.

***Resumo*—**
A laminina polimerizada (*polyLM*) apresenta uma organização supramolecular complexa capaz de influenciar processos de sinalização celular e regeneração neural. Neste trabalho, realizou-se uma revisão bibliográfica com o objetivo de investigar como métricas fractais e modelos de crescimento não linear podem caracterizar a organização estrutural da polyLM e auxiliar na compreensão de suas propriedades funcionais. Foram analisados estudos relacionados à geometria fractal, à estimativa da dimensão fractal por meio do método de *box-counting* e às aplicações da polyLM em contextos de neuroengenharia e regeneração nervosa. Os resultados indicam que a polyLM apresenta comportamento fractal, com dimensão variando aproximadamente entre 1,55 e 1,70 durante sua formação, exibindo padrões compatíveis com modelos de Agregação Limitada por Difusão (*Diffusion Limited Aggregation* – DLA). Além disso, a literatura sugere que sua organização geométrica favorece a exposição de sítios de ligação celular, contribuindo para processos de adesão, diferenciação neuronal e crescimento de neuritos. Conclui-se que a geometria fractal da polyLM constitui um importante elo entre estrutura molecular e função neurobiológica, destacando o potencial de abordagens geométricas para o desenvolvimento de biomateriais aplicados à regeneração neural e à neuroengenharia.

***Palavras-chave*—Fractais, Matriz extracelular, Polilaminina, Neuroengenharia, Dimensão Fractal, Neurociência**

I. Introdução

A organização estrutural da matriz extracelular exerce papel fundamental na regulação de processos celulares, influenciando mecanismos de adesão, diferenciação, migração e regeneração tecidual. Nesse contexto, a laminina (*LM*) destaca-se como uma das principais glicoproteínas da matriz extracelular, participando da organização de membranas basais e da sinalização celular em diferentes tecidos [1].

Estudos recentes demonstram que a laminina polimerizada (*polyLM*) apresenta uma organização supramolecular complexa caracterizada por propriedades fractais, incluindo autosimilaridade e dimensão não inteira [2]. Segundo Hochman-Mendez, M. et al. [2], a morfologia da polyLM mantém padrões semelhantes em diferentes escalas de observação, indicando um comportamento compatível com sistemas fractais encontrados em diversos fenômenos naturais e biológicos.

Na Engenharia Biomédica e na Neuroengenharia, a compreensão dessas propriedades geométricas torna-se relevante devido à influência da organização espacial da matriz extracelular sobre a sinalização celular e o crescimento neural. Trabalhos anteriores demonstram que a estrutura fractal da polyLM favorece a exposição de sítios de ligação celular e contribui para a formação de nichos neurogênicos especializados, como os *fractones*, associados à diferenciação neuronal e à regeneração do tecido nervoso [1], [3].

Além disso, métricas fractais e modelos de crescimento não linear têm sido utilizados para descrever a formação e a evolução temporal de estruturas biológicas complexas, permitindo relacionar propriedades geométricas a funções biológicas específicas [4], [5]. Dessa forma, sua geometria fractal surge como um possível elo entre organização molecular e funcionalidade neurobiológica.

Diante desse contexto, o presente trabalho busca responder à seguinte questão de pesquisa: **Como métricas fractais e modelos de crescimento não linear podem contribuir para a compreensão da organização estrutural e funcional da laminina polimerizada (*polyLM*)?**

Para responder a essa questão, foi realizada uma revisão bibliográfica de estudos relacionados à caracterização fractal da polyLM, aos métodos de estimativa de dimensão fractal e às suas aplicações em neuroengenharia e regeneração neural.

II. Objetivos

Investigar como métricas fractais e modelos de crescimento não linear podem contribuir para a compreensão da

Trabalho desenvolvido com apoio da Universidade Federal do Norte do Tocantins por meio do programa PIBIC.

organização estrutural e funcional da polyLM, correlacionando propriedades geométricas com processos de sinalização celular, regeneração neural e aplicações em neuroengenharia.

A. Objetivos Específicos

- Descrever as principais características fractais da polyLM reportadas na literatura, incluindo propriedades de auto-similaridade e dimensão fractal.
- Analisar os métodos utilizados para caracterizar a complexidade geométrica da polyLM, com ênfase na estimativa da dimensão fractal por meio do método de *box-counting*.
- Comparar os valores de dimensão fractal da polyLM com padrões matemáticos e modelos físicos de crescimento, como a Agregação Limitada por Difusão (*Diffusion Limited Aggregation* – DLA).
- Investigar a relação entre a organização geométrica da polyLM e seus efeitos sobre processos de sinalização celular, diferenciação neuronal e regeneração neural descritos na literatura.
- Discutir limitações metodológicas das técnicas de caracterização fractal e apresentar perspectivas futuras para a aplicação de métricas geométricas no desenvolvimento de biomateriais voltados à neuroengenharia.

III. Fundamentação Teórica

A. Geometria Fractal

De acordo com Feldman [5], os fractais são estruturas geométricas complexas caracterizadas por propriedades como auto-similaridade, invariância de escala e dimensão não inteira. Diferentemente das formas descritas pela geometria euclidiana clássica, os fractais apresentam padrões que se repetem em diferentes escalas de observação, mantendo semelhanças estatísticas entre suas partes e o todo. Essa propriedade permite descrever sistemas naturais marcados por irregularidade, ramificação e elevada complexidade estrutural.

Segundo Barreiras [6], uma das principais características dos fractais é a presença de uma dimensão de Hausdorff não inteira, utilizada como métrica quantitativa da complexidade geométrica. Estruturas fractais podem apresentar dimensões intermediárias entre linhas e superfícies planas, permitindo descrever objetos biológicos que não podem ser representados adequadamente pela geometria convencional.

Conforme discutido por Oliveira [7], muitos fractais são gerados por processos iterativos capazes de produzir estruturas complexas a partir de regras simples de crescimento. Em sistemas biológicos, esses modelos auxiliam na compreensão de padrões de organização espacial e evolução morfológica observados em diferentes escalas, permitindo relacionar propriedades geométricas com características funcionais dos tecidos.

Entre os exemplos clássicos de fractais descritos na literatura, encontram-se a Curva de Koch [4], o Conjunto de Cantor [6] e o Triângulo de Sierpiński [7], frequentemente utilizados como modelos matemáticos para validação de métodos de cálculo de dimensão fractal, como o método de *box-counting*.

B. Dimensão de Hausdorff, Box-Counting e Agregação Limitada por Difusão

A dimensão fractal é uma métrica utilizada para caracterizar a complexidade geométrica e a capacidade de preenchimento espacial de estruturas irregulares. Entre as diferentes definições existentes, a dimensão de Hausdorff-Besicovitch (D_H) apresenta uma formulação matemática rigorosa para descrever conjuntos que possuem propriedades de auto-semelhança e dimensões não inteiras, permitindo a caracterização de estruturas cuja complexidade não pode ser representada adequadamente pelas dimensões euclidianas tradicionais [5], [6].

A dimensão de Hausdorff é definida a partir da medida de Hausdorff s-dimensional, baseada na construção de coberturas sucessivas de um conjunto por elementos de diâmetro menor ou igual a uma escala ϵ. O valor crítico de s, no qual a medida de Hausdorff sofre uma transição de infinito para zero quando $\epsilon \to 0$, corresponde à dimensão do conjunto analisado [5], [6]. Apesar de sua fundamentação matemática, o cálculo direto de D_H apresenta limitações computacionais para dados experimentais, pois envolve a avaliação de infinitas possibilidades de cobertura. Dessa forma, métodos aproximativos, como a dimensão de *box-counting*, são amplamente utilizados para estimar a dimensão fractal de imagens e estruturas biológicas discretizadas [2], [8].

A dimensão de *box-counting* (D_B), também denominada dimensão de capacidade ou dimensão de Minkowski-Bouligand, baseia-se na análise da ocupação espacial de um objeto em diferentes escalas. O método consiste na sobreposição de uma grade composta por caixas de tamanho r sobre a estrutura analisada, sendo $N(r)$ o número de caixas necessárias para cobrir o conjunto. A dimensão fractal é obtida pelo limite:

$$D_B(F) = \lim_{r \to 0^+} \frac{\ln N(r)}{\ln(1/r)} \tag{1}$$

Para aplicações em imagens digitais, a dimensão é estimada pela inclinação da reta obtida no gráfico log-log entre $\ln(N(r))$ e $\ln(1/r)$, utilizando regressão linear para determinar o coeficiente angular. O processamento das imagens normalmente envolve etapas de pré-tratamento, como equalização de histograma, segmentação binária e aplicação de diferentes escalas de grade para determinar a ocupação espacial da estrutura analisada [2], [8].

Embora a dimensão de Hausdorff seja a definição matemática mais geral, a dimensão de *box-counting* apresenta maior aplicabilidade computacional em sistemas reais. Para conjuntos matemáticos ideais, ambas podem apresentar valores equivalentes; entretanto, para estruturas gerais, observa-se a relação $D_H \leq D_B$, indicando que a dimensão de *box-counting* pode atuar como uma estimativa superior da dimensão fractal verdadeira [5]. Além disso, estruturas biológicas apresentam limitações associadas à resolução experimental e à ausência de detalhamento infinito, fazendo com que a análise fractal seja válida apenas dentro de determinados intervalos de escala [4].

Na caracterização da laminina polimerizada (*polyLM*), Hochman-Mendez *et al.* [2] utilizaram o método de *box-counting* para quantificar a organização fractal da matriz

supramolecular. O procedimento experimental envolveu a equalização das imagens microscópicas, binarização pelo método de Otsu e análise de múltiplos recortes para aumentar a estabilidade estatística da estimativa. Os resultados demonstraram que a *polyLM* apresenta dimensões fractais entre aproximadamente $1,55$ e $1,70$, enquanto a laminina não polimerizada apresentou comportamento compatível com estruturas de preenchimento bidimensional, com dimensão próxima a $2,0$ [2].

A organização fractal observada na *polyLM* pode ser interpretada por meio do modelo de Agregação Limitada por Difusão (*Diffusion-Limited Aggregation* – DLA). Esse modelo descreve processos nos quais partículas submetidas a movimentos aleatórios por difusão se agregam progressivamente a uma estrutura inicial, produzindo padrões ramificados e com propriedades fractais [4]. Devido à sua capacidade de gerar arquiteturas complexas a partir de regras simples, o DLA tem sido empregado para modelar processos de crescimento biológico, incluindo a formação de redes neurais e padrões de ramificação celular [4].

A proximidade entre a dimensão fractal característica do modelo DLA e os valores obtidos para a *polyLM* sugere que sua formação apresenta mecanismos de auto-organização compatíveis com esse modelo [2]. Essa arquitetura ramificada pode favorecer uma elevada relação superfície-volume e maior disponibilidade de regiões funcionais da matriz extracelular, contribuindo para processos de interação célula-matriz, crescimento de neuritos e regeneração neural [1], [3], [9].

C. Laminina Polimerizada: Estrutura Fractal e Função Biológica

A laminina polimerizada (*polylaminin* ou *polyLM*) constitui um modelo biológico de interesse para o estudo da organização da matriz extracelular e de sua influência sobre a regeneração neural. Segundo Hochman-Mendez et al. [2], sua formação ocorre em meio ácido, favorecendo a interação dos três braços curtos da molécula heterotrimérica da laminina e originando uma rede supramolecular altamente ramificada.

Diferentemente da laminina convencional, que tende a formar agregados mais compactos e contínuos, a polyLM apresenta uma arquitetura compatível com estruturas fractais, caracterizada por ramificações distribuídas em múltiplas escalas e elevada conectividade. Essas características aproximam sua organização dos modelos de Agregação Limitada por Difusão (*Diffusion Limited Aggregation* – DLA), discutidos na subseção anterior [2], [9].

Além dos aspectos estruturais, a organização da polyLM exerce influência sobre processos celulares. Mesquita et al. [7] demonstram que essa arquitetura favorece a exposição dos domínios de ligação da laminina, intensificando a interação com receptores celulares, como integrinas e distroglicanas. Como consequência, observa-se maior eficiência em processos de adesão celular, crescimento de neuritos e regeneração neural.

Assim, a polyLM representa um modelo biológico que evidencia a relação entre organização estrutural e função celular. Sua arquitetura ramificada fornece um contexto adequado para investigar como propriedades geométricas da matriz extracelular podem influenciar mecanismos de sinalização e regeneração neural, servindo de base para a análise quantitativa apresentada nas seções seguintes.

D. Da Estrutura Fractal à Função Neurobiológica

Segundo Bianchi [4], a caracterização matemática de sistemas biológicos complexos permite descrever padrões de crescimento, organização espacial e conectividade por meio de modelos fundamentados na geometria fractal e na teoria dos sistemas complexos. Essas abordagens são particularmente relevantes em processos neurobiológicos, nos quais estrutura e função estão intimamente relacionadas em diferentes escalas espaciais.

Conforme discutido por López et al. [10], estruturas com organização fractal apresentam elevada eficiência na distribuição espacial de recursos, na conectividade e na propagação de sinais. A auto-semelhança observada nesses sistemas possibilita a formação de redes altamente conectadas com menor custo estrutural, característica frequentemente encontrada em diferentes sistemas biológicos.

Nesse contexto, a caracterização matemática da polyLM por meio da dimensão fractal fornece uma ferramenta para quantificar sua organização espacial e relacioná-la ao comportamento biológico observado experimentalmente. A proximidade entre a dimensão fractal da polyLM e aquela prevista por modelos de Agregação Limitada por Difusão (*Diffusion Limited Aggregation* – DLA) sugere que mecanismos físicos de auto-organização podem contribuir para a formação dessa arquitetura supramolecular [2], [9]. Essa interpretação estabelece uma ponte entre os modelos matemáticos apresentados anteriormente e a organização estrutural da matriz extracelular.

Sob essa perspectiva, a geometria fractal deixa de representar apenas uma característica morfológica e passa a constituir um parâmetro quantitativo para investigar a relação entre estrutura e função em sistemas biológicos. A integração entre modelos matemáticos e evidências experimentais amplia a compreensão de como propriedades geométricas da matriz extracelular podem influenciar processos de adesão celular, organização espacial de sinais bioquímicos e regeneração neural, reforçando o potencial da análise fractal como ferramenta de investigação em neuroengenharia.

IV. Metodologia

A presente pesquisa caracteriza-se como um estudo qualitativo, de natureza exploratória e fundamentação teórica, desenvolvido por meio de revisão bibliográfica e análise comparativa de modelos matemáticos e biológicos relacionados à geometria fractal, à laminina polimerizada (*polyLM*) e às suas implicações na sinalização celular, regeneração neural e neuroengenharia.

A metodologia adotada foi estruturada a partir da leitura, seleção e análise de artigos científicos, dissertações, teses e livros especializados relacionados à dinâmica de crescimento da polyLM, aos métodos de quantificação fractal e

às aplicações neurobiológicas associadas à organização da matriz extracelular. Entre os principais referenciais utilizados destacam-se os trabalhos de Hochman-Mendez et al. [2], [9], Siqueira-Santos et al. [3], Bianchi [4] e Feldman [5].

Segundo Hochman-Mendez, M. et al. [2], a caracterização da natureza fractal da polyLM foi realizada por meio da estimativa da dimensão de Hausdorff utilizando o método de *box-counting*. Conforme descrito pelos autores, o procedimento inicia-se com o pré-processamento digital das imagens de microscopia, incluindo equalização de histograma e binarização pelo método de Otsu, com o objetivo de isolar a estrutura proteica do fundo da imagem.

Após essa etapa, uma grade de caixas quadradas de tamanho variável é sobreposta à imagem binarizada, contabilizando-se o número de caixas que interceptam qualquer parte da estrutura analisada. O cálculo da dimensão fractal é então obtido pela relação logarítmica entre o tamanho da grade e o número de caixas ocupadas, conforme descrito na literatura pelo método de *box-counting*. De acordo com os trabalhos analisados, esse procedimento permite quantificar matematicamente a complexidade estrutural da laminina polimerizada e acompanhar sua evolução temporal.

Os estudos revisados também descrevem que a evolução da dimensão fractal da polyLM ocorre progressivamente ao longo do tempo de adsorção, apresentando valores aproximados de 1,55 após 1 hora, 1,62 após 8 horas e 1,70 após 12 horas [2]. Esses resultados foram utilizados neste trabalho como referência comparativa para a análise dos padrões de crescimento fractal descritos na literatura.

Além da caracterização geométrica da polyLM, foram analisados estudos que investigam as relações entre a organização fractal da matriz extracelular e processos neurobiológicos, incluindo adesão celular, crescimento de neuritos, formação de nichos neurogênicos e regeneração neural. Também foram revisados trabalhos relacionados à aplicação de substratos biomiméticos funcionalizados com laminina em processos regenerativos do nervo ciático, especialmente aqueles que avaliam a influência da topologia de filamentos de policaprolactona (PCL) funcionalizados na orientação axonal e recuperação funcional *in vivo* [3].

Apesar de sua ampla utilização na literatura para estimativa da dimensão fractal, o método de *box-counting* apresenta limitações que devem ser consideradas na interpretação dos resultados. A estimativa da dimensão fractal depende diretamente das etapas de segmentação e binarização da imagem, sendo sensível à escolha de limiares, à qualidade do contraste e aos procedimentos de pré-processamento empregados [4], [8], [11]. Técnicas como equalização de histograma, suavização de ruído e correção de artefatos podem modificar a distribuição espacial dos pixels e influenciar os valores obtidos para a dimensão fractal.

Além disso, a precisão do método está relacionada à resolução da imagem e à faixa de escalas analisada. Diferentemente dos fractais matemáticos ideais, estruturas biológicas apresentam tamanho finito e apenas regiões limitadas de comportamento fractal, o que pode restringir a validade das estimativas obtidas [4], [5]. Outro aspecto relevante refere-se à sensibilidade do ajuste linear utilizado no gráfico log-log do algoritmo, uma vez que pequenas variações na distribuição dos dados podem produzir diferenças significativas na inclinação estimada e, consequentemente, na dimensão fractal calculada.

Dessa forma, os valores de dimensão fractal reportados para a polyLM devem ser interpretados como estimativas dependentes das condições experimentais, da qualidade das imagens analisadas e dos procedimentos computacionais empregados, não constituindo uma medida absoluta da complexidade geométrica da estrutura.

Também foram revisadas abordagens complementares utilizadas na caracterização de estruturas biológicas complexas, incluindo análise multifractal, lacunaridade, análise de textura, esqueletização (*skeletonization*), análise de redes e grafos e métodos de estimação fractal multiescala. Embora essas técnicas não tenham sido aplicadas diretamente neste estudo, sua discussão permitiu identificar potenciais descritores capazes de fornecer informações adicionais sobre a organização espacial da matriz extracelular, complementando as limitações associadas ao uso exclusivo da dimensão fractal.

A análise dos materiais selecionados foi conduzida de forma interpretativa e comparativa, buscando correlacionar propriedades geométricas fractais da polyLM com aspectos funcionais relacionados à sinalização celular, à organização de nichos neurogênicos e à regeneração neural. Dessa forma, a metodologia adotada permitiu integrar evidências provenientes da matemática, da biologia e da engenharia biomédica para compreender como a geometria da matriz extracelular pode influenciar processos neurobiológicos.

V. Resultados e Discussões

Os resultados apresentados nesta seção foram organizados a partir das análises e interpretações descritas nos trabalhos de Menezes et al. [1], Hochman-Mendez et al. [2], [9], Siqueira-Santos et al. [3] e demais autores utilizados como fundamentação teórica desta pesquisa.

A. Padrões Fractais e Comparações Matemáticas

Os estudos analisados demonstram que a laminina polimerizada (polyLM) apresenta uma organização geométrica compatível com sistemas fractais físicos. Segundo Hochman-Mendez, M. et al. [2], ela mantém padrões morfológicos semelhantes mesmo sob ampliações de diferentes ordens de magnitude, evidenciando propriedades de auto-similaridade estrutural.

Para validar a natureza fractal da polyLM e comparar o método de cálculo da dimensão fractal por estimativa de Hausdorff, os autores utilizaram padrões matemáticos clássicos reconhecidos na literatura. Entre eles, destacam-se o Conjunto de Cantor, com dimensão aproximada de 0,6309, a Curva de Koch, com dimensão aproximada de 1,2619, e o Triângulo de Sierpiński, cuja dimensão fractal é próxima de 1,585 [5], [6].

Esses modelos servem como referências matemáticas para validação do algoritmo de *box-counting*, permitindo comparar a complexidade estrutural da polyLM com sistemas fractais

teóricos. Além disso, o fractal quádrico, com valores próximos de 1,50 e 1,67 dependendo da iteração, apresenta comportamento geométrico semelhante ao observado nas fases iniciais da polimerização da polyLM.

Os trabalhos de Hochman-Mendez, M. et al. [2] demonstram que a polyLM apresenta dimensão fractal variando entre 1,55 e 1,70, enquanto a laminina comum (LM), preparada em pH neutro, apresenta dimensão próxima de 2,0. Esses resultados evidenciam diferenças quantitativas entre as duas organizações estruturais e reforçam o potencial da dimensão fractal como parâmetro de caracterização da matriz extracelular.

A Fig. 1 evidencia diferenças marcantes entre a organização da laminina convencional e da polyLM. Enquanto a LM apresenta deposição mais compacta e contínua, a polyLM forma redes ramificadas e lacunadas distribuídas em múltiplas escalas, em concordância com os valores de dimensão fractal observados.

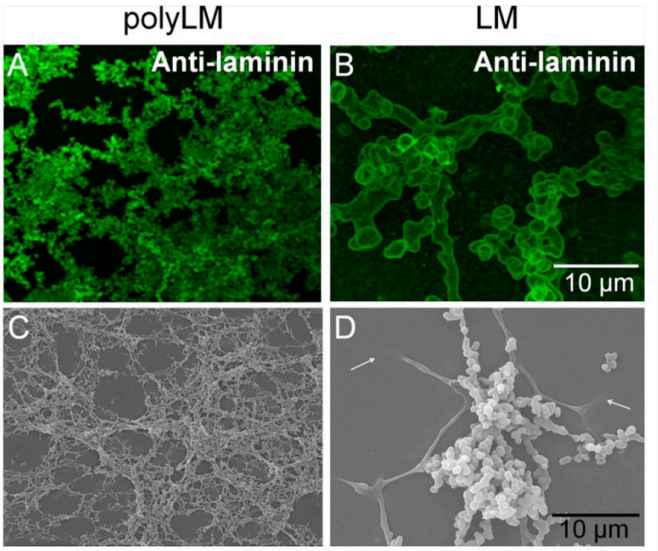

Figura 1. Estrutura tridimensional dos polímeros de laminina observada por microscopia confocal de fluorescência e microscopia eletrônica de varredura. A laminina foi incubada sobre lamínulas de vidro por 12 horas em meio ácido (polyLM) ou em tampão neutro (LM). (A, B) A imunofluorescência indireta foi realizada utilizando anticorpo policlonal anti-laminina. As imagens representam empilhamentos-z obtidos pela superposição de 74 cortes confocais renderizados pelo software 7.2.3. (C, D) Micrografias obtidas por microscopia eletrônica de varredura (MEV) dos polímeros em ampliação semelhante. As setas em D indicam depósitos lamelares de laminina. As barras de escala aplicam-se aos painéis A–D e representam 10 μm. Adaptado de Hochman-Mendez, M. et al. [2], sob licença Creative Commons CC BY.

Os resultados também indicam que a dimensão fractal da polyLM se aproxima daquela prevista pelos modelos de Agregação Limitada por Difusão (*Diffusion Limited Aggregation* – DLA), cujo valor típico é próximo de 1,7 [5], [9]. Essa proximidade reforça a hipótese de que mecanismos de auto-organização descritos por esse modelo físico contribuem para a formação da arquitetura supramolecular observada experimentalmente.

Além dos padrões matemáticos, os autores relacionam a organização da polyLM com estruturas biológicas naturais conhecidas como “fractones”, presentes em nichos neurogênicos do sistema nervoso central [1]. Essas estruturas apresentam organização espacial complexa responsável pela distribuição de fatores de crescimento e pela regulação da diferenciação celular.

Em conjunto, os resultados revisados demonstram que a geometria da polyLM é compatível com modelos matemáticos clássicos de crescimento fractal. A concordância entre as estimativas obtidas por *box-counting*, as referências fractais teóricas e o modelo DLA reforça a utilização da dimensão fractal como ferramenta para caracterização quantitativa de sistemas biológicos complexos.

B. Cinética de Crescimento e Evolução da Complexidade Fractal

Os trabalhos analisados demonstram que a cinética de crescimento da polyLM está diretamente relacionada à evolução de sua complexidade geométrica ao longo do processo de adsorção [2], [9].

A polyLM apresenta cinética de adsorção linear e organizada, atingindo aproximadamente 45% de adsorção após 20 minutos e cerca de 90% após 12 horas. Em contraste, a laminina convencional apresenta deposição rápida e heterogênea, ultrapassando 60% de adsorção nos primeiros 20 minutos e estabilizando em aproximadamente 80% após 12 horas [2].

A evolução da organização estrutural é acompanhada pelo aumento da dimensão fractal da polyLM. Após 1 hora de adsorção, a estrutura apresenta dimensão aproximada de 1,55; após 8 horas, esse valor aumenta para 1,62; e, após 12 horas, alcança aproximadamente 1,70 [2]. Esses resultados indicam que o crescimento da rede ocorre de forma progressiva, com aumento da complexidade espacial ao longo do tempo.

Os autores também descrevem que a formação inicial da polyLM ocorre a partir de estruturas poligonais planas, frequentemente hexagonais, com dimensões próximas de 30 nm. Essas unidades básicas propagam-se em escalas maiores preservando a conectividade estrutural, comportamento compatível com mecanismos de auto-organização descritos pelos modelos de Agregação Limitada por Difusão (*Diffusion Limited Aggregation* – DLA) [9].

A Fig. 2 apresenta o procedimento experimental empregado para estimar a dimensão fractal da polyLM por meio do método de *box-counting*. O processamento digital das imagens permitiu acompanhar a evolução da organização da rede proteica e quantificar o aumento da complexidade estrutural durante o processo de adsorção.

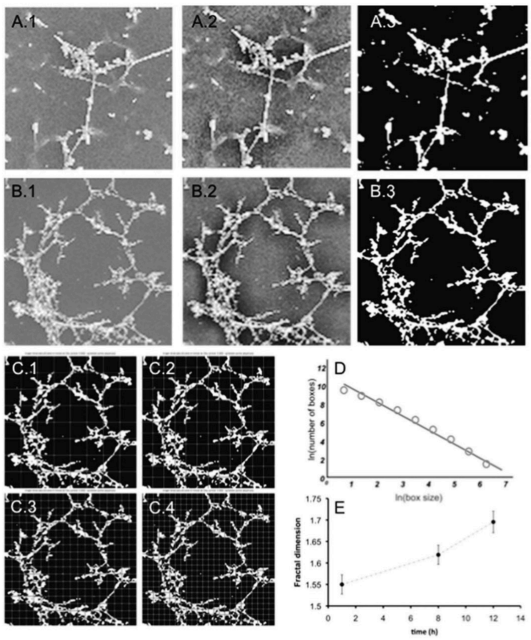

Figura 2. Cálculo da dimensão fractal (estimativa de Hausdorff). (A, B) O processamento das imagens foi realizado para preparar as imagens para o algoritmo de *box-counting* aplicado à LM (A) e à polyLM (B). 1, imagem original; 2, imagem original com histograma equalizado; 3, imagem binarizada utilizando o método de Otsu. (C) A partir das imagens A.3 e B.3, as estimativas da dimensão de Hausdorff podem ser calculadas por meio da sobreposição de uma grade de tamanho variável. (D) Repetindo o processo para diferentes tamanhos de grade e calculando o número de células que contêm qualquer parte da estrutura analisada, obtém-se a dimensão fractal. (E) Evolução temporal da dimensão fractal da polyLM ao longo do processo de adsorção. Adaptado de Hochman-Mendez, M. et al. [2], sob licença Creative Commons CC BY.

C. Proposta de Integração Conceitual

A análise conjunta dos trabalhos revisados permite propor um modelo conceitual que relaciona a geometria fractal da polyLM às suas propriedades estruturais e funcionais. Os resultados indicam que o aumento da dimensão fractal está associado à formação de redes progressivamente mais complexas e conectadas, refletindo um processo de auto-organização da matriz extracelular.

Nesse contexto, a dimensão fractal pode ser interpretada como um descritor quantitativo da organização espacial da polyLM, permitindo correlacionar propriedades geométricas com características estruturais observadas experimentalmente. A concordância entre os valores obtidos por *box-counting*, os modelos fractais clássicos e a aproximação com o modelo de Agregação Limitada por Difusão (*Diffusion Limited Aggregation* – DLA) reforça a consistência dessa abordagem para a caracterização da matriz extracelular.

A integração entre geometria fractal, crescimento não linear e organização estrutural fornece uma perspectiva capaz de conectar modelos matemáticos às evidências experimentais apresentadas nos estudos revisados. Sob essa perspectiva, a análise fractal constitui uma ferramenta quantitativa para investigar a arquitetura da matriz extracelular e sua evolução durante o processo de polimerização.

Embora os estudos revisados indiquem uma associação entre o aumento da complexidade geométrica e propriedades funcionais da matriz extracelular, as evidências disponíveis ainda não permitem estabelecer uma relação causal direta entre dimensão fractal e eficiência da sinalização celular. Assim, o modelo conceitual proposto deve ser interpretado como uma hipótese integradora, cuja validação depende de investigações experimentais e computacionais futuras.

D. Implicações Funcionais da Geometria Fractal da polyLM

Do ponto de vista funcional, a organização fractal da polyLM influencia diretamente os processos de sinalização celular e regeneração neural.

Os estudos analisados indicam que a geometria em rede favorece a exposição do braço longo da LM, região onde se localizam domínios responsáveis pela interação com integrinas e receptores celulares, como a distroglicana [9]. Essa disposição espacial facilita processos de adesão celular, diferenciação neuronal e crescimento de neuritos.

Segundo Menezes et al. [1], estruturas semelhantes à polyLM participam da organização de nichos neurogênicos no sistema nervoso central, contribuindo para a distribuição de fatores de crescimento e para a regulação do microambiente celular.

Além disso, os resultados apresentados por Siqueira-Santos et al. [3] demonstram que filamentos de policaprolactona funcionalizados com LM favorecem a regeneração do nervo ciático, influenciando diretamente parâmetros de densidade axonal, reinervação muscular e recuperação motora *in vivo*.

Os autores observaram que filamentos revestidos com LM comum apresentaram maior densidade de ramificações axonais e maior número de placas motoras marcadas com α-bungarotoxina, enquanto a polyLM promoveu crescimento mais linear dos neuritos. Esses resultados sugerem que diferentes geometrias da matriz extracelular podem ativar vias distintas de sinalização neurobiológica.

Nesse contexto, a geometria fractal da polyLM pode ser interpretada não apenas como uma propriedade estrutural, mas também como um possível elemento funcional associado à sinalização celular e à regeneração neural. Os estudos analisados sugerem que a organização fractal da matriz extracelular influencia a exposição de sítios de ligação celular, a distribuição espacial de sinais biológicos e a interação com receptores de membrana. Sob essa perspectiva, descritores geométricos como dimensão fractal, lacunaridade e conectividade podem contribuir para o desenvolvimento de biomateriais biomiméticos capazes de reproduzir características estruturais observadas em ambientes neurobiológicos naturais.

E. Limitações do Método de Box-Counting e Perspectivas Analíticas

Embora o método de *box-counting* seja amplamente utilizado para estimar a dimensão fractal de estruturas biológicas, sua aplicação apresenta limitações importantes que devem ser consideradas na interpretação dos resultados. Conforme discutido por Bianchi [4] e Silva [11], a estimativa da dimensão

fractal depende fortemente das etapas de pré-processamento da imagem, incluindo equalização de histograma, remoção de ruídos, correções de contraste e procedimentos de binarização.

A escolha do limiar de segmentação constitui uma das principais fontes de variabilidade do método. Mesmo quando técnicas automáticas, como o método de Otsu, são empregadas, pequenas alterações na separação entre objeto e fundo podem modificar significativamente o valor estimado da dimensão fractal. Em sistemas biológicos complexos, nos quais frequentemente existem regiões com baixo contraste ou fronteiras difusas, essa dependência torna-se particularmente relevante [4].

Outra limitação importante está relacionada à resolução espacial das imagens analisadas. Diferentemente dos fractais matemáticos ideais, que apresentam auto-similaridade em infinitas escalas, estruturas biológicas possuem limites físicos de observação. Dessa forma, a validade da dimensão fractal depende da existência de uma faixa adequada de escalas na qual a relação logarítmica utilizada pelo método permaneça aproximadamente linear [4], [7].

Além disso, procedimentos de pré-processamento utilizados em técnicas de microscopia, como suavizações gaussianas, correções geométricas e filtros de realce, podem alterar a distribuição espacial dos pixels e influenciar diretamente os valores obtidos para a dimensão fractal [11]. Consequentemente, a dimensão calculada deve ser interpretada como uma estimativa dependente das condições experimentais e computacionais empregadas.

Diante dessas limitações, abordagens complementares têm sido propostas para fornecer descritores mais abrangentes da complexidade geométrica de sistemas biológicos. Entre elas destacam-se a análise multifractal, a lacunaridade, a análise de textura, a esqueletização multiescala (*skeletonization*), a modelagem por redes e grafos e os métodos de estimação fractal multiescala [4].

A análise multifractal permite caracterizar heterogeneidades locais da estrutura por meio de múltiplos expoentes de escala, fornecendo informações que não podem ser capturadas por uma única dimensão fractal. Já a lacunaridade quantifica a distribuição dos espaços vazios da rede, possibilitando avaliar aspectos relacionados à conectividade e permeabilidade da matriz extracelular.

Por sua vez, técnicas de esqueletização permitem representar a estrutura como uma rede topológica simplificada, preservando sua conectividade e possibilitando a extração de parâmetros como comprimento de ramos, ângulos de bifurcação e organização hierárquica. A partir dessas representações, métodos baseados em grafos podem ser utilizados para investigar propriedades associadas à conectividade estrutural e à propagação de sinais biológicos [4].

Outra possibilidade consiste na utilização de métodos de dimensão fractal multiescala, nos quais a complexidade é analisada em diferentes intervalos de escala. Esses métodos permitem identificar regiões de maior fractalidade e avaliar a estabilidade do comportamento fractal ao longo da estrutura, reduzindo parte da sensibilidade observada nos algoritmos convencionais de *box-counting* [4].

No contexto da polyLM, essas abordagens podem fornecer descritores mais completos da organização da matriz extracelular, permitindo correlacionar propriedades geométricas com processos funcionais como adesão celular, orientação axonal, distribuição de fatores de crescimento e eficiência de sinalização neurobiológica. Dessa forma, a integração entre métricas fractais avançadas e modelos de sistemas dinâmicos constitui uma perspectiva promissora para investigações futuras em neuroengenharia e medicina regenerativa.

F. Lições Aprendidas, Lacunas de Pesquisa e Perspectivas Futuras

A análise da literatura permitiu identificar importantes contribuições para a compreensão da geometria fractal da polyLM e de suas implicações na organização de sistemas neurobiológicos. Os trabalhos revisados demonstram de forma consistente que ela apresenta propriedades de auto-similaridade e dimensões fractais compatíveis com modelos de crescimento auto-organizado, particularmente aqueles associados à Agregação Limitada por Difusão (*Diffusion Limited Aggregation* – DLA). Além disso, observou-se que o aumento progressivo da dimensão fractal ao longo do tempo de adsorção está associado à formação de redes cada vez mais complexas, sugerindo uma relação entre organização geométrica e potencial funcional da matriz extracelular [2], [9].

Outra lição importante refere-se ao papel biológico da sua geometria. Os estudos analisados indicam que a arquitetura fractal favorece a exposição de domínios de interação celular, contribuindo para processos de adesão, diferenciação neuronal, orientação axonal e regeneração tecidual. Dessa forma, a dimensão fractal não deve ser interpretada apenas como um parâmetro geométrico, mas como um possível indicador estrutural associado à eficiência de sinalização celular e à organização funcional de nichos neurogênicos [1], [3], [12].

Apesar dos avanços observados, diversas limitações metodológicas e conceituais permanecem em aberto. Uma das principais refere-se à dependência da análise fractal em relação à qualidade das imagens utilizadas. A resolução espacial limitada dos sistemas de aquisição de imagem restringe a faixa de escalas na qual o comportamento fractal pode ser investigado. Os próprios trabalhos pioneiros sobre a polyLM relatam dificuldades históricas relacionadas à ausência de imagens em magnificações intermediárias e às limitações técnicas de microscopia para observação de estruturas em escalas nanométricas [2].

Outra limitação importante está associada ao método de *box-counting*. Embora amplamente utilizado devido à sua simplicidade computacional, esse método fornece apenas uma estimativa da dimensão de Hausdorff e apresenta elevada sensibilidade às etapas de pré-processamento, segmentação e escolha de limiares. Além disso, a determinação da dimensão fractal depende da seleção da faixa de escalas utilizada na re-

gressão log-log, o que pode introduzir variabilidade estatística nos resultados obtidos [4], [7], [11].

Também foi identificada uma lacuna significativa relacionada à caracterização geométrica da matriz extracelular. A maior parte dos estudos concentra-se na utilização de uma única dimensão fractal como descritor da estrutura. Entretanto, propriedades relevantes da organização espacial, como distribuição de lacunas, heterogeneidade local, conectividade e hierarquia estrutural, permanecem pouco exploradas no contexto da polyLM.

Nesse sentido, abordagens modernas de análise geométrica representam oportunidades promissoras para pesquisas futuras. Técnicas como análise multifractal, lacunaridade, análise de textura, esqueletização multiescala (*skeletonization*), modelagem por grafos e métodos de dimensão fractal multiescala podem fornecer descritores mais completos da matriz extracelular. Essas ferramentas permitem investigar não apenas o grau de complexidade geométrica, mas também aspectos relacionados à conectividade estrutural, distribuição espacial de vazios, organização hierárquica e robustez da rede biológica [4], [11].

No contexto da neurociência, essas abordagens apresentam potencial para estabelecer relações quantitativas entre geometria e função biológica. A integração entre métricas fractais avançadas e modelos de sistemas dinâmicos pode contribuir para compreender como propriedades estruturais da matriz extracelular influenciam processos de sinalização celular, crescimento neural, plasticidade e regeneração do tecido nervoso.

Como perspectiva futura, propõe-se a ampliação desta investigação por meio da implementação computacional de métodos avançados de caracterização fractal e da construção de modelos matemáticos capazes de correlacionar parâmetros geométricos da polyLM com indicadores funcionais de atividade celular. Essa abordagem poderá contribuir para o desenvolvimento de novos biomateriais inspirados em arquiteturas fractais e para o avanço das aplicações da neuroengenharia e da medicina regenerativa.

VI. Considerações Finais

O presente estudo evidenciou que a laminina polimerizada (*polyLM*) apresenta uma organização estrutural complexa e não aleatória, compatível com propriedades fractais, incluindo auto-semelhança e dimensão não inteira. Durante seu processo de formação, a evolução da arquitetura da rede, marcada pelo aumento da complexidade ao longo do tempo de adsorção, apresentou parâmetros compatíveis com o modelo clássico de Agregação Limitada por Difusão (DLA), sugerindo a existência de mecanismos de auto-organização física associados à formação da estrutura supramolecular.

Essa caracterização geométrica apresenta implicações relevantes para a neurobiologia e para a engenharia de tecidos. A arquitetura ramificada e lacunar da *polyLM* é consistente com uma organização capaz de favorecer a disponibilidade de domínios bioativos, influenciando processos como adesão celular, neuritogênese e regeneração tecidual. Além disso, os resultados indicam que diferentes organizações supramoleculares da laminina podem desempenhar papéis distintos durante a regeneração neural, reforçando que a geometria da matriz extracelular atua não apenas como uma característica morfológica, mas como um elemento regulador da interação célula-matriz.

A consolidação dessa relação entre estrutura e função depende, entretanto, da superação das limitações técnicas associadas às metodologias convencionais de análise fractal, como a dependência de contraste, sensibilidade à escala e restrições do método de *box-counting*. Como perspectivas futuras, destaca-se a integração de simulações computacionais e métricas geométricas complementares, incluindo multifractalidade, lacunaridade, esqueletização multiescala e análise de redes, visando estabelecer correlações quantitativas entre os descritores matemáticos da matriz extracelular e o desempenho funcional de novos biomateriais aplicados à neuroengenharia.

***Abstract*—The development of pediatric anthropomorphic phantoms faces limitations regarding high costs and the scarcity of customized devices on the market. This study characterizes three 3D printing filaments (Hyper PLA, PLA Stone, and TPU Silk) as affordable alternatives for simulating biological tissues for computed tomography (CT). Cubic samples with infill densities ranging up to 100% were printed for each material and scanned across multiple tube voltages (90, 120, and 140 kV). Linear regression showed a relationship between infill density and Hounsfield Units (HU), yielding(R^2) greater than 0.93. The PLA Stone filament demonstrated higher radiological density, proving suitable for simulating bone structures, while Hyper PLA and TPU Silk showed equivalence to soft tissues. The stability of HU values against voltage variation suggests that the radiological attenuation of these materials is predominantly dependent on physical density. The results validate the efficacy of these materials in the manufacture of customized phantoms, offering a solution for quality control and radiological protection in pediatrics.**

***Index Terms*—3D printing, computed tomography, 3D filaments, pediatric phantoms**

I. Introduction

Recent advancements in software design and 3D printing techniques have propelled the manufacturing of anthropomorphic phantoms, expanding their utility across the medical imaging field. Compared to high-cost and rigid commercial alternatives, 3D-printed phantoms manufactured via fused deposition modeling (FDM) stand out for their affordability, accessibility, and rapid prototyping capabilities. This technology enables the fabrication of customized medical simulators with complex geometries at significantly reduced costs. Within this approach, printed thermoplastic materials are combined to achieve tissue-mimicking structures with equivalent radiological properties [1]–[3].

Phantoms are used in computed tomography (CT) to evaluate dose and image quality, PMMA phantoms analyze dosimetric parameters such as CTDIvol and DLP, while quality assurance phantoms verify uniformity, noise, and CT number accuracy [4]. However, these devices present limitations regarding anatomical representation and adequate differentiation between tissues, particularly in simulating bone structures at different ages [3].

The evolution of diagnostic imaging technologies, particularly in CT, demands continuous advancements in quality assurance and radiological protection. In the pediatric context, this need is amplified by growth and changes in bone density. From a dosimetric perspective, these tissue-equivalent structures enable the precise and safe simulation of radiation dose deposition and spatial distribution within the human anatomy, allowing for realistic analyses without exposing patients to ionizing radiation [5]–[7]. This customization is particularly vital for pediatric applications. Standard adult phantoms fail to accurately represent the unique density, size, and elemental composition of children's tissues as recommended by the ICRU Report 44 [8], [9]. Practical studies reinforce the technical feasibility of constructing complex and detailed physical phantoms using CT images from real patients, thereby overcoming cost limitations and the simplified geometries of commercial models. Furthermore, The age ranges found in the literature cover phantoms for ages 1, 5, 10, and 15 years to represent the diversity of the pediatric population [9], [10].

Given these limitations, it is necessary to develop alternative materials capable of accurately simulating the Hounsfield

Fundação Araucária de Apoio ao Desenvolvimento Científico e Tecnológico do Estado do Paraná financial support/fellowship (Protocols No. SUS2025831000030)

Unit (HU) range of biological tissues, thereby enabling the fabrication of more realistic 3D-printed phantoms.

Polylactic acid (PLA) is widely utilized in medical simulators due to its printing versatility, cost-effectiveness, low toxicity, and biodegradable nature [11]. Furthermore, PLA exhibits attenuation properties similar to those of soft tissues. Previous studies indicate that employing a rectilinear infill pattern with a density between 80% and 100% yields high radiological equivalence to adult and pediatric thoracic and abdominal tissues. Among the variations of this polymer, Hyper PLA stands out as a variant that maintains the chemical composition of classic PLA but is optimized to withstand high extrusion flow rates while exhibiting higher tensile strength than acrylonitrile butadiene styrene (ABS). This characteristic allows the material to reach printing speeds of up to 600 mm/s without compromising the structural integrity or dimensional accuracy of the parts, making it ideal for producing large-scale phantoms that require high mechanical strength [10].

The technique of incorporating additives into PLA is widely recognized in the literature as an effective method for developing composite filaments. A notable example is StoneFil, manufactured by FormFutura, which is used in 3D-printed phantoms to accurately simulate the radiological properties of human bone structures [1], [11]. In the Brazilian context, the addition of mineral filler powder from other brands is commercially available, featuring a composition starting from 35% stone powder.

Thermoplastic polyurethane (TPU) stands out in 3D printing for providing physical properties such as high elasticity, strength, and durability. However, its malleable nature demands greater technical complexity in equipment setup, requiring meticulous adjustments to printing parameters to ensure the final quality of the part [11], [12].

Although previous studies have characterized conventional polymers for use in anthropomorphic phantoms, the specific and comparative characterization of high-performance filaments such as Hyper PLA, PLA Stone, and TPU Silk for simulating pediatric tissues is currently lacking [12]. In this research, the experimental and quantitative characterization of 3D printing materials was performed to evaluate their radiological properties under clinical CT scanning conditions, aiming at the development of realistic human mimicking tissues for quality assurance anthropomorphic phantoms in diagnostic imaging examinations and the radiological protection of pediatric patients.

II. Materials and Methods

A. Materials

To characterize which biological tissues can be simulated through 3D printing, three materials were tested: Hyper PLA (Creality), PLA Stone (Voolt3D), a composite filled with stone powder, and thermoplastic polyurethane (TPU Silk). These filaments were selected to encompass a broad range of radiological attenuation, spanning from soft tissues to high-density bone structures. PLA and TPU are commercially prevalent materials across multiple brands. However, PLA Stone requires targeted selection to verify the presence of stone powder in the filament blend.

B. 3D printing

The samples were produced with infill densities between 10% and 100% using a Creality K2 PLUS printer, configured with a 0.4 mm nozzle, 0.35 mm line width, and 0.08 mm layer height (Fig. 1). The objective of this controlled variation was to enable the rigorous adjustment of Hounsfield Units (HU) for mimicking various biological tissues.

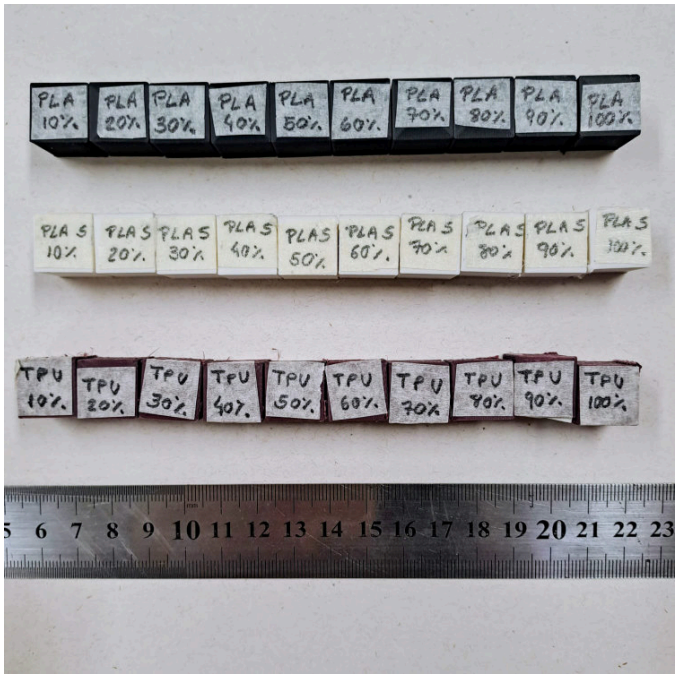

Fig. 1. Fabricated samples with Hyper PLA, PLA Stone, and TPU Silk.

The choice of the rectilinear pattern is based on published studies [13], [14], which claim that this pattern ensures better image quality and greater fidelity to real tissues compared to other infill patterns. For manufacturing solid structures, this rectilinear infill provides a more homogeneous laydown between layers, preventing the formation of interlayer voids.

The physical density of each sample was determined from the average of two weighings and the measurement of the faces of the cubes using a digital caliper, aiming for future comparison with ICRU 44 data at the density level of each material to develop tissue-equivalent density properties.

The printing parameters, including temperature and speed, were set according to the recommendations of each filament manufacturer, using Creality parameters for Hyper PLA and manufacturer specifications for TPU, for PLA Stone, nozzle temperature was adjusted based on prior temperature tower calibrations, and outer wall speed was set to 60 mm/s before infill deposition, as listed in Table I. To accommodate the stone powder composite in the PLA matrix, which demands lower processing speeds than standard PLA, the printing speed was manually reduced by 50% on the printer itself to ensure optimal infill.

TABLE I
SUMMARY OF PRINTING PARAMETERS FOR TESTED FILAMENTS

Parameter	Hyper PLA	PLA Stone	TPU Silk
Nozzle Temp. (°C)	220	215	230
Bed Temp. (°C)	50	65	60
First Layer Speed (mm/s)	60	50	60
Inner Wall Speed (mm/s)	120	70	100

C. Radiological Characterization

The cubes were subjected to computed tomography scans Philips MX 16-Slice for radiological characterization, using tube voltage variations of 90 kV, 120 kV, and 140 kV, combined with tube currents of 18 mAs, 60 mAs, 100 mAs, and 150 mAs, covering the typical clinical range for pediatric and adult CT protocols found in the literature. The selection of 120 kV and 140 kV is widely used in the literature for phantom testing and characterizing simulator materials, while 90 kV is suitable for pediatric protocols, where values between 70 kV and 90 kV are recommended. [15], [16].

Images were acquired with a slice thickness of 0.75 mm, applying mediastinum and bone filters for the subsequent analysis of the CT number (Hounsfield Units). Hounsfield Units (HU) value is calculated using [17]:

$$HU = 1000 \times \frac{\mu_{\text{material}} - \mu_{\text{water}}}{\mu_{\text{water}} - \mu_{\text{air}}} \tag{1}$$

where μ represents the linear attenuation coefficient of the tissue, μ_{water} is the coefficient of water, and μ_{air} is the coefficient of air. This scale allows a direct correlation between pixel values in the image and the physical density of the simulated tissues. Following the acquisition of the DICOM tomographic images, processing and volumetric analysis were performed using the open-source software 3D Slicer. For each printed sample, a centralized volumetric region of interest (ROI) of approximately 0.180 cm³ with a voxel count of 1009 was established using the Sphere Brush tool, avoiding the edges and sides in the axial, sagittal, and coronal planes to encompass a homogeneous volume of the cubes (Fig 2).

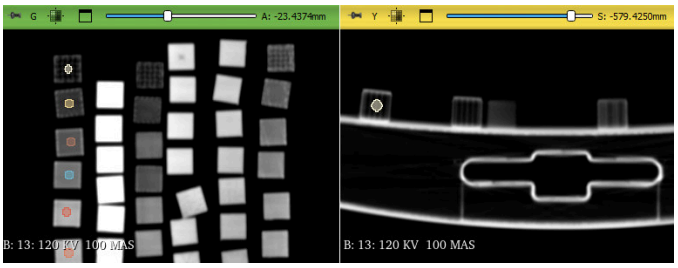

Fig. 2. 3D Slicer interface showing volumetric sample ROIs defined via the Sphere Brush tool in the coronal (left) and axial (right) views.

When defining a region of interest using tools such as the sphere, brush, or ROI, 3D Slicer calculates the simple arithmetic mean of the HU values across all voxels within that segment via modules like Segment Statistics, rather than performing voxel-by-voxel smoothing. For visualization and resampling along oblique planes where sampling coordinates do not align with a voxel's geometric center, Slicer applies default trilinear interpolation, computing a weighted average of neighboring voxel intensities to represent that specific point. Furthermore, individual voxel HU values are only replaced by the average of their immediate neighborhood if a spatial smoothing filter, such as the Mean Filter from the SimpleITK module, is explicitly applied manually.

Each acquisition was performed in triplicate, reporting the maximum, minimum, and mean HU values provided by the 3D Slicer software. This procedure aimed to extract the mean HU values and their respective standard deviations, ensuring that the edges of the cubes did not interfere with the measurement due to potential beam hardening effects or interface artifacts. The obtained data were organized and plotted in scatter plots to evaluate the dependence of HU values on the infill density percentage for each of the three tested materials: Hyper PLA, PLA Stone, and TPU Silk. The characterization of the radiological response was consolidated through a regression analysis, allowing the establishment of the mathematical relationship between the internal printing density and the observed attenuation, according to the linear fit equation:

$$HU = a \times \text{Infill} + b \tag{2}$$

In this expression, the angular coefficient 'a' represents the sensitivity of HU variation per infill (HU/%) increment, while the linear coefficient 'b' correlates to the attenuation of the base material with minimum porosity. In addition to the equation, fit quality indicators, such as the Coefficient of Determination (R^2), will be reported to demonstrate the correlation between the infill density (%). and the observed attenuation.

III. Results and Discussion

When comparing the physical densities obtained in this study with the reference values reported in ICRU Report 44, the Hyper PLA and TPU Silk filaments, with a density of 1.17 g/cm^3 at 100% infill, presented values close to soft and structural tissues of lower attenuation as shown in Table II. These results indicate that Hyper PLA and TPU Silk are more suitable for mimicking soft tissues, lung, and adipose tissue at infill densities between 80% and 100%.

Based on ICRU Report 44, the mean mass densities of the selected tissues are 916 kg/m^3 for adipose tissue, 1053 kg/m^3 for liver, 1050 kg/m^3 for deflated lung, 260 kg/m^3 for inflated lung, and 1100 kg/m^3 for skin. However, biological changes resulting from growth and maturation cause variations in tissue density, which prevents the direct application of adult model values to pediatric models. Therefore, the fabrication of pediatric phantoms requires specific materials calibrated for each age group and for the physical properties of pediatric tissues.

For the development of a dosimetric phantom, in addition to the physical density required to simulate tissue-equivalent

TABLE II
PHYSICAL PROPERTIES OF THE TESTED MATERIALS AT DIFFERENT INFILL PERCENTAGES.

Material	Infill (%)	Mass (g)	Volume (cm^3)	Density (g/cm^3)
PLA Stone	100%	4.39	3.398	1.29
	90%	3.94	3.398	1.16
	80%	3.53	3.443	1.03
	70%	3.24	3.420	0.95
Hyper PLA	100%	3.98	3.398	1.17
	90%	3.64	3.398	1.07
	80%	3.25	3.398	0.96
	70%	2.99	3.420	0.87
TPU Silk	100%	4.00	3.409	1.17
	90%	3.36	3.420	0.98
	80%	3.22	3.420	0.94
	70%	3.11	3.420	0.91

materials, it is essential to analyze the CT number for each utilized filament. Following the CT scan, the DICOM images enabled the extraction of HU values for each combination of voltage and current across the different tested filaments.

Based on the generated scatter plots for the radiological attenuation analysis, the parameters of the linear regression equations for the tested materials were extracted. The statistical fit, validated by the coefficient of determination (R^2), yielded values greater than 0.93 across all conditions, as detailed in Table III. When analyzing the influence of the tube voltage (kV) on the radiological response of the materials, a negligible variation in the HU values was observed for all tested samples (90, 120, and 140 kV). The coefficients of the linear fit equations showed notable stability across the different energy conditions, displaying minimal variations in both the slope (a) and y-intercept (b) parameters.

TABLE III
LINEAR FIT PARAMETERS FOR 18 MAS, ORGANIZED BY VOLTAGE AND MATERIAL

Voltage	Material	a	b	R^2
90 kV	PLA Stone	14.12	-981.01	0.984
	Hyper PLA	11.14	-986.44	0.997
	TPU Silk	9.46	-886.30	0.962
120 kV	PLA Stone	13.57	-992.07	0.995
	Hyper PLA	11.00	-982.41	0.997
	TPU Silk	9.42	-878.08	0.969
140 kV	PLA Stone	14.05	-973.08	0.983
	Hyper PLA	11.04	-978.93	0.996
	TPU Silk	9.49	-880.89	0.970

This behavior reveals that the radiological attenuation of the analyzed filaments, within the applied energy range, is essentially due to physical density and internal architecture, as already presented in literature [6], [17], [18], showing a negligible dependence on the X-ray beam energy. Since the attenuation of Hyper PLA, PLA Stone, and TPU Silk proved to be independent of the tube voltage within the tested range. We can inferred that the same 3D-printed object can be utilized in the CT scanner tests across multiple clinical scenarios. For the diagnostic energy range (90 to 140 kV) and for low atomic number (Z) materials, the dominant physical phenomenon in X-ray attenuation is Compton Scattering (μ_{Compton}). This process depends almost exclusively on the electron density (ρ_e), and consequently on the physical density (ρ_{mass}) of the material, as described [18]:

$$\mu \approx \mu_{\text{Compton}} \propto \rho_e \propto \rho_{\text{mass}} \tag{3}$$

Conversely, the Photoelectric Effect (μ_{photo}), which is highly dependent on both the atomic number and the beam energy (E), remains negligible in this regime due to the absence (or low concentration) of high-Z elements in the polymer matrices [18]:

$$\mu_{\text{photo}} \propto \frac{Z^3}{E^3} \approx 0 \tag{4}$$

Therefore, the independence of the linear attenuation coefficient relative to the beam energy validates these 3D-printed filaments as tissue-equivalent materials for multi-protocol phantom development. This stability represents a significant advantage for phantom construction, as the HU defined for a specific CT protocol can be faithfully preserved under various operating voltages.

In Figures 3 and 4, the results showed at 100% infill and 120 kV a considerable disparity between conventional Hyper PLA (99 to 113 HU) and PLA with mineral additive (372 to 379 HU). Due to its higher HU values, PLA Stone proves to be suitable for simulating denser biological tissues, specifically bone structures, with the exception of cortical bone. Regarding the simulation of cortical bone, the results obtained for PLA Stone, which exhibited values of 372 to379 HU at 100% infill, are significantly lower than the range typical of human cortical bone, which generally presents between 1000 and 1500 HU. This discrepancy indicates that current commercial PLA Stone filaments have limitations in fully replicating the radiodensity of dense cortical bone. To address this, future strategies may involve the development of composite filaments with higher concentrations of radiopaque mineral additives, such as hydroxyapatite or calcium carbonate, or the use of multi-material 3D printing techniques to increase the effective structural density.

To validate the radiodensity properties of the evaluated filaments, the CT number (HU) values obtained in this work were compared with data reported in previous studies for similar 3D printing materials.

Table IV summarizes these attenuation values alongside findings from Savi et al. [14]. Discrepancies observed across the literature highlights the influence of distinct manufacturing formulations, additive concentrations, and scanner reconstruction parameters on the final CT numbers.

Savi presents a comparison with Okkalidis, Shin, and Sole et al. for PLA and copper mixtures, as well as other filaments and variations such as ABS, ABS+, PETG, TPE, HIPS, PVA, and TPU. The authors present the CT number results for 120 kV and 100% infill using a rectilinear pattern. PLA+Cu is widely

TABLE IV
COMPARISON OF CT NUMBERS (HU) ACROSS LITERATURE

Study / Reference	Hyper PLA	PLA+ additives	TPU
This Study	104 ± 9	379 ± 5 (PLA Stone)	90 ± 9
Savi et al.	30 ± 13 (PLA)	330 ± 19 (PLA+Cu)	-37 ± 5 (TPU)
Okkalidis et al.	136	130 (PLA+Cu)	136 ± 27 (TPU)
Solc et al.	-59 ± 19	–	–
Shin et al.	168 ± 16	–	-53 ± 46

used and prominent in the literature, being one of the most commonly used PLA mixtures for testing filaments intended for phantoms. Copper additives typically account for around 25% to 30% of the composition found in these filaments [13], [14], [19], [20].

It is important to highlight that variations in mineral concentration among different manufacturers can influence the obtained HU values, a factor that must be considered according to the printing objective and the phantom's age. In contrast, the results revealed that TPU Silk maintained a equivalence with Hyper PLA, showing similarities in both physical density and radiological behavior. It is worth noting that, although both exhibit close performance, Hyper PLA demonstrated higher statistical precision, with R^2 values closer to unity.Additionally, as illustrated in Figures 3 and 4, TPU Silk exhibits stability in HU values between the infill densities of 50% and 60%, a pattern repeated in the 70% and 80% intervals, suggesting lower sensitivity to infill variation within these specific ranges. TPU Silk is a highly flexible material, variations in its radiological properties may be attributed to printing challenges, such as the requirement for low printing speeds and the material's tendency to absorb moisture if not stored properly, which can affect the consistency of the deposited layers.

When using the software for the mediastinum and bone filters, a contrast adjustment (window/level threshold) is necessary. Comparing the HU values and the standard deviation, we observe that the values for the bone filter applied to the cubes show a greater variation in CT numbers, in addition to having a significantly higher standard deviation. For values of 100 mAs and 90 kV with 100% infill in Hyper PLA, the mediastinum filter yields an average value of 100.3 HU ± 5.3, whereas for the same element using the bone filter, this value changes to 89.3 HU ± 28.6. For 10% infill values, this deviation reaches up to 150. For this study, the values acquired from the mediastinum filter were used.

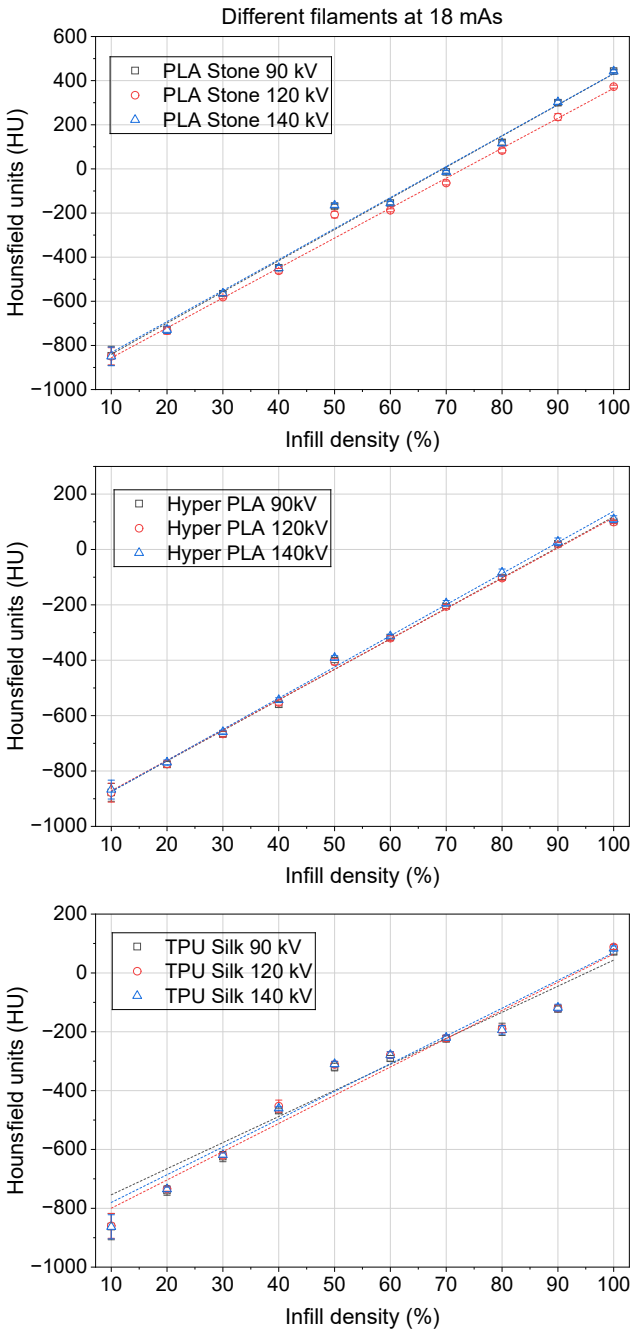

Fig. 3. CT Number in different filaments at each different infill at 18 mAs

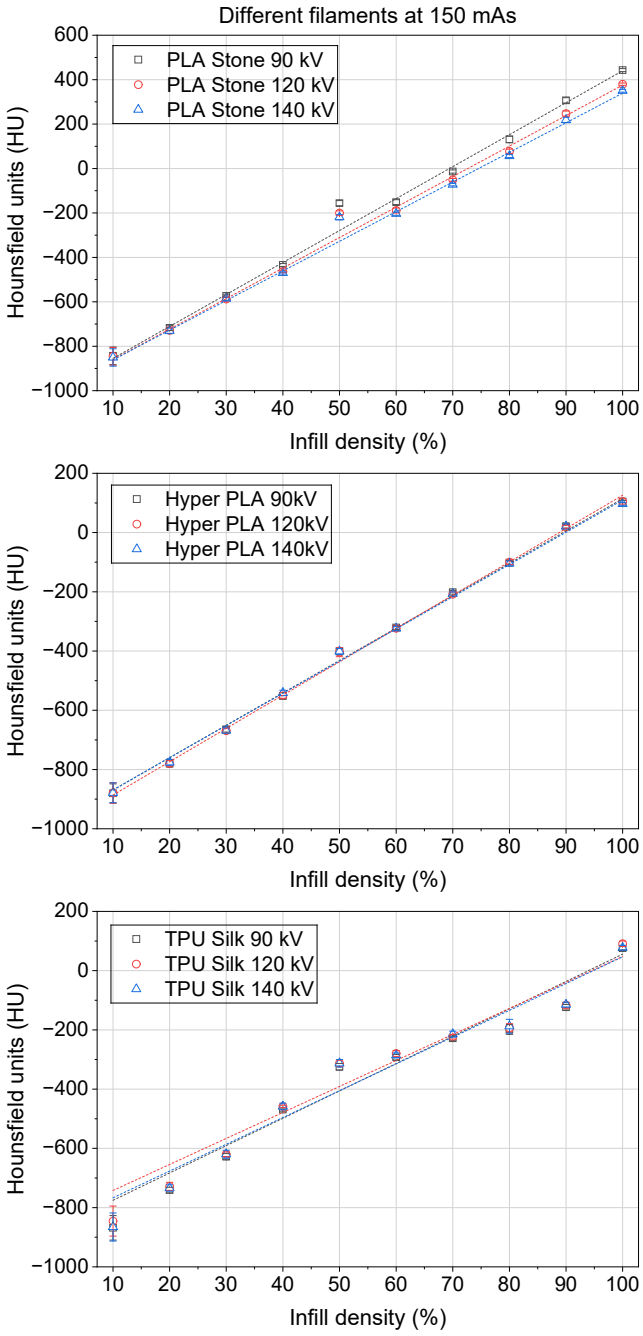

Fig. 4. CT Number in different filaments at each different infill at 150 mAs

Conclusion

When discussing quality assurance,3D-printed phantoms serve as standardized devices for calibrating and verifying parameters in CT systems, including geometric accuracy and HU stability. Therefore, using low-cost and customizable phantoms may facilitate their application in CT quality control. Additionally, it is worth emphasizing the importance of evaluating Hyper PLA and TPU Silk, which, despite presenting similar radiological attenuation, exhibit significant differences in workability and print quality.

The characterization of Hyper PLA, PLA Stone, and TPU Silk filaments validates the use of these materials as cost-effective alternatives for producing pediatric phantoms. The observed relationship between infill density and HU indicates that the radiological response of the printed samples can be adjusted by changing their physical density, highlighting density control through the correlation of attenuation coefficients and photon scattering in matrices that mimic biological tissues. The relatively stable HU values observed at 90, 120, and 140 kV also indicate that, within the conditions evaluated in this study, changes in tube voltage had a limited effect on the measured CT numbers.

Regarding the limitations of this study, we highlight the use of a limited number of filament brands, validation conducted on a single CT scanner model, and sampling restrictions, which may influence the generalizability of the results to other imaging systems or materials.

For future work, we recommend expanding this study to include mechanical and durability tests of the printed materials, as well as printing a phantom for validation with actual dosimetry. Furthermore, PLA Stone formulations and other mineral-filled filaments should be investigated to determine how composition and mineral concentration affect CT attenuation. These additional evaluations will help determine the suitability of these materials for specific anatomical structures and support their application in the development and validation of pediatric CT phantoms.

Abstract*—Colorectal cancer diagnosis based on histopathological assessment remains challenging due to subtle morphological differences among tissue subtypes and interobserver variability. This study evaluates a computer-aided classification pipeline for hematoxylin-and-eosin (H&E)-stained biopsy patches from the EBHI-SEG dataset. Deep features were extracted using an ImageNet-pretrained EfficientNet-B0 network to generate a complete feature representation (Base 1), while Particle Swarm Optimization (PSO) was employed to produce a reduced feature subset (Base 2). Nine conventional classifiers implemented in Weka were evaluated using 30 repetitions of stratified 10-fold cross-validation under two experimental settings, with and without the Synthetic Minority Over-sampling Technique (SMOTE). The dataset comprised 2,228 highly imbalanced image patches distributed across six histopathological classes, with an approximately 13.7:1 ratio between the largest and smallest categories. The second-degree polynomial SVM achieved the highest composite score during cross-validation, reaching 0.8762 without SMOTE and 0.9737 with SMOTE. Although SMOTE substantially improved the training performance of most classifiers, these gains were not fully reflected on the independent test set. The complete feature representation achieved the best held-out performance, with 85.49% accuracy, a Cohen's kappa of 0.801, and a weighted AUC of 0.949. Class-wise analysis further revealed that high-grade intraepithelial neoplasia and serrated adenoma remained considerably more difficult to recognize than adenocarcinoma (recall > 0.93), demonstrating that weighted aggregate metrics may conceal clinically relevant deficiencies in minority classes. Overall, the proposed pipeline provides a reproducible baseline for AI-assisted colorectal histopathology and highlights the importance of class-aware evaluation when developing machine learning models for severely imbalanced multiclass datasets.

***Index Terms*—colorectal cancer, histopathology, EfficientNet, SMOTE, particle swarm optimization, EBHI-SEG**

I. Introduction

Colorectal cancer (CRC) is among the most common malignant diseases worldwide, with approximately 1.9 million new cases and more than 900,000 deaths estimated for 2022 [1]. Histopathological examination of hematoxylin-and-eosin (H&E) stained tissue remains central to confirming malignancy and characterizing precursor lesions. The diagnostic spectrum includes normal mucosa, polyps, serrated lesions, low- and high-grade intraepithelial neoplasia, and invasive adenocarcinoma. These categories may exhibit subtle glandular and cytological differences, while the growing volume of digital pathology creates a strong motivation for reproducible decision-support systems.

The clinical difficulty is not limited to separating normal tissue from invasive carcinoma. Colorectal biopsy interpretation involves a continuum of architectural and cytological alterations, including gland crowding, loss of polarity, nuclear stratification, and stromal response. In this setting, minority patterns are especially important because high aggregate performance can coexist with weak recognition of less frequent categories.

Artificial intelligence (AI) in computational pathology has progressed from small patch benchmarks to weakly supervised analysis of whole-slide images (WSIs). Deep models have classified colorectal polyps with high accuracy [2], learned cancer representations with limited dense annotation [3], and

supported prescreening or interpretable diagnosis across large WSI cohorts [4], [5]. Nevertheless, the literature consistently shows that high internal performance does not imply clinical readiness. Scanner variation, staining differences, dataset artifacts, patient leakage, and prevalence shifts can substantially alter performance [6], [7].

Although these advances clearly illustrate the capabilities of AI, most studies typically operate at the whole-slide image (WSI) level or rely on large cohorts with dense annotations [2], [4], [5]. For academic and clinical laboratories with limited computational infrastructure and access to modestly sized datasets, leveraging feature extraction from pre-trained backbones coupled with lightweight classifiers presents a feasible and inexpensive alternative. However, this strategy has received limited attention in settings characterized by severe class imbalance and morphologically subtle distinctions among categories-such as the EBHI-SEG dataset used as the benchmark for our experiments.

While full fine-tuning of neural networks remains a widely employed approach, it inherently couples the representation learning stage with the downstream decision model, thereby complicating the isolated assessment of post-hoc techniques such as class balancing and feature selection. Conversely, adopting a pre-trained convolutional network as a frozen feature extractor decouples these stages, yielding a stable and reproducible representation on which various conventional classifiers can be trained and systematically compared under controlled conditions [7], [8].

This work therefore addresses a narrower experimental question: how effectively can conventional classifiers distinguish six EBHI-SEG histological categories when trained on transferred EfficientNet features, and how do class balancing and particle-swarm-based feature selection affect performance? Tree research questions (RQs) guide the analysis:

- **RQ1:** Which conventional classifier provides the best overall discrimination using the complete EfficientNet representation?
- **RQ2:** How does SMOTE affect accuracy, agreement, sensitivity, specificity, AUC, and the composite ranking?
- **RQ3:** Does PSO-based feature selection improve predictive performance consistently across classifier families?

The study contributes a reproducible characterization of the local EBHI-SEG subset, a comparison of nine classifiers across complete and PSO-selected features with and without SMOTE, a paired analysis of PSO selection, and a critical assessment of the internal evaluation setting.

II. Background and Related Work

A. Clinical and Computational Context

Digital pathology enables computational processing of glass slides. Because a WSI can contain billions of pixels, typical systems require tissue detection, tiling, feature extraction, regional prediction, and slide-level aggregation [4], [7]. Patch datasets simplify these steps and support controlled experiments, but patch performance represents local morphological discrimination rather than complete case-level diagnosis [4], [5].

Current evidence supports decision assistance rather than autonomous replacement of the pathologist. High-sensitivity systems may prioritize suspicious cases or regions; consequently, sensitivity and negative predictive value may be more relevant than raw accuracy [4], [7].

B. AI-Assisted Colorectal Histopathology

Early deep-learning studies demonstrated that colorectal gland morphology and polyp type can be learned from histological images. Kainz *et al.* combined convolutional networks and regularization for gland segmentation and tissue classification [9]. Korbar *et al.* evaluated five polyp classes on independent WSIs and reported 93.0% accuracy [2]. More recent work has focused on reducing annotation requirements and moving closer to clinical workflows. Yu *et al.* reported semi-supervised CRC recognition approaching fully supervised and pathologist-level performance while using fewer labeled samples [3].

At WSI scale, weak supervision and multiple-instance learning are attractive because slide-level diagnoses are easier to obtain than exhaustive pixel annotations. Campanella *et al.* established a large-scale weakly supervised framework for clinical-grade pathology tasks [7], while attention-based methods such as CLAM improved data-efficient slide aggregation [10]. For CRC specifically, Bilal *et al.* developed an AI prescreening system for large-bowel biopsies from the United Kingdom and Portugal [4]. Neto *et al.* proposed an interpretable mixed-supervision system trained on approximately 10,500 WSIs, reporting 93.44% internal accuracy and high sensitivity, with lower performance on external cohorts [5]. The difference between internal and external results reinforces the importance of domain-aware validation.

Table I summarizes key AI studies in colorectal histopathology, highlighting that most operate at the whole-slide image (WSI) level using weak supervision or dense annotations. In contrast, our study adopts a controlled patch-level design, which allows us to isolate the effects of class balancing and feature selection across nine conventional classifiers.

III. Materials and Methods

A. Proposed Method

Figure 1 illustrates the methodological workflow adopted in this study. The proposed pipeline begins with the acquisition of histopathological images from the EBHI-SEG dataset, followed by deep feature extraction using a pre-trained EfficientNet-B0 network. The extracted feature vectors are then divided into training and independent test sets, after which class balancing using the Synthetic Minority Oversampling Technique (SMOTE) is applied to the training data. Two feature representations are subsequently evaluated: the complete feature set (Base 1) and a reduced feature subset obtained through Particle Swarm Optimization (PSO) (Base 2). Finally, conventional machine learning classifiers are trained and validated using repeated cross-validation, and the best-performing models are evaluated on the independent test set.

TABLE I
REPRESENTATIVE LITERATURE AND ITS RELATIONSHIP TO THE PRESENT STUDY

Study	Data and task	Method and contribution	Relationship to this work
Kainz *et al.* [9]	Colon glands; segmentation and benign/malignant classification	CNNs with total-variation regularization showed that gland morphology is learnable	Supports learned morphology but addresses segmentation rather than six-class classification
Korbar *et al.* [2]	239 independent WSIs; five polyp types	ResNet classification reached 93.0% accuracy and 88.8% F1	Provides a related benchmark with independent slide testing
Yu *et al.* [3]	Labeled and unlabeled CRC images	Semi-supervised learning reduced annotation requirements while retaining high AUC	Motivates data-efficient transfer learning
Bilal *et al.* [4]	UK and Portuguese large-bowel biopsies	Weakly supervised, externally validated prescreening	Illustrates the validation level required for clinical triage
Neto *et al.* [5]	Approximately 10,500 WSIs with external cohorts	Mixed supervision with interpretable tile severity	Represents a translational WSI target beyond this patch study

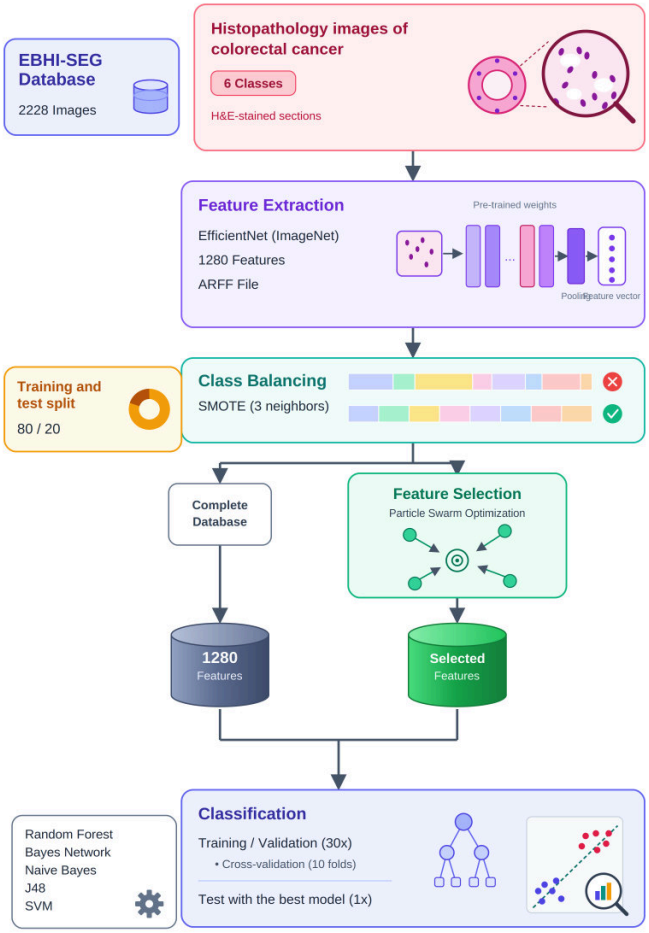

Fig. 1. Workflow of the proposed methodology, including the following stages: dataset, feature extraction, class balancing, feature selection, and classification.

Each stage of the proposed methodology is described in detail in the following sections.

B. Dataset

EBHI-SEG was introduced as a public enteroscope biopsy H&E dataset for segmentation and contains six tumor-differentiation categories with corresponding masks [11]. The complete release is described as 5,170 files comprising images and ground truth. The local copy audited for this study contained 2,228 RGB image patches of 224×224 pixels and 2,227 masks. Two low-grade intraepithelial-neoplasia masks were absent, but masks were not used in classification.

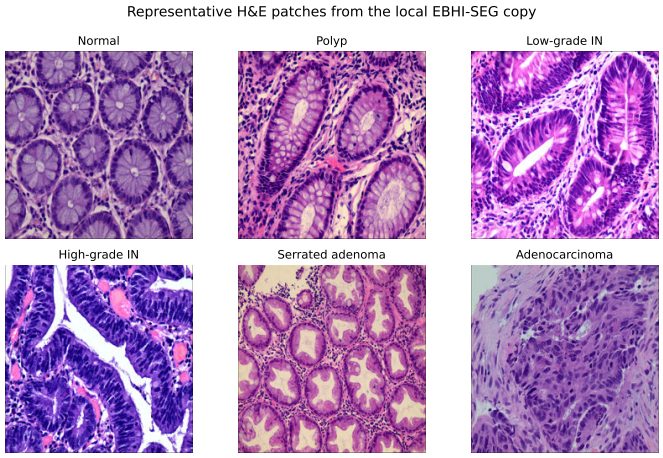

Fig. 2. Representative H&E patches from the six classes in the local EBHI-SEG copy.

TABLE II
CLASS DISTRIBUTION IN THE LOCAL DATASET

Class	Images	Share (%)
Normal	76	3.41
Polyp	474	21.27
Low-grade IN	639	28.68
High-grade IN	186	8.35
Serrated adenoma	58	2.60
Adenocarcinoma	795	35.68
Total	**2,228**	**100.00**

Fig. 2 illustrates the morphological diversity of the classes, and Table II quantifies the imbalance. EBHI-SEG does not provide sociodemographic variables in the distributed directory structure; therefore, age, sex, ethnicity, and other patient-level covariates were not analyzed. According to the dataset

documentation, the images originate from enteroscope biopsy histopathology and are distributed as PNG patches with segmentation masks.

The imbalance ratio between adenocarcinoma and serrated adenoma was approximately 13.7:1, while normal tissue was also scarce. Thus, high multiclass accuracy could coexist with poor minority-class recognition, motivating weighted sensitivity, specificity, kappa, and AUC.

C. Experimental Pipeline

The experiments were conducted in the Weka data mining platform [8]. Initially, an ARFF file was created to reference the image directories, and deep features were extracted from the histopathological images using a pre-trained EfficientNet-B0 network with ImageNet weights. EfficientNet employs a compound scaling strategy that jointly balances network depth, width, and input resolution, producing highly transferable image representations with relatively low computational cost [12]. This characteristic makes transfer learning particularly suitable for medical imaging applications, where labeled datasets are often insufficient to train deep architectures from scratch. In the proposed pipeline, EfficientNet-B0 was used as a fixed feature extractor, generating a 1,280-dimensional feature vector for each image, while the final classification was performed using conventional machine learning algorithms.

Two feature representations were subsequently investigated. **Base 1** consisted of the complete set of features extracted by EfficientNet-B0. **Base 2** was generated by applying Particle Swarm Optimization (PSO), a population-based optimization algorithm inspired by the collective behavior of biological swarms [13]. Feature selection aims to reduce redundancy and eliminate less informative attributes, potentially simplifying the classification models while preserving their discriminative capability.

The dataset was then divided into an 80% development set and an independent 20% test set. Since the EBHI-SEG dataset is highly imbalanced—with 795 adenocarcinoma patches but only 58 serrated adenoma and 76 normal patches—models trained directly on the original distribution may become biased toward the majority classes. To investigate this effect, both feature representations were evaluated under two experimental settings: with and without the Synthetic Minority Over-sampling Technique (SMOTE) [14]. SMOTE generates synthetic minority samples by interpolating neighboring instances in the feature space, potentially improving the recognition of underrepresented classes. To avoid information leakage, oversampling was applied exclusively to the training partitions within the development set, while the validation and independent test sets preserved the original class distribution.

Although transfer learning and class balancing have been extensively investigated in the literature, relatively few studies have systematically analyzed their combined effects in severely imbalanced histopathological datasets containing morphologically similar classes. Moreover, most previous studies emphasize global performance metrics, often overlooking detailed class-wise analyses of clinically relevant minority categories, such as serrated adenoma.

For each experimental scenario, nine classifier configurations were evaluated: Naive Bayes, BayesNet (K2 search with SimpleEstimator), Random Tree, Random Forest with 100, 300, and 500 trees, and Support Vector Machines (Weka SMO) with first-degree polynomial, second-degree polynomial, and radial basis function (RBF) kernels. These classifiers represent distinct learning paradigms, including probabilistic models, decision-tree ensembles, and margin-based classifiers, allowing a comprehensive evaluation of which family best exploits the transferred deep representations. Model performance was assessed through 30 repetitions of stratified 10-fold cross-validation, resulting in 300 performance measurements for each classifier and experimental scenario.

Finally, the best-performing classifier from each feature representation was selected and evaluated on the independent test set, comprising 448 histopathological image patches that were not used during model development.

D. Evaluation

The reported metrics were accuracy, Cohen's kappa, weighted sensitivity, weighted specificity, and weighted area under the receiver-operating-characteristic curve (AUC). For C classes with class weights $w_c = n_c/N$, weighted sensitivity and specificity were interpreted as

$$\mathrm{Sens}_w = \sum_{c=1}^{C} w_c \frac{TP_c}{TP_c + FN_c}, \tag{1}$$

$$\mathrm{Spec}_w = \sum_{c=1}^{C} w_c \frac{TN_c}{TN_c + FP_c}. \tag{2}$$

Cohen's kappa measures observed agreement beyond agreement expected by chance,

$$\kappa = \frac{p_o - p_e}{1 - p_e}, \tag{3}$$

where p_o is observed agreement and p_e is expected chance agreement. AUC summarizes ranking discrimination across decision thresholds. In the Weka multiclass output, class-wise AUC values were combined through prevalence weighting.

Accuracy was converted from percentage to the $[0, 1]$ interval. To summarize performance using the same rule applied in the project analysis, a composite score was defined as

$$S = \frac{\mathrm{Acc} + \kappa + \mathrm{Sens} + \mathrm{Spec} + \mathrm{AUC}}{5}. \tag{4}$$

The score is not proposed as a clinical utility function. It is an equal-weight descriptive index used to avoid selecting a model from accuracy alone. Means and sample standard deviations were calculated across the 300 exported measurements. Differences between Base 1 and Base 2 were explored by pairing equal run/fold identifiers. Wilcoxon signed-rank tests were used descriptively because the score distributions were not assumed to be Gaussian. Since repeated cross-validation folds are not statistically independent, these p-values are interpreted as exploratory.

IV. Results

A. Training Phase

Table III summarizes the best-performing classifier for each feature representation and balancing scenario during the training phase. Without SMOTE, the highest composite score was achieved by the second-degree polynomial SVM (SVM Poly-2) in Base 1 ($S = 0.8762$), whereas Base 2 slightly favored the first-degree polynomial SVM ($S = 0.8705$). After applying SMOTE, SVM Poly-2 consistently became the best-performing classifier for both feature representations, achieving composite scores of 0.9737 and 0.9704 for Base 1 and Base 2, respectively.

Random Forest with 500 trees produced the highest AUC in both feature bases, reaching 0.9618 and 0.9946 for Base 1, and 0.9613 and 0.9940 for Base 2, without and with SMOTE, respectively. This result indicates that the classifier providing the highest AUC was not necessarily the one with the highest overall composite score, highlighting that model ranking depends on the performance metric considered.

The influence of class balancing is illustrated in Fig. 3. SMOTE improved the composite score for all nine classifier configurations in both feature representations, with average gains of +0.1025 for Base 1 and +0.0956 for Base 2. The largest improvements were observed for Random Forest, reaching +0.1365 (500 trees) in Base 1 and +0.1332 (300 trees) in Base 2.

The performance gains were particularly evident for the SVM models. In Base 1, the best-performing classifier increased its mean accuracy from 84.66% to 96.42%, while weighted sensitivity improved from 0.8466 to 0.9642. Similar improvements were observed for Base 2. In addition to increasing the average performance, SMOTE also reduced variability across cross-validation runs. For SVM Poly-2 in Base 1, the standard deviation of accuracy decreased from 2.4475 to 0.9928 percentage points, whereas the standard deviation of Cohen's kappa decreased from 0.0334 to 0.0119, indicating more stable model behavior.

In addition, Fig. 3 also shows three consistent performance tiers: polynomial SVMs led, Random Forest and RBF SVM formed an intermediate group, and Bayesian or single-tree methods generally ranked lower. Increasing the forest size from 100 to 500 trees changed the score by only about 0.002, suggesting diminishing returns in the fixed feature space.

The effect of PSO-based feature selection was classifier dependent. While Base 2 substantially improved the performance of Naive Bayes (+0.2317 without SMOTE and +0.2053 with SMOTE), only marginal improvements were observed for BayesNet and Random Tree (up to 0.0140). In contrast, the SVM classifiers exhibited slight reductions in composite score after feature selection, with the largest decrease occurring for the RBF kernel under SMOTE ($\Delta S = -0.0380$). For the best-performing SVM Poly-2 model with SMOTE, the reduction from 0.9737 to 0.9704 was significant, although the magnitude of the difference remained very small ($\Delta S = -0.0034$). Overall, these results indicate that PSO can benefit classifiers that are more sensitive to redundant features, whereas the complete EfficientNet-B0 representation already provides an effective feature space for margin-based classifiers.

Based on these results, the best-performing classifiers from each feature representation were selected for evaluation on the independent held-out test set.

B. Held-Out Test Performance

The best-performing classifier from each feature representation was selected based on the training phase and evaluated on the independent test set, comprising 448 histopathological image patches not used during model development. Although the selected models were identified from the SMOTE-based experiments, the independent test set preserved the original class distribution, without any synthetic oversampling. Interestingly, the test results were more consistent with the ranking observed during the non-SMOTE cross-validation, suggesting that the substantial performance gains obtained with SMOTE during training did not fully translate into improved generalization.

Table IV summarizes the overall performance of the two feature representations on the held-out test set. Base 1 correctly classified 383 of the 448 patches, achieving an accuracy of 85.49%, whereas Base 2 correctly classified 378 patches (84.38%). The difference between the two approaches was modest, corresponding to 1.12 percentage points in accuracy and 0.014 in Cohen's kappa. Both models achieved the same weighted AUC (0.949), indicating that PSO-based feature selection largely preserved the discriminative capability of the EfficientNet representation, despite the slight reduction observed in the remaining performance metrics.

The class-wise performance presented in Table V reveals important differences that are not evident from the weighted metrics alone. Base 1 achieved higher recall for Polyp, Low-grade IN, Serrated Adenoma, and Adenocarcinoma, whereas Base 2 showed better performance only for the Normal and High-grade IN classes. Adenocarcinoma remained the easiest category to recognize, with recall exceeding 0.93 for both feature representations. In contrast, High-grade IN and Serrated Adenoma were consistently the most challenging classes, reaching maximum recall values of only 0.500 and 0.583, respectively.

The confusion matrices in Table VI provide further insight into the classification errors. The predominant confusion occurred between High-grade IN and Adenocarcinoma. Fourteen High-grade IN patches were classified as Adenocarcinoma by Base 1, compared with eleven in Base 2. Conversely, Base 2 misclassified eight Adenocarcinoma patches as High-grade IN, whereas Base 1 produced five such errors. These misclassifications are morphologically plausible because both categories share several architectural and cytological characteristics; however, they remain clinically relevant since they involve the distinction between preinvasive and invasive disease.

V. Discussion

Interestingly, although the best-performing models were selected from the SMOTE-based training experiments, their performance on the independent test set was much closer

TABLE III
BEST CONFIGURATION IN EACH FEATURE BASE AND BALANCING SCENARIO (MEAN ± STANDARD DEVIATION)

Base	Scenario	Model	Accuracy (%)	Kappa	Sensitivity	Specificity	AUC	Score
Base 1	Without SMOTE	SVM Poly-2	84.6629 ± 2.4475	0.7898 ± 0.0334	0.8466 ± 0.0245	0.9508 ± 0.0084	0.9473 ± 0.0092	0.8762

TABLE IV
HELD-OUT TEST RESULTS ($N = 448$)

Metric	Base 1	Base 2
Correct / incorrect	383 / 65	378 / 70
Accuracy (%)	**85.491**	84.375
Kappa	**0.801**	0.787
Weighted precision	**0.848**	0.841
Weighted recall	**0.855**	0.844
Weighted F1	**0.849**	0.840
Weighted MCC	**0.810**	0.797
Weighted AUC	0.949	0.949
Weighted PRC area	**0.796**	0.789
MAE / RMSE	0.2266 / 0.3168	0.2268 / 0.3171
RAE / RRSE (%)	81.569 / 84.993	81.658 / 85.083

to that observed in the non-SMOTE cross-validation. This finding suggests that the substantial improvements produced by synthetic oversampling primarily benefited the internal training evaluation rather than the model's ability to generalize to unseen data. Moreover, SMOTE generates synthetic feature vectors from existing observations and therefore does not increase the diversity of patients, laboratories, scanners, or staining conditions represented in the dataset.

The class-wise results provide additional insight beyond the overall performance metrics. Although both feature representations achieved a weighted AUC of 0.949, High-grade IN and Serrated Adenoma remained the most challenging classes, with recall values ranging from 0.447 to 0.500 and from 0.417 to 0.583, respectively. The confusion matrices further showed that the predominant error involved misclassification between High-grade IN and Adenocarcinoma, a morphologically plausible but clinically important distinction. These findings demonstrate that high weighted performance metrics may conceal substantial deficiencies in clinically relevant minority classes.

The proposed six-class framework should therefore be interpreted as a morphology recognition system operating at the image-patch level rather than as a complete diagnostic solution. While the proposed pipeline achieved robust overall discrimination of histopathological patterns, reliable recognition of minority categories remains an important challenge for practical deployment.

Several limitations should also be considered. First, the dataset was partitioned at the image level, allowing patches originating from the same specimen to appear in different subsets, which may have introduced optimistic performance estimates. In addition, the composite score assigns equal importance to partially correlated performance metrics and has not been clinically validated. Finally, the EBHI-SEG

dataset was obtained from a single public source and does not provide demographic metadata. Consequently, variability related to staining protocols, scanners, geographic origin, and patient populations cannot be assessed, limiting the generalizability of the reported results. Future studies should therefore investigate patient-level data partitioning, external validation on independent cohorts, and more diverse datasets to better assess the robustness and clinical applicability of the proposed methodology.

VI. CONCLUSION

This study evaluated conventional classifiers trained on EfficientNet-B0 representations for six-class colorectal histopathology classification. The polynomial SVM (Poly-2) with SMOTE achieved the highest cross-validation composite score (0.9737). However, when evaluated on the 448 held-out patches using non-SMOTE models, Base 1 achieved 85.49% accuracy ($\kappa = 0.801$, AUC $= 0.949$), marginally outperforming Base 2 (84.38%, $\kappa = 0.787$, AUC $= 0.949$). Although PSO substantially reduced the feature dimensionality, it did not improve the generalization performance of the best-performing classifiers, indicating that the original EfficientNet-B0 representation already provided highly discriminative features for this task.

SMOTE consistently improved the composite score, AUC, and sensitivity during cross-validation, although its application prior to data splitting may have introduced optimistic estimates. Moreover, the benefits of PSO-based feature selection were classifier-dependent: while Naive Bayes exhibited substantial improvements, the top-performing SVM models showed no practical gains and, in some cases, experienced slight performance degradation.

The most clinically relevant finding lies not in the aggregate metrics but in the class-wise results. Although adenocarcinoma achieved recall above 0.93, high-grade intraepithelial neoplasia and serrated adenoma remained considerably more difficult to recognize (recall ≤ 0.583). This discrepancy highlights that weighted performance measures may conceal important deficiencies in minority classes, particularly for lesions with malignant potential.

Overall, the proposed pipeline provides a reproducible baseline for AI-assisted colorectal histopathology rather than a clinically deployable system. The results highlight the importance of carefully evaluating the effects of class balancing and feature selection in severely imbalanced datasets, while reinforcing the need for patient-level data partitioning, stain normalization, and external validation in future translational studies.

***Abstract*—Respiratory rehabilitation requires precise and continuous monitoring of lung parameters to ensure the efficacy of treatment and the participation of the patient. This work presents the mechatronic development of an affordable sensorized respiratory assessment system designed to capture airflow dynamics. The system integrates a 3D-printed adaptation tube designed to fit conventional mechanical incentive spirometers, transforming them into digital biofeedback-driven rehabilitation systems. Using an airtight pneumatic structural design, the adapter incorporates a differential pressure sensor (MPX5700DP) and an ESP32-C3-Mini microcontroller, enabling high-resolution data acquisition and transmission through Python-based processing interfaces. Data are processed to control a serious game interface, offering immersive patient motivation while generating objective evaluation reports for clinicians. Set in a dynamic deep-sea environment spanning the world's four oceans, the game utilizes real-time inspiratory and expiratory pressures to control avatar navigation and adapt difficulty levels.The proposed device addresses the limitations of high cost and mechanical fragility commonly associated with commercial spirometers, offering a robust alternative for remote, engaging, and decentralized clinical settings.**

***Index Terms*—pulmonary function, assistance, pressure measurement, physiotherapy, bioengineering**

I. Introduction

Pulmonary rehabilitation with mechanical training and incentive spirometers is critical to the management of chronic airway disorders and the acceleration of post-surgical trauma recovery [1], [2]. Traditional incentive spirometers are widely accessible and effective in clinical settings; however, they rely heavily on manual verification and lack objective digital logging, often leading to low patient compliance and decentralized monitoring deficits [3]. To overcome these barriers, contemporary research has focused on diverse state-of-the-art approaches to extract breathing parameters. Some advanced trends suggest that one completely abandons mechanical spirometry through alternative sensing topologies, such as machine learning-driven pharyngeal phonetic analysis [4], flexible near-field coupling printed radiofrequency resonators placed on the diaphragm [5], or complex multimodal wearable chest patches combining bioimpedance and mechanomyography [6]. While highly innovative, these methods lack direct physical resistance or active volumetric training loops, limiting their deployment in targeted physical therapeutic training.

Conversely, specialized hardware modifications have emerged to introduce targeted monitoring. These include

customized non-invasive extratracheal respiratory assessment ports tailored strictly for laryngectomized patients [7], individualized localized training units built from three-dimensional-printed prototype based on two spring valves to limit the air flux during inspiration and expiration [8], high-accuracy calibration-free architectures utilizing Fiber Bragg Grating (FBG) optical arrays [9], and dedicated portable closed-source wireless spirometers based on thin-sheet flexible flow sensor [10]. Furthermore, frugal design frameworks highlight the cost efficiency of 3D-printed pressure-differential Venturi implementations over standard delicate turbine units [11].

Nevertheless, a critical technological gap remains: the literature rarely explores low cost, open-source hybridization capable of retrofitting existing conventional clinical respiratory hardware. Most current platforms require purchasing entirely proprietary digital devices [1], [10]. There is an evident need for seamless physical adapters that maintain pneumatic integrity while introducing precise real-time biofeedback and automated clinical reporting through gamified structures.

Respiratory dysfunctions, whether resulting from chronic conditions such as asthma and chronic obstructive pulmonary disease (COPD) or from acute events such as stroke and rib fractures, impose a substantial burden on global healthcare systems [1]. Pulmonary rehabilitation programs incorporating individualized respiratory muscle training have demonstrated significant effectiveness in improving lung function, enhancing ventilatory capacity, and reducing the risk of severe complications [12], [13], [2]. Nevertheless, the provision of continuous, standardized, and accessible physiotherapy during and after hospitalization remains challenged by infrastructure constraints, limited availability of specialized professionals, and interruptions in follow-up care. These limitations highlight the need for affordable and reliable technological solutions capable of supporting objective respiratory assessment and facilitating the expansion of rehabilitation services beyond conventional clinical settings. To address these challenges, the objective of this work is to integrate a low-cost mechatronic device based on a Venturi tube geometry, utilizing differential pressure readings to estimate key respiratory parameters in real-time. Furthermore, aiming to mitigate patient drop-out rates and enhance engagement, this hardware system is embedded into an underwater-themed serious game. Through a bi-directional breathing control mechanism, patients embark on an ocean de-pollution mission, transforming repetitive clinical exercises into an immersive, adaptive, and educational therapeutic experience that fosters long-term rehabilitation adherence.

II. Methodology

The proposed hardware architecture is divided into three fundamental layers: the physical pneumatic adaptation, the electronic sensing framework, and the embedded processing unit.

A. 3D-Printed Adaptation Tube and Pneumatic Sealing

The proposed system is based on the mechatronic design of a sensorized adapter tube developed to interface a conventional mechanical incentive spirometer with a digital monitoring platform. Unlike mechanical turbine spirometers, the fluid-dynamic sensing structure employs a custom-designed Venturi-style flow-restricting tube modeled via computer-aided design (CAD) and fabricated through 3D printing. Grounded in Bernoulli's principle, the tube features restricted internal cross-sectional areas that generate a localized fluid velocity variation during patient expiration, creating a proportional differential pressure between two measurement ports [11]. Its internal geometry was designed to function as an in-line flow-conditioning structure, enabling the integration of pressure sensing elements without interfering with the operation of the original rehabilitation device.

A critical design requirement was the preservation of pneumatic sealing throughout all mechanical interfaces. Air leakage during inspiratory or expiratory maneuvers can significantly affect flow estimation accuracy and reduce the pressure load necessary for the proper operation of the mechanical spirometer. To address this issue, the adapter incorporates high-tolerance slide-fit connections and strategically positioned pressure ports for differential pressure measurement. This configuration allows the acquisition of the true pressure differential (ΔP) generated by the airflow while minimizing additional flow resistance and preserving the fluid dynamic characteristics of the conventional rehabilitation process. Applying Bernoulli's principle and the continuity equation, the theoretical volumetric flow rate (Q) is derived from the differential pressure ($\Delta P = p_1 - p_2$) across the Venturi constriction, 'Eq. 1'.

$$Q = A_1 \sqrt{\frac{2(p_1 - p_2)}{\rho \left(1 - \left(\frac{A_1}{A_2}\right)^2\right)}} \tag{1}$$

Where:

- Q is the volumetric flow rate (m^3/s),
- A_1 and A_2 represent the internal cross-sectional areas at the primary and constricted ports (m^2),
- p_1 and p_2 are the corresponding static pressures (Pa), and
- ρ is the fluid density of air.

The resulting hybrid architecture enables the simultaneous execution of standard respiratory therapy exercises and real-time digital interaction through a serious game environment. In this way, physiological data can be continuously monitored without altering the therapeutic protocol or the patient's experience with the conventional spirometer.

B. Electronic Sensing and Embedded Hardware

The conversion from pneumatic pressure to electrical signal is performed by the MPX5700DP (NXP Semiconductors), a piezoresistive, monolithic silicon differential pressure sensor. This sensor was selected for its robust signal conditioning and wide operating range (up to 700 kPa),

enabling the accommodation of forced expiratory maneuvers without saturation. Pressure sensing is accomplished via an MPX5700DP piezoresistive differential transducer. Although its nominal operating range extends up to 700 kPa—providing high structural headroom against overpressure during forceful exhalation—respiratory maneuvers typically induce pressures below 20 kPa. To compensate for reduced dynamic range resolution over lower pressure regimes, signal conditioning relies on full 12-bit ADC quantization on the ESP32-C3 sampled at 100 Hz. Future iterations will evaluate lower-range differential sensors (e.g., MPX5010DP, 0–10 kPa) to maximize signal-to-noise ratio during subtle inspiratory flows. The core processing and connectivity consist of an ESP32-C3-Mini microcontroller module, with 32-bit RISC-V single core and a 12-bit analog-to-digital converter (ADC) that samples the analog output of the MPX5700DP at a calibrated frequency of 100 Hz to prevent aliasing during sudden respiratory bursts. The processing flow involves signal filtration, analog-to-digital conversion, data buffering, and real-time packet transmission using USB cable in order to reduce latency.

C. Software and Processing Interface

The data stream is captured by a nearby workstation or smartphone running a Python processing pipeline. The game architecture and user loop are structured as follows:

Initialization and Customization: The protocol begins with a digital onboarding phase where patients select and customize their marine avatar, enhancing psychological ownership and initial compliance.

Bi-directional Motion Mapping: Once gameplay begins, the real-time differential pressure generated during the patient's expiration (blowing) and inspiration (inhaling) is mapped to multi-axial navigation. These pneumatic inputs control the avatar's upward, downward, and lateral movements, enabling the character to dodge underwater obstacles and defeat oceanic enemies. Concurrently, the magnitude of the measured pressure dynamically modulates the avatar's swimming speed, directly tying physical exertion to in-game velocity.

Phase-Dependent Sensor Calibration: To enforce progressive clinical training, the game is structured around the world's four major oceans, with each phase representing a different ocean. Programmatically, the software alters the input sensitivity of the sensor across different stages. Lowering or increasing the sensitivity scale changes the physical effort required to move the avatar a given distance, establishing an automated, firmware-driven rehabilitation progression.

Educational and Difficulty Scaling: As the player advances through the levels of each ocean, the difficulty increases, and the main characters, background landscapes, and enemies dynamically change to mirror that specific geographical region. Indigenous marine animals are displayed in the background, and each new level unlocks environmental or biological trivia (curiosities regarding the ecosystem or its fauna), combining clinical rehabilitation with active cognitive learning.

Win Condition: Patients collect rewards and extra lives while fulfilling the core mission of purging ocean pollution.

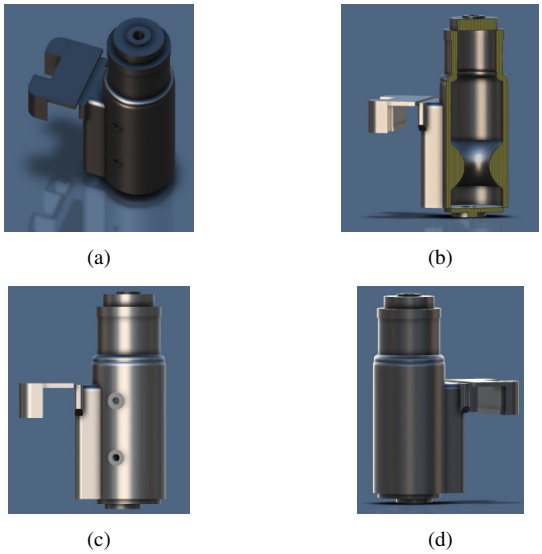

Fig. 1: Results obtained for the proposed method: (a) isometric view, (b) section view: Venturi detail, (c) front view , and (d) back view.

The game is won when the patient completes the entire aquatic journey and successfully unlocks a mystical sunken chest containing the ultimate water-cleansing antidote.

III. Results and Discussion

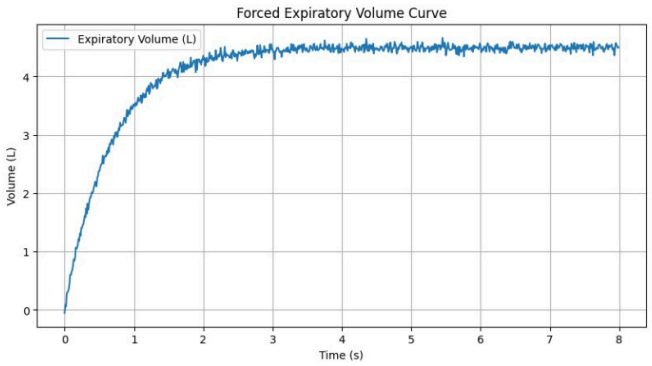
A. 3D-Printed Adaptation Tube and Pneumatic Sealing

The modeled device to be connected directly to a conventional mechanical incentive spirometer is presented in "Fig. 1" which details the CAD model of the adapter, highlighting the Venturi geometry and pressure ports (b). Grounded in Bernoulli's principle, the tube features restricted internal cross-sectional areas that generate a localized fluid velocity variation during patient breath, creating a proportional differential pressure between the two measurement ports. Although the airflow from breathing is pulsatile, simplifications in the modeling assumed a uniform and continuous flow, remaining steady during the interval of measurements and evaluations along the same streamline. In addition, the internal walls of the device were printed with minimal roughness to reduce the discharge coefficient of the duct, minimizing losses and the user's effort during breathing.

B. Electronic Sensing and Embedded Hardware

Initial bench tests were carried out to correlate the differential pressure read by the sensor with the volumetric flow of the air. Preliminary bench tests for the estimation of forced expiratory volume in one second (FEV_1) were performed with the proposed device, by a simulated flow, "Fig.2".

However, additional experimental cycles are required to optimize the device geometry and evaluate alternative filament materials. These improvements may reduce pressure losses within the duct and minimize the respiratory effort required from patients during training.



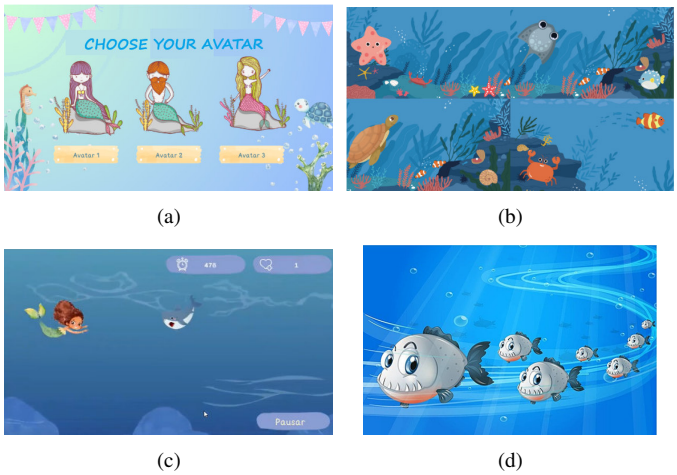


Fig. 2: Curve of Forced expiratory volume.

Furthermore, the MPX5700DP sensor has a measurement range of up to 700 kPa, which substantially exceeds the pressures typically observed during respiratory maneuvers. It was a choice for initial prototyping/bench availability. Therefore, sensors with narrower measurement ranges should be evaluated to improve resolution under the intended operating conditions. Nevertheless, the MPX5700DP provides a sensitivity of 6.4 mV/kPa and demonstrated an adequate response during forced expiratory volume in one second (FEV_1) measurements.

Upon completion of this stage, the physiological parameters associated with respiratory training can be estimated, enabling the generation of reports for subsequent analysis and comparison. Preliminary assessments demonstrated signal stability, a short response time, and the feasibility of obtaining measurements during both inhalation and exhalation.

C. Software, Processing and Serious Game Interface

The digital stream is captured by a localized workstation or smartphone running a Python processing pipeline. In the current stage of the research, differential pressure was used to control the serious game. At this stage of the work, the focus was on hardware development and bench validation of the signal processing algorithms, without conducting tests with humans. The graphical interface and game mechanics were designed to be intuitive and motivating, aiming for future clinical applicability. Fig. 3 shows the game interface developed based on deep sea. The introduction screen is shown in "Fig. 3a", the four game oceans in "Fig. 3b", a villain animal example in "Fig. 3c" and one of the obstacles, ocean current, in "Fig. 3d". Within the application, the mathematical conversion from raw differential pressure (ΔP) to volumetric flow rate (Q) is executed in real-time, mapping values to deliver parameters like Forced Vital Capacity (FVC) and Peak Expiratory Flow (PEF).These estimated physiological parameters serve as direct telemetry inputs for a serious game, where the patient's respiratory flow controls in-game mechanics (like overcoming obstacles or achieving targets), transforming repetitive clinical exercises into an immersive therapeutic experience. The effectiveness of the system with real users and the clinical validation of the estimated spirometry parameters will be the subject of future studies, subject to approval by the Research Ethics Committee (CEP).

IV. Comparative Analysis with State-of-the-Art Systems

To evaluate the mechatronic design and clinical feasibility of the developed system, its characteristics were cross-examined with other works of the literature considered as summarized in "Tab. 1".

V. Design Insights and Advantages

In recent years, the integration of biomedical technology with mobile health (mHealth) and telemedicine has emerged as a strategy to decentralize care, allowing objective home evaluation [1] and [12]. Traditional methods often rely on subjective self-reporting or fragile and expensive mechanical devices that are impractical for remote follow-ups [1]. Although portable spirometers exist, there is a clear technological gap for solutions that combine clinical accuracy, structural durability, and low cost. Frugal engineering guidelines address this discrepancy by eliminating delicate moving components—such as turbines or rolling seals—which are highly susceptible to dust, moisture, and mechanical wear, replacing them with solid-state pressure-differential techniques such as the one developed by [11]. In addition, [11] utilized an MPX5010DP sensor, which operates within a 10 kPa range. While highly accurate for quiet breathing, it risks saturation during forced expiratory maneuvers executed by robust individuals. The selection of the MPX5700DP provides an expanded dynamic headroom, assuring sensor integrity and linear output across diverse patient profiles. The platform implemented by [1] relies on a commercial mechanical-turbine device (ezOxygen). Turbine-based mechanisms introduce moving components that deteriorate due to saliva condensation, moisture, and dust contamination. By adopting a Venturi model, the developed system significantly drops maintenance costs and ensures device longevity in home-care scenarios. However, experimental

TABLE I: Comparison of Recent Respiratory Monitoring and Spirometry Systems

System	Sensing	Hardware	Biofeedback/UI	Report	Hybridization	Vulnerability
Proposed Adapter	Differential pressure (MPX5700DP)	3D-printed tube + ESP32-C3	Serious game interface	Yes	Retrofits standard incentive spirometers	Very low
Wallace et al. (2026)	Differential pressure (MPX5010DP)	3D-printed tube + Arduino	Character LCD	No	No	Low
Liao et al. (2025)	Commercial turbine	Proprietary ezOxygen device	Mobile app	Partial	No	High
Ren et al. (2025)	Airflow deformation	Wireless spirometer	Mobile graphs	No	No	Low
Zhang et al. (2025)	FBG optical sensor	Optical system + AI	Laboratory software	Yes	No	Very low

Berkebile et al. (2026)	Bioimpedance + MMG	Wearable chest strap	Workstation monitor	No	No	Low
Nardi et al. (2025)	Spirometer interface	Silicone tracheal adapter	Commercial UI	Dependent	Yes	Low

evaluations of the behavior of airflow in the tube, taking energy losses and pressure drops into account, are needed in order to establish the uncertainties in pressure assessment, which will directly impact the evaluation of respiratory flow. Computational Footprint and Connectivity: Although the implementation by [11] relies on an external display (LCD/LEDs) on an Arduino platform, the proposed system channels the efficiency of the ESP32-C3-Mini. This enables a downscaled physical footprint, a lower production cost, and direct Native IoT cloud integration out-of-the-box, resembling the wireless versatility used in clinical trials, which can be evaluated in the future.

Unlike standalone digital devices such as those by [1] and [10], which oblige clinics to purchase redundant electronic spirometers, the proposed device utilizes an adapter configuration. It retains the validated physical mechanisms of conventional devices [3], augmenting them with precise sensing at a fraction of the cost. While flexible antennas [5] and multi-sensory chest patches [6] offer excellent passive vital sign logging, they cannot guide or enforce active respiratory volumes. The proposed 3D-printed structural enclosure ensures absolute sealing, keeping user breathing efforts directly linked to active exercise execution. Furthermore, eliminating turbine wheels eliminates mechanical failure modes caused by saliva moisture buildup, outperforming commercial clinical equivalents.

Standalone frugal systems [11] lack interactive software layer tracking, rendering home rehabilitation repetitive. The proposed integrated architecture bridges accurate solid-state transducer mapping with serious gaming, filling a prominent clinical gap by generating structural analytics for remote patient reporting.

Future work will focus on implementing the real-time mathematical conversion from raw differential pressure (ΔP) to volumetric flow rate (Q), mapping these values to deliver clinical parameters such as Forced Vital Capacity (FVC) and Peak Expiratory Flow (PEF).

ACKNOWLEDGMENT

The authors thank the Federal Institute of Education, Science, and Technology of Southeast Minas Gerais — Juiz de Fora Campus, and the Tutorial Education Program (PET), through the Pro-Rectorate of Teaching and the Ministry of Education (MEC), whose scholarships and resources were essential to support the research and extension activities presented here.

VI. CONCLUSION

The mechatronic development of the proposed device achieves a good balance between frugal engineering paradigms and the high-performance requirements of modern biomedical instruments. By replacing expensive closed commercial hardware with a low-cost and robust differential sensing array based on the ESP32-C3 and MPX5700DP, this solution proves to be capable of providing reliable metrics for decentralized respiratory rehabilitation, bridging the gap between clinical accessibility and engineering durability. Furthermore, the device was developed to ensure the airtightness of the pneumatic flow, allowing the patient to use conventional physiotherapy equipment while simultaneously interacting with the serious game. This hybrid integration between hardware and software makes it possible to provide real-time biofeedback, filling the literature gaps on the connection between precise measurement and gamification-based rehabilitation systems.

Abstract— Cardiac arrhythmias arise from a complex interplay between the heart's electrical activation and its structural architecture. Ventricular tachycardia (VT), a major cause of sudden cardiac death, typically requires detailed substrate mapping and signal analysis to delineate arrhythmogenic channels and scar regions for targeted ablation. Nevertheless, the quantitative relationship between local electrical and optical signals—acquired simultaneously via high-resolution optical and electrical mapping—and the underlying myocardial microstructure has rarely been characterized. This study aims to evaluate the spatial correspondence between electrophysiological mapping data and myocardial microstructure in the heart undergoing VT. Using a Langendorff perfusion system, hearts from two New Zealand White rabbits underwent VT induction with 1 µM carbachol and an S1–S2 stimulation protocol (100 bursts, 2 ms pulse duration, 1.3 s inter-burst interval); a third heart served as a non-arrhythmic control. High-resolution epicardial electrical and optical mapping were performed. Myocardial samples corresponding to each electrode site (n = 12 tissue samples per heart) were carefully excised and processed for histological analysis. Preliminary observations indicated that structural remodeling varied spatially across electrode-mapped regions. Some regions exhibited tissue organization comparable to that of the control heart, whereas others demonstrated mild myocyte disarray, increased intercellular spacing, and mild to moderate interstitial cellular infiltration. Notably, areas with near-normal histological appearance could still display abnormal electrical signals. These findings point to a complex, heterogeneous, and non-linear relationship between myocardial structure and local electrical activity. While cellular disorganization appears to contribute to arrhythmogenesis, it does not invariably manifest as abnormal electrical activity at the electrode site. Voltage mapping findings were concordant with these observations and suggest that voltage mapping alone may not fully capture the extent and pattern of underlying myocardial remodeling. This work underlines the importance of integrating detailed electrophysiological mapping with spatially comprehensive histological assessment in experimental models. Such an integrative approach may enhance mechanistic understanding of VT, refine identification of arrhythmogenic substrates, and ultimately improve the precision and efficacy of catheter ablation strategies.

Keywords— *Ventricular tachycardia, Electrophysiological mapping, Myocardial remodeling, Histological correlation, Arrhythmogenic substrate.*

I. INTRODUCTION

Cardiac arrhythmias arise from complex interactions between cardiac electrophysiology and myocardial microarchitecture, including fibrosis and myofiber orientation [1,2]. Ventricular tachyarrhythmias are associated with a substantial risk of sudden cardiac death; catheter ablation is an effective therapeutic modality but is limited by arrhythmia recurrence and procedural complications [3]. Ventricular tachycardia (VT) therefore remains a major contributor to sudden cardiac mortality, and detailed substrate characterization—encompassing high-resolution mapping and advanced electrophysiological signal analysis—is required to delineate arrhythmogenic channels and scar heterogeneities that can guide targeted ablation and improve clinical outcomes. Multimodal imaging approaches (optical and epicardial) in Langendorff-perfused rabbit hearts demonstrate good concordance for organized rhythms but reveal significant discrepancies during complex arrhythmias [4–6]. Structural remodeling, including myocyte disarray and alterations in wall thickness, generates heterogeneous patterns of activation and repolarization that facilitate reentrant activity. Fibrosis itself is highly heterogeneous in space: some fibrotic regions maintain conduction and exhibit pro-arrhythmic behavior, others are electrically quiescent,

and, conversely, certain areas with complex electrical activity may appear structurally normal on standard histological assessment [7–9]. The impact of fibrosis on conduction properties and rotor dynamics remains incompletely understood, largely due to its heterogeneous spatial distribution [2,10–12]. Integrative methodologies that combine electrophysiological recordings with three-dimensional microstructural information indicate the presence of frequency-dependent conduction block within fibrotic regions, effectively acting as a “low-pass filter” that can facilitate reentry [10,11]. Multi-electrode arrays (MEAs) alone may fail to detect intramural fibrotic substrates [12], whereas optical mapping offers high-resolution, contact-free recordings but is only rarely co-registered with histology in the same preparation. MEAs enable high-density epicardial mapping across sinus rhythm, paced activation, and reentrant circuits [11,13]. Three-dimensional correlative studies have demonstrated that myocardial architecture, non-myocyte content, and gap junction remodeling collectively modulate arrhythmia dynamics [10–12].

Rabbits constitute a well-established experimental model for reentrant arrhythmias and pharmacological testing, with repolarization characteristics that closely resemble those of humans. The Langendorff-perfused rabbit heart model provides a robust platform to relate structural remodeling to arrhythmogenic conduction patterns. However, despite the availability of high-resolution mapping of activation sequences, rotor behavior, and fibrillatory dynamics, direct histological validation at individual recording sites remains relatively uncommon [4,6,8,11–13]. Consequently, the integration of MEA-derived electrophysiological data with the corresponding underlying microstructure remains a critical and largely unmet need.

This study proposes a spatially defined histology method at the MEA segment level by combining optical-electrical rabbit mapping [4,5] with correlative electrophysiological pipelines [10,11,12]. To determine whether electrophysiological patterns correlate with healthy versus remodeled arrhythmogenic tissue, this study performed histological analysis on distinct ventricular regions dissected from beneath the MEA during VT, while electrical activity was also mapped with optical mapping.

II. METHODOLOGY

The study was authorized by the Federal University of ABC's Animal Ethics Committee (protocol 3947230519).

A. Experimental design

Three New Zealand rabbits (3-4 kg) had their hearts isolated and perfused using the Langendorff system. One heart perfused for 4-5 hours without arrhythmia induction served as a control. Sustained VT was induced in the remaining two hearts using programmed stimulation and 1 μM carbachol and pinacidil. To induce cardiac arrhythmias, a custom-made bipolar pacing catheter with two electrodes on its tip and 4 mm intra electrode spacing was used. The system included a custom-built, battery-powered, programmable current-source stimulator (Aleksa Tech) designed to deliver timed and controlled cardiac stimulation. In the S1-S2 protocol, a train of ten S1 (pulse width of 2 ms 1.3 s intervals) pulses with a 300 ms period was followed by an S2 pulse, with the interval decreasing from 150 ms to 20 ms until the refractory period was reached. Optical mapping was conducted by utilising the voltage-sensitive dye Di-4-ANBDQPQ. Norpix-StreamPix 9 software was used to capture simultaneous recordings at 500 frames per second, with a resolution of 1600 × 1000 pixels, 12-bit depth, and a total duration of 10 seconds (5000 frames total) [4]. To evaluate the Langendorff system's effects, heart weight was compared before and after perfusion.

B. Electrophysiological mapping

Electrical and optical mapping, along with signal plotting, were used to confirm the mechanism of generated arrhythmias, as described before [4]. Voltage maps give a static assessment of cardiac tissue, with local electrogram (EGM) amplitude inversely related to the degree of remodelling or scar tissue replacement [14,15]. Voltage maps were used to characterize the epicardial substrates of the produced arrhythmias and to compare them with histological characteristics. The voltage cutoff for healthy epicardial tissue in unipolar configuration was defined as 17.4 mV for the ventricle (V) [14,15] . MEAs were produced from platinum electrodes removed from a reprocessed mapping catheter (St. Jude Medical Livewire, Medline ReNewal), insulated, and embedded in a PET substrate to improve flexibility, epicardial conformity, and signal acquisition. Voltage maps of the ventricular region were generated utilizing MEAs (with square shape 4×4 electrodes with a side length of 1 mm), specifically the 16 electrodes arranged from 81 to 97 with 4 mm distance between them, at 4 kHz, that make up each array [14]. Each voltage map was created using a single beat and 16 peak-to-peak amplitudes taken simultaneously from 16 sites. Peak-to-peak amplitudes were manually derived from unipolar signals.

Purple represents amplitudes above the relevant threshold (≥17.4 mV for the normal healthy ventricle). Values between 17.4 to 0.5 mV were classified as transition regions with reduced voltage but not compatible with dense scar, while values below 0.5 mV were defined as low voltage areas (LVAs), representing completely nonfunctional tissue (displayed in red), following the colour scale convention used in clinical electroanatomical mapping [14,16]. No spatial interpolation was used. Maps were displayed, with the 16 points represented as 16 squares (each holding the MEA electrode number), and the colour of each square denoting the amplitude range. Values over the healthy epicardial voltage cutoff are referred to as "Healthy Values" (HV), values below 0.5 mV are LVAs, and values within the transition region (17.4 to 0.5 mV) are "non healthy tissue".

C. Histology and tissue sampling

After labelling the MEA areas on the heart and photographing them, the hearts (control and arrhythmogenic) were perfused with 4% formaldehyde at the same flow rate as throughout the experiment and placed in a small beaker containing 4% formaldehyde for 30 minutes. Heart weight was measured again to compare pre- and post-Langendorff values. Keeping the same orientation as during Langendorff perfusion, the mapped tissue sections were dissected and sliced into four spatial pieces that were exactly aligned with electrode placements.

For each ventricular MEA, three-quarters of the mapped tissue area (12 mapped electrodes tissue area per heart = 36 tissue samples) was immersed in 4% formaldehyde overnight at room temperature, then refrigerated until histological processing. Each tissue segment (representing one electrode) was stained with hematoxylin and eosin (H&E) to evaluate

cellular morphology, myocyte alignment, and inflammatory alterations, as previously described [17]. The features examined were cardiac hypertrophy, intercellular spacing, nuclear clustering, and mononuclear or interstitial cell infiltration, normal myocytes are parallel orientated, but damaged tissue has scattered and disorganized myocytes with oblique fibers. Each feature was semi-quantitatively evaluated by an experienced investigator blinded to the electrophysiological mapping data, as follows: 0 = minimal, 1 = mild, 2 = moderate, and 3 = severe [18,19]. Based on these variables, a semi-quantitative histological analysis of mapped tissue areas at the electrode level was performed on the control and arrhythmogenic hearts to determine concordance or discordance with abnormal signals recorded at each electrode.

D. Statistical analysis

Statistical analyses were performed in MATLAB (version R2024a; MathWorks, Natick, MA, USA) using the Statistics and Machine Learning Toolbox. Spearman's rank correlation coefficient and paired t-test were computed, and figures were generated using native MATLAB plotting functions.

III. RESULTS

Heart weight before and after the experiment, voltage mapping and histological analysis are depicted in the following tables and figures.

As shown in Table I, on the average, the hearts showed a very slight decrease of 1.4% from the extraction to the end of the experiment. The average difference was -0.21 g, with a 95% confidence interval ranging from -0.87 to +0.45 g, which indicates that the true population effect could be a decrease, no change, or even a slight increase. Consequently, the paired t-test was not statistically significant ($t(2) = -1.34$, $p = 0.311$) difference in the heart weights of the animals at the time of immediate extraction following the initial surgical procedure or at the end of the experimental protocol either in control or non-control condition. This data show that the experimental interventions used throughout the study period did not cause any obvious or only minor detectable changes in heart mass, that would distinguish the non-control heart from the control heart. Furthermore, the lack of a significant difference at both time points suggests that any potential procedural or physiological variability impacting heart weight was probably low and uniformly distributed across the two conditions.

TABLE I: Animals' hearts weigh right after the extraction and at the end of experiment in control heart vs hearts under ventricular tachycardia (VT).

Heart weight / Experiments	Right after heart extraction (g)	End of the experiment (g)
Control	14.4	13.98
VT: Case 1	12	11.7
VT: Case 2	9.1	9.2

The figs 1 and 2 below depicted the simultaneous acquisition of optical (in blue) and electrical (in red) signals from the mapped region of the heart, as defined by the MEA recording area, during a VT episode.

Notably, the observed rhythms follow a fast and consistent pattern across both modalities, implying a stable and repeating electrophysiological activation sequence. The simultaneous nature of these recordings enables a direct comparison of electrical and optical activities. The detected rhythms' regularity and frequency indicate a sustained tachyarrhythmia.

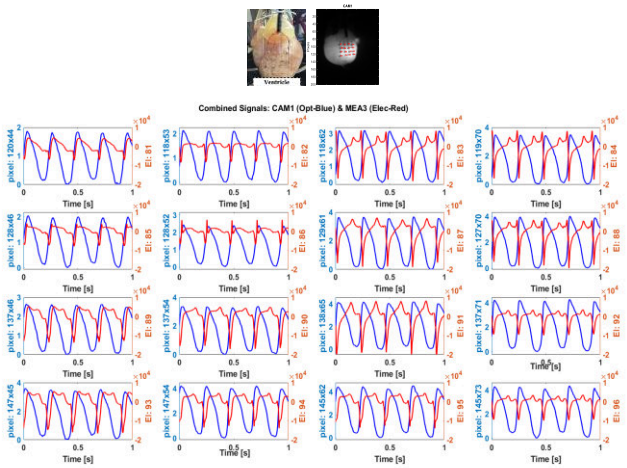

Fig. 1. Electrical and optical signals at the electrode scale of the heart under ventricular tachycardias: case 1 (Blue: optical, Red: electrical).

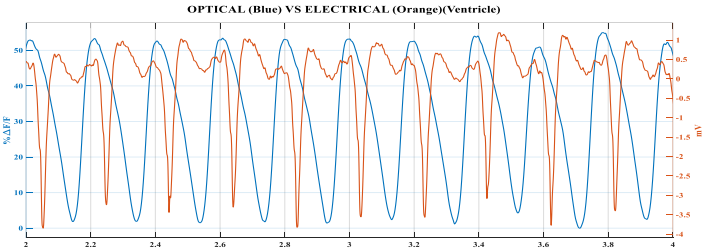

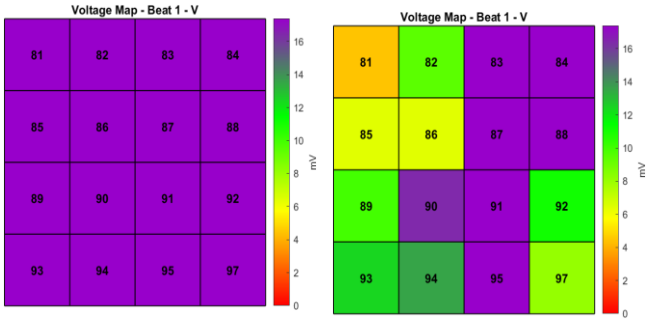

Fig. 2. Electrical and optical signals at one electrode of the heart under ventricular tachycardias: case (Blue: optical, Orange: electrical)

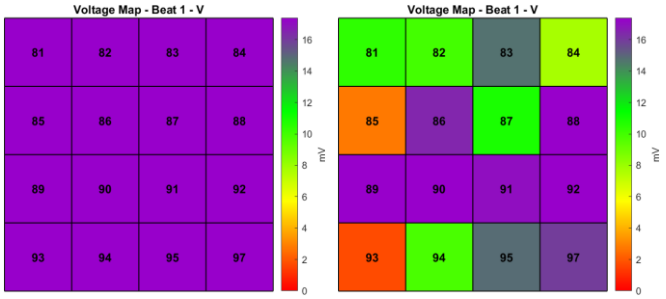


The peak-to-peak voltage mapping of the control heart's ventricular region (see figs. 3,4) showed that all 16 electrodes within the multi-electrode array recorded voltage values within the normal physiological range. The mapping area was consistently purple. This uniform distribution of normal voltages indicates that the control heart, which was perfused in the Langerdoff system without inducing cardiac arrhythmia, has intact myocardial electrical integrity. The absence of low-voltage zones indicates that the control condition maintained healthy despite perfused until heart is arrested, uniform tissue excitability, providing a reliable baseline.

In notable contrast, voltage maps obtained from hearts subjected to experimentally generated VT revealed a very distinct pattern. In these VT conditions, several of the electrodes reported peak-to-peak voltage values below the defined threshold. Low voltage areas often indicate re-entrant arrhythmias, such as VT. The increasing size of these abnormal voltage areas in the VT group emphasizes the electrophysiological alterations associated with sustained tachyarrhythmias.

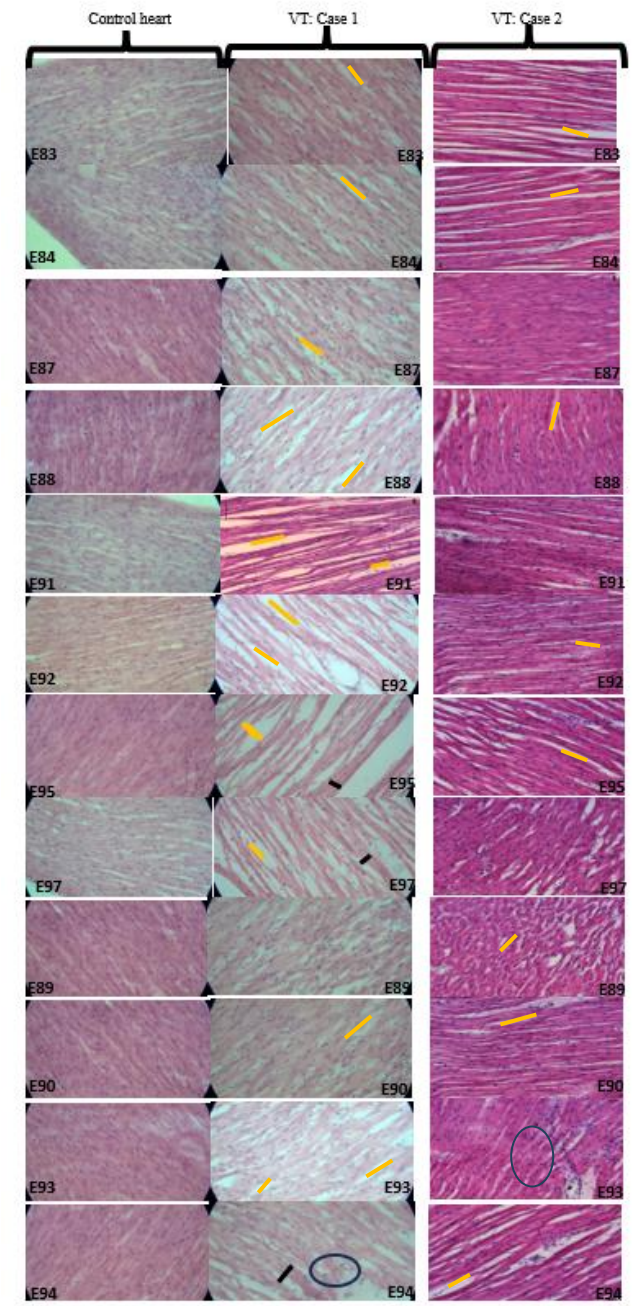
Sinus Rhythm: Control heart heart VT: Case 1

Fig. 3. Peak to peak voltage mapping of control heart vs VT case 1 (Colours: Purple-normal voltage areas while Red-low voltage areas).

Sinus Rhythm: Control heart VT: Case 2

Fig. 4. Peak to peak voltage mapping of control heart vs VT case 2 (Colours: Purple-normal voltage areas while Red-low voltage areas).

The histological study (see fig.5), of the control heart showed well-preserved and organized tissue architecture across all myocardial areas. Each of the analyzed histological parameters—such as myocyte alignment, interstitial space width, and absence of inflammatory infiltrates —was assigned a score of zero, indicating a minimal degree of abnormalities. This uniform scoring suggests that the control heart, which received only standard perfusion without arrhythmia induction, was structurally intact throughout the experimental procedure. The lack of identifiable histological changes confirms the electrophysiological findings indicating the control preparation was healthy and free of pathological remodelling. In contrast, hearts from induced VT cases showed changes in tissue organization. These modifications included altered myofiber hypertrophy (black bar), increased intercellular spacing (yellow bar), isolated areas of myocyte disarray, and, in some cases, mild to moderate interstitial or inflammatory cell infiltration (blue circle). Importantly, the severity of these changes did not vary uniformly across the tissue; rather, histological scores varied inconsistently among the various tissue segments examined. Some segments exhibited very minor modifications (scores 0 or 1), whilst others showed more substantial anomalies (scoring 2 or 3), indicating a diverse pattern of structural remodelling. This inconsistency is consistent with the known pathophysiology of ventricular tachycardia.



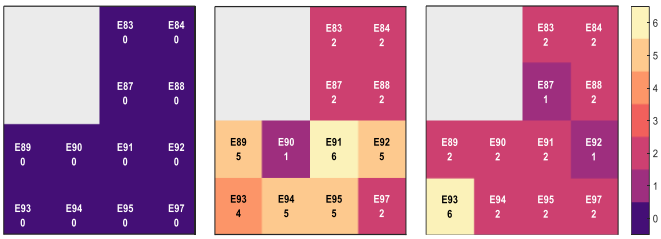


Fig. 5. Histological imaging (Hematoxylin Eosin 20x; scale bar 500 µm) of the mapped tissue area of each electrode in control heart and in the hearts under ventricular tachycardias (VT) cases. Hypertrophy fiber (black bar), intercellular space (yellow bar), Clusters of nuclei (blue circle).

After scoring each histological parameter in each electrode mapped tissue area (12 mapped electrodes area per heart = 36 tissue samples) in control heart and VT cases hearts, the sum of the score per electrode lead to generate the map depicted on fig.6. The total histology score in the control heart remained zero, whereas in the induced VT hearts it ranged from one to six. This range implies that the structural changes detected during VT were not equally severe across different tissue segments. A score of one represents minor alterations, whereas a score of six indicates more disruption of tissue architecture. This demonstrated the degree and distribution of non-fibrotic remodelling in the ventricular segments investigated during VT.

SR: Control heart heart VT: Case 1 VT: Case 2

Fig. 6. Ventricle MEA-Total histological score per electrodes (12 per condition) of the studied histological biomarkers in control and VT cases. Each colour indicated different score.

The pooled dataset (Control, VT1, and VT2 hearts; n = 12 electrode sites per heart) revealed a weak-to-moderate negative correlation between histological score and voltage amplitude (Spearman's ρ = -0.39), although this relationship did not reach statistical significance (p = 0.87).

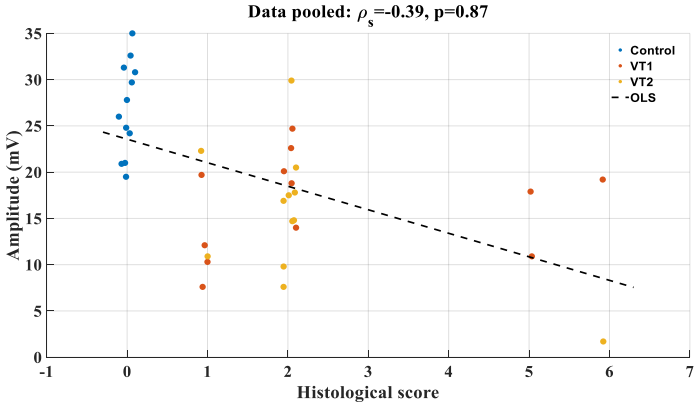

Fig. 7. Scatter plot graph of the histological score vs voltage amplitude in different condition.

The data in the table below show varied patterns among the electrodes examined in hearts subjected to induced VT. Specifically, some electrodes in the VT condition showed normal voltage values while having a total histology score that exceeded the normal reference range. Other electrodes showed abnormally low voltage values while also having total histology scores that are above the normal range.

TABLE II: Summary of histological scores for normal versus low peak-to peak voltage of the electrodes across VT cases.

VT Case	Voltage Status	Electrodes (n)	Total histological Score per electrode
1	Normal	7 (E83,E84,E87,E88,E90,E91,E95)	2, 2, 2, 2, 1, 6, 5
1	Low	5 (E89,E92,E93,E94,E97)	5, 1, 2, 1, 1
2	Normal	6 (E88,E89,E90,E91,E92,E97)	2, 2, 2, 2, 1, 2
2	Low	6 (E83,E84,E87,E93,E94,E95)	2, 2, 1, 6, 2, 2

IV. DISCUSSSION

The successful induction of sustained ventricular tachycardia (VT) in Langendorff-perfused rabbit hearts, combined with reproducible, simultaneous electrical and optical recordings obtained using the MEA system (Figs. 1 and 2), aligns with established rabbit and rodent models of experimental arrhythmogenesis [4]. The lack of a significant difference in heart weight before versus after the experiments may indicate that Langendorff perfusion did not promote an obvious myocardial water absorption or induce appreciable non-fibrotic structural remodeling (Table I). This interpretation is further supported by the preserved peak-to-peak voltage and the minimal histological score (0) observed in the control heart (Figs. 3–6; Table II).

In contrast, multiple electrodes in the VT group exhibited reduced peak-to-peak voltage accompanied by higher histological scores relative to the control, thereby demonstrating that voltage mapping can discriminate between electrophysiologically and structurally normal myocardium and arrhythmic substrate (Figs. 3, 4, 6, and 7). Notably, none of the mapped electrodes in the VT hearts showed histological scores comparable to those in the control heart, indicating persistent structural alterations following arrhythmia induction. These data further suggest that the pacing and VT induction protocols contributed to non-fibrotic structural remodeling. Although remodeling was evident in all VT cases, its distribution was regionally heterogeneous across the mapped tissue, consistent with prior multimodality investigations that have demonstrated spatial heterogeneity of structural and functional remodeling within the VT substrate [20,21].

Joint analysis of the site-matched histological and voltage data from the mapped electrodes (n = 12 per condition) revealed heterogeneous associations between tissue architecture and local electrical activity (Table II). Several electrodes displayed preserved peak-to-peak voltage despite elevated histological scores, indicating that structural remodeling does not uniformly manifest as a reduction in measured voltage. Comparable findings have been described in prior studies examining VT substrates and arrhythmogenic remodeling [21–23]. Conversely, tissue regions exhibiting both low voltage and high histological scores likely correspond to severely compromised myocardium with advanced remodeling. However, some recording sites displayed reduced voltage in the presence of only mild histological abnormalities, suggesting that electrophysiological impairment may precede overt structural remodeling or may reflect microstructural changes not captured by conventional histological evaluation.

Collectively, these observations corroborate earlier reports on the limited specificity of fixed voltage thresholds for identifying critical arrhythmogenic substrate [21–23]. Overall, this preliminary study supports the concept that structural remodeling and electrophysiological abnormalities are closely interrelated yet not uniformly coupled within the VT substrate, particularly in the context of post–myocardial infarction ventricular tachycardia [3,20,21]. The integration of simultaneous electrical and optical mapping with sites-matched histological analysis establishes a robust experimental framework for elucidating the mechanisms underlying arrhythmia initiation and maintenance, and provides mechanistic insight that is not attainable from clinical mapping studies alone.

V. CONCLUSION

This pilot study suggests that arrhythmogenesis and myocardial remodeling are closely related, but not always in a direct correlation. Using voltage mapping, as well as electrode-matched histology, we discovered that structural alterations can be arrhythmogenic or electrically quiet.

Furthermore, certain parts of tissue with aberrant voltage appeared structurally close to normal. On the other hand, not all low-voltage sites cause or maintain arrhythmia. The proposed spatial correlation pipeline could aid in understanding disease mechanisms and revising the criteria for ablation therapy targets.

***Abstract*—The electric potential across the cell membrane, known as the resting potential under quiescent conditions, is fundamental to the transport of nutrients, water, and salts to and from the cell. The GHK equation describes membrane electric potential as a function of the involved ions concentrations and respective permeabilities. However, GHK equation does not account for the active ion transport (ion pump). In other words, GHK equation does not explain the stability of intracellular ion concentrations over time. Recently, an extended GHK equation, including terms describing the ion pumps, has been proposed. The aim of this communication is to discuss the ionic currents through the cell membrane, including those due to the ion pumps, using this novel mathematical model. Because the developed model is based on the ion currents, a simplified version of it, valid for potassium and sodium ions, is presented and evaluated using experimental data available in the literature. A brief comment on energy consumption by the ion pumps is also provided.**

***Index Terms*—membrane potential, resting potential, ion pumps, GHK equation**

I. Introduction

The electrical potential difference across the cell membrane, known as the resting potential under quiescent conditions, is fundamental to solute and water transport, embryonic development, and cancer, among other processes [1]. Membrane potential (V) is classically attributed to the concentration difference of some ionic species across the cell membrane [2]-[4]. By applying Fick's first law and Ohm's law, and assuming, a constant electric field across the cell membrane, a relationship between V and the concentrations of the ion involved, each weighted by its respective membrane permeability, can be derived [5],[6]. This relationship is known as the Goldman-Hodgkin-Katz (GHK) equation and, for a cell membrane permeable to potassium, sodium, and chloride ions, it can be written as

$$V = \frac{kT}{q} \ln \frac{P_K[K]_o + P_{Na}[Na]_o + P_{Cl}[Cl]_i}{P_K[K]_i + P_{Na}[Na]_i + P_{Cl}[Cl]_o}, \qquad (1)$$

where k is the Boltzmann constant, T the absolute temperature, q the elementary electrical charge, [K] the potassium ion concentration, [Na] the sodium ion concentration, and [Cl] the chloride ion concentration, with the subscripts "o" and "i" indicating that the concentrations are in the external and internal media of the cell, respectively, and P_K the membrane permeability to the potassium ion, P_{Na} the membrane permeability to the sodium ion, and P_{Cl} the membrane permeability to the chloride ion. It should be noted that if an ion species is in equilibrium across the membrane, V can be calculated using the Nernst equation applied to this ion [2],[3]. For example, for chloride ion, the Nernst equation can be written as

$$V_{Cl_{NERNST}} = \frac{kT}{q} ln \frac{[Cl]_i}{[Cl]_o}, \qquad (2)$$

Whenever the membrane potential calculated using GHK coincides with the Nernst potential for one of the ions involved, in this example $V_{Cl_{NERNST}} = V$, it is easy to demonstrate that GHK can be simplified to

$$V = \frac{kT}{q} \ln \frac{P_K[K]_o + P_{Na}[Na]_o}{P_K[K]_i + P_{Na}[Na]_i}, \qquad (3)$$

The Nernst equation describes a situation of passive thermodynamic equilibrium [7]. Thus, it can be concluded that in this example, chloride ion does not require active ion transport across the membrane. On the other hand, potassium and sodium ions, which are not in passive thermodynamic equilibrium, require specific "ion pumps."

From the perspective of the mathematical model, it remains a matter of debate whether the relationship between V and ion concentrations is influenced indirectly by the action of ion pumps maintaining the stability of ionic concentrations over time or directly [8]-[13]. If the influence is direct, it can be stated that equation (3) is incomplete, as it lacks a specific term related to the action of ion pumps.

One experimental approach to evaluating (3) is to modify gradually one of the concentrations while observing the resulting effect on V. The literature contains studies that follow this methodology. For instance, the relationship between V and $[K]_o$ with the other concentrations held constant was studied in detail, showing that in certain situations there are discrepancies between (3) and the experimental values [14]. Thus, the direct influence of the ion pump on V was clearly

demonstrated; specially when temperature was reduced or ouabain was applied, both known methods of blocking ion-pump activity, because (3) can, this way, accurately account for the potential V across a wide range of $[K]_o$ values.

The derivation of an equation relating the concentrations of ions permeable to the membrane and V and explicitly incorporating terms describing the action of ion pumps was recently presented (work submitted to publication) [15]. This equation has a generic format as it can be applied to numerous ions permeable to the membrane simultaneously, including those with valence with modulus greater than one. In addition, several properties of the developed model had been discussed, such as its correlation with Donnan equilibrium and Nernst equation. However, the implications of this new mathematical model for interpreting ionic currents have not yet been discussed.

The aim of this work is to discuss the ionic currents through the cell membrane, including those due to ion pumps, using a novel mathematical model which relates the concentrations of ions permeable to the membrane and V, and explicitly incorporates terms describing the action of ion pumps [15]. Because the developed model is based on, both passive and active, ion currents, a simplified form of it (valid for potassium and sodium ions) is presented and compared with experimental data available in the literature [14]. As active transport of ion requires energy, a brief comment on energy consumption by the ion pumps is also provided. To facilitate the communication reading, a list of mathematical symbols used, and respective dimensions, is appended.

II. Development

Figure 1 schematically illustrates a typical cell with a membrane permeable to potassium and sodium ions represented by their concentrations $[K]$ and $[Na]$, where the subscripts "*o*" and "*i*" indicate the concentrations in the external and internal cellular environments, respectively. The x-axis indicates directions perpendicular to the cell membrane surface. It is known that these ion species cross the membrane only through specific channels [17]-[20]. Thus, it can be stated that the number of open channels determines the surface area through which each ion species crosses the membrane. Consequently, it is not possible to compare the ion fluxes (ionic current per unit area) of potassium and sodium; instead, it is necessary to analyze the absolute ion currents.

In Figure 1, I_C, I_D, I_E, and I_P represent the currents, associated with membrane equivalent capacitance (*C*), the ion concentration gradient, the electric potential gradient, and ion pumps, respectively, with the subscripts K, Na, and Cl indicating that the currents are those of potassium, sodium, and chloride ions, respectively.

From a conceptual point of view, I_C, I_D, and I_E can be considered passive currents, as they do not directly consume energy, whereas I_P can be classified as an active current because it directly consumes energy (ATP) directly during ion transport [13].

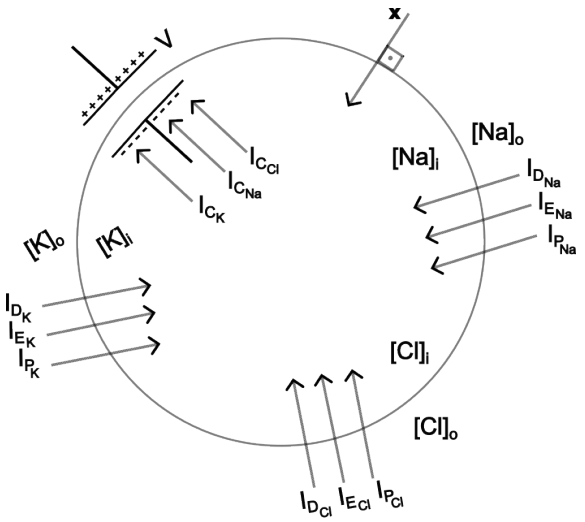

Fig. 1. Schematic representation of a typical cell indicating ion currents due to membrane capacitance (I_C), the ion concentration gradient (I_D), electric potential (I_E), and the ion pump (I_P). The x-axis indicates directions perpendicular to the cell membrane.

A. Potassium currents

The intracellular compartment is generally much smaller than the extracellular one, therefore, $[K]_o$ and $[Na]_o$ can be considered constant [13]. Consequently, for $[K]_i$ and $[Na]_i$ to remain constant over time, the total membrane currents (I_{T_K} and $I_{T_{Na}}$) must be zero.

Thus, for the potassium ion, it is possible to write

$$I_{T_K} = I_{C_K} + I_{D_K} + I_{E_K} + I_{P_K} = 0 \tag{4}$$

The capacitive current is given by

$$I_{C_K} = C\frac{dV}{dt}, \tag{5}$$

where *t* is the time.

The ion current due to the ion concentration gradient can be calculated using Fick's first law, and is given by

$$I_{D_K} = -A_K D\left(\frac{d[K]}{dx}\right), \tag{6}$$

where *D* is the diffusion coefficient, and A_K is the total area, through which K ions circulate passively.

The ion current due to the electric field (ε) can be determined using Ohm's Law, and can be represented as

$$I_{E_K} = A_K \mu_K [K]\varepsilon, \tag{7}$$

where μ_K is the ion mobility, while (ε) is given by

$$\varepsilon = -\frac{dV}{dx}. \tag{8}$$

Ion pumps can have a structure similar to that of selective ion channels, that is, they can be activated or deactivated by external factors such as temperature and the action of ion-pump blockers [21],[22]. According to [13],[23],[24], the

current density resulting from the ion pump is a function of *V*. However, it is known that ε directly influences I_{E_K} and the membrane characteristics (ε can influence the number of simultaneously opened potassium and sodium channels) that determine both I_{E_K} and I_{D_K} [25],[26]. Thus, assuming that ion concentrations remain constant for any value of *V*, it can be concluded that I_{P_K} must be a function of ε. In this work, it will be assumed that I_{P_K} is a linear function of ε. Therefore, using (8), one can write

$$I_{P_K} = -\alpha_k \frac{dV}{dx}, \tag{9}$$

where, α_k is a function of the other factors influencing I_{P_k}, such as $[K]_o$, $[K]_i$, $[Na]_o$, $[Na]_i$, blockers and *T*.

B. Potassium and sodium equilibrium electric potential

Substituting (6), (7), and (9) in (4) and considering that the electric potential is constant that is, $I_{C_K} = 0$ one obtain

$$-A_k D \frac{dK}{dx} - A_k \mu_k [K] \frac{dV}{dx} - \alpha_k \frac{dV}{dx} = 0. \tag{10}$$

Knowing that Einstein's relationship is given by $\frac{D}{\mu} = \frac{kT}{q}$ and that α_K is not a function of x, integrating from the outer side to the inner side of the cell, after manipulation (10) can be written as

$$V_K = \frac{kT}{q} ln \left(\frac{\alpha_K + A_K \mu_K [K]_o}{\alpha_K + A_K \mu_K [K]_i} \right), \tag{11}$$

where, the logarithmic term cannot be negative, that is

$$\left(\frac{\alpha_K + A_K \mu_K [K]_o}{\alpha_K + A_K \mu_K [K]_i} \right) > 0. \tag{12}$$

It is observed that, respecting (12), α_K can assume any value, including the null value, i.e., $I_{P_K} = 0$, for which from (11) it follows that

$$V_{K_{NERNST}} = \frac{kT}{q} ln \frac{[K]_o}{[K]_i}, \tag{13}$$

which is the Nernst equation applied to the potassium [2],[3].

Sodium, like potassium, is a monovalent positive ion. Therefore, for sodium ion the development is analogous to that for potassium ion. Thus, (11) and (12) can be rewritten replacing the potassium ion for the sodium ion providing

$$V_{Na} = \frac{kT}{q} ln \left(\frac{\alpha_{Na+} A_{Na} \mu_{Na} [Na]_o}{\alpha_{Na} + A_{Na} \mu_{Na} [Na]_i} \right), \tag{14}$$

and

$$\left(\frac{\alpha_{Na} + A_{Na} \mu_{Na} [Na]_o}{\alpha_{Na} + A_{Na} \mu_{Na} [Na]_i} \right) > 0. \tag{15}$$

Similarly to potassium, provided that (15) is respected, α_{Na} can to assume any value, including the null value, i.e., $I_{P_{Na}} = 0$, for which from (14) it follows that

$$V_{Na_{NERNST}} = -\frac{kT}{q} ln \frac{[Na]_o}{[Na]_i}, \tag{16}$$

which is the Nernst equation applied to the sodium [2],[3].

C. Calculation of the membrane electric potential

For the cell with membrane potential *V* necessarily we have

$$V_K = V_{Na} = V. \tag{17}$$

Finally , using (11), (14) and (17) together with the identity

$$y = K\ ln \frac{a}{b} = K\ ln \frac{c}{d} = K\ ln \frac{a+c}{b+d} \tag{18}$$

after manipulation, one obtains

$$V = \frac{kT}{q} \ln \frac{A_K \mu_K [K]_o + A_{Na} \mu_{Na} [Na]_o + \alpha_K + \alpha_{Na}}{A_K \mu_K [K]_i + A_{Na} \mu_{Na} [Na]_i + \alpha_K + \alpha_{Na}}. \tag{19}$$

It is observed that in this case doing $P = A \frac{kT}{q} \frac{\mu}{w}$, where *w* is the thickness of the membrane (*P* was originally defined as $P = \frac{kT}{q} \frac{\mu}{w}$ [3]), (19) becomes (3), or in other words, GHK applied to the sodium and to potassium ions is recovered for $\alpha_K = \alpha_{Na} = 0$. In addition, knowing that, in quiescent conditions, the membrane permeability to potassium ion is much greater than that to the sodium ion ($P_K \gg P_{Na}$) and that in intracellular media the sodium ion concentration is much lower than potassium ion concentration ($[K]_i \gg [Na]_i$) [17], (19) can be rewritten in a simplified form

$$V = \frac{kT}{q} ln \left(\frac{[K]_o + \frac{A_{Na} \mu_{Na}}{A_K \mu_K} [Na]_o + \frac{\alpha_{Na} + \alpha_K}{A_K \mu_K}}{[K]_i + \frac{\alpha_{Na} + \alpha_K}{A_K \mu_K}} \right). \tag{20}$$

III. EXPERIMENTAL MODEL AND RESULTS

To test the validity of (20) one can follow the classic methodology which consists, as already mentioned, in to obtain the relationship between V and $[K]_o$. However, first it is necessary to determine $\frac{\alpha_{Na} + \alpha_K}{A_K \mu_K}$. For this purpose, it was used the experimental data from the work of [14] obtained using the cell of the gastroesophageal ganglion of the marine mollusk *Anisodoris Nobilis*. Among the reasons for this choice, one can mention the differences between the theoretical, using GHK, and the practical results, experimental data obtained under various temperatures and under conditions in which the ion pumps cease to operate, such as low temperatures and the action of blockers [14]. Unfortunately, the experimental data are not presented in tabular form [14]. Thus, it was necessary import the figures into the AutoCAD application, allowing, using ID POINT function, to construct a table $[K]_o$ versus V. Note that it is not available a table $\frac{\alpha_{Na} + \alpha_K}{A_K \mu_K}$ versus $[K]_o$, which would allow to use conventional methods of curve fitting. However, using equation (20), it is known that $\frac{\alpha_{Na} + \alpha_K}{A_K \mu_K}$ is a function of $[K]_0$, it is not a function of V, and must have the dimensions of concentration. Moreover, figure (2) shows a point of minimum, and to increase in modulus a logarithmic function (20), the first choice is an exponential function.

Thus, using the data from [14] $\frac{A_{Na} \mu_{Na}}{A_K \mu_K} = \frac{P_{Na}}{P_K} = 0.033$, $[Na]_o = 480.5 mM/l, [K]_i = 235 mM/l$ and $T \approx 290K (\approx 17°C)$, after trial and error, it was observed that the experimental data were better adjusted using following expression

$$\frac{\alpha_K + \alpha_{Na}}{A_K \mu_K} = [K]_R \left[-p e^{-d \left(\sqrt{\frac{[K]_o}{[K]_R}} - 1 \right)^4} + s \right], \tag{21}$$

with the parameters $[K]_R$, p, d and s, adjusted for 7.5 mM /l ; 1.49 ; 14 and 0.16 , respectively . Combining (21) with (20) gives

$$V = \frac{kT}{q} ln \left[\frac{[K]_o + \frac{A_{Na}\mu_{Na}}{A_K\mu_K}\ [Na]_o + [K]_R \left(-pe^{-d\left(\sqrt{\frac{[K]_o}{[K]_R}}-1\right)^4} + s \right)}{[K]_i + [K]_R \left(-pe^{-d\left(\sqrt{\frac{[K]_o}{[K]_R}}-1\right)^4} + s \right)} \right] \quad (22)$$

Then, (22) was evaluated using the remained experimental data from [14]. Here also were used $\frac{A_{Na}\mu_{Na}}{A_K\mu_K} = \frac{P_{Na}}{P_K} = 0.033$, $[Na]_o$=480.5 mM/l, $[K]_i$=235 mM/l for temperatures 277K($\approx 4°C$), 284K($\approx 11°C$) and 290K($\approx 17°C$), with and without the application of a ion-pump blocker, ouabain. The parameters $[K]_R$, *p*, *d* and *s*, were adjusted as shown in Table I.

Figure 2 shows experimental data from [14] together with theoretical results obtained using (22) highlighting the curve (continuous black line) used to obtain empirically (21).

TABLE I
PARAMETERS *p*, *d*, $[K]_R$ AND *s* USED TO ADJUST THE GRAPHS GENERATED USING (21).

Adjusted Parameters	**Experimental data**				
	277K	284K	290K	284K + Ouabain	284K $[Na]_o$=0
p	0.16	1.14	1.49	0	0
d	14	14	14	14	14
$[K]_R$(mM/l)	7.5	7.5	7.5	7.5	7.5
s	0.16	0.16	0.16	0.16	- 0.67

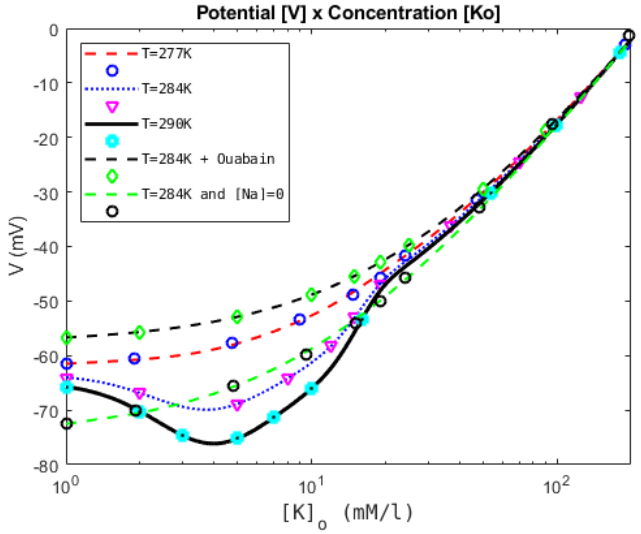

Fig. 2. Graph of *V* versus $[K]_o$ using (22) for the experimental data of [14]. The experimental conditions includes *T*=277K, *T*=284K,*T*=290K, *T*=284K with ouabain, *T*=284K with *Na*=0 and $\frac{A_{Na}\mu_{Na}}{A_K\mu_K} = \frac{P_{Na}}{P_K} = 0.033$, $[Na]_o$=480.5 mM/l, $[K]_i$=235 mM/l with $[K]_R$=7.5 mM/l. Parameters *p*,*d* and *s* were adjusted as show in Table I.

The correlation coefficient between the theoretical values using (22) and the available experimental values are greater than 0.95.

IV. Discussion and Conclusion

Based on the hypothesis that the electric current due to the ion pump is proportional to the electric field through membrane (see (9)), a mathematical model describing the relationship between V and the ion concentrations weighted by the respective permeabilities and the action of ionic pumps was presented. The correlation coefficient between the experimental data available in literature and the developed model was higher than 0.95. It is important to emphasize that the ion-pump characteristics are defined by α, which may not necessarily to be a linear function. In fact, (21) shows that $\frac{A_{Na}\mu_{Na}}{A_K\mu_K}$ is not a linear function of $[K]_o$.

Among the characteristics of the developed model, it can be observed that all the descriptive equations of the equilibrium state of involved ions, equations (11) and (14), the general equation (20), the simplified one (22) and the Nernst potential for chloride ion result in the membrane electric potential *V*. The equation to be used to determine *V* will depend on knowledge of the involved parameters. In this way, the empirical determination of the relationship $\frac{\alpha_{Na}+\alpha_K}{A_K\mu_K}$(see (21)) in the present work justifies the use of (20) or, more specifically for its simplicity, of (22). From a conceptual point of view, it is interesting to note that (11) and (14) explicitly show the difference between the equilibrium electric potential for the sodium and potassium ions (V_K=V_{Na}=V) and the respective thermodynamic equilibrium electric potential (Nernst potential) for the mentioned ions (chloride ion is in thermodynamic balance, $V_{Cl_{NERNST}}$=V). Figure 3 shows the comparison between electric potential of the membrane, which represents the equilibrium potential for all ions, and the Nernst electric potentials for sodium and potassium ions with $V_{Cl_{NERNST}}$=V, where here it was considered, as for most cells,$[K]_o < [K]_i$, $[Na]_o > [Na]_i$ and $[Cl]_o > [Cl]_i$, with the membrane permeability to sodium ion being much lower than that to potassium ion.

Note that, as demonstrated for sodium and potassium ions, in case of α for a given ion to be equal to zero, necessarily the membrane and Nernst electric potentials for this ion will equal to each other, see (13) and (16). In other words, for this ion I_P=0. Therefore, it is possible to conclude that for a membrane permeable to the sodium, potassium, and chloride ions, with $V_{Cl_{NERNST}}$=V, $I_{P_{Cl}}$ is equal to zero, while I_{P_K} and $I_{P_{Na}}$ are different from zero. In fact, several studies indicate that $V_{Cl_{NERNST}}$ is equal or nearly equal to *V* [7].

Unfortunately, in the present study, it is not possible to determine the absolute value of the electric current due to the ion pump. However, the current due to the ion concentration gradient I_D, for a given membrane electric potential *V*, can be considered constant. In other words, I_D can be taken as a reference.

The directions of I_E and I_D can be easily determined by observing the differences in ion concentrations between the

internal and external cell's media and the polarity of *V*. Thus, remembering that according to (4) the sum of the currents must be zero, and knowing that I_C=0, the value of $I_E + I_P$ can be determined, allowing also to determine the direction of I_P, as the direction of I_E is known. Figure 4 illustrates the currents due to the ionic concentration gradient I_D , to electric potential gradient I_E and to ion pumps I_P, for sodium, potassium and chloride ions.

The fact that, for a given ion, the sum $I_E + I_P$ being directly related to I_D may be important for understanding membrane energy consumption due to ion pumps. According to (22), the membrane potential has a value between the Nernst potential for sodium and for potassium (see figure 3). As $P_K \gg P_{Na}$, *V* tends to have a value closer to the Nernst potential for potassium, therefore, I_{E_K} has opposite direction and a lower value than that of I_{D_K}. Thus, based on the presented arguments, the current due to the potassium ion pump I_{P_K} has a relatively small value (see Figure 4). For sodium ion, $I_{E_{Na}}$ and $I_{D_{Na}}$ have the same direction, therefore the current due to the sodium ion pump $I_{P_{Na}}$ has a relatively high value. However, remembering that $P_K \gg P_{Na}$, the value of $I_{D_{Na}}$ must certainly be much smaller than I_{D_K}. This way, the values of I_{P_K} and $I_{P_{Na}}$ should not be very different from each other. In fact, it can be found in the literature works demonstrating that the ratio between the sodium and potassium ion pumps is 3 to 2 ions [27]. In conclusion, the energy consumption to maintain I_{P_K} and $I_{P_{Na}}$ may be minimized provided that I_{D_K}, and $I_{D_{Na}}$ are kept at minimum values.

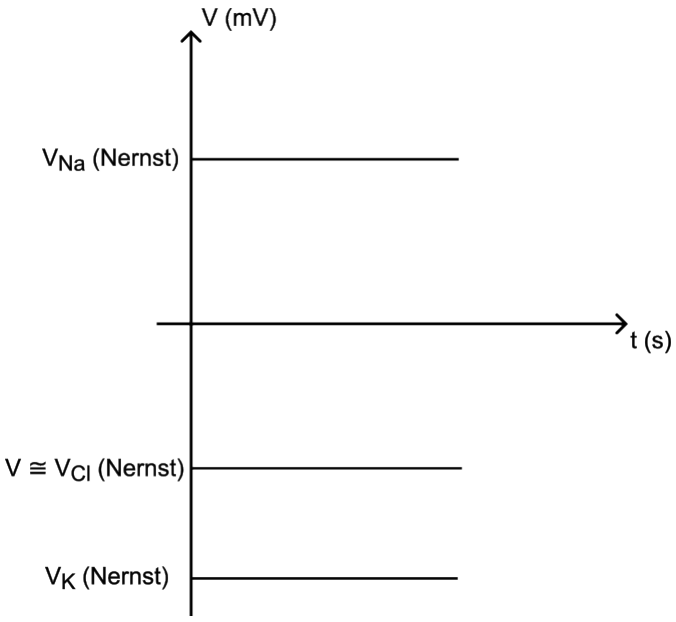

Fig. 3. Comparison between membrane electric potential (V), and K, Na and Cl Nernst's electric potentials.

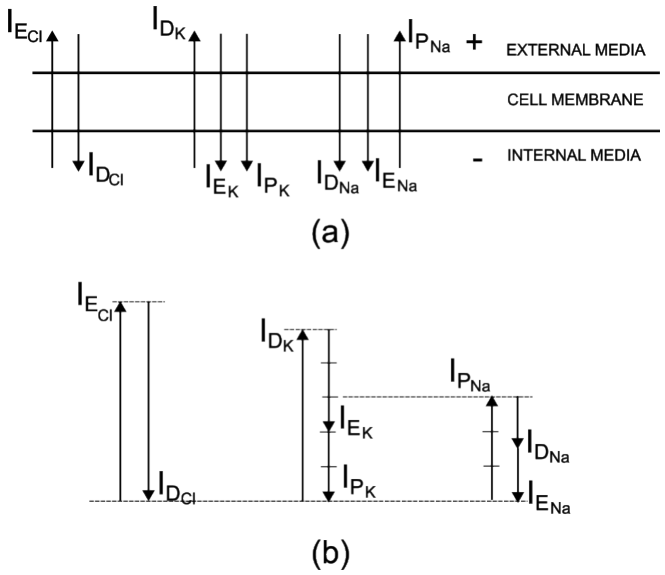

Fig. 4. Figure 4a) Ionic currents across the membrane due to the concentration gradient I_D, the electrical potential I_E, and the ion pump I_P, for chloride, potassium, and sodium ions across the membrane. b) The ratio between the sodium and potassium ion pumps is 3 to 2 ions.

New experimental data can confirm the validity of the developed mathematical model or suggest adjustments to improve it. In any case, the authors believe that developed model can be useful to understand the factors that affect the physiological/pathological conditions influenced by cell membrane electric potential, perhaps encouraging the development of automatic methods to measure *V*.

APPENDIX A
LIST OF USED MATHEMATICAL SYMBOLS AND RESPECTIVE DIMENSIONS.

Symbol	Definition	Dimension
A_K	Area of membrane through which potassium ion can cross	m^2
A_{Na}	Area of membrane through which sodium ion can cross	m^2
α_K	Potassium ion pump factor	Am/V
α_{Na}	Sodium ion pump factor	Am/V
ATP	Adenosine triphosphate	J/M
C	Membrane equivalent capacitance	F
$[Cl]$	Chloride ion concentration	M/l
D_K	Potassium ion diffusion coefficient	m^2/s
D_{Na}	Sodium ion diffusion coefficient	m^2/s
d	Fitting parameter	dimensionless
ε	Electric field	V/m
I_{TK}	Potassium ion total current	A
I_{CK}	Potassium ion capacitive current	A
I_{EK}	Potassium ion electric current	A
I_{DK}	Potassium ion diffusion current	A
I_{PK}	Potassium ion pump current	A
I_{TNa}	Sodium ion total current	A
I_{CNa}	Sodium ion capacitive current	A
I_{ENa}	Sodium ion electric current	A
I_{DNa}	Sodium ion diffusion current	A
I_{PNa}	Sodium ion pump current	A
k	Boltzmann's constant	J/K
$[K]$	Potassium ion concentration	M/l
$[K]_R$	Potassium ion reference concentration	M/l
μ_K	Potassium ion mobility	m^2/Vs
μ_{Na}	Sodium ion mobility	m^2/Vs
$[Na]$	Sodium ion concentration	M/l
p	Fitting parameter	dimensionless
P_{Cl}	Membrane permeability to chloride ion	m/s
P_K	Membrane permeability to potassium ion	m/s
P_{Na}	Membrane permeability to sodium ion	m/s
q	Elementary charge	C
s	Fitting parameter	dimensionless
t	Time	s
T	Absolute temperature	K
V	Membrane electric potential	V
x	Direction perpendicular to cell membrane	m
w	Membrane thickness	m

***Abstract* — Distraction osteogenesis using Ilizarov external fixators requires periodic quarter-turn adjustments to achieve controlled bone lengthening. These adjustments are typically performed manually by patients or caregivers, making the process susceptible to operational errors and variability. This study presents the design and preliminary evaluation of a mechanical ratchet mechanism capable of producing a nominal quarter-turn rotation of the adjustment nut with each actuation of the lever. The device employs a compact gear-based transmission and a unidirectional ratchet system that allows the lever to be manually returned to its initial position without reversing the adjustment. A preliminary laboratory test was conducted over 120 consecutive actuation cycles to assess the mechanical operation and cumulative linear displacement of the prototype. The mechanism completed the single 120-cycle test without critical transmission failures or operational interruptions. The theoretical cumulative displacement was 30.00 mm, while the measured displacement was 30.28 mm, corresponding to a deviation of 0.28 mm (0.93%). The findings support further development and mechanical validation of the proposed indexing concept before any assessment of clinical applicability.**

Keywords — Ilizarov Fixator, Distraction Osteogenesis, Mechanical Design, Biomedical Engineering, Assistive Device.

I. INTRODUCTION

Distraction osteogenesis is a well-established orthopedic technique for treating limb-length discrepancies, congenital deformities, bone defects, nonunions, and complex fractures. The method relies on the biological principle that the gradual, controlled mechanical distraction of two bone segments stimulates the formation of new bone tissue within the distraction gap, while simultaneously promoting the adaptation of adjacent soft tissues—including muscles, blood vessels, nerves, and skin [1], [8]. Since its introduction by Gavriil A. Ilizarov in the second half of the 20th century, the technique has become one of the most important procedures in reconstructive orthopedic surgery.

The Ilizarov external fixator remains one of the most widely adopted systems for distraction osteogenesis due to its versatility, mechanical stability, and ability to correct deformities in multiple planes [1]. During treatment, threaded rods connected by rings and fixation wires gradually separate the bone segments according to a prescribed distraction protocol. A commonly adopted regimen involves approximately 1 mm of distraction per day—typically divided into four equal increments of 0.25 mm—aimed at optimizing bone regeneration and minimizing complications [2], [3]. Consequently, patients or caregivers must perform multiple manual adjustments daily throughout the treatment, which can last several months depending on the clinical indication.

Although the mechanical principles of the Ilizarov system are well established, the adjustment procedure itself remains almost entirely dependent on manual operation. In conventional practice, patients or caregivers must manually turn each adjustment nut by a prescribed quarter-turn during every distraction cycle. This repetitive procedure requires strict adherence to the prescribed protocol and must be performed consistently throughout the entire treatment period [6], [7]. Since multiple threaded rods require independent adjustment at regular intervals, maintaining consistent angular displacement can be challenging, particularly outside the clinical setting [8], [9].

Various technological approaches have been proposed to enhance distraction osteogenesis, including computer-assisted external fixators, motorized distraction systems, and hexapod-based orthopedic frames [4], [5]. Although these systems offer advanced control capabilities, they are often associated with greater mechanical complexity, higher manufacturing costs, and specialized clinical requirements, which limit their widespread adoption in many healthcare settings. Consequently, conventional, manually adjusted Ilizarov fixators remain the standard treatment option at a large number of orthopedic centers worldwide [7].

Despite the extensive literature addressing biological responses, fixation biomechanics, and treatment outcomes, relatively few studies have focused on improving the manual adjustment mechanism itself [9], [10]. In particular, little attention has been paid to simple mechanical devices capable of assisting patients in performing standardized quarter-turn adjustments without the need for motors, electronics, or modifications to the original treatment protocol. Such solutions may provide a simple mechanical means of indexing

the adjustment movement while preserving the conventional configuration of the external fixation system [6].

The central hypothesis of this study is that a mechanically indexed ratchet device can produce nominal quarter-turn adjustment increments through a manual lever actuation while maintaining the adjustment direction during lever return. The present work therefore focuses on the preliminary mechanical evaluation of this operating concept under laboratory conditions. By introducing a mechanically simple, purely mechanical assistance mechanism, this work aims to contribute to the development of accessible technologies for mechanically indexed adjustment of distraction osteogenesis systems without increasing treatment complexity.

II. Materials And Methods

A. Device Design

The proposed device was developed to assist in the manual adjustment of threaded rods used in Ilizarov external fixation systems during distraction osteogenesis. The primary design requirement was to produce a nominal quarter-turn (90°) rotation of the adjustment nut through a single lever actuation, while maintaining the simplicity of conventional treatment protocols.

The gear transmission was designed using involute spur gears with a 20° pressure angle and a module of 1 mm. The driving gear, represented by the yellow component in Fig. 1, has 12 teeth, while the driven gear, represented by the red component, has 24 teeth. Both gears have a 7 mm face width. The resulting gear ratio is 2:1, such that the driven gear rotates at half the angular displacement of the driving gear. Therefore, a 180° rotation of the driving gear results in a nominal 90° rotation of the driven gear, corresponding to the required quarter-turn adjustment of the threaded mechanism.

The mechanical concept relied on a compact gear transmission integrated with a unidirectional ratchet mechanism. The transmission converts the rotational movement of the operating lever into rotational movement of the adjustment nut. The ratchet mechanism allows the lever to return to its initial position without reversing the rotation of the threaded rod, enabling consecutive actuations while preserving the accumulated distraction displacement. In other words, it enables the user to perform only the tightening movement in the correct direction for treatment.

The device was designed to operate independently on each threaded rod of the external fixator. Therefore, four identical units can be installed on a conventional Ilizarov frame when simultaneous adjustment of all rods is required. The design process was carried out using computer-aided design (CAD) software. During development, special attention was paid to geometric compatibility with commercially available Ilizarov fixators, ease of installation, compact dimensions, manufacturability, and user operation.

B. Mechanical Operating Principle

The operating principle of the proposed mechanism is illustrated in Figure 1.

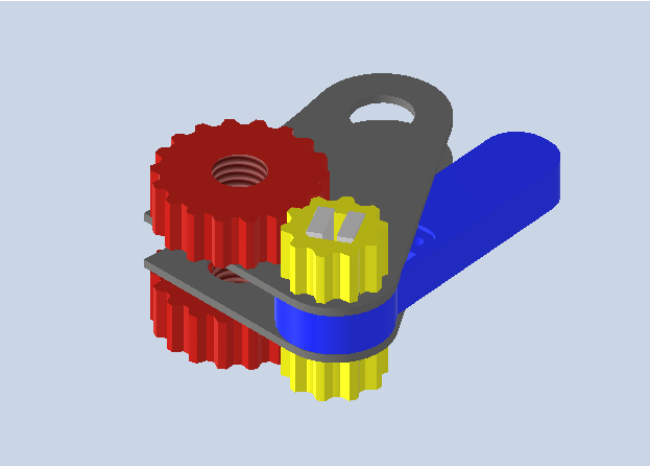

Fig. 1. System designed in CAD (original design).

When the user applies force to the operating lever, the lever rotates the yellow driving gear through a nominal 180°. The 12-tooth driving gear engages the 24-tooth red driven gear, producing a 2:1 reduction in angular displacement. Consequently, the red gear rotates by a nominal 90° for each complete lever stroke, corresponding to one quarter-turn of the threaded adjustment mechanism.

After the adjustment stroke, the lever can be manually returned to its initial position. During this return movement, the ratchet mechanism disengages the transmission, preventing reverse rotation of the adjustment mechanism while maintaining the previously achieved displacement. This allows successive quarter-turn increments to be applied through repeated lever actuation.

C. Prototype Development

A functional prototype was manufactured to evaluate the feasibility of the proposed concept. Additive manufacturing was used to produce a functional prototype for preliminary mechanical evaluation of the proposed concept. With the exception of the commercially available Ilizarov nuts and spring, the mechanism components were manufactured from ASA (Acrylonitrile Styrene Acrylate) using additive manufacturing. ASA was selected as the prototype material because of its suitability for functional polymeric components and its mechanical resistance compared with other commonly used prototyping polymers.

The complete prototype, including the polymeric components and metallic fastening elements, had an approximate mass of 20 g and overall dimensions of 5 × 3 × 2 cm. The system was designed to fit onto 6 mm threaded rods with a 1 mm pitch. Several prototype iterations were produced during the development process to optimize gear engagement, lever ergonomics, structural rigidity, and operational reliability.

D. Experimental Evaluation

Preliminary laboratory tests were conducted to evaluate the operational performance of the proposed mechanism.

1) Repeated Performance Test

A repeated actuation test was conducted to characterize the mechanical behavior of the prototype during consecutive operation. A single series of 120 consecutive actuation cycles was performed on the prototype. The test was considered a preliminary functional assessment rather than a statistical repeatability or fatigue test. Each operational cycle consisted

of a full forward actuation of the lever, followed by the lever's return. During the tests, the following parameters were observed:

a) Occurrence of mechanical failure;

b) Gear disengagement;

c) Ratchet malfunction;

d) Structural deformation;

e) Operational interruptions.

At the end of the test, the mechanism was visually inspected for wear or permanent deformation.

2) Linear Displacement Verification

The cumulative linear displacement produced by the mechanism was compared with the theoretical displacement expected based on the threaded rod's pitch. Given that each actuation of the lever corresponds to a quarter-turn of the adjustment nut, the theoretical displacement after 120 operating cycles was calculated based on the thread pitch. Cumulative linear displacement was measured at 12-cycle intervals using a caliper throughout the 120-cycle test. The measured values were compared with the theoretical displacement calculated from the 1 mm thread pitch and the nominal quarter-turn per actuation. Subsequently, the percentage error between the theoretical and measured displacements was calculated.

E. Experimental Test Bench

To enable the preliminary evaluation of the proposed mechanism under controlled laboratory conditions, a dedicated experimental test bench was designed and manufactured. The apparatus was developed to reproduce the basic threaded adjustment configuration of an Ilizarov external fixator in a simplified laboratory setup. The test bench was not intended to reproduce physiological loading conditions or the complete biomechanical behavior of a clinical Ilizarov frame.

The test bench consists of two structural frames connected by three threaded rods arranged in parallel, reproducing the threaded adjustment system commonly employed in circular external fixation devices. The proposed ratcheting mechanism was mounted on the central threaded rod, allowing repeated quarter-turn adjustments to be performed while the resulting linear displacement of the movable frame was observed.

The structural components of the test bench were fabricated by additive manufacturing using ASA thermoplastic, whereas the threaded rods and fastening elements were manufactured from steel. This configuration provided sufficient rigidity for repeated laboratory testing while enabling rapid assembly, component replacement, and geometric modifications during prototype development.

The primary purpose of the test bench was to evaluate the operational feasibility of the proposed mechanism, including its ability to produce successive indexed adjustments, maintain transmission integrity during repeated actuation cycles, and verify the cumulative linear displacement generated throughout the experimental procedure.

Figure 2 illustrates the experimental test bench developed for the preliminary validation of the proposed mechanism.

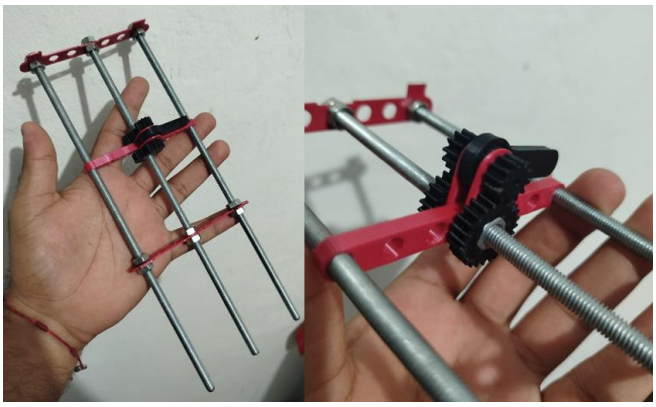

Fig. 2. Equipment similar to the Ilizarov apparatus for testing (original design).

III. Initial Prototype Results

Based on the model developed in the CAD software, it was possible to manufacture initial prototypes using 3D printing; these were the closest in dimensions and functionality to the final model produced in any other material. Following the tests and analyses outlined in the previous section, the following results were obtained.

A. Operational Performance

Figure 3 shows the initial prototype in yellow—a color that does not affect the material's properties—while Figure 4 displays the individual black components prior to their assembly into the testing equipment. In addition to the elements shown in the images, the system incorporates nuts from the commercial Ilizarov system and a spring (20 mm long, 3 mm in diameter) that actuates the ratchet mechanism. The experimental evaluation focused on the mechanical operation of the prototype during repeated actuation.

Fig. 3. Mechanism assembled without being inserted into the Ilizarov apparatus (original design).

Fig. 4. Disassembled mechanism (original design).

No critical failure of the gear train or ratchet mechanism was observed during this single test series. During the test, the gear train remained properly engaged, and no loosening of the adjustment gear mounted on the threaded shaft was observed. The ratchet mechanism also maintained its unidirectional operation, allowing the operating lever to return to its initial position without causing reverse rotation of the adjustment nut.

Given that each operational cycle produces a quarter-turn of the threaded nut, the expected theoretical linear displacement after 120 cycles was 30 mm, based on the thread pitch used in the experimental setup. The measured cumulative displacement was approximately 30.28 mm, representing a deviation of about 0.28 mm (0.93%) from the theoretical value; Table 1 summarizes the obtained data.

TABLE I. THEORETICAL AND EXPERIMENTAL CUMULATIVE DISPLACEMENT AFTER 120 ACTUATION CYCLES

Parameter	Theoretical	Experimental	Deviation
Linear advance	30mm	30.28mm	0.28mm (0.93%)

(Original design)

Figure 5 shows the theoretical and experimental cumulative displacement throughout the 120-cycle test, with measurements obtained at 12-cycle intervals. The experimental curve followed the theoretical trend over the evaluated range, reaching 30.28 mm at the end of the test compared with 30.00 mm theoretically expected. The accumulated deviation was therefore 0.28 mm (0.93%). This result indicates that the prototype maintained the expected direction and approximate magnitude of linear displacement during the evaluated test. However, because only one test series was performed, the result should not be interpreted as a statistical assessment of repeatability.

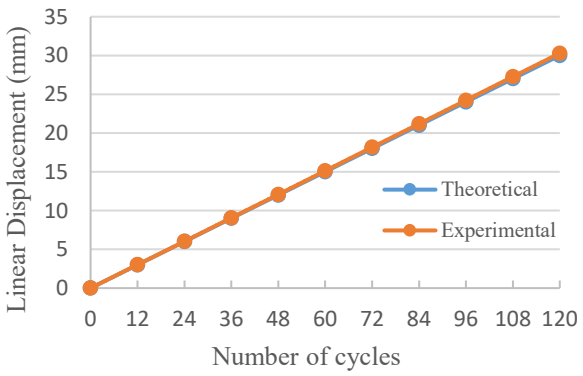

Fig. 5. Comparison between theoretical and experimental cumulative linear displacement during the 120-cycle actuation test. (original design).

Although the cumulative displacement differed slightly from the theoretical prediction, the mechanism consistently generated incremental movement throughout the test, demonstrating the feasibility of the proposed transmission concept. The observed deviation may be related to manufacturing tolerances inherent to the additive manufacturing process, dimensional variations in the printed gears, assembly clearances, and elastic deformation of the polymeric components. However, the contribution of each factor was not independently quantified in the present study and requires further investigation.

B. Structural Assessment

Visual inspection following the repeated actuation test revealed no evidence of failure in the gear transmission or the ratchet system. Likewise, the threaded adjustment gear remained securely attached to the shaft, indicating that the gear remained mechanically engaged throughout the evaluated test.

However, whitish cracks were identified on the wall surrounding the ratchet shaft mount—which is integrated into the operating lever—in the region shown in Figure 6. These cracks appeared after repeated use and suggest that this area represents the primary structural weak point of the current prototype.

Fig. 6. Area of possible fracture (original design).

The cracks did not result in loss of function during the 120-cycle test; however, their occurrence indicates localized structural damage and limits the conclusions that can be drawn regarding durability. Nevertheless, the results indicate that improvements to the structural design and material selection are necessary before clinical application can be considered. Future versions of the device could benefit from the use of engineering-grade polymers or metal components in high-stress regions, while retaining additive manufacturing as the rapid prototyping technique.

C. Limitations and Future Validation

The present study represents a preliminary mechanical proof of concept and has several limitations. The experimental evaluation consisted of a single 120-cycle test performed on a simplified laboratory test bench without physiological loading conditions. Therefore, the results do not establish the long-term durability, fatigue resistance, angular accuracy, or clinical safety of the mechanism. In addition, actuation force,

transmitted torque, mechanical backlash, gear wear, and cycle-to-cycle angular error were not quantitatively measured.

Further development should include repeated independent test series, angular displacement measurements, characterization of actuation force and transmitted torque, evaluation of backlash and gear wear, and extended fatigue testing. Tests under representative axial and mechanical loading conditions should also be conducted. A comparison with conventional manual adjustment would be necessary to determine whether the proposed mechanism provides any measurable improvement in adjustment consistency or usability. Material compatibility with sterilization or disinfection procedures was not evaluated in the present study and should be addressed in future development if clinical use is pursued.

IV. Conclusions And Future Work

This study presented the design and preliminary laboratory evaluation of a gear-based ratcheting mechanism intended to assist the manual adjustment of Ilizarov external fixators. The proposed mechanism was designed to produce a nominal quarter-turn adjustment of the nut for each lever actuation while allowing the lever to return without reversing the adjustment direction.

In the single 120-cycle laboratory test, the mechanism remained operational without critical failure of the gear transmission or ratchet system. The theoretical cumulative displacement was 30.00 mm, while 30.28 mm was measured experimentally, corresponding to a deviation of 0.28 mm (0.93%). A localized crack was also observed in the operating lever around the ratchet shaft mounting region, indicating a structural limitation of the current prototype.

These results provide preliminary evidence of the feasibility of the mechanical indexing concept under simplified laboratory conditions. However, the study does not establish angular accuracy, fatigue resistance, long-term durability, safety, or clinical applicability. Further work should include repeated independent tests, measurements of angular error, actuation force and transmitted torque, assessment of backlash and gear wear, fatigue testing under representative mechanical loads, and comparison with conventional manual adjustment before any consideration of clinical use.

Acknowledgment

The authors would like to thank the Federal Rural University of the Semi-Arid (UFERSA) for the institutional support provided during the development of this work, as well as the laboratories of the Center for Engineering and their respective faculty members.

Abstract — Accurate identification of the components of the His Bundle Electrogram (HBE) is fundamental for mapping intracardiac bioelectrical activity. However, the automatic detection of the H-wave is challenged by pronounced interpatient morphological variability. This paper presents a methodology based on an LSTM Recurrent Neural Network for the automatic detection of the H-wave from invasive electrophysiological signals obtained exclusively through the Distal Ablation (ABLD) intracardiac channel. The proposed method utilizes sliding window segmentation and a post-processing algorithm based on a temporal persistence criterion, requiring continuous model activation for at least three consecutive windows to validate the event. The methodology was evaluated at the event level against an expert-defined gold standard. Quantitative results demonstrated the robustness of the classifier, which achieved maximum sensitivity (100%) by correctly identifying all 104 His potentials, with a precision of 86.67% and an F1-score of 92.86%. Visual analysis confirmed the consistency of the detections, showing that false activations were restricted to the signal's transition edges, without compromising the discrimination of the H-wave from adjacent atrial and ventricular activities. The system presents itself as a promising tool for future integration into automatic electrophysiological interval estimation systems and for supporting the diagnosis of conduction blocks.

Keywords — His Bundle Electrogram, LSTM, Biomedical Signal Processing, Pattern Recognition, Temporal Persistence.

I. INTRODUCTION

Cardiovascular diseases are the leading cause of mortality worldwide, representing an ongoing challenge for healthcare systems [1]. In addition to coronary artery disease, which stands out as the most lethal [2], disorders of the cardiac conduction system, such as atrioventricular blocks, are clinically critical as they present an asymptomatic evolution and a risk of severe hemodynamic compromise [3]. Various risk factors significantly increase the probability of acute cardiovascular events [4]. In this context, the early detection of alterations in electrical conduction is fundamental, with the conventional Electrocardiogram (ECG) and Holter monitoring being the primary non-invasive tools for evaluating myocardial bioelectrical activity [5], [6].

High-Resolution ECG (HRECG) systems employ enhanced electronics to detect low-amplitude signals on the surface [7], [8]. However, specific intracardiac potentials, such as the depolarization of the bundle of His, remain difficult to record superficially, requiring invasive procedures for their acquisition [9], [10]. The His Bundle Electrogram (HBE), acquired via electrophysiological studies, provides the H-wave, which is essential for the evaluation of ventricular conduction delays [3], [11]. However, the automatic determination of this parameter in a clinical environment remains a challenge due to the pronounced interpatient morphological variability of the H-wave [12]–[15].

The automatic detection of the H-wave is characterized as a pattern recognition problem in biomedical time series [16]. Although feedforward networks can incorporate temporal context [17], Long Short-Term Memory (LSTM) architectures prove to be highly suitable for modeling the complex temporal dependencies of these records, presenting promising results in the identification of short-duration physiological events [18]–[22].

Classical approaches based on amplitude thresholding or adaptive filtering exhibit severe limitations in H-wave detection due to the pronounced interpatient morphological and dimensional variability of the deflection [Shah et al., 2020; Boonstra et al., 2020]. Rigid techniques cannot adapt to changes in the shape of the His potential, frequently failing when attempting to parameterize dimensions that fluctuate from case to case. The combined use of an LSTM architecture with temporal persistence evaluation bridges this gap in the literature, since the network maps contextual dependencies regardless of the exact morphological dimensions, whereas the temporal criterion requires activation to be physiologically sustained, thereby overcoming the geometric inflexibility of traditional methods.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

Therefore, this work proposes a method based on an LSTM network, trained with the ADAM (Adaptive Moment Estimation) optimizer [23], combined with a post-processing algorithm based on temporal persistence for the automatic detection of the H-wave. The system's performance is validated against expert delineations using exclusively the Distal Ablation (ABL D) intracardiac channel. The method aims to provide a robust tool to assist, in the future, in the automatic estimation of electrophysiological intervals and the identification of conduction blocks in clinical routine.

II. Materials and Methods

A. Signal Database

The data employed in this work originate from invasive electrophysiological studies performed at the Pronto-Socorro Cardiológico de Pernambuco (PROCAPE), conducted by cardiologists specializing in cardiac electrophysiology. All signals were acquired under the approval of the ethics committee (CAAE 53171921.6.0000.5208, opinion number 5.135.351). For the development of this work, the clinical records were partitioned into disjoint sets to ensure a robust hold-out validation. The independent test set, utilized to evaluate the model comprised continuous signals from 4 distinct patients. Each test record had a duration of 60 seconds with a sampling rate of 1000 Hz. The network was previously optimized on a separate, non-overlapping training set. The clinical electrophysiological procedure generates a set of multichannel records via catheters with intracardiac electrodes, which reflect different perspectives of the myocardial electrical activity. However, the proposed Recurrent Neural Network (RNN) architecture utilizes the ABL D channel as the input signal, since this is the only record in which the deflection associated with the His potential manifests itself viably for detection, due to the direct anatomical proximity of its electrode to the conduction bundle.

B. Use of ANN for H-Wave Identification

The HV (His-Ventricular) interval is a clinical metric widely used in intracardiac electrophysiology, defined as the interval between the H-wave deflection and the onset of the ventricular activation signal [3],[11]. As illustrated in Fig. 1, the system synchronously displays the surface records (leads I, II, III, aVF, V1, and V6, in gray), referring to the non-invasive signals of the cardiac cycle, and the invasive records obtained by intracardiac electrodes (ABL P and ABL D channels, in green). In this mapping of the atrioventricular conduction system, the His potential (H-wave) is observed, which manifests in the ABLD channel, being highlighted in orange in specific cycles. The precise acquisition of these intervals in a clinical environment therefore requires the exact identification of the temporal positions of the H-wave in the records of the His bundle electrogram.

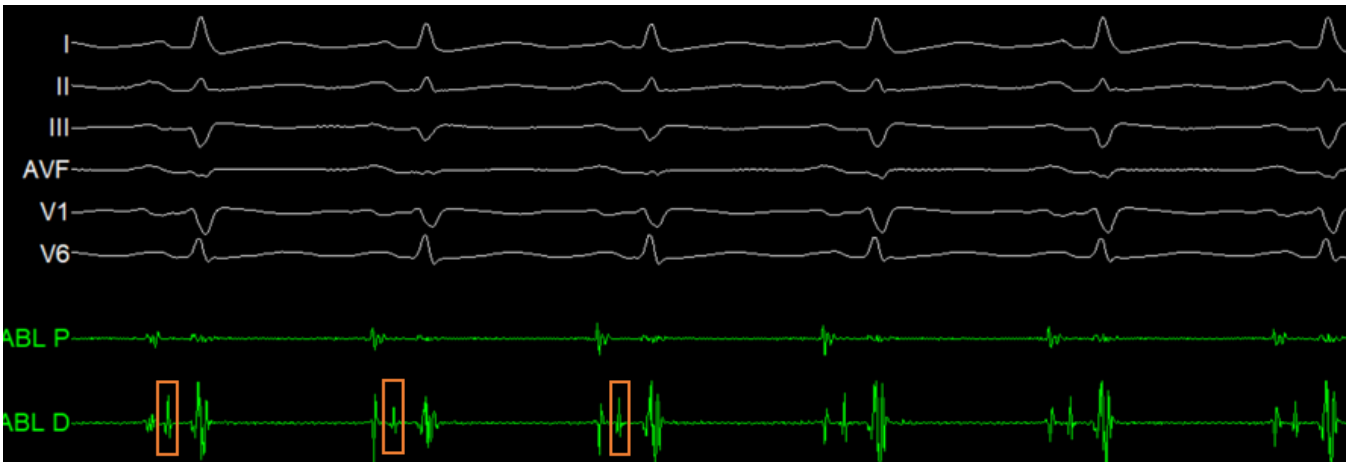

Fig. 1. Surface records (in gray) and invasive records obtained by intracardiac electrodes (in green). The His bundle electrogram (HBE) corresponds to the signal recorded in the ABL D channel, and the H-wave is highlighted in some cycles (in orange).

A widely employed strategy to incorporate temporal information in feedforward artificial neural networks is the use of the variation of activity over time, rather than the specific shape of the signal, such as the Artificial Neural Network with Input Dynamics (ANN-ID). However, its capacity to model longer or variable temporal dependencies is strongly conditioned by the choice of the window size and the number of delays considered [17]. In scenarios where the events of interest are transient, exhibit low amplitude, and are immersed in extensive and noisy sequences (as occurs in the detection of the His bundle electrogram), this dependency can limit the model's generalization and require specific adjustments for each dataset [12], [13].

Long Short-Term Memory (LSTM) architectures were designed to directly address these limitations by incorporating explicit memory mechanisms and controlling the flow of information over time. Unlike ANN-IDs, LSTMs allow temporal dependencies to be learned adaptively, without the need to predefine the extent of the relevant temporal dynamics. This characteristic is particularly advantageous in biomedical signals characterized by interpatient morphological variability, uncertainty regarding the exact temporal position of the event of interest, and the strong influence of the surrounding temporal context.

Reviews on the application of recurrent neural networks in electrocardiographic signals show that the LSTM presents consistent performance in detecting short-duration physiological events, reinforcing its suitability for the processing of intracardiac signals [18], [19].

In this work, a Long Short-Term Memory (LSTM) recurrent neural network was utilized, configured to operate directly on one-dimensional temporal sequences. This choice is based on the LSTM's ability to adaptively model temporal dependencies without the need for prior definition of the relevant temporal horizon, a characteristic especially suited

for the detection of the H-wave in noisy and low-amplitude bioelectrical signals.

C. *Architecture, Dynamic Nature, and Training Parameters of the ANN*

The proposed architecture presents a dynamic nature at both the input and the output: the input is provided in the form of time series (windows of consecutive samples), and the output consists of a continuous numerical value, between 0 and 1, representing the degree of activation or the probability of the H-wave occurrence for each evaluated window.

The HBE signal, previously pre-processed, is segmented into sliding windows of 40 samples (1000 Hz - 40 ms), with a step size of one sample. This window length was defined to fully encompass the typical duration of the deflection associated with the His bundle potential, as well as part of its immediate temporal surroundings, allowing the network to access the local context necessary to distinguish the H-wave from other components of the PR segment, without introducing excessively long windows that dilute the information of interest.

The processing flow of the proposed model was structured for the analysis of the signal's temporal dynamics, comprising three main stages (Fig. 2). Initially, a sequential input layer receives the one-dimensional time series in 40-sample windows. Next, an LSTM layer with 50 hidden units processes the sequence and extracts a compact vector that represents the entire temporal and morphological dynamics of the window. This high-level representation feeds a fully connected layer with a single neuron, which generates a continuous scalar prediction indicating the degree of H-wave presence. Finally, the output layer operates with a regression approach, using the Mean Squared Error (MSE) loss function to evaluate the prediction error and guide the adjustment of the network parameters via backpropagation during training.

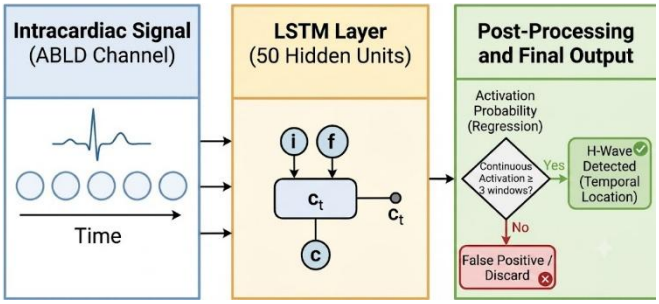

Fig. 2. Structure of LSTM Network

Subsequently, in the algorithm's detection stage, this continuous output is converted into a binary decision by means of a decision threshold: windows with an output greater than or equal to this value are considered as containing the H-wave, while the others are classified as negative.

The training of the network was performed using the ADAM algorithm [23] with an initial learning rate of 1×10^{-3}, $\beta_1 = 0.9$, and $\beta_2 = 0.999$, executed over 150 epochs, utilizing the Mean Squared Error (MSE) as the loss function.

Once the training phase is concluded, the consolidated model is applied to perform a continuous scan across the unseen examination records (60 seconds per patient), generating a time series of predictions. The final H-wave annotations are then extracted by applying an amplitude threshold of 0.89 to these predictions, followed by the validation of the temporal persistence criterion across three successive windows, as structured in the post-processing stage in Fig. 2.

D. *HBE Identification Procedure*

The sequential integration of the described steps, starting from the raw data master file to the final mapping of the H-wave annotations, is structured chronologically in the flowchart of Fig. 3

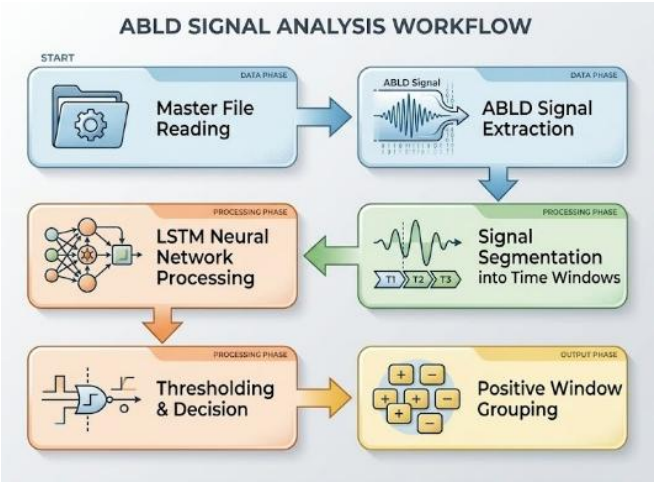

Fig. 3. Flowchart of the HBE identification procedure

The procedure is divided into sequential stages of pre-processing, inference, and post-processing:

- Signal Reading and Extraction: Initially, the system reads the master file containing the multichannel electrophysiological records. From this set, the ABL D intracardiac channel is specifically extracted, since it is the record in which the visualization of the His potential is viable, due to the direct anatomical proximity of its electrode to the bundle of His.
- Window Segmentation: The extracted signal is segmented using a sliding window technique. Each window has a fixed length of 40 samples (40 ms), with a unit step (1-sample stride), ensuring that the temporal dynamics of the H deflection are fully captured across multiple adjacent windows.
- LSTM ANN Processing: The segmented windows feed the LSTM neural network, which processes the morphology of each block and generates a continuous scalar output. This output represents the degree of activation or the probability of the His potential's presence for that specific instance in time.
- Thresholding and Decision: The continuous activation curve is subjected to a fixed decision threshold. Samples resulting in values above this threshold are candidates for positive classification, while the rest are discarded as noise or atrial/ventricular components.
- Grouping and Persistence: In the final post-processing stage, the mechanism for grouping positive windows is applied. To mitigate spurious activations and ensure physiological consistency, a detection is only validated as an effective His potential if there is temporal persistence of the activation for at least three consecutive windows above the threshold. This criterion ensures that only segments with a temporal

sustainment compatible with the physiology of the conduction system are identified by the system.

Based on the final temporal positions consolidated by the window grouping block (post-processing), the results generated by the model were subjected to performance evaluation. The metrics used to compare the model's results against the expert gold standard and to measure the system's accuracy are detailed below.

E. Data Evaluation Metrics

The quantitative evaluation of the classifier is conducted from the perspective of detecting discrete events localized at specific instants within a continuous signal. Each event of interest corresponds to the occurrence of the deflection associated with the His bundle potential (H-wave).

An actual His potential is considered correctly detected when a valid model activation occurs within the tolerance window associated with the gold standard.

This temporal tolerance window was established at ± 20 ms relative to the peak demarcated by the expert, corresponding to the typical physiological duration of the H-wave deflection. Furthermore, the decision threshold of 0.89 was optimized through Precision-Recall (PR) curve analysis during the validation phase to maximize the F1-score. To increase the model's robustness against false alarms, the training phase explicitly included 'hard negatives', defined as signal segments that did not contain the H-wave but exhibited high-amplitude artifacts or atrial/ventricular deflections with confounding morphologies.

For an activation to be considered valid, a temporal persistence criterion was established in which the network output must exceed the decision threshold for at least three consecutive windows, mitigating isolated spurious triggers caused by background noise. The classification process is based on three main components of the confusion matrix adapted for events:

- True Positives (TP): Number of His potentials correctly identified by the classifier within the tolerance window established by the expert.
- False Negatives (FN): His potentials present in the gold standard that were not accounted for or detected by the model.
- False Positives (FP): Classifier activations that occur outside the gold standard tolerance regions, characterizing false alarms or incorrect detections.

Based on these components, the overall performance of the system is measured using the metrics of Precision (P), Sensitivity (S, or Recall), and F1-score, mathematically defined by:

$$P = \frac{TP}{TP + FP},$$

$$S = \frac{TP}{TP + FN},$$

$$F1 = 2 \cdot \frac{P \cdot S}{P + S}.$$

The F1-score metric provides the harmonic mean between precision and sensitivity, synthesizing the dynamic balance between the exactness of the detections and the robustness of the classifier against the incidence of false alarms.

III. RESULTS AND DISCUSSION

The detection of the events precisely demarcated in the gold standard served as the basis for the quantitative evaluation of the classifier's performance. An actual event was considered correctly detected when at least one valid network activation occurred within the time interval corresponding to the His potential. In this mechanism, a detection is considered valid only when the classifier output exceeds the decision threshold across consecutive windows over time, which reduces isolated activations and ensures that only patterns with a temporal sustainment compatible with the His potential are considered as detected events.

The quantitative results are summarized in Table I, which gathers the values of TP, FN, and FP, along with the derived metrics after refining the training with hard negative windows and applying the consecutive window voting mechanism.

TABLE I. LSTM NETWORK METRICS AFTER TRAINING

Metric	Value
True Positives (TP)	104
False Negatives (FN)	0
False Positives (FP)	16
Precision (P)	86.67%
Sensitivity (Recall)	100.00%
F1-score	92.86%

It is observed that all His potentials present in the evaluated set were correctly identified (104), resulting in maximum sensitivity (100%). The occurrence of false positives remained limited to 16, indicating that the majority of the classifier's activations effectively corresponded to real events, as reflected by the high precision value of 86.67%. The resulting F1-score of 92.86% confirms the balance between detection capability and the control of false alarms.

The results from the table demonstrate that the combination of the LSTM-based recurrent architecture, the use of appropriate methodological choices in the decision stage, and the temporal aggregation mechanism of the decisions resulted in a robust and consistent classifier for the automatic detection of the His potential.

The individualized evaluation proves the classifier's consistency against morphological variability. When analyzing the detections separately for the 4 patients in the test set (Table II), sensitivity remained at 100% for all individuals. The occurrence of false positives ranged from 3 to 5 events per patient, generating stable F1-scores between 91.80% and 94.12%. The mean F1-score across patients was 92.90% with a standard deviation of only 0.97%. This narrow variance statistically attests that the method generalizes H-wave recognition, without overfitting bias to a specific individual.

TABLE II. LSTM NETWORK METRICS PER PATIENT

Patient	TP	FN	FP	P (%)	R (%)	F1 (%)
Patient 1	28	0	5	84.85	100.00	91.80
Patient 2	24	0	3	88.89	100.00	94.12
Patient 3	25	0	4	86.21	100.00	92.59
Patient 4	27	0	4	87.10	100.00	93.10
Total Test	**104**	**0**	**16**	86.67	100.00	92.86

To ensure clinical feasibility in the future estimation of the HV interval, the temporal localization error was evaluated. The Mean Absolute Error (MAE) between the activation instant detected by the model and the expert-demarcated H-wave peak was 2.3 ± 0.8 ms, demonstrating high temporal adherence and accuracy suitable for precise electrophysiological interval measurements. This minimal temporal offset confirms that the combination of LSTM-based modeling and temporal persistence filtering preserves the precise alignment required for clinical deployment [Chen & Upadhyay, 2021].

Fig. 4 presents the relationship between the original signal and the classifier's response within a recording interval. The original signal is located in the upper part of Fig. 4, in which the pattern of interest (gold standard) was identified by an expert, indicated by orange arrows. The lower part of the same figure presents the network output for the same sample interval, allowing a direct comparison of the model's behavior with the gold standard. The green curve represents the binarized reference signal previously marked by the expert. Overlaid on this trace are the components corresponding to true positives (TP), false positives (FP), and false negatives (FN). This trace allows for the verification, throughout the signal, of whether the network activation coincides with the presence of the pattern of interest, whether an undue activation occurs, or whether there is an absence of detection. Furthermore, from the same figure, it can be noted that in the regions indicated by the orange arrows, the network output exhibits concentrated activations that are temporally aligned with the intervals defined in the gold standard, characterizing correct detections of the His potential and demonstrating the model's capability to identify the occurrence of the physiological event.

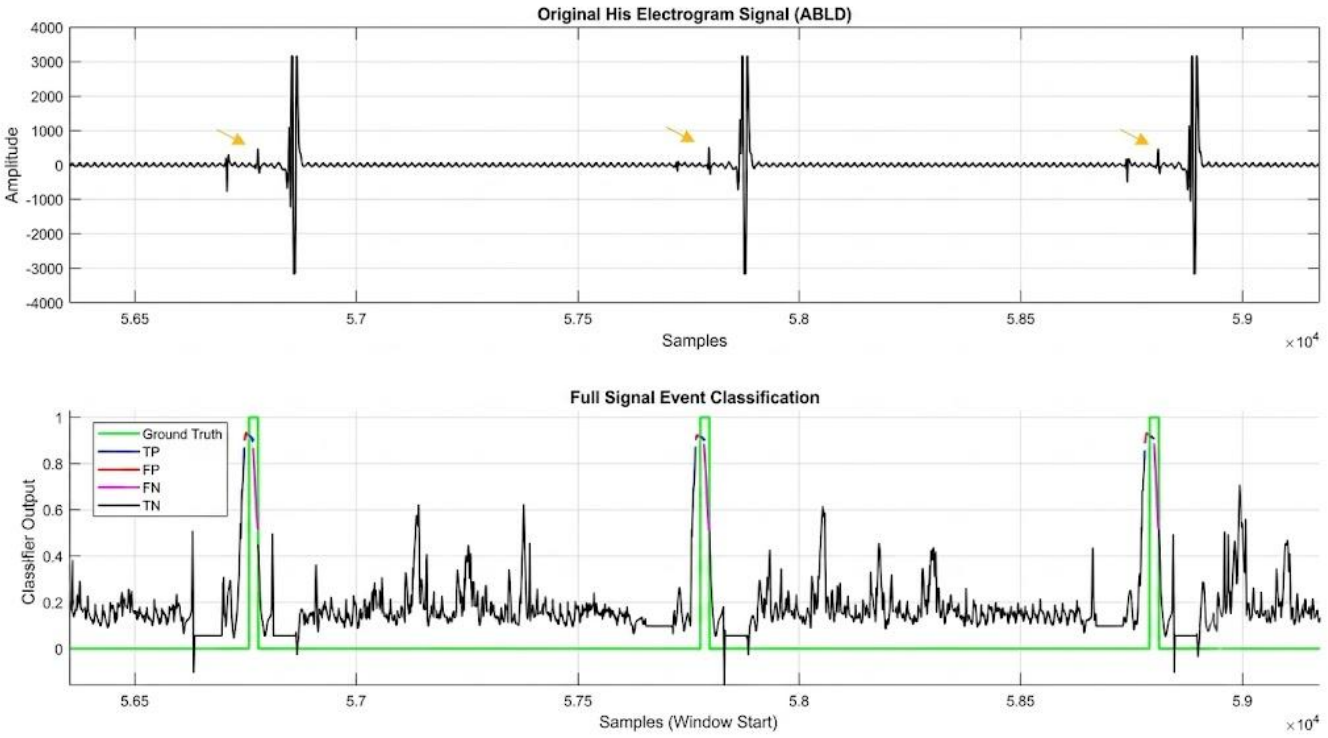

Fig. 4. Network Output

The occurrence of 16 false positives (FP), as indicated in Table I, is predominantly concentrated in small residual oscillations adjacent to the onset and offset limits of the H-wave (represented in red in Fig. 4). From the perspective of bioelectrical signal processing, these small false alarms at the margins of the deflection do not represent discrimination failures against atrial or ventricular activities, but rather a characteristic of the conservative nature of the unidirectional LSTM architecture, which tends to subtly extend the activation horizon before returning to the resting state. The aggregation mechanism using three consecutive windows proved robust by confining these undue alarms to the immediate surroundings of the His bundle itself, preventing erratic triggers along the PR segment and preserving the necessary rigor for the subsequent automatic estimation of the HV interval.

It is important to highlight the methodological distinction between the event-level evaluation, summarized in Table I, and the local dynamics observed in the signal trace in Fig. 3. Although Fig. 3 shows small regions of false negatives (FN, in magenta) at the transition edges of the H-wave, the final count of missed events in Table I is null (FN = 0). This behavior stems from the adopted validation criterion: the local discontinuities and the slight phase delay

in the network's initial activation merely reflect the model's sample sensitivity to the rapid morphological variation of the deflection. However, as the main body of the His potential is captured in a sustained manner, the post-processing algorithm consolidates the activation, ensuring that 100% of the reference physiological events are computed as true positives (TP).

The temporal synchronization of the two signals shows that the classifier maintains temporal coherence in identifying patterns of interest. The network activations occur temporally aligned with the intervals annotated in the gold standard, without undue prolongations or relevant shifts over time. This comparison reinforces the presented quantitative results, confirming that the network achieves good overall results and produces temporally consistent detections when analyzed at a detailed level on the original trace.

Although Fig. 4 has shown false negatives (segments in pink), there is no compromise in the final identification of the physiological event. The FN segments reflect the response time/phase delay of the unidirectional temporal LSTM modeling before the stabilization of the activation curve.

The model consistently detects the His Bundle Electrogram (HBE) after the temporal aggregation of the windows, and the punctual reductions in activation merely reflect the local sensitivity of the method, without impairing the localization, extent, or interpretation of the HBE. These FNs are physiologically irrelevant and methodologically expected, not interfering with the overall accuracy of the detections nor with the clinical visualization of the identified pattern.

During the model's development, temporal aggregation mechanisms were implemented to eliminate dispersed activations and reflect continuous segments, coherent with the morphology of the HBE.

From the perspective of clinical feasibility, the model demonstrated high computational efficiency. The mean inference time for processing one second of signal (considering the sliding window stride) was approximately 18.5 ms on a standard CPU (Intel Core i7), ensuring full capability for real-time execution in hospital routine.

The network maintained its detection capability in segments where the His potential occurs, without detecting deflections associated with atrial and ventricular activities. The algorithm is able to discriminate the morphology and the temporal position of the H-wave within the atrioventricular segment, resulting in a precise temporal delimitation of the event, with small local variations associated with the granularity of the temporal segmentation and the relative positioning of the analysis windows, without compromising the physiologically correct localization of the H-wave.

IV. Conclusions

This work presented a methodology based on an LSTM Recurrent Neural Network for the automatic detection of the H-wave in the His Bundle Electrogram (HBE). The proposed approach addressed the limitations arising from morphological variability and the intrinsic noise of the biosignal through a post-processing algorithm based on the temporal persistence criterion in sliding windows.

The quantitative results validated the robustness of the model, which achieved maximum sensitivity (100%) by correctly identifying all 104 gold-standard events, in addition to an F1-score of 92.86%. Visual analysis confirmed the temporal consistency of the detections and evidenced that the residual false positives were confined to the signal's transition edges, without compromising the clinical integrity of the diagnosis. The system demonstrated the ability to precisely discriminate the H deflection from adjacent atrial and ventricular components using exclusively the ABL D intracardiac channel.

As future work, the integration of this classifier into systems for the automatic estimation of electrophysiological intervals (such as AH and HV) is proposed, aiming to consolidate the tool as a robust support for the identification of conduction blocks in clinical routine.

Abstract - Motor impairments affecting the upper limbs constitute a significant challenge in rehabilitation. High-Density Surface Electromyography (HD-sEMG) provides detailed information on muscle activity; however, its high dimensionality poses significant processing challenges. This study proposes a hybrid approach that converts HD-sEMG signals into heat maps, extracts features using a pre-trained LeNet network, and classifies hand gestures through decision tree-based algorithms. The publicly available Hyser dataset, containing 10 functional gestures, was used. The data were divided into training (80%) and testing (20%) sets and evaluated using the J48, Random Tree, and Random Forest classifiers (100 to 500 trees). The Random Forest models achieved superior performance during cross-validation, with mean accuracy > 91.7% and AUC > 0.994. Considering the balance between performance and computational cost, the Random Forest model with 200 trees was selected for final validation. On the test set, it achieved an accuracy of 78.87%, a Kappa coefficient of 0.765, and a mean AUC of 0.962. The greatest misclassifications occurred between antagonistic gestures with similar muscle activation patterns, such as pronation and supination with a closed hand. The results demonstrate the feasibility of the proposed approach for technology-assisted motor rehabilitation systems by integrating the spatial information provided by HD-sEMG, automatic feature extraction via deep learning, and the rule-based nature of decision tree models, which-although still requiring complementary explainability analyses-provide a structurally interpretable decision framework.

Keywords - HD-sEMG; hand gestures; machine learning; decision trees.

I. Introduction

Motor impairments affecting the upper limbs constitute a significant challenge in rehabilitation, as they directly compromise an individual's ability to perform activities of daily living and maintain functional independence [1]. Such impairments may arise from a wide range of neurological and neuromuscular conditions, including cerebral palsy, traumatic brain injury, spinal cord injury, multiple sclerosis, and neurodegenerative diseases [1], [2]. Additionally, inherited ataxias, motor neuron diseases, polyneuropathies, and myopathies can result in impairments in hand strength, muscle tone, movement, dexterity, joint range of motion, and sensation. Regardless of etiology, the resulting loss of hand and wrist function imposes severe limitations on daily activities and diminishes quality of life. Consequently, the development of effective rehabilitation strategies targeting distal motor function is of paramount importance for promoting functional recovery and enhancing independence [1], [3].

In this context, some movement rehabilitation therapies require gesture recognition methods that can be employed in interfaces designed to support therapy for the affected limb [3]. Such recognition can be achieved through the analysis of High-Density Surface Electromyography (HD-sEMG) neuromuscular signals, providing a non-invasive means of decoding the user's motor intention, thereby enabling the control of external devices or providing feedback on muscle contraction [3], [4], [5].

HD-sEMG represents a significant advancement over conventional sEMG. By capturing detailed spatial information regarding muscle activity over a larger skin surface area, it enables the analysis of muscle activation patterns with a high level of detail, opening new possibilities for the recognition of more complex gestures and motor nuances. However, the high dimensionality inherent to HD-sEMG signals, which may contain hundreds of channels generating multivariate time series, imposes a substantial computational challenge for efficient processing and extraction of discriminative features [6], [7].

Traditionally, Machine Learning (ML) approaches applied to gesture classification from sEMG signals rely on feature extraction in the time and frequency domains. Although effective, these approaches may not fully capture the large amount of spatial information contained in HD-sEMG data. Strategies that convert multichannel signals into visual representations, such as heat maps, have emerged as a promising alternative [8], [6]. This conversion enables the problem to be transferred into the computer vision domain,

where Deep Learning architectures, particularly Convolutional Neural Networks (CNNs), have demonstrated strong performance in extracting hierarchical and spatially relevant features [8], [9].

Accordingly, there has been a growing number of studies and proposals focused on gesture classification using HD-sEMG signals. Among these, studies employing recurrent neural networks directly applied to instantaneous signal amplitude images, as presented in [10], achieved promising frame-by-frame classification performance and even higher accuracy when majority voting mechanisms over consecutive windows were employed. Another study implemented instrumented electrode grids combined with fully connected neural networks, achieving high accuracy rates for sequential movements, although relying on manual feature extraction [11]. More recently, [12] applied Vision Transformer (ViT)-based architectures to multi-day classification with ultra-short windows, demonstrating robustness even under reduced calibration conditions. Despite their high performance, these approaches depend on complex deep architectures with high computational cost and, in many cases, limited interpretability, which is a critical aspect for clinical applications.

In contrast, other authors emphasize the continued relevance of traditional machine learning methods, such as [13], who proposed hybrid feature selection algorithms combined with Support Vector Machine (SVM) classifiers, achieving competitive performance with significantly lower training time than deep networks. Nevertheless, these approaches still depend on manual feature engineering and do not exploit the automatic representation learning capabilities of CNNs. Therefore, a gap remains in the literature regarding the integration of automatic feature extractors based on deep learning (applied directly to visual representations of HD-sEMG signals) with structurally simpler, interpretable, and computationally efficient classifiers, such as decision trees.

Given this scenario, the present study aimed to evaluate the performance of Machine Learning algorithms implemented in the WEKA environment for hand gesture classification based on image representations of HD-sEMG signals. The proposed methodology was based on converting the signals into heat maps, extracting features using a pre-trained Convolutional Neural Network (LeNet), and classifying gestures using decision tree algorithms (J48, Random Tree, and Random Forest with 100 to 500 trees). These algorithms were selected due to their interpretability, robustness to noise, and suitability for high-dimensional data, which are essential attributes for clinical applications requiring transparency in decision-making processes.

II. Background

A. High-Density Surface Electromyography

Surface electromyography (EMG) records the electrical activity generated by muscle fibers during contraction through electrodes positioned on the skin [14], [15]. Unlike conventional EMG, which employs bipolar configurations with a limited number of channels and provides a global measure of muscle activation, High-Density Surface Electromyography (HD-sEMG) uses two-dimensional arrays containing dozens to hundreds of electrodes (typically 64-256), arranged in regular grids with reduced interelectrode spacing [14]. This configuration enables the acquisition of detailed spatial gradients of muscle activity, generating topographic maps that reveal intramuscular and intermuscular recruitment patterns [15], [16].

The main advantages of HD-sEMG include: (1) the generation of spatial activation maps, enabling visualization of the topographic distribution of muscle activity; (2) greater robustness due to spatial redundancy, reducing sensitivity to small electrode displacements; and (3) the potential ability to discriminate the activity of adjacent muscles [14], [16]. However, the high dimensionality inherent to these data (hundreds of multivariate time series) imposes significant computational challenges for the extraction of discriminative features, motivating the development of alternative processing strategies [16].

B. Transformation of HD-sEMG Signals into Visual Representations

A promising strategy for addressing the high dimensionality of HD-sEMG involves converting multichannel signals into two-dimensional visual representations, thereby transferring the problem to the computer vision domain [16], [8]. Among the available techniques, heat maps stand out due to their simplicity and their ability to preserve the anatomical topology of the electrode array: each position in the image corresponds to a specific electrode, while the color intensity represents the signal amplitude at that region [8].

Transforming the signal into the visual domain provides significant conceptual advantages. It enables structured dimensionality reduction by converting hundreds of time series into a single object (image) that preserves the essential spatial relationships [8], [17]. More importantly, this representation allows the automatic exploration of spatial patterns (such as contours, gradients, symmetries, and activation regions) through CNN architectures, which are specialized in detecting hierarchical features in grid-structured data [17]. Thus, the image-based representation functions as a methodological bridge connecting the spatial information of HD-sEMG data with advances in artificial intelligence and computer vision, expanding the possibilities for robust classification and analysis of complex motor patterns [9], [16].

C. Decision Trees

Decision trees are classifiers that recursively partition the feature space through tests applied to attributes, forming a hierarchical structure in which each internal node represents a decision and each leaf node corresponds to a predicted class. Their main advantage lies in their rule-based structure, which can be expressed as a set of IF-THEN rules. This structural property facilitates model inspection and constitutes a relevant starting point for clinical contexts that value decision transparency [18], [19], [20].

J48 is the implementation of the C4.5 algorithm, which employs the gain ratio criterion for attribute selection and incorporates post-pruning to avoid overfitting [20]. Random

Tree introduces controlled randomness into tree construction by considering a random subset of attributes at each node for splitting, thereby promoting greater structural diversity [19].

Random Forest is an ensemble method that combines bagging (bootstrap sampling of the training set) with the random attribute selection characteristic of Random Tree [19]. Multiple trees are trained in parallel, and the final prediction is obtained through majority voting. This dual randomness provides the model with high robustness, low sensitivity to overfitting, and excellent performance in high-dimensional scenarios while maintaining a reasonable degree of interpretability through feature importance analysis [19], [21].

D. Deep Learning and Convolutional Neural Networks

Deep learning is a subfield of machine learning that employs neural networks with multiple layers to learn hierarchical representations directly from raw data, eliminating the need for manual feature extraction [23]. Among its architectures are Convolutional Neural Networks (CNNs), which are designed to process grid-structured data, such as images, by exploiting properties of local correlation and translation invariance [24]. A typical CNN alternates convolutional layers, which apply learnable filters to detect features ranging from low-level to high-level patterns (edges, textures, semantic patterns), and pooling layers, which reduce spatial dimensionality [23], [24], [25].

Among the various applications of CNNs, their ability to function as automatic feature extractors is particularly noteworthy, transforming an input image into a compact vector of relevant attributes that can subsequently be used by other classifiers. The LeNet architecture, proposed by Yann LeCun in 1998, is a classical example of this paradigm, originally developed for handwritten digit recognition [26]. Transfer learning further enhances this capability by allowing a CNN pre-trained on a large dataset (such as MNIST) to provide generic visual representations (edges, corners, textures) transferable to other domains, including biomedical images [24], [26]. Pooling layers provide a relevant methodological trade-off: max pooling emphasizes salient features but is more sensitive to noise, whereas average pooling preserves the overall signal energy and produces representations that are more robust to local variations, making it more suitable when the spatial distribution of activity is informative [27].

E. Evaluation Metrics and Statistical Analysis

Several metrics can be employed to evaluate classifiers, each being sensitive to specific characteristics of the problem. Among the most commonly used metrics in healthcare applications, and those adopted in this study, are accuracy, the Kappa index, the Area Under the ROC Curve (AUC), sensitivity, and specificity [28], [29].

Accuracy represents the overall proportion of correctly classified instances. The Kappa index measures the agreement between predictions and true labels while correcting for agreement expected by chance, making it particularly useful in multiclass problems. AUC quantifies the discriminative capability of the model. Sensitivity (true positive rate) and specificity (true negative rate) enable a more granular analysis of class-wise performance, complementing the overall evaluation. In addition, the confusion matrix provides a detailed visualization of the classifier's correct and incorrect predictions for each gesture [28], [30].

Of particular relevance to this study is the Friedman test, a non-parametric test suitable for multiple comparisons involving related samples [22]. When the null hypothesis is rejected ($p < 0.001$), the Durbin–Conover post-hoc test may be applied. This test adjusts p-values to control the Type I error rate (false positives) in multiple comparisons, providing an appropriate balance between statistical power and error control [31], [32].

III. Methodology

The methodology adopted in this study is illustrated in Figure I, which describes the main stages addressed throughout the research and will be detailed in the following sections.

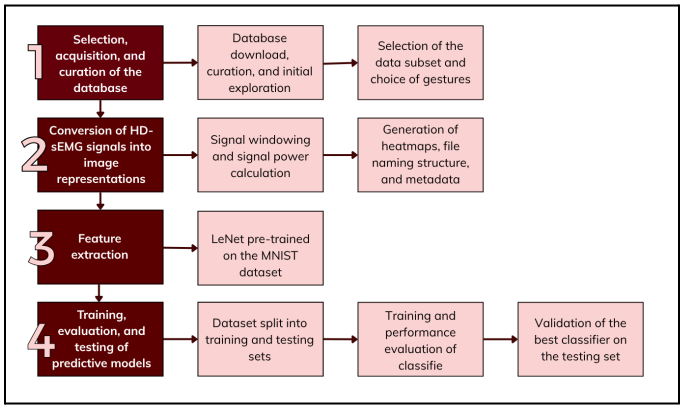

Figure I. Flowchart of the methodological stages of the study.

A. Dataset

For this study, the publicly available Hyser (High-density sEMG Recordings) dataset, available in the PhysioNet repository, was used. The dataset consists of HD-sEMG recordings from 20 healthy right-handed subjects (12 men and 8 women; age range: 21-34 years). Each participant performed two experimental sessions on different days, with an average interval of 8.5 ± 6.7 days between sessions [33].

The acquisition system employed four electrode arrays positioned on the forearm - two over the flexor muscles and two over the extensor muscles (distal and proximal) - totaling 256 channels arranged in a 16 × 16 grid. Signals were acquired using the Quattrocento system (OT Bioelettronica, Italy) with a sampling rate of 2048 Hz, a gain of 150, and 16-bit resolution, using high-pass (10 Hz) and low-pass (500 Hz) filters.

The Hyser dataset contains five experimental subsets. For this study, the Pattern Recognition (PR Dataset) subset was selected, comprising 34 hand gestures performed in two repeated trials. Only the maintenance segments (4 - second duration), during which participants sustained the gesture in a stable manner, were used in order to ensure greater signal stability.

Ten functional gestures (Figure II) were selected due to their relevance to activities of daily living and motor

rehabilitation: thumb extension, wrist flexion, wrist extension, wrist supination, radial deviation with a closed hand, pronation with a closed hand, supination with a closed hand, hand closing, hand opening, and three-finger pinch.

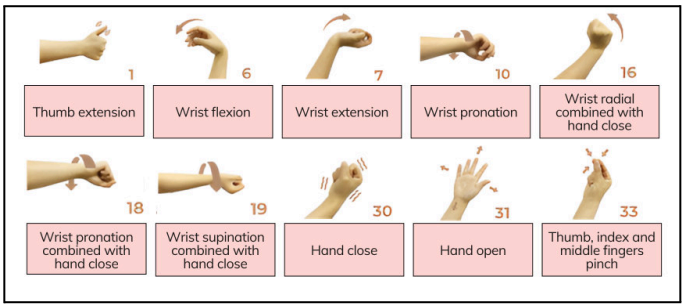

Figure II. Hand gestures selected for the study. Adapted from [34].

B. Preprocessing and Conversion to Images

The raw 4-second signals were segmented into 250 ms windows with 125 ms overlap. This configuration was adopted with future real-time applications in mind, such as human–machine interfaces or gamified rehabilitation systems, where short response times are essential.

For each temporal window and each of the 256 channels, the RMS value was calculated and reorganized into a 16 × 16 matrix reflecting the physical arrangement of the electrodes. To ensure that the visual representation corresponded to the actual anatomical orientation, geometric correction transformations were applied through horizontal mirroring followed by vertical mirroring using the NumPy library.

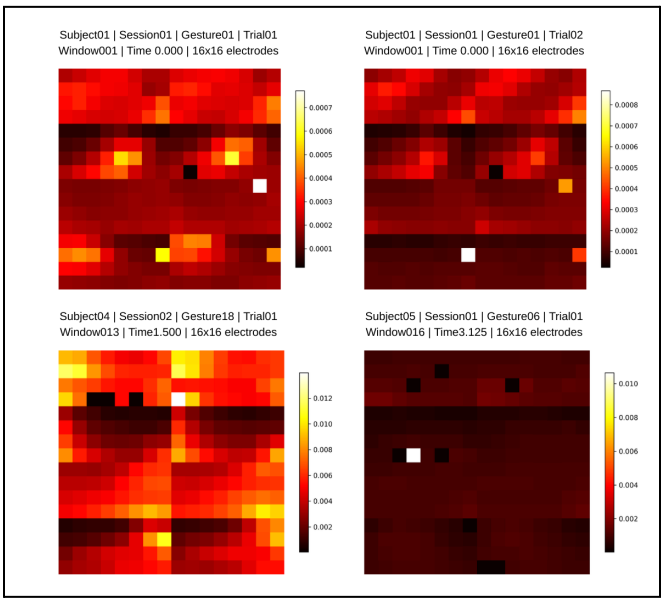

Figure III. Examples of heat maps generated from HD-sEMG signals. The images used in the machine learning experiments did not contain textual annotations in order to avoid bias during classifier training.

The corrected matrix was then converted into heat maps using the Matplotlib library in Python. The "hot" colormap was selected due to its effectiveness in representing intensity gradients: dark tones indicate low activation, orange/yellow tones represent moderate activation, and light/white tones correspond to high muscle activation. The images were generated at a resolution of 300 DPI, with all axis elements removed so that only the relevant visual information was retained.

At the end of the process, 24,707 images were generated - 2,400 per gesture, except for the three-finger pinch gesture (gesture 33), which totaled 2,387 images due to missing acquisitions in the original dataset. Each image was named according to a systematic protocol containing metadata (subject, session, gesture, trial, window, and time), enabling complete traceability (Figure III).

C. Feature Extraction with Deep Learning

To extract discriminative features from the heat maps, a transfer learning approach was employed using the LeNet architecture, a classical CNN widely validated for image recognition tasks. The network was initialized with weights pre-trained on the MNIST dataset, providing filters capable of detecting fundamental visual features (edges, corners, and textures) transferable to the analysis of HD-sEMG heat maps.

A fundamental adaptation consisted of replacing the original Max Pooling layer with Average Pooling, as the latter tends to better preserve the global spatial information of muscle activation by smoothing local peaks and producing a more robust and generalizable representation.

The extracted feature vectors (500 attributes) from the penultimate layer of the network were consolidated and structured into an ARFF (Attribute-Relation File Format) file, the native format of WEKA, containing the image paths and their corresponding labels (gestures). This structure enabled efficient integration between feature extraction in Python and the classification stage in WEKA.

D. Classification and Experimental Configuration

The dataset was divided into training (80%) and testing (20%) sets using the WEKA Resample filter with stratification to preserve the proportion of each gesture in both sets and without replacement, ensuring that training instances were not repeated in the test set. Due to the balanced distribution of the 10 classes in the original dataset, no additional artificial balancing techniques were required.

Eight decision tree-based classifiers were evaluated: J48, Random Tree, and Random Forest with 100, 200, 300, 400, and 500 trees.

The experiments were conducted in the Experimenter module of WEKA using the training set (80% of the data), employing 10-fold cross-validation with 10 repetitions. This protocol (100 executions in total) enables robust statistical estimation of model performance while compensating for the variability inherent to data partitioning.

The evaluated metrics were accuracy, Kappa index, Area Under the ROC Curve (AUC), sensitivity, and specificity. To verify statistically significant differences among classifiers, the Friedman test ($\alpha = 0.05$) was applied. Once the null hypothesis was rejected, the Durbin-Conover post-hoc test was employed to identify which pairs of algorithms differed significantly, with adjustments applied to control the Type I error rate.

E. Best Model Selection and Validation

The classifier that achieved the best balance among predictive performance (with emphasis on the Kappa index), low variability across repetitions, and lower computational cost (training and testing time) was selected for the final validation stage.

The selected model was then evaluated on the independent test set (20% of the data, not used in any training or cross-validation stage). From this validation, the confusion matrix and the final class-wise performance metrics were generated, providing a realistic estimate of the model's behavior when faced with unseen data.

IV. Results and Discussion

A. Classifier Performance

After training the classifiers using the 80% training set, the performance metrics summarized in Table I were obtained, presenting the mean values and standard deviations for the eight evaluated classifiers.

TABLE I - Performance metrics (mean and standard deviation) of the classifiers on the training set

Classifier	Accuracy	Kappa coefficient	Sensitivity	Specificity	ROC area
J48	79.80 ± 0.914	0.775 ± 0.010	0.842 ± 0.024	0.981 ± 0.003	0.930 ± 0.011
RF 100	91.70 ± 0.620	0.907 ± 0.007	0.947 ± 0.015	0.992 ± 0.002	0.994 ± 0.003
RF 200	91.90 ± 0.601	0.910 ± 0.006	0.948 ± 0.015	0.993 ± 0.002	0.995 ± 0.003
RF 300	92.00 ± 0.594	0.910 ± 0.006	0.948 ± 0.014	0.993 ± 0.002	0.995 ± 0.003
RF 400	92.00 ± 0.594	0.911 ± 0.006	0.948 ± 0.014	0.993 ± 0.002	0.995 ± 0.002
RF 500	79.70 ± 0.837	0.911 ± 0.006	0.948 ± 0.014	0.993 ± 0.002	0.995 ± 0.002
RT	79.40 ± 1.040	0.775 ± 0.009	0.830 ± 0.026	0.981 ± 0.003	0.910 ± 0.013

RF: Random Forest; RT: Random Tree.

The quantitative analysis of the data presented in Table I demonstrates distinct performance levels among the algorithms. The Random Forest classifiers consistently outperformed the single-tree algorithms (J48 and Random Tree). While J48 and Random Tree achieved mean accuracies of 79.8% and 79.7%, respectively, all Random Forest models achieved accuracies above 91.7%. An increase in mean performance was observed as the number of trees increased from 100 to 200, with the results stabilizing (saturating) from 200 trees onward, reaching a maximum accuracy of 92.0%.

A similar pattern was observed for the Kappa Index, with Random Forest values ($k \approx 0.907$-0.911) being classified as exhibiting "almost perfect" agreement according to the scale proposed by Jacob Cohen and substantially outperforming the single-tree models ($k \approx 0.775$). The Area Under the ROC Curve (AUC) was also notably superior for the Random Forest models (AUC > 0.994), indicating an almost ideal distinction among gesture classes.

The mean Sensitivity and Specificity metrics were consistently higher for the multi-tree models, with values close to 0.948 and 0.993, respectively. This result is clinically relevant because high sensitivity ensures that a user's or patient's motor commands are correctly recognized (minimizing false negatives), whereas high specificity prevents unintended activations in assistive systems (minimizing false positives).

The robustness of the Random Forest models is further evidenced by their low standard deviations across all metrics, especially when compared with the J48 and Random Tree algorithms. This indicates lower variability and greater stability in model performance across different validation data subsets.

B. Statistical Analysis of Performance Differences

To investigate whether the observed differences in classifier performance were statistically significant, the consolidated Kappa Index and ROC Area results were submitted to the Friedman test, a non-parametric test suitable for multiple comparisons involving related samples. Since the null hypothesis was rejected ($p < 0.001$ for both metrics), the Durbin-Conover post-hoc test was subsequently applied to identify specific classifier pairs with significant differences. The detailed results are presented in Tables II and III.

TABLE II - Results of the Durbin–Conover post-hoc test for the Kappa Index

Classifier 1	Classifier 2	Statistic	p
Random Tree	Random Forest 100	13.602	<.001

Random Forest 400	J48	19.897	<.001
Random Forest 500	J48	19.069	<.001

The statistical analysis corroborates the initial observations. For the Kappa Index, the vast majority of comparisons between a Random Forest classifier and a single-tree classifier (J48 or Random Tree) showed statistical significance ($p < 0.001$). However, one particular finding deserves attention: although the mean Kappa values for the Random Forest models with 200 ($k = 0.910$) and 300 ($k = 0.910$) trees were virtually identical, the post-hoc test indicated a statistically significant difference between them ($p < 0.010$).

This apparent discrepancy between identical means and statistical significance can be explained by considering the nature of the analyses performed. Table I reports the central means of the 100 executions. In contrast, the Friedman test and its post-hoc procedure do not simply compare means, but rather the complete distribution of ranks assigned to each of the 100 executions of each classifier. Thus, it is plausible that throughout the 100 iterations, the RF300 classifier consistently achieved slightly higher ranks than RF200, even though the final mean values were identical. This small yet consistent difference in relative performance across all cross-validation repetitions is captured by the statistical test, resulting in a significant p-value.

In contrast to the statistical significance observed for the Kappa Index, the AUC analysis showed that differences among Random Forest models with adjacent numbers of trees (e.g., RF200 vs. RF300, p = 0.104; RF300 vs. RF400, p = 0.154) were not statistically significant, reinforcing the observation that performance gains saturate beyond 200 trees.

C. Processing Time Analysis of the Classifiers

To support the selection of the most suitable model, computational cost was considered in addition to predictive performance. Training times increased proportionally with the number of trees: the Random Forest model with 200 trees required 31,275 ms, whereas the model with 300 trees required 47,723 ms, representing an increase of approximately 52%. Testing times followed the same trend, as shown in Table IV.

TABLE IV - PROCESSING TIME OF THE CLASSIFIERS

Classifiers	Training time (ms)	Testing time (ms)
J48	22476	5.1
Random Forest 100	15722	109
Random Forest 200	31275	247
Random Forest 300	47723	414
Random Forest 400	62900	603
Random Forest 500	79105	790
Random Tree	00248	3.5

D. Model Selection and Validation on the Test Set

Based on the aggregated analysis of performance, stability, statistical significance, and computational cost (lower processing time), the Random Forest classifier with 200 trees was selected for the final validation stage. The choice of RF200 over configurations with a larger number of trees was based on the principle of parsimony: this model reached a performance plateau, presenting mean metrics equivalent to those of configurations with a greater number of trees (as shown in Table I), but with lower computational cost and inference time. As advocated by the principle, when equally valid explanations are available, less complex models are preferred. Furthermore, reduced computational cost is a critical factor for the development of real-time applications, such as brain-machine interfaces or biofeedback systems for motor rehabilitation.

The RF200 model was then subjected to a final critical evaluation on the independent test set (20% of the data). The results, presented in Table V, reveal solid performance, although lower than that observed during cross-validation, indicating a typical generalization scenario with controlled performance degradation.

The analysis of performance on the test set reveals that the model maintained robust discriminative capability, although with reduced classification precision. The accuracy of 78.87%, Kappa Index of 0.765, and sensitivity of 0.789 represent a significant decrease compared with the cross-validation values (91.9%, 0.910, and 0.948, respectively), yet still constitute clinically relevant performance for the complex task of classifying 10 hand gestures.

TABLE V - COMPARISON OF THE RF200 CLASSIFIER PERFORMANCE METRICS BETWEEN TRAINING AND TESTING

Metric	Training set	Test set	Variation
Accuracy	91.90%	78.87%	-13.03%
Kappa coefficient	0.910	0.765	-0.145
ROC area	0.995	0.962	-0.033
Sensitivity	0.948	0.789	-0.159
Specificity	0.993	0.977	-0.016

TABLE VI – DETAILED CLASS-WISE ACCURACY OF THE RF200 CLASSIFIER ON THE TEST SET

Class	TPR	FPR	Precision	F1 score	MCC	ROC area	PRC area
Gesture 1	0.883	0.025	0.759	0.839	0.821	0.974	0.915

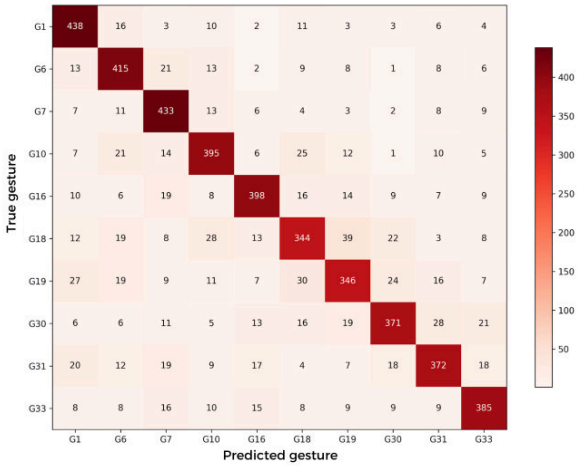

Figure IV. Confusion matrix of the RF200 classifier performance on the test set

The analysis of the Confusion Matrix (Figure IV) and the detailed class-wise accuracy table (Table VI) reveals important patterns regarding model behavior. Gestures 1, 6, and 7 exhibited the best results, with sensitivity values above 83%, indicating that the model can consistently identify these muscle activation patterns. In contrast, gestures 18 and 19 showed the lowest sensitivity values (69.4% and 69.8%, respectively), suggesting that these movements share similar electromyographic characteristics with other gestures, leading to greater classification confusion.

Based on the confusion matrix analysis, the most pronounced classification errors occurred between antagonistic gestures sharing similar muscle groups, particularly pronation and supination with a closed hand (gestures 18 and 19), which

accounted for 69 reciprocal misclassifications, representing the greatest challenge for the classifier. This pattern was also observed, although to a lesser extent, in the hand opening and hand closing pair (gestures 30 and 31), with 46 misclassifications, and in wrist flexion and wrist extension (gestures 6 and 7), with 32 misclassifications. In addition to these antagonistic pairs, other significant confusions following a functional logic were identified, such as wrist supination (gesture 10) being confused with wrist flexion (gesture 6) in 21 instances, and pronation with a closed hand (gesture 18) presenting considerable confusion with radial deviation (gesture 16) in 28 instances.

These patterns suggest that although the model demonstrates good discriminative capability across broad gesture categories, it faces difficulties in distinguishing subtle variations within similar functional groups, where muscle activation patterns overlap substantially. This finding is particularly relevant for rehabilitation applications, as it indicates that certain antagonistic gestures may require specific model training strategies or even the consolidation of functional classes to ensure greater robustness in human-machine interfaces.

Furthermore, the AUC metric remained high (mean value of 0.962), indicating that the model preserved strong discriminative capability among classes despite the reduction in pointwise accuracy. This is a positive indicator for clinical applications, where confidence in gesture discrimination is crucial.

In summary, the obtained results validate the feasibility of the proposed approach, with the 200-tree Random Forest classifier demonstrating robust performance in discriminating hand gestures from HD-sEMG heat maps, achieving an accuracy of 78.87% on validation using an independent test set. The analysis of confusion patterns provides valuable insights for future refinements, particularly regarding the discrimination of antagonistic gestures with overlapping muscular synergies.

V. Conclusion

The present study introduced a hybrid approach for hand gesture classification based on High-Density Surface Electromyography (HD-sEMG) signals, combining signal conversion into image representations (heat maps), deep feature extraction using a pre-trained Convolutional Neural Network (LeNet), and classification through decision tree-based algorithms in the WEKA environment. The methodology was evaluated using the publicly available Hyser dataset, composed of healthy participants. Ten functionally relevant gestures were selected for their potential in motor rehabilitation applications. Accordingly, the results provide a methodological foundation for future clinical validation.

The results demonstrated that ensemble-based models, particularly Random Forest, consistently outperformed single decision trees (J48 and Random Tree), achieving mean accuracy above 91.7%, Kappa Index values higher than 0.907, and Area Under the ROC Curve values greater than 0.994 during cross-validation. Statistical analysis using the Friedman test and the Durbin-Conover post-hoc test confirmed significant differences among classifiers, with the Random Forest models exhibiting statistically superior performance.

Considering the balance between predictive performance and computational cost, the Random Forest model with 200 trees (RF200) was selected for final validation. When applied to an independent test set, the RF200 model maintained robust discriminative capability, although with reduced performance metrics, achieving an accuracy of 78.87%, a Kappa Index of 0.765, and a mean AUC of 0.962. Analysis of the confusion matrix revealed that the greatest misclassifications occurred between antagonistic gestures with similar muscle activation patterns, such as pronation and supination with a closed hand, highlighting the model's difficulty in discriminating subtle variations within overlapping functional groups.

The results reinforce the potential of the proposed approach for technology-assisted motor rehabilitation applications, where the combination of HD-sEMG visual representations with classifiers that offer a structurally interpretable decision framework provides a feasible path toward the development of accessible and clinically relevant human–machine interfaces. The presented methodology constitutes a methodological contribution that integrates the informational richness provided by HD-sEMG, the representational capability of deep learning, and the rule-based structure of tree-based models, providing a starting point for explainability analysis. This aligns with the growing demand for rehabilitation support systems that are both effective and amenable to explainability analysis.

The data split was performed at the instance level, following standard practice in exploratory machine learning studies. The reported metrics therefore reflect the model's discriminative capability under controlled conditions, rather than its generalization to unseen participants. Given the well-documented inter-subject variability in HD-sEMG signals, subject-wise validation constitutes a necessary next step for assessing the robustness of the proposed approach in realistic deployment scenarios.

Future work will focus on expanding the hybrid approach to include a larger number of classifiers, enabling a broader comparison of their performance with that of decision tree-based methods. In addition, other deep learning architectures will be explored for feature extraction to evaluate whether alternative representations can improve the discrimination of antagonistic gestures. Finally, the model will be validated on independent datasets using a subject-wise split, ensuring that no data from test participants are used during training.

DECLARATION ON THE USE OF ARTIFICIAL INTELLIGENCE

The DeepSeek large language model was employed exclusively for orthographic and grammatical editing of the manuscript. No artificial intelligence was involved in the conception of the research, methodological design, data collection or analysis, interpretation of results, or generation of intellectual content. All AI-assisted processes and outputs were rigorously validated and audited by the human authors, who assume full responsibility for the accuracy, originality, and

scientific integrity of this work.

***Abstract*—Nowadays, portable handheld ultrasound systems continuously demand higher acquisition and processing capabilities, while maintaining the power and resource constraints imposed by embedded platforms. Heterogeneous ARM–FPGA architectures have emerged as an effective solution by combining the flexibility of embedded processors with the parallel processing capabilities of FPGAs. Consequently, a high-speed communication interface between these subsystems becomes essential. This work presents a PCIe-based Scatter-Gather DMA data transfer architecture for a portable embedded ultrasound platform composed of an NXP i.MX8M Plus processor and a AMD Artix-7 XC7A200T FPGA. The proposed architecture employs the AMD XDMA IP core and Linux XDMA driver to implement high-speed DMA communication between the FPGA and the embedded processor. Experimental tests were performed using data generated by the FPGA to simulate the ultrasound acquisition. The PCIe communication achieved a sustained throughput of up to 122 MB/s, exceeding the 40.6 MB/s required by the target portable handheld ultrasound application.**

***Index Terms*—PCIe, FPGA, Ultrasound, Embedded System**

I. Introduction

Portable handheld ultrasound systems have increasingly adopted heterogeneous embedded architectures that combine ARM processors and FPGAs to achieve real-time imaging under strict power and resource constraints [1] [2]. In these systems, the FPGA is commonly responsible for data acquisition and low-latency processing tasks, while the embedded processor performs system control, image processing, and visualization or streaming.

In ultrasound devices, as the number of acquisition channels and supported imaging modalities increases, the communication bandwidth between acquisition and processing devices becomes a critical design requirement [3]. Under real-time operating conditions, the system must sustain dozens of MB/s of continuous data throughput. High-speed interfaces such as USB 3.0, Ethernet and PCI Express (PCIe) can support these data rates [4], but present different trade-offs in terms of latency, implementation complexity, and power consumption.

In the ARM-FPGA architecture considered in this work, based on the NXP i.MX8M Plus and AMD Artix-7, USB 3.0, Ethernet, and PCI Express were evaluated as possible communication interfaces. USB 3.0 provides sufficient bandwidth for the target application, but its implementation on the FPGA side would require an additional proprietary USB 3.0 IP or a custom implementation, increasing the cost or complexity of the implementation. Ethernet also provides sufficient bandwidth and offers advantages when network connectivity or longer communication distances are required. However, its use for direct FPGA-to-processor communication introduces additional interface logic and protocol processing on the FPGA side.

PCI Express in particular, provides a direct point-to-point connection between the FPGA and the embedded processor, provides a low-latency and high-bandwidth communication interface, in addition, AMD provides the XDMA IP core and the corresponding Linux driver [5], which simplify the implementation of DMA-based communication between FPGA devices and embedded ARM platforms. The IP XDMA enables the DMA-based transfers, improving the transmission efficiency, because in this method, the transfer is made mostly by a dedicated controller for this hardware interface [6] [7]. Considering these trade-offs and the characteristics of the target hardware, PCIe was selected as the communication interface for the proposed architecture.

This work presents a firmware architecture for high-speed PCI Express communication between an AMD Artix-7 FPGA and an NXP i.MX8M Plus embedded platform through Scatter-Gather DMA based on PCI Express focusing to support the real-time data transfer in the portable handheld ultrasound device.

II. System Architecture

The proposed high-speed communication architecture is designed to support the ultrasound system, which can perform four main tasks:

- Signal generation - Transmission (TX).
- Scanline acquisition - Reception (RX).
- Image processing.
- Streaming of ultrasound images.

The proposed ultrasound platform has 86 acquisition elements, with up to 32 channels. The analog signals are sampled at 20 MHz, and the system supports imaging depths of up to 20 cm, corresponding to a maximum of 5,184 samples per scanline. Four imaging modes are supported: B, Harmonic B, Color Doppler, and Power Doppler. Under real-time operating conditions, the system must sustain approximately 40.6 MB/s of continuous data throughput to achieve 30 FPS in B and Harmonic B, 10 FPS in Color and Power Doppler.

A. Hardware Architecture

The hardware architecture is based on a heterogeneous ARM–FPGA platform composed of an AMD Artix-7 XC7A200T-L2SBG484E FPGA and an NXP i.MX8M Plus embedded processor connected through a PCI Express interface.

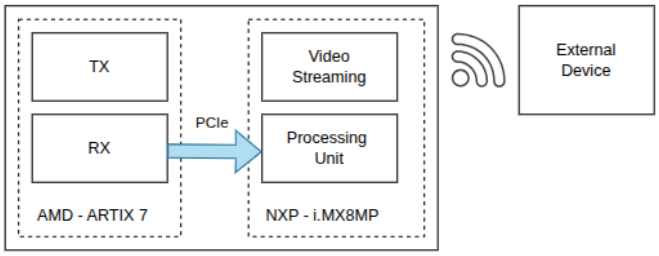

Fig. 1. System Architecture.

The FPGA is responsible for the time-critical ultrasound operations, including the generation of transmission pulses, the management of the reception chips, apply the beamforming technique on the receive data, also apply the apodization, and the management of data transfer. The acquired samples are stored in internal buffers and transferred to the embedded processor using the AMD XDMA IP core through a DMA-based PCI Express communication channel.

The i.MX8M Plus operates as the host processing platform and runs an embedded Linux operating system. On the processor side, the XDMA Linux driver is responsible for receiving the acquisition data transferred from the FPGA. The received data is then processed to generate ultrasound images, which are subsequently encoded and transmitted through a Wi-Fi connection for real-time visualization on external devices.

B. Communication Requirements

The ultrasound platform supports four acquisition modes: B, Harmonic B, Color Doppler and Power Doppler. In all cases, each acquired sample is represented using 16 bits (2 bytes).

For B and Harmonic B mode, each frame consists of 56 ultrasound scanlines. The number of samples per scanline depends on the selected imaging depth. For the maximum supported depth of 20 cm, each scanline contains 5,184 samples, resulting in 10,368 bytes per scanline and 580,608 bytes per frame. To sustain the target frame rate of 30 FPS, a throughput of approximately 17.4 MB/s is required.

The most demanding operating condition occurs during Color and Power Doppler modes. In this modes, each frame contains 56 B scanlines and 336 Doppler scanlines, resulting in a frame size of 4,064,256 bytes. At 10 FPS, the required throughput increases to approximately 40.6 MB/s.

TABLE I
COMMUNICATION BANDWIDTH REQUIREMENTS

Imaging Mode	Frame Size (Bytes)	FPS	Throughput (MB/s)
B	580,608	30	17.4
Harmonic B	580,608	30	17.4
Color Doppler	4,064,256	10	40.6
Power Doppler	4,064,256	10	40.6

As shown in Table I, the Color Doppler and Power Doppler represents the worst case communication scenario and was therefore used as the reference requirement for evaluating the PCI Express communication architecture.

III. PCI EXPRESS COMMUNICATION ARCHITECTURE

PCI Express (PCIe) is a high-speed serial communication standard widely used for data transmission. PCIe employs a point-to-point topology, providing dedicated communication resources between connected devices [7]. Each PCIe lane consists of two differential signal pairs, one for transmission and one for reception, enabling full-duplex communication. Multiple lanes can be aggregated to form wider links, such as x1, x2, x4, x8, and x16 configurations, allowing the available bandwidth to scale according to application requirements [8].

TABLE II
PCI EXPRESS THEORETICAL THROUGHPUT [8].

PCIe Version	Code	Transmission Speed	Throughput			
			x1	*x4*	*x8*	*x16*
1	8b/10b	2.5 GT/s	250 MB/s	1 GB/s	2 GB/s	4 GB/s
2	8b/10b	5 GT/s	500 MB/s	2 GB/s	4 GB/s	8 GB/s
3	128b/130b	8 GT/s	984 MB/s	3.9 GB/s	7.8 GB/s	15.7 GB/s
4	128b/130b	16 GT/s	1.969 GB/s	7.87 GB/s	15.754 GB/s	31.508 GB/s

The NXP i.MX8M Plus processor provides a PCIe Gen3 x1 controller capable of operating as either a Root Complex or an Endpoint. On the other side of communication, the AMD Artix-7 XC7A200T-L2SBG484E FPGA provides native hardware supporting a PCIe Gen2 x4 capable of operating as either a Root Complex or an Endpoint.

AMD provides three main IP cores for implementing PCIe communication in 7-Series FPGAs: the 7-Series Integrated Block for PCI Express, AXI Memory Mapped to PCI Express, and DMA/Bridge Subsystem for PCI Express (XDMA). In this work, the XDMA IP was selected because it provides a complete Scatter-Gather DMA engine, enabling efficient high-speed data transfers with minimal processor intervention [7]. Compared with a software-managed PCIe implementation, this approach reduces software complexity and frees processor

resources for ultrasound image processing and other real-time functions.

According to the minimum device requirements of the XDMA IP, the selected Artix-7 FPGA device supports only PCIe Gen1 operation and can operate only as a PCIe Endpoint [9]. Therefore, the FPGA is configured as a PCIe Gen1 Endpoint, while the i.MX8M Plus operates as the PCIe Root Complex. Since the processor provides a single PCIe lane and the negotiated link speed is limited by the lowest supported PCIe generation, the resulting communication link operates at PCIe Gen1 x1.

The PCIe configuration was limited by the choice of XDMA IP usage, which was adopted to reduce CPU intervention in data transfers and simplify the integration between the FPGA and the i.MX8M Plus. Despite this limitation, the resulting PCIe Gen1 x1 configuration provides sufficient communication bandwidth, since its theoretical maximum throughput is approximately 250 MB/s, which is above the 40.6 MB/s required by the proposed ultrasound application.

A. FPGA Endpoint Architecture

As ultrasound scanline samples are acquired, they are temporarily stored in a FIFO to synchronize the acquisition process with the data transfer subsystem. The samples are subsequently written to a dual-port RAM, in which one port is used by the acquisition of logic for writing incoming data while the second port is accessed by the XDMA engine for DMA transfers.

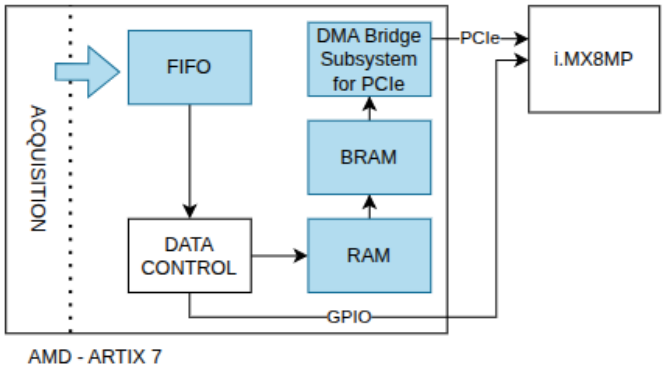

Fig. 2. FPGA Architecture.

Since PCIe transactions must be initiated by the Root Complex, the data transfer is controlled by the i.MX8M Plus processor. To synchronize both devices, a dedicated FPGA GPIO is connected to the processor and configured as a data-ready interrupt. Whenever a new set of scanline samples becomes available, the FPGA asserts the interrupt signal. Upon receiving the interrupt, the embedded processor initiates a DMA transaction through the XDMA driver to retrieve the acquired data from the FPGA.

The acquisition buffer was designed to store 28 ultrasound scanlines before initiating each DMA transfer. As a result, every PCIe transaction transfers to a fixed data block of approximately 300 kB. This organization reduces the number of PCIe transactions and decreases the frequency of GPIO interrupts generated by the FPGA. Although larger DMA transfers provide higher throughput, the buffer size represents a trade-off between communication efficiency, interrupt latency, and the available on-chip memory resources of the FPGA.

A custom data organization protocol is used to store the acquired scanlines in the FPGA RAM, as shown in Fig. 3. Each DMA buffer includes an 8-byte packet counter that allows the i.MX8M Plus to identify the transfer sequence. The buffer is further divided into scanline subpackets containing control information and padding fields to delimit each scanline. The control information identifies the ultrasound acquisition mode, scanline length, line number within the frame, and scanline number within the acquisition sequence. The scanline length depends on the configured imaging depth, while the line identification fields allow the processor to correctly reconstruct frames for B, Harmonic B, Color Doppler and Power Doppler types processing.

Each DMA transaction transfers an acquisition buffer containing up to 28 scanlines. The ultrasound frames are progressively assembled on the i.MX8M Plus from the received acquisition buffers. A B and Harmonic B frame consists of 56 scanlines and therefore requires two DMA transfers. Similarly, the Color and Power Doppler configuration contains 392 scanlines and requires 14 DMA transfers.

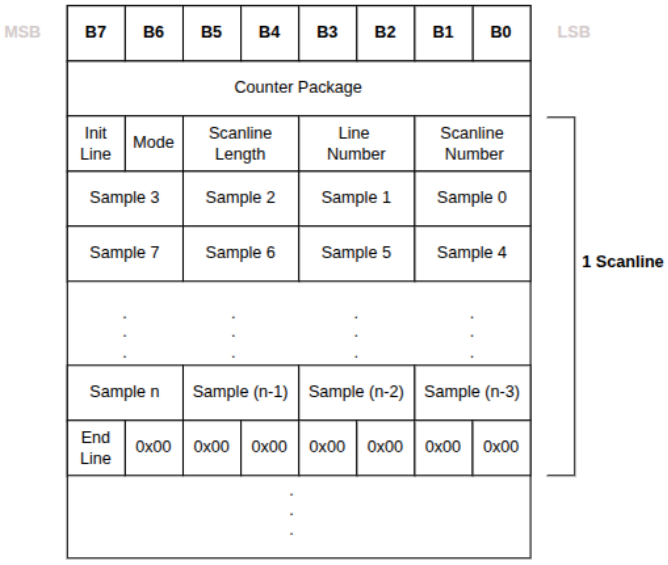

Fig. 3. RAM Memory Mapping.

B. i.MX8M Plus Root Complex Architecture

The embedded platform runs an Embedded Linux operating system generated using the Yocto Project. The AMD XDMA Linux driver XDMA was cross compiled for the ARM architecture and integrated into the system image.

The XDMA driver exposes character devices that provide user-space access to the DMA channels, including Host-to-Card (H2C) and Card-to-Host (C2H) interfaces. Since the

ultrasound data flow considered in this work is unidirectional, from the FPGA to the processor, only C2H channel is used.

A user-space application written in C was developed to manage ultrasound data after reception by the i.MX8M Plus. The FPGA delivers the ultrasound data after beamforming and apodization, organized as scanlines. In the embedded processor, the application is responsible for receiving the scanlines, performing the subsequent signal processing, and transmitting the resulting ultrasound images. Since these operations can be executed independently, the application was implemented using a multithreaded architecture divided into three main tasks: PCIe Data Manager, Signal Processing, and Video Transmission.

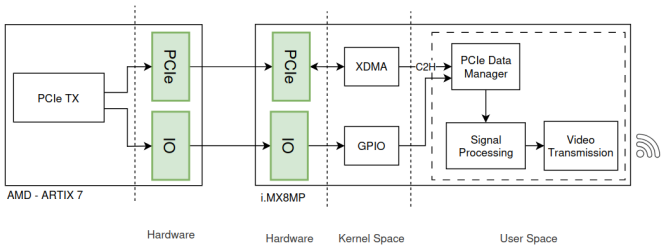

Fig. 4. i.MX8MP Architecture.

The PCIe Data Manager is responsible for communication with the FPGA and reassembly of the ultrasound frames from the received acquisition buffers. The thread waits for the data-ready GPIO interrupt and then initiates a C2H DMA transfer of 300 kB size. After each transfer, the packet counter field defined in the communication protocol as seen in Fig. 3, is checked to detect missing or out-of-sequence packets. The scanlines contained in the received buffer are then extracted and placed at their corresponding positions in the frame buffer. Once all scanlines belonging to the current frame have been received, the completed frame is forwarded to the Signal Processing thread. If a missing packet is detected, the incomplete frame is discarded and frame reassembly resumes when packets belonging to the next frame are received.

The Signal Processing thread performs the remaining processing required to generate a 640 × 480 ultrasound image. The resulting image is then forwarded to the Video Transmission thread. This thread divides each image into packets and transmits them through UDP at the target rate of 30 FPS.

IV. Results

The proposed architecture was evaluated using the hardware prototype composed of a custom board that integrates an AMD Artix-7 FPGA, connected to the variscite evaluation board "VAR-DT8MCustomBoard" through a Mini PCIe interface.

A. PCIe link

The first validation step consisted of verifying the PCIe communication between both devices. After system initialization, the PCIe link was successfully established and recognized by the embedded Linux operating system. As shown in Fig. 5, the PCIe link was negotiated as PCIe Gen1 x1.

Fig. 5. PCIe link successfully established as Gen1 x1.

B. PCIe communication performance

The second step evaluated PCIe communication performance using the AMD XDMA *dma_from_device* application from the AMD XDMA Linux driver test suite, instrumented to measure each C2H DMA transaction using a monotonic clock. The measurements were used to calculate throughput, transfer latency and inter-transfer jitter. The tests were performed using transfer sizes ranging from 64 kB to 64 MB. The number of consecutive DMA transfers was adjusted according to the transfer size, resulting in a total of approximately 25 GB transferred for each configuration. In addition, CPU utilization was measured during the tests.

TABLE III
C2H XDMA PERFORMANCE RESULTS

Transfer Size	Transfer Count	Throughput		Latency		Mean Jitter (μs)	CPU Util. (%)
		Mean (MB/s)	Std. Dev. (MB/s)	Mean (ms)	Std. Dev. (μs)		
64 kB	390000	89.739	23.56	0.767	211.163	90.604	20.1
128 kB	195000	90.149	14.682	1.454	215.809	138.365	15.6
256 kB	98000	100.751	8.526	2.558	205.262	154.097	12.3
300 kB	83000	105.269	8.058	2.866	223.548	127.958	11.3
512 kB	49000	108.235	3.548	4.736	164.345	98.340	8.6
1 MB	25000	114.567	2.531	8.733	201.461	163.347	6.3
2 MB	12500	118.658	1.959	16.860	322.589	318.597	5.0
4 MB	6250	120.921	1.154	33.083	315.987	580.540	4.7
8 MB	3125	121.047	0.414	65.544	221.275	230.690	4.3
16 MB	1560	122.453	0.355	130.663	378.27	413.238	3.7
32 MB	780	122.436	0.327	261.362	699.348	770.519	3.6
64 MB	390	122.524	0.342	522.352	1463.595	1580.370	3.4

Table III summarizes the results for different DMA transfer sizes. The throughput increased with the transfer size and stabilized at approximately 122 MB/s for transfers above 8 MB. This represents 48.8% of the theoretical 250 MB/s bandwidth of a PCIe Gen1 x1 link. The difference from the theoretical limit is expected considering the hardware platform used in this work, which has more limited hardware resources than conventional PC-based architectures.

Despite the achieved throughput, the results also show that throughput variability and CPU utilization decrease with increasing transfer size, while transfer latency increases pro-

portionally to the amount of data transferred. Therefore, there is a trade-off between throughput, communication stability, CPU utilization, and latency.

To meet the system requirements, the communication must provide sufficient and stable throughput without affecting the video transmission rate, while maintaining low CPU utilization. The available processing time per frame is approximately 33 ms for B and Harmonic B mode, and 100 ms for Doppler mode. This time must be shared among the three threads implemented on the application, with signal processing being the most computationally demanding stage. Therefore, the communication stage should introduce only a small fraction of the available processing time.

To meet the minimum system latency of 33 ms in B mode, the transfer size is limited by the B mode frame size of 580,608 bytes, since a larger transfer would require data from more than one frame to complete a DMA transaction. On the other hand, increasing the transfer size also requires a larger FIFO in the FPGA to store the acquired scanlines before each DMA transfer. Considering these constraints, a transfer size of 300 kB was selected. With this configuration, each DMA transaction transfers up to 28 scanlines, corresponding to half of a B mode frame.

According to the acquisition buffer organization described previously, DMA transfers are triggered by a GPIO interrupt approximately every 16.5 ms in B mode and Harmonic B mode, and every 7.14 ms in Doppler modes. For the selected 300 kB configuration, the transfer latency remains below the shortest DMA trigger interval of 7.14 ms. Therefore, the selected transfer size provides a suitable trade-off between throughput, CPU utilization, FPGA memory usage, and transfer latency for the target application.

C. PCIe communication integration

After validating the PCIe communication subsystem, the proposed architecture was integrated into the portable handheld ultrasound application running on the i.MX8M Plus. Since the ultrasound acquisition hardware is still under development, a data generation module was implemented in the FPGA to emulate the output of the acquisition subsystem. The generated data reproduces the expected acquisition rate and buffer organization of the final ultrasound hardware, allowing the communication and processing pipeline to be evaluated under representative operating conditions.

The integrated system achieved frame rates of 29.3 FPS for B mode, 29.1 FPS for Harmonic B, 9.8 FPS for Color Doppler, and 9.2 FPS for Power Doppler. During these experiments, the CPU utilization of the i.MX8M Plus reached a maximum of 88% in the most demanding imaging mode.

The integrated system was also continuously tested for five hours to evaluate the communication reliability between the FPGA and the i.MX8M Plus. An average of 21 dropped acquisition packets per hour was observed. When a packet is lost, the corresponding incomplete frame is discarded, which may temporarily reduce the video frame rate. However, the observed packet loss rate was sufficiently low to maintain continuous video streaming during the experiments.

V. Conclusion

Experimental validation demonstrated that the proposed architecture provides sufficient communication throughput for the portable handheld ultrasound system. The PCIe communication reached a maximum throughput of approximately 122 MB/s. The communication subsystem was also successfully integrated into the ultrasound application running on the i.MX8M Plus, together with the signal processing and video streaming stages, while maintaining the target frame rates for the evaluated imaging modes.

Compared with previous PCIe-based FPGA communication architectures reported in the literature, the proposed solution achieves approximately 48.8% of the theoretical PCIe Gen1 x1 bandwidth while targeting an embedded platform with limited hardware resources. Du et al. [7] reported an efficiency of approximately 39% using a Xilinx Virtex-7 FPGA connected to a desktop PC, while Boyang [8] achieved approximately 64% with a Xilinx Kintex-7 FPGA and a desktop PC. Zhang and Li [1] also reported an efficiency of approximately 64% using an ARM-FPGA architecture based on an Artix-7 FPGA and an NVIDIA Jetson TX2. Although some of these implementations achieved higher PCIe efficiency, they were evaluated on platforms with greater processing and hardware capabilities, including Virtex-7 and Kintex-7 FPGAs, desktop PCs, and the NVIDIA Jetson TX2. In contrast, this work targets a mid-range embedded platform based on the Artix-7 and i.MX8M Plus. Despite these hardware limitations, the achieved communication bandwidth is sufficient to meet the requirements of the target ultrasound application.

The selection of the XDMA framework provides a DMA infrastructure and Linux driver support, reducing processor intervention and facilitating the integration between the FPGA and the embedded Linux platform. Although the selected XDMA limits the implemented interface to PCIe Gen1, this limitation does not affect the communication requirements of the target application. Alternative PCIe IP implementations could potentially provide higher bandwidth on compatible hardware, but would require additional implementation effort.

Future work includes integrating the proposed communication architecture with the complete ultrasound acquisition hardware, enabling validation using real ultrasound scanline data acquired from the final RX front-end.

***Abstract*—This study presents a motion analysis tool applied to Pilates equipment exercises, designed to support the evaluation of movement quality through biomechanical parameters and graphical outputs. Based on a Machine Learning model (MoveNet) previously developed by the authors, the system identifies joint kinematics and generates biomechanical reports on range of motion, cadence, bilateral symmetry, and real-time feedback. Three exercises were analyzed: the lunge on the Reformer, lateral abduction and adduction, and hip flexion on the Pilates Cadillac Trapeze Table. The analysis focused on joint angles, lumbopelvic stability, and kinematic behavior across repetitions. The results revealed movement asymmetries, including reduced cadence and neuromuscular control between the lower limbs during the lunge, as identified through knee angle analysis. In lateral abduction and adduction, postural compensations were observed, reducing movement symmetry and indicating lateral dominance or deficits in hip mobility and strength. Additionally, deficits in lumbopelvic control were identified during the Stretch with Handles exercise, likely associated with insufficient activation of deep stabilizing musculature. Overall, the proposed tool provides an objective framework for biomechanical assessment in Pilates practice, offering potential applications in exercise monitoring, rehabilitation, and data-driven movement analysis aligned with current trends in biomedical engineering.**

***Index Terms*—Image analysis, MoveNet, Pilates exercises monitoring.**

I. INTRODUCTION

The Pilates method, developed by Joseph Hubertus Pilates (1883–1967), is widely recognized for its integration of body control, breath awareness, and precision in movement execution. Initially conceived as a rehabilitation technique, the method has evolved into a consolidated practice in training, rehabilitation, and health promotion settings, standing out for its focus on lumbar pelvic stability, postural alignment, and core strength development. Exercises can be performed both on the floor and on specific equipment—such as the Reformer, Cadillac, Chair, and Barrel—which offer graduated resistance and guided trajectories, allowing for greater control and safety in execution. The correct execution of the exercises is essential to achieve the benefits frequently attributed to the method, such as improved lumbar pelvic stability, increased body awareness, and optimized postural alignment. Biomechanics, in this context, becomes an indispensable tool for understanding joint and muscle behavior during movements, favoring more precise and safe interventions [1]. Deviations in joint range of motion, trunk compensations, or muscle imbalances can compromise the benefits of the method and increase the risk of overload. Biomechanical analysis in these contexts provides valuable insights into the interaction between joints, muscles, and motor patterns, allowing for individualized adjustments in exercise prescription. The analysis of human movement integrates knowledge of biomechanics, kinesiology, and motor control, allowing us to understand the behavior of the musculoskeletal system in dynamic tasks.

In Pilates, the importance of core stability and segmental alignment has been reinforced by recent studies [2], which highlight the need for precision in execution to avoid overload, especially in the lumbar region. The increasing incorporation of technologies for movement analysis, such as video capture systems, expands the potential for studying Pilates by allowing the identification of asymmetries, joint deviations, and compensatory patterns. Thus, investigating movement analysis in the Pilates method, especially with the support of technological resources, contributes to scientific, educational, and clinical advancements. Almeida Alves et al. [3] observed that biomechanics applied to Pilates makes it possible to identify inadequate joint patterns and functional limitations, contributing to personalized interventions. This understanding becomes even more robust with the use of motion analysis technologies. Lee et al. [4], for example, demonstrated that cameras and inertial sensors (IMUs) allow quantification of joint angles in different planes, with the potential for real-time correction. High-resolution cameras and body tracking soft-

ware have been explored for non-invasive analyses. Jongbae et al. [5] proposed, with high precision, recall, and f1-score, a real-time Pilates posture recognition system on a smartphone for exercise monitoring aimed to recognize 8 Pilates exercises (i.e., Bridge, Head roll-up, Hundred, Roll-up, Teaser, Plank, Thigh stretch, and Swan). Shakya et al. [6] used OpenCV and MediaPipe in order to evaluate motion analysis for Pilates ring-based exercises. They analyzed patient movements and evaluated posture accuracy by measuring the range of motion through qualitative assessments. Zhao et al. [7] employed MediaPipe and a convolutional neural network to extract features from human keypoints, and combined these with a Long Short-Term Memory (LSTM) algorithm to recognize ten Pilates poses (i.e., Criss Cross, Rolling Ball, Spine Twist, High Plank to Pike, One Hundred, Climber, Squat, Kneel Side Kick, Roll Up, and Bird Dog) in real-time video, achieving an accuracy above 94%. Although these studies have shown the capability of detecting the Pilates different actions, they are not prone for favoring longitudinal studies and objective assessments through movement details analyses. Therefore, this study aims to analyze, from a theoretical and conceptual perspective, the biomechanical fundamentals involved in the execution of Pilates movements with equipment, with emphasis on the evaluation of joint angles, postural stability, and movement precision. It seeks to discuss how movement analysis, supported by technological recording and processing resources, can contribute to technical improvement, postural correction, and injury prevention. Furthermore, the study presents foundations for the future validation of objective measurement systems in the context of Pilates.

II. MATERIALS AND METHODS

This study adopts a theoretical and exploratory approach, based on conceptual analysis of the biomechanical principles applied to the Pilates method. Essential aspects for the execution of movements on equipment were considered, including joint mobility, lumbar pelvic stability, postural alignment, and motor coordination, as indicated in research on motor control and segmental stability. The basis is the monitoring of joint angles achieved during the execution of exercises, taking as a reference standard described in biomechanical literature. The study incorporates a cohort evaluation of 18 healthy participants aged between 20 and 65 years to analyze inter-subject variability under identical experimental conditions. The sample comprised both regular practitioners and non-practitioners of physical activities, as well as individuals with and without prior experience in Pilates. The video protocol was captured using a standard smartphone camera positioned on a stable tripod, ensuring a perpendicular viewpoint of the sagittal plane recorded at 30 frames per second (FPS) with a resolution of 1080p. During the pose estimation pipeline, a confidence threshold of 0.5 was established for keypoint detection using MoveNet; missing keypoints or frames with high occlusion were handled using a linear interpolation algorithm based on the adjacent valid frames.

A. Proposed System Application

The proposed system was developed in Python, mainly using the TensorFlow and OpenCV libraries. TensorFlow is commonly used to train and apply machine-learning models for pattern recognition [8]. In this study, it was used simply to load the pre-trained model and run the inference needed to identify key body points in each video frame. The machine-learning model applied was MoveNet [8], developed by Google and available on Kaggle. MoveNet is designed to estimate human posture in images or videos by identifying key body landmarks—such as the head, shoulders, elbows, knees, and ankles—in real time. It uses compact deep-learning architectures that allow the model to operate efficiently even on devices with more limited processing capacity, including mobile phones and embedded systems. The analysis of movements in the Pilates method requires a detailed understanding of the biomechanical principles that guide the safe and efficient execution of exercises. During practice with equipment, variables such as joint range of motion, postural control, lumbar pelvic stability, and muscle activation play a determining role in the quality of movement and its impact in the health of the individual. Precise monitoring of joint angles has the potential for providing objective information to identify possible compensations and asymmetries, allowing for technical interventions and improvement of execution.

Studies reinforce that core stability and motor control are fundamental to the efficiency and safety of the method [9], [10]. Biomechanics plays a central role in the safe and efficient execution of Pilates exercises. Precise observation of joint angles allows for the identification of compensations, such as unwanted trunk rotations, excessive pelvic anteversion, or lumbar hyperextension—conditions frequently associated with pain and injuries [1]. Recent research reinforces the relevance of motor control in the practice of the method. Silva et al. [2] highlight that core stabilization is crucial not only for performance but also for the health of the lumbar spine. Similarly, Almeida Alves et al. [3] show that biomechanics helps differentiate between efficient and inefficient movement patterns, supporting therapeutic and preventive interventions.

The incorporation of motion analysis technologies significantly expands the scope of Pilates. Camera systems make it possible to identify small deviations that are not perceptible to the naked eye—such as subtle variations in pelvic tilt, internal rotation of the knees, or scapulohumeral misalignment. Studies such as those by Lee et al. [4] demonstrate that such tools offer promising resources for immediate feedback and evidence-based teaching. In this paper, the developed system intends to recognize joint points and segment angles to monitor: 1. Maximum range of motion achieved in abduction; 2. Symmetry between right and left sides; 3. Trunk and pelvic displacements; 4. Cervical and thoracic stability; 5. Execution time and cadence; 6. Initial and final isometric pauses; 7. Eccentric control in adduction. The system proposed in this study allows for measuring the rhythm of the movements, the execution time of each repetition, and the time spent in

the initial and final positions. These parameters are essential within the philosophy of the Pilates method, which emphasizes precision and control, including the ability to maintain a given position (example: for approximately 2 to 3 seconds), as traditionally guided in pedagogical practice [11], [12]. Thus, in addition to the angular aspects, the temporal component of the execution provides a more complete assessment of stability and fidelity to the proposed movement.

B. Angle Estimation and Validation

The angles between body-segment vectors were computed using the standard angle formula for two gradient vectors in 2D analytic geometry. Each vector was defined by the (x, y) joint coordinates obtained from the MoveNet model. For every pair of segments sharing a common point P_1, the corresponding vectors $\mathbf{v}_1$ and $\mathbf{v}_2$ were defined as in Equations (1) and (2).

$$\mathbf{v}_1 = (x_2 - x_1, y_2 - y_1) \tag{1}$$

$$\mathbf{v}_2 = (x_3 - x_1, y_3 - y_1) \tag{2}$$

The absolute angle of each vector relative to the x-axis was computed using the `arctan2` function from the Python NumPy library, as shown in Equations (3) and (4). This function simultaneously evaluates both the horizontal and vertical components, ensuring correct quadrant identification and producing angles within the appropriate interval $(-\pi, \pi]$.

$$\alpha_1 = \arctan2(y_2 - y_1, x_2 - x_1) \tag{3}$$

$$\alpha_2 = \arctan2(y_3 - y_1, x_3 - x_1) \tag{4}$$

Equation (5), in radians, is used for determining the smallest angular difference θ.

$$\theta = \min(|\alpha_1 - \alpha_2|, 2\pi - |\alpha_1 - \alpha_2|) \tag{5}$$

This angle calculation method was validated using the Kinovea software [13], demonstrating strong agreement, with a mean bias of $-0.036°$, narrow limits of agreement ($-0.408°$ to $0.336°$) by Bland-Altman method [14], and minimal variability, indicating no evidence of systematic error [15]. To transition this framework into a quantitative evaluation tool, absolute angular errors across participants are evaluated relative to instructor-defined clinical targets [32]. For the Lunge on the Reformer, a target internal flexion angle of $90°$ was established for both knees, while for Lateral Abduction and Adduction, a target aperture angle of $75°$ was defined based on functional flexibility thresholds.

C. Biomechanical Report

As joint angles were calculated for each frame analyzed by the model, the results were stored in a `.csv` file containing the frame number, the corresponding video or recording time, and the angle of each joint. These data were later used to generate a biomechanical report summarizing key information for each joint, including range of motion (maximum and minimum values), indicators of movement symmetry when applicable, and graphs showing how joint angles changed over time [15].

D. Pilates Exercises

In the present work, three Pilates exercises were analysed to exemplify the usage of the tool: Lunge, Lateral Abduction/Adduction Movements on the Reformer, and Cat Stretch with Handles as presented in the following sections. All participants provided written informed consent for participation and publication of data.

1) Lunge Movement on the Reformer: The lunge movement on the Reformer is one of the examples in this study and involves placing one foot on the stable platform and the other on the moving carriage. It is generally the case the usage of springs for resistance to move the carriage in and out while maintaining a strong, upright torso and deep core engagement to work legs, gluts, and stability, with variations like low lunges (knee on carriage), reverse lunges, or explosive "flying lunges" for advanced control and strength. Therefore, the exercise begins with the practitioner in an upright position, with one foot on the fixed base and the other on the moving board. The controlled descent involves simultaneous flexion of the knees, aiming to reach approximately $90°$ in both joints.

2) Lateral Abduction and Adduction on the Reformer: Lateral abduction and adduction on the Reformer, performed standing, is an exercise that demands high motor coordination, lumbar pelvic stability, and overall postural control. Unlike other movements with a specific angular target, this exercise aims to achieve the greatest possible functional range of motion, limited by the practitioner's height, the length of the apparatus, and the spring adjustments. Thus, the quality of execution is more relevant than an absolute angular value in a movement. From a biomechanical point of view, the abduction phase requires controlled recruitment of the hip abductor muscles, with special attention to the gluteus medius, an essential muscle for pelvic stabilization and important in avoiding compensatory lateral tilts [16]. The adduction phase, in turn, represents an even greater challenge, as it requires active braking, segmental deceleration, and precise alignment of the lower limbs, preventing the return to the initial position from occurring abruptly. This eccentric control is fundamental for both strength development and joint stabilization [17]. The ability to adjust the spring resistance allows for individualizing the load, adapting the intensity to each student's specific capabilities. Stronger resistances tend to challenge eccentric control during adduction, while lighter resistances may require greater postural control during abduction. This variability is beneficial, but reinforces the importance of monitoring execution through objective parameters such as relative range of motion and trunk stability. In standing lateral abduction and adduction on the Reformer, the primary goal is to maximize functional range of motion while maintaining trunk stability and postural control. Although anthropometric factors and apparatus configuration may influence range, these are secondary to motor control and biomechanical integrity. It is important to emphasize that the proposed framework does not generate autonomous clinical text diagnoses; coordinate trajectories strictly output objective kinematic graphs while clinical interpretation is performed

by evaluators. Regarding model selection, MoveNet balances computational efficiency and joint angle accuracy for clinical biofeedback compared to OpenPose or heavy transformer architectures [7].

3) Stretch with Handles on Cadillac: Hip flexion on the Cadillac requires adequate dissociation between the hip and trunk, efficient activation of the trunk flexors, and maintenance of a neutral pelvis. The goal is to achieve approximately 90° of flexion without pelvic displacement or knee movement.

III. RESULTS AND DISCUSSION

A. Lunge Results and Discussion

Fig. 1(a) and (b) presents the Lunge exercise with the joint's angles measured after the processing by the tool and Fig. 1(c) presents the joint angle results relative the exercise session (b). Kinematic analysis from image capture enabled assessment of joint angles, movement cadence, and neuromuscular control. The mean repetition duration (∼10s), with balanced eccentric and concentric phases, is consistent with protocols targeting motor control, eccentric strength, joint stability, and increased time under tension [18], [19]. Despite appropriate cadence, qualitative deviations were observed, including prolonged end-range holds of 2–3 seconds, particularly in the posterior limb. This pattern suggests difficulty coordinating concurrent task demands and may represent a compensatory response to instability or insufficient force production, indicating deficits in intermuscular coordination, neuromuscular control, and proximal stability [20]. The quantitative analysis across participants demonstrated that the system effectively tracks multi-subject deviations from predefined instructor targets, verifying automated thresholding feasibility as supported by digital health literature [33].

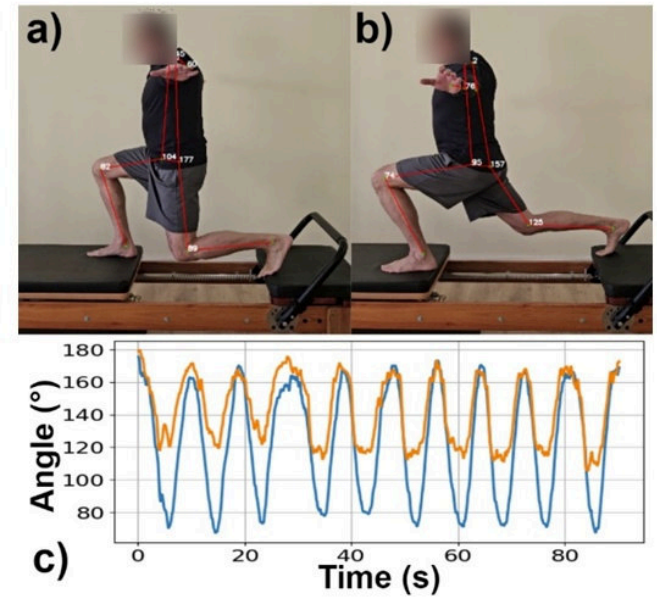

Fig. 1. (a) Lunge with the right leg at the front, (b) Lunge with the left leg at the front, (c) Knee internal angles for left (blue line) and right (orange line) legs relative the movement session (b). All images on the Reformer machine.

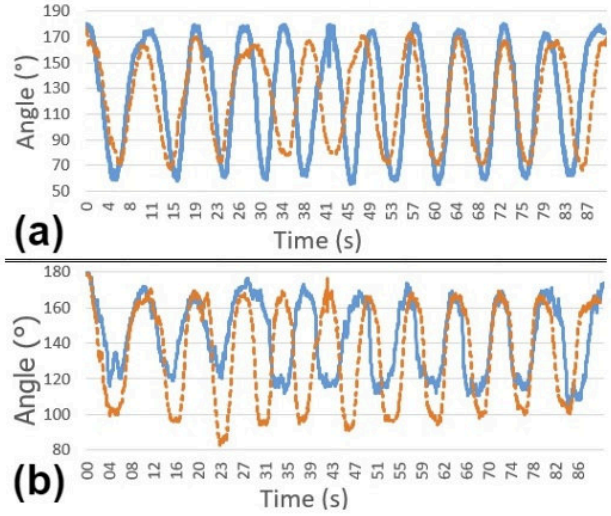

Fig. 2. (a) Right (blue line) and left (orange line) knees internal angles considering only the legs when they are in the frontal position, (b) Right (blue line) and left (orange line) knees internal angles considering only the legs when they are in the posterior position.

Additionally, the participant did not achieve and maintain the optimal knee flexion angle (∼90°) in both limbs during any repetition as shown in Fig. 1(c). This deviation suggests limitations in joint range of motion, strength, and/or neuromuscular control, potentially compromising load distribution, exercise effectiveness, and safety [21]. Stability analysis revealed increased signal oscillations, particularly in the limb on the fixed base, indicating difficulty in postural control and carriage displacement. These oscillations were most pronounced during movement initiation, suggesting impaired stabilization under unstable conditions, likely related to insufficient activation of core and hip stabilizing musculature [22], [23].

These findings indicate that, despite an appropriate cadence for motor control training, limitations persist in coordination, joint control, and postural stability. Accordingly, targeted training focusing on hip extensor and stabilizer strength and enhanced core activation and endurance is warranted to improve neuromuscular coordination, stability, and movement quality during Reformer-based exercises. Fig. 2(a) shows the left and right legs in front, there is a clear reduction in range of motion for the left foot in front compared to the right, as well as instabilities in maintaining the movement (at 28 s). Fig. 2(b) shows that for the knee angles, considering now the leg positioned behind, the left leg shows better results, possibly because with the right leg in front, the movement is more stable.

In general, the video analysis of the Reformer lunge shows transient increases in posterior-leg flexion during board displacement, likely reflecting compensatory stabilization demands. Across repetitions, reduced angular variability suggests improvements in motor control, neuromuscular balance, and movement precision, consistent with adaptive responses to functional exercise [24]. The lunge requires coordinated knee

flexion with trunk stabilization. Initial posterior-leg flexion exceeding 90° suggests compensatory frontal-plane stabilization, which decreases with repetition, indicating neuromuscular adaptation typical of closed kinetic chain tasks [17]. Trunk and pelvic oscillations and the absence of end-range isometric holds further suggest limited deep stabilizer activation and reduced integration of stability and proprioceptive control [11].

B. Lateral Abduction and Adduction Results and Discussion

Fig. 3 presents an example of lateral abduction and adduction performed with the left leg on the moving platform of the Reformer machine: (a) the initial position and (b) the final position of the leg-opening exercise. The (c) plot shows the hip angle trajectories for the left (blue) and right (orange) legs during the movement on the Reformer machine. Integrated analysis of image data and angular comparisons of the shoulders and hips enables assessment of postural control, movement symmetry, and biomechanical efficiency during lower-limb abduction and adduction on the Reformer. This exercise places high demands on dynamic stability, intermuscular coordination, and trunk control due to the mobile carriage and the need to maintain an upright posture throughout the movement.

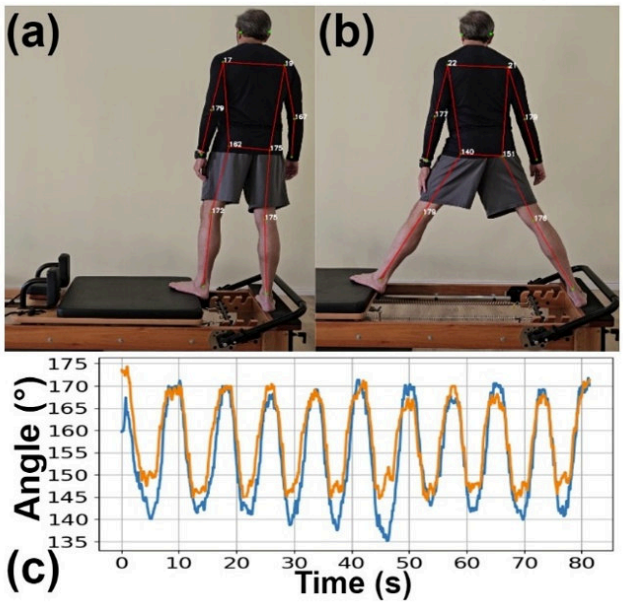

Fig. 3. Lateral Abduction and Adduction with left leg at the moving part of the Reformer showing the (a) initial and (b) final leg opening exercises. (c) Hip angles considering the left (blue) and right (orange) legs at the moving part of the Reformer Machine.

Hip angular analysis shows in Fig. 3(c) a cyclical pattern consistent with abduction and adduction phases, with a systematic side-to-side difference. The right hip exhibits higher angular values at specific time points, suggesting anterior projection and postural compensation that reduce movement symmetry. This asymmetry may reflect lateral dominance or deficits in hip mobility, strength, or motor control, particularly of the hip abductors and stabilizers, and has been associated with reduced mechanical efficiency and increased joint loading [25], [26]. Analysis of range of motion reveals variability in angular peak magnitude, indicating inconsistent movement across repetitions. The prescribed isometric hold at end-range abduction is not consistently maintained, suggesting limited capacity to sustain muscular activation under eccentric load. Irregular shoulder and hip angular patterns further indicate continuous postural adjustments in response to Reformer instability, reflecting compensatory balance strategies and highlighting the need for improved neuromuscular control and endurance of trunk and hip stabilizers [20], [27], [28]. In summary, integrated graph and image analysis indicates that, despite correct execution of the abduction-adduction pattern on the Reformer, deficits persist in movement symmetry, trunk stability, and hip position control. These findings support the need for targeted interventions to improve hip abductor strength, lumbopelvic and core stabilization, and movement consistency, with emphasis on upright posture and end-range isometric control.

C. Stretch with Handles Results and Discussion

Fig. 4 presents the (a) initial and (b) stretched positions, (c) hip angle and (d) shoulder angle for the Stretch with Handles exercises, respectively. Integrated analysis of image and angular data revealed biomechanical alterations during the Stretch with Handles exercise on the Cadillac, with failure to maintain optimal alignment of the pelvis, trunk, shoulders, and upper limbs, particularly under increased mechanical demand. This pattern reflects disruption of global kinetic chain integration, consistent with postural control principles of the Pilates method [11], [29]. Hip kinematic data show failure to maintain the reference 90° hip angle as shown in Fig. 4(c), associated with pelvic stabilization in quadruped. Continuous oscillations in left hip angulation, reflecting repeated anterior-posterior pelvic displacement, indicate deficits in lumbopelvic control, likely related to insufficient activation of deep stabilizing musculature, particularly the transversus abdominis and multifidus [31]. Pelvic oscillations impair spinal organization and postural stability, as inadequate pelvic control disrupts lumbar alignment and increases mechanical load on passive structures [16].

Shoulder angular data flexion peaks near 170–180° as shown in Fig. 4(d). The absence of stable plateaus and side-to-side differences could indicate scapular instability and asymmetric motor control, which might compromise efficient shoulder function during closed kinetic chain tasks. Angular variabilities would indicate difficulty sustaining shoulder flexion, likely due to insufficient scapular stabilizer activation and compensatory upper trapezius dominance [16]. Such instability might disrupt force transmission and global alignment, that would indicate reliance on compensatory pelvic and shoulder strategies and reflect into inadequate application of core Pilates principles, suggesting that task demands exceed the participant's neuromuscular control capacity [11], [29]. This analysis highlights the value of integrating biomechanical data with clinical observation to identify technical deficits and guide

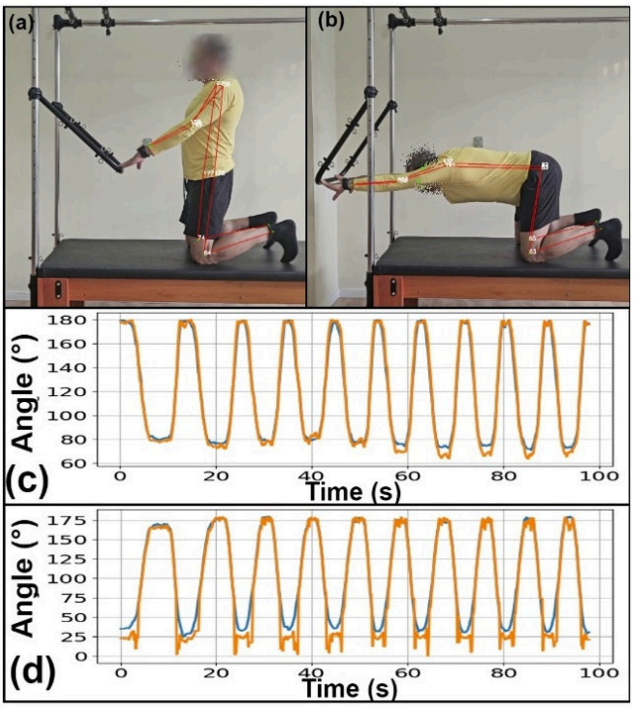

Fig. 4. (a) initial and (b) final stretched positions, (c) Hip left (blue) and right (orange) angle and (d) Shoulder left (blue) and right (orange) angle for the Stretch with Handles exercises.

safer, more effective interventions. Priority should be given to improving lumbopelvic and scapular stability before exercise progression. In general, the absence of sustained holds may reduce execution precision and reflect insufficient activation of deep stabilizers. Observed trunk compensations, including slight rightward cervical deviation, suggest asymmetries or deficits in core and shoulder-pelvic stabilizer balance, which are commonly reported during unilateral or lateral balance tasks [30].

IV. CONCLUSIONS

In general, low-cost computer vision tools can provide quantitative kinematic indicators that help monitor performance in Pilates equipment exercises, making movement analysis more accessible and objective. The proposed method allows the extracted joint angles and coordinate trajectories to be converted into clear visual reporting metrics, providing useful biofeedback to assist instructors in identifying execution patterns and guiding movement alignment.

Although this study provides a conceptual framework for motion-analysis systems and demonstrates how variations in motor control, lumbopelvic stability, and movement amplitude directly affect execution quality, subsequent investigations are planned to expand its translational value. Future works will focus on evaluating larger and more diverse clinical cohorts, specifically comparing performance variations between experienced practitioners, novices, and patient populations. Additionally, integrating multiple camera viewpoints to mitigate joint occlusion and validating these high-level indicators against optical 3D motion capture systems remain crucial steps to further consolidate the clinical utility of this reporting pipeline in real-world rehabilitation settings.

ACKNOWLEDGMENT

The authors express their gratitude for making the infrastructure of the sports practice facilities of the Paraná Military Police (PMPR) available for this research.

***Abstract*—This study investigates the influence of body mass index (BMI) and other physiological variables on skin electrical impedance at the wrist joint in the context of iontophoresis, a promising technique for transdermal drug delivery in the treatment of chronic pain. For this purpose, data were collected from 30 volunteers (15 men and 15 women), classified into four BMI categories, who underwent impedance measurements by electrical impedance sprectrosocpy at 41 frequencies between 10 Hz em 500 kHz, using three distinct electrode positioning protocols. The data were modeled using a modified Cole equivalent circuit, incorporating a Constant Phase Element. Statistical analysis, performed using Linear Mixed Models, aimed to identify the influencing factors on impedance changes. The results reveal that the impact of BMI on skin impedance is not direct, but rather conditional, being distributed across multiple parameters of the bioimpedance model and modulated by factors such as volunteers' sex and electrode placement.**

***Index Terms*—Iontophoresis; Electrical bioimpedance; Skin impedance; Body mass index; Transdermal drug delivery; Alternating current.**

I. Introdução

O aprimoramento de técnicas terapêuticas seguras tem sido intensificado nos últimos anos, visando reduzir seus impactos físicos, mentais e funcionais [1], especialmente considerando que a prevalência dessa condição pós-pandemia nos Estados Unidos atingiu 24,3%, com destaque para dores articulares [2]. Nesse contexto, embora os anti-inflamatórios não esteroides (AINEs) sejam amplamente utilizados e eficazes no manejo dessas dores [3], seu uso prolongado está associado a graves efeitos adversos gástricos, renais e cardiovasculares [4]. Diante disso, torna-se urgente o desenvolvimento e o controle rigoroso de estratégias terapêuticas mais seguras para o tratamento.

Os autores agradecem à FAPEMIG pelo suporte financeiro.

Entre as alternativas terapêuticas em análise, a entrega transdérmica de fármacos tem se destacado devido ao seu elevado potencial terapêutico, que alia conforto, não invasividade, ação local e controle preciso da liberação do medicamento, reduzindo, assim, a exposição sistêmica e os efeitos adversos típicos das administrações orais [5]. Contudo, a principal limitação dessa via de administração é a resistência significativa oferecida pela camada mais externa da pele, o estrato córneo, que age como uma barreira seletiva à penetração de substâncias exógenas [6].

Nesse contexto, a iontoforese destaca-se como uma estratégia promissora para aumentar a permeação transdérmica por meio da aplicação de correntes elétricas com densidade de até 0,5 $\mathrm{mA/cm^2}$, favorecendo o transporte de fármacos por eletromigração e eletrosmose sem comprometer a integridade da pele e dos tecidos subjacentes [7]. Essa técnica pode ampliar a eficácia terapêutica e reduzir efeitos adversos sistêmicos no tratamento de condições dolorosas crônicas [8].

As propriedades elétricas da pele, especialmente sua impedância, influenciam diretamente a eficiência da iontoforese, pois determinam a potência necessária e a corrente efetivamente entregue ao tecido. Essa impedância varia em função de fatores como hidratação, temperatura, sexo, região anatômica e frequência da corrente aplicada [9; 10]. A bioimpedância elétrica permite caracterizar esse comportamento por meio da aplicação de correntes de baixa amplitude e da medição da oposição dos tecidos, enquanto modelos de circuitos equivalentes possibilitam estimar resistências intra e extracelulares e capacitâncias de membrana em diferentes frequências [11]. Na iontoforese, essa abordagem contribui para compreender a distribuição da corrente nas camadas cutâneas e dimensionar adequada-

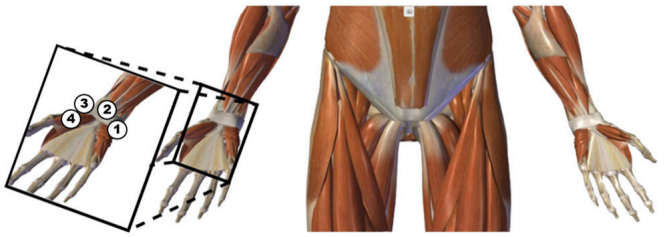
mente os parâmetros do sistema de entrega transdérmica.

Diante desse contexto, este trabalho tem como objetivo investigar a influência do índice de massa corporal (IMC) e de variáveis fisiológicas sobre a impedância elétrica da pele em condições associadas à aplicação da iontoforese. Foram avaliados os efeitos da posição dos eletrodos (protocolos de coleta), da frequência de excitação utilizada na medição da bioimpedância e do sexo dos voluntários, bem como suas interações com o IMC, sobre os valores de impedância da articulação do punho. A partir da varredura de frequências, foram ajustados modelos de circuito equivalente para estimar e comparar os parâmetros elétricos da pele, contribuindo para a compreensão da distribuição da corrente e para o dimensionamento mais adequado de sistemas de entrega transdérmica.

II. Materiais e Métodos

A. Coleta do banco de dados

Os procedimentos de coleta da impedância elétrica foram realizados utilizando um sistema bipolar de dois eletrodos, constituído por um eletrodo positivo e um negativo. Para avaliar a influência do posicionamento dos eletrodos sobre os valores medidos, foram definidos três protocolos para as articulação do punho, conforme exibido na Figura 1. O eletrodo negativo foi mantido sobre o processo estiloide da ulna (marcador 1), enquanto o eletrodo positivo foi posicionado sobre o pronador quadrado proximal (marcador 2), o adutor do polegar distal (marcador 3) e o processo estiloide do rádio (marcador 4), constituindo assim, respectivamente, os Protocolos 1, 2 e 3. A coleta de dados foi aprovada pelo Comitê de Ética em Pesquisa da Universidade Federal de Viçosa, sob o CAAE 78939024.5.0000.5153.



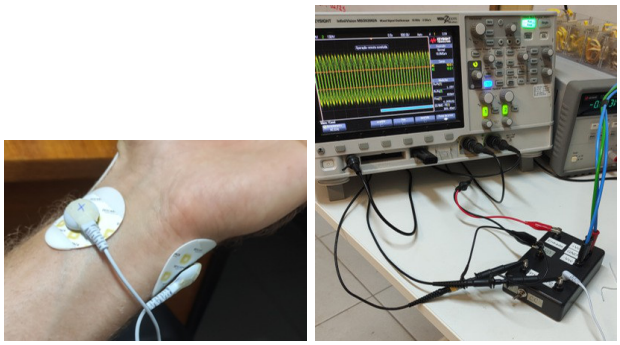


Fig. 1: Posicionamento dos eletrodos na articulação do punho: 1 - Processo estiloide da ulna; 2 - Pronador quadrado proximal; 3 - Processo estiloide do rádio e 4 - Adutor do polegar distal.

Os participantes foram recebidos na sala de coleta e, inicialmente, permaneceram em repouso por 10 minutos em ambiente climatizado (24°C), recebendo uma limpeza da articulação com álcool iodado.

Foram coletados dados de 30 voluntários, sendo 15 do sexo masculino e 15 do sexo feminino, com idade entre 19 e 40 anos e peso entre 42,7 e 94 kg. Para cada participante, cada coleta durou cerca de 340 segundos, sendo obtidos valores de impedância em 41 frequências diferentes para o punho por meio de espectroscopia de impedância elétrica (EIS), utilizando o osciloscópio MSOX2002A de 70 MHz.

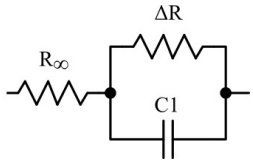
A EIS foi realizada com eletrodos descartáveis de eletrocardiograma de Ag/AgCl, escolhidos por sua compatibilidade com a iontoforese e pela redução da impedância de contato com a pele. O sistema de aquisição, automatizado em *MATLAB*®, comunica-se via USB e protocolo VISA com o osciloscópio, cujo gerador de sinais excitava uma fonte de corrente de Howland melhorada. Uma foto do aparato e do posicionamento dos eletrodos do Protocolo 3 é apresentada na Figura 2. A fonte injetava corrente alternada de até $0,1\ mA_{RMS}$, enquanto o osciloscópio monitorava simultaneamente a tensão sobre a articulação e a queda de tensão em um resistor de $3,3\ k\Omega$, utilizada para estimar a corrente. A impedância foi calculada no

(a) (b)

Fig. 2: Coleta de dados nos voluntários: (a) Posicionamento dos eletrodos no Protocolo 3 e (b) equipamentos utilizados para estimulação de correntes em diferentes frequências.

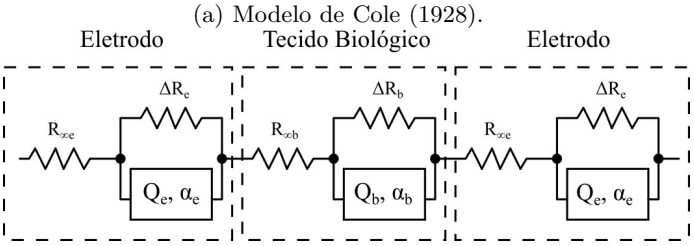
domínio da frequência por meio da Transformada Rápida de Fourier, durante a varredura das 41 frequências distribuídas logaritmicamente entre 10 Hz e 500 kHz.

B. Cálculo de IMC



Para cada voluntário, foram registrados a altura e o peso, a partir dos quais foi calculado o IMC, definido como o peso dividido pelo quadrado da altura (kg/m^2). O cálculo do IMC e a classificação nutricional foram conferidos por meio da calculadora *on-line* disponibilizada pela Associação Brasileira para o Estudo da Obesidade e Síndrome Metabólica (ABESO).

Os participantes foram classificados em quatro categorias de acordo com o IMC: abaixo do peso (IMC $<$ $18,5\ kg/m^2$), peso normal ($18{,}5 - 24{,}9\ kg/m^2$), sobrepeso ($25{,}0 - 29{,}9\ kg/m^2$) e obesidade grau I (IMC $\geq$ $30{,}0\ kg/m^2$). Dois voluntários apresentaram baixo peso (1 do sexo masculino e 1 do sexo feminino); cinco apresentaram sobrepeso (3 do sexo feminino e 2 do sexo masculino), quatro foram classificados com obesidade grau I (3 do sexo feminino e 1 do sexo masculino) e os demais



voluntários foram classificados como peso normal (8 do sexo feminino e 11 do sexo masculino).

C. Modelagem de Bioimpedância

Os modelos matemáticos de bioimpedância desempenham um papel essencial na compreensão do comportamento elétrico dos tecidos biológicos, ao modelar os parâmetros elétricos do comportamento tecidual. Entre as abordagens disponíveis na literatura, um dos primeiros foi o modelo proposto por [12], apresentado na Figura 3a, denominado de Modelo B, em que R_∞ representa a resistência dos meios intra e extracelular, ΔR denota a resistência das membranas celulares e do estrato córneo e C_1 corresponde à capacitância da membrana.

(a) Modelo de Cole (1928).

(b) Associação de modelos para representação do tecido de articulação.

Fig. 3: Circuitos equivalentes para a modelagem de impedâncias da pele: (a) Modelo de Cole (1928) e (b) representação do circuito elétrico equivalente completo, composto pela associação em série de dois modelos de eletrodo e o modelo tecidual. Adaptado de [13].

Para melhor representar a modelagem dos tecidos, foi utilizado um modelo de Cole que substitui o capacitor $C1$ por um componente denominado Elemento de Constante de Fase (Constant Phase Element – CPE) com impedância Z_{CPE} de acordo com (1), na qual Q é um coeficiente proporcional, j é a unidade imaginária, ω representa a frequência angular e α é um expoente que varia entre 0 e 1 determinando o grau de dispersão do sistema. O uso do CPE como substituto do capacitor ideal foi introduzido posteriormente ao modelo original de Cole e consolidou-se na literatura de impedância eletroquímica e bioimpedância, não sendo atribuído a um único autor [14].

$$Z_{\mathrm{CPE}}(\omega) = \frac{1}{Q(j\omega)^{\alpha}} \tag{1}$$

Os eletrodos também foram modelados e tratados em série com o tecido biológico. A Figura 3b mostra o circuito equivalente completo da associação. Os subscritos e e b foram utilizados para representar os parâmetros referentes aos eletrodos e tecido biológico (articulações), respectivamente. O comportamento dos tecidos biológicos frente à corrente elétrica varia de acordo com a frequência aplicada. Essa característica possibilita separar a impedância total medida em parâmetros específicos, que refletem os fluidos fisiológicos presentes, a capacidade dielétrica e a organização estrutural das membranas celulares.

1) Impedância em Alta Frequência (Z_{∞_b}): Corresponde à impedância quando a frequência tende ao infinito ($\omega \to \infty$).

$$Z_{\infty_b} \approx R_{\infty_b} \tag{2}$$

Fisiologicamente, em altas frequências, a reatância capacitiva das membranas celulares torna-se desprezível, permitindo que a corrente flua através dos meios intra e extracelulares. Portanto, R_{∞_b} é um indicador do volume condutivo total e da hidratação global.

2) Largura de Dispersão (ΔR_b): Representa a resistência na malha paralela ao CPE, quantificando a variação da impedância devido ao relaxamento dielétrico. Em frequências muito baixas ($\omega \to 0$), as membranas bloqueiam a corrente, fazendo com que a impedância total (Z_{0_b}) seja a soma dos componentes resistivos:

$$Z_{0_b} \approx R_{0_b} = R_{\infty_b} + \Delta R_b \tag{3}$$

3) Coeficiente de Dispersão (α_b): Este parâmetro adimensional ($0 \leq \alpha_b \leq 1$) modela o desvio do tecido em relação a um sistema homogêneo ideal ($\alpha_b = 1$). Fisiologicamente, reflete a heterogeneidade da arquitetura tecidual: como as células reais variam em tamanho, formato e orientação, elas geram uma distribuição estatística de tempos de relaxamento, em vez de uma constante única.

4) Pseudocapacitância (Q_b): Devido à rugosidade e à arquitetura fractal das membranas biológicas, o armazenamento de carga não é uniforme como num capacitor ideal. Assim, Q_b mede essa capacidade de armazenamento modulada pelo fator α_b. Sua unidade é $\mathrm{S} \cdot \mathrm{s}^{\alpha_b}$, tornando-a dimensionalmente dependente da heterogeneidade do tecido.

Para a obtenção dos parâmetros elétricos do modelo, adotou-se uma estratégia de otimização em duas etapas. Inicialmente, aplicou-se o Algoritmo Genético (GA), um método estocástico baseado em seleção natural, para realizar uma busca global ampla na superfície de erro. Através de operadores de seleção (roleta), cruzamento (*crossover*) e mutação, o GA avaliou a aptidão (*fitness*) de uma população de soluções candidatas.

Em seguida, a estimativa resultante do GA foi utilizada como ponto de partida para a Programação Quadrática Sequencial (SQP). Sendo um método iterativo local que utiliza informações de gradiente e aproximações da matriz Hessiana, a SQP refinou a solução, garantindo uma rápida taxa de convergência e alta precisão. Esta etapa final determinou os valores ótimos dos parâmetros elétricos.

D. Teste estatístico

A análise estatística foi conduzida por meio de Modelos Lineares Mistos (LMM), utilizando o *software* Jamovi (v. 2.7.11). Essa abordagem foi selecionada para acomodar a estrutura hierárquica e a dependência intrassujeito dos dados, em que as frequências das medidas estão aninhadas aos protocolos de posicionamento dos eletrodos e estes à articulação do punho. O modelo permitiu a inclusão simultânea de preditores categóricos e contínuos como efeitos fixos, controlando adequadamente as correlações residuais provenientes das medidas repetidas.

Devido à natureza não linear e à heterocedasticidade inerente aos dados de bioimpedância, os valores de impedância foram transformados em base logarítmica (log_{10}) antes da análise, assegurando a normalidade dos resíduos e a homogeneidade das variâncias, atendendo aos pressupostos dos Modelos Lineares Mistos [15]. Adicionalmente, a frequência foi submetida à transformação logarítmica, permitindo uma representação linear das variações de impedância ao longo do espectro de frequências [15].

A Figura 4 ilustra os valores de impedância obtidos para a coleta do punho utilizando o Protocolo 1 em todos os IMCs. Os valores representam a média dos valores de impedância de cada grupo de IMC juntamente ao seu respectivo desvio padrão. É possível observar que a impedância logarítmica apresenta valores de variância mais próximos do que teriam em escala linear, exemplificando a heterocedasticidade necessária para o LMM.

Na configuração final do modelo, o logaritmo da impedância foi definido como a variável dependente, enquanto o logaritmo da frequência foi inserido como covariável. Os parâmetros sexo, articulação, protocolo de coleta e IMC foram tratados como fatores de efeito fixo.

O teste LMM analisou os efeitos dos fatores sobre a impedância de forma isolada e em conjuntos, verificando a interdependência entre as variáveis. Para cada análise, reportam-se a estatística F, os graus de liberdade do efeito (df) e dos resíduos (df (res)), além do valor-p (p), adotando-se o nível de significância de 5%.

III. Resultados e discussões

A. Testes globais

Os resultados dos testes globais (*omnibus*) dos efeitos fixos e de suas interações encontram-se na Tabela I. Uma vez que a frequência de excitação foi incorporada ao modelo como preditor contínuo no eixo logarítmico (log_frequência) quando há interações envolvendo log_frequência, não são cabíveis comparações *post hoc* entre níveis (apropriadas a fatores categóricos).

1) Efeitos principais: Os testes globais indicaram efeitos principais significativos de Protocolo e Log_frequência ($p < 0{,}001$). Como esperado, mantidos os demais fatores constantes, a variação isolada de qualquer um desses preditores altera o módulo de impedância. Em contraste, IMC ($p = 0{,}997$) e Sexo ($p = 0{,}384$) não apresentaram efeito principal significativo.

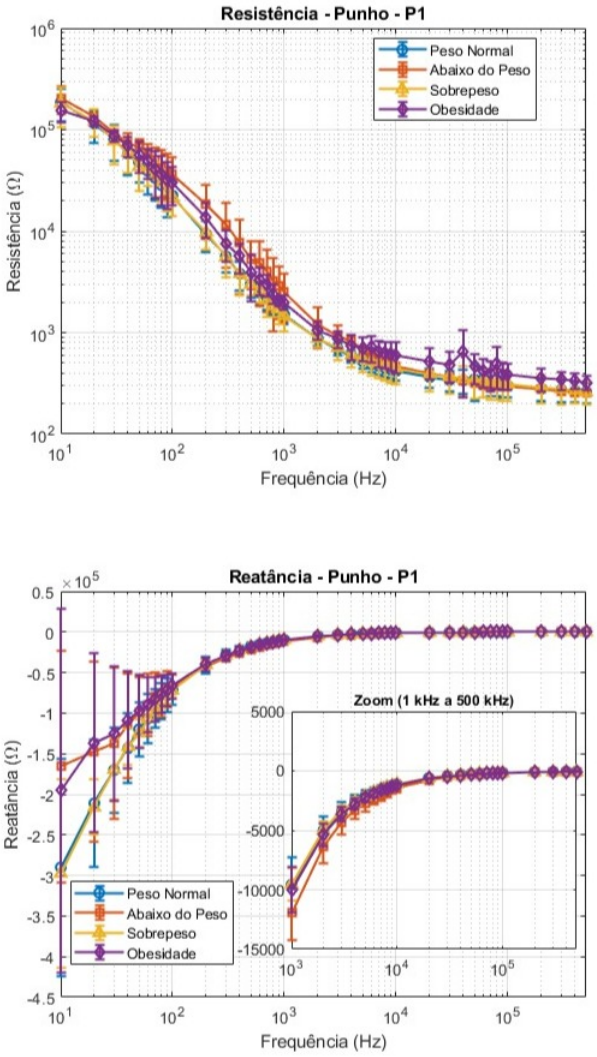


Fig. 4: Média e desvio padrão de impedância do punho (Protocolo 1) no domínio da frequência para todos os IMCs.

2) Teste 2 vias: Nos testes de duas vias que envolveram o IMC, apenas a interação com a Protocolo foi significativa ($p < 0{,}001$), indicando que a associação do IMC com a impedância varia conforme o protocolo de coleta utilizado. As interações com Sexo ($p = 0{,}417$) e Log_frequência ($p = 0{,}45$) não alcançaram significância, sugerindo que, isoladamente, o efeito do IMC não depende do sexo ou da frequência de excitação.

3) Teste 3 vias: Nos testes de três vias, observaram-se interações significativas do IMC com Sexo × Protocolo e Protocolo × Log_frequência (todas $p < 0.001$), indicando que a associação do IMC com a impedância depende simultaneamente desses fatores.

4) Teste 4 vias: No teste de quatro vias, o IMC revelou interagir com Sexo × Protocolo × Log_Frequência ($p = 0.004$), indicando que a associação entre IMC e a impedância é simultaneamente modulada pelo sexo,

pela posição do eletrodo e pela frequência da corrente de excitação.

TABLE I: Testes globais dos efeitos fixos

Efeito	F	df	df (res)	p
IMC	0,831	3	22	0,491
Sexo	0,113	1	22	0,740
Protocolo	23,635	2	3598	<0,001
Log_Frequência	7865,648	1	22	<0,001
Sexo × Protocolo	3,169	2	3598	0,042
IMC × Sexo	0,988	3	22	0,417
IMC × Protocolo	4,856	6	3598	<0,001
Sexo × Log_Frequência	0,771	1	22	0,389
Protocolo × Log_Frequência	6,558	2	3598	0,001
IMC × Log_Frequência	0,915	3	22	0,450
IMC × Protocolo × Sexo	5,956	6	3598	<0,001
Sexo × Protocolo × Log_Frequência	2,176	2	3598	0,114
IMC × Sexo × Log_Frequência	1,039	3	22	0,395
IMC × Protocolo × Log_Frequência	4,342	6	3598	<0,001
IMC × Protocolo × Sexo × Log_Frequência	3,223	6	3598	0,004

B. Análise Post Hoc

1) IMC × Protocolo: O IMC "Abaixo do peso" apresentou influenciar as impedâncias entre o protocolo 1 e 2, e entre 1 e 3. No IMC "Peso normal", a influência para o Protocolo 3 em relação aos demais.

2) IMC × Sexo × Protocolo: Para o sexo masculino, o IMC "Abaixo do peso" revelou uma influência na impedância para o Protocolo 1 em relação ao 2 e 3. Além disso, para esse mesmo sexo, o IMC "Peso normal" apresenta influência na comparação do Protocolo 3 em relação ao 1 e 2. O IMC "Peso normal" também demonstrou influenciar a comparação entre o Protocolo 1 e 3 no sexo feminino.

Esses resultados corroboram com os obtidos na interação de duas vias entre IMC × Protocolo. A adição do sexo como preditor agregou em uma análise mais precisa da influência dos fatores IMC e Protocolo.

Apesar de não apresentar efeito principal isolado, o IMC aparece em interações de ordem superior, como IMC × Protocolo × Sexo. Isso pode ser explicado pela quantidade de tecido adiposo presente na região analisada, variando entre os sexos, ou até mesmo o nível de hidratação entre eles. Embora este estudo traga contribuições consistentes, sua limitação está na baixa representatividade de voluntários em determinadas categorias de IMC compromete a precisão das médias obtidas individualmente.

C. Parâmetros de Bioimpedância

Para uma análise quantitativa, os parâmetros de bioimpedância do punho foram calculados para todos os 30 voluntários, independente de sexo ou IMC correspondentes, para os 3 protocolos de posicionamento do eletrodo. A Tabela II permite analisar os parâmetros de bioimpedância sob múltiplas perspectivas. É importante ressaltar que alguns agrupamentos possuem apenas 1 voluntário, o que influencia cálculos de média.

Dentre as alternativas possíveis, se o sexo feminino for selecionado como foco de análise no Protocolo 1, percebe-se que os valores de R_∞ apresentam médias próximas independente do IMC – média máxima de $263,68\ \Omega$ e mínima de $201,01\ \Omega$ – mas com grandes desvios ao redor desses valores – valor mínimo de $132,11\ \Omega$ e máximo de $349,58\ \Omega$.

Ainda nessa linha de análise, os valores médios de α_b do punho para o sexo feminino em Protocolo 1 de coleta apresentam valores mais próximos da homogeneidade ($\alpha_b = 1$), sendo o IMC de sobrepeso o que mais se distanciou do ideal, com uma diferença de $0,1047$. Essa observação pode ser explicada pela quantidade de voluntários que compõem esse grupo.

IV. Conclusão

A relevância do IMC em interações de ordem superior demonstra que parâmetros morfofisiológicos podem afetar os valores de impedância independente da frequência de excitação utilizada. As análises *post hoc* confirmaram a influência do IMC mesmo entre grupos com perfis de bioimpedância heterogêneos. Esse achado reforça que as variações de impedância decorrentes do IMC tendem a se distribuir por múltiplos parâmetros estimados, o que impossibilita isolar um único fator como o responsável exclusivo por essas alterações.

Entretanto, devido a limitação do estudo, para investigações futuras, sugere-se a adoção de uma amostra mais robusta e homogênea em cada faixa de IMC, fortalecendo a confiabilidade estatística e o poder de comparação dos resultados. A utilização de pelo menos 3 voluntários de cada sexo para cada IMC pode trazer valores mais confiáveis de média e desvio padrão.

Os resultados deste estudo podem nortear o dimensionamento de dispositivos direcionados a perfis específicos de IMC ou a protocolos particulares de coleta. Além disso, representam um avanço para o desenvolvimento de sistemas inteligentes de iontoforese, capazes de ajustar autonomamente a impedância de entrada em resposta às características anatômicas e fisiológicas do paciente.

***Abstract*—This study investigated the neuromechanical characteristics of two functional upper-limb tasks—the Box and Block Test (BBT) and the Southampton Hand Assessment Procedure (SHAP)—using kinematic and surface electromyographic (sEMG) analyses. Eight healthy participants performed both tasks with their dominant and non-dominant limbs. The kinematic analysis included marker traveled distance, average speed, and range of motion, whereas the sEMG analysis assessed mean absolute value (MAV), sample entropy (SampEn), the coefficient of variation of root-mean-square (RMS) values ($\mathrm{CoV_{RMS}}$), and Willison amplitude (WAMP). In both tasks, the wrist marker exhibited greater traveled distance and average speed than the shoulder and elbow markers ($p < 0.001$, $\eta_p^2 = 0.89$–0.996). The sEMG analysis revealed significant main effects of muscle during the BBT for all metrics ($p < 0.001$, $\eta_p^2 = 0.64$–0.94) and during the SHAP for MAV, SampEn, and $\mathrm{CoV_{RMS}}$ ($p < 0.001$, $\eta_p^2 = 0.72$–0.79). Furthermore, the SHAP revealed significant muscle-by-side interactions for SampEn, $\mathrm{CoV_{RMS}}$, and WAMP ($p = 0.004$–0.034). The trapezius muscle exhibited the most distinctive sEMG profile, characterized by greater temporal complexity and lower amplitude variability. These results show that the combined analysis of kinematic and sEMG variables enables the characterization of complementary aspects of neuromuscular coordination during functional upper-limb tasks. Given the small sample size (n = 8), these findings should be considered exploratory.**

***Index Terms*—Electromyography, functional assessment, kinematics, motor control, neuromechanics, upper limb.**

I. Introduction

The human upper limb is a versatile biomechanical system capable of performing a wide range of motor tasks, from gross movements to fine object manipulation [1]. Understanding the neuromechanical principles underlying object manipulation and goal-directed upper-limb movements is important not only for motor control research but also for clinical applications, including the assessment of neuromuscular disorders, the development of rehabilitation strategies, and the design of prostheses [2], [3].

This work was supported in part by CAPES through process nos. 88887.977117/2024-00 and 88887.145539/2025-00 (PROEX – Academic Excellence Program), granted to Laura Valentina Montealegre. Ricardo G. Molinari was supported by the Brazilian Public Ministry of Labor under Contract No. 002118.2019. Leonardo A. Elias is a CNPq Research Productivity Fellow, process no. 316320/2023-4. The kinematic data were collected using the Vicon Motion Capture system, a multi-user facility funded by FAPESP, process no. 2020/13293-0.

The Box and Block Test (BBT) and the Southampton Hand Assessment Procedure (SHAP) are widely used functional tests for assessing manual dexterity and motor performance [2], [4]. However, these tests rely primarily on global performance scores, such as the number of blocks transferred or the time required to complete the tasks. Although these scores quantify functional performance, they do not reveal the joint coordination and muscle activation strategies underlying movement execution [3], [5], [6].

Previous studies have shown that kinematic analyses of modified or instrumented versions of the BBT provide additional information on movement quality and compensatory mechanisms involving the trunk and upper limbs [5], [6]. Similarly, combining motion analysis with the SHAP has enabled the characterization of functional aspects that are not always reflected in the overall score [3]. Nevertheless, conventional functional assessments provide limited insight into the neuromechanical mechanisms underlying task performance. Similar global scores may result from different patterns of joint coordination or muscle activation. Integrating joint kinematics and muscle activity may therefore help characterize how movement is organized beyond the final task outcome.

Evidence combining kinematic analysis of the shoulder, elbow, and wrist with characterization of muscle activity using surface electromyography (sEMG) during the same functional tasks remains limited. Kinematic measurements describe the displacement and coordination of body segments, whereas sEMG provides noninvasive information on muscle activation. In addition to measures of overall amplitude, temporal features of the sEMG signal can provide complementary information on the variability and complexity of muscle activity [7]. Together, these measurements may help identify how specific functional demands are associated with different joint and muscle activation patterns.

A key question is whether the functional differentiation between proximal and distal segments, previously described in reaching and grasping, is also observed in more complex and functionally diverse tasks such as the BBT and SHAP. Proximal segments may contribute primarily to transporting and positioning the limb, whereas distal segments are more directly involved in object grasping and manipulation. This distinction is relevant because upper-limb control depends not

only on the final position of the hand but also on interjoint coordination [8], [9]. Moreover, temporal properties of muscle activation beyond average signal amplitude may provide additional information for differentiating muscle involvement across tasks with different motor demands [7].

Therefore, this study presents a neuromechanical characterization of the BBT and SHAP by combining kinematic analysis of the shoulder, elbow, and wrist with complementary sEMG features related to activation amplitude, variability, complexity, and transient changes: mean absolute value (MAV), sample entropy (SampEn), coefficient of variation of root-mean-square (RMS) values (CoV_{RMS}), and Willison amplitude (WAMP). By integrating these measurements within the same functional tasks, this study aimed to characterize the movement of proximal and distal upper-limb segments and identify differences in muscle activation patterns across muscles and limb sides. This approach may provide a basis for understanding the neuromechanical strategies underlying functional upper-limb performance. We hypothesized that these measurements would provide complementary information beyond the global performance indices of the BBT and SHAP.

II. Methods

A. Study Participants

Eight healthy volunteers participated in this study (7 males and 1 female; mean age ± standard deviation: 27 ± 7.8 years; body weight: 72.1 ± 15.1 kg; height: 1.73 ± 0.10 m). All participants provided written informed consent before the experimental procedures. The experimental protocol was conducted in accordance with the principles of the Declaration of Helsinki and was approved by the Research Ethics Committee of the State University of Campinas (UNICAMP), under CAAE 90477225.9.0000.5404, on August 10, 2025. Data collection took place after ethical approval, during the year 2025.

B. Experimental Protocol

Participants performed two standardized hand function tests: the BBT and the SHAP (Fig. 1). The BBT assesses manual dexterity by measuring the number of wooden blocks a participant can transfer from one side of the box to the other in 60 seconds, which was used as the functional index [4]. The SHAP assesses hand function using 26 timed tasks that involve manipulating abstract objects and performing activities of daily living [2]. The SHAP Index of Function (IOF) was calculated from the performance scores obtained across the 26 tasks, which are derived from task completion times and normalized into a global functional score.

Both tasks were performed while the participant was standing in front of a table whose height was individually adjusted to ensure the participant's comfort. Participants received standardized verbal instructions to complete the tasks as quickly and accurately as possible using only the limb being assessed. The tests were performed bilaterally in separate trials using the dominant and non-dominant limbs. The order of the tests (BBT or SHAP) and the limb tested (dominant or non-dominant) were randomized across participants to minimize potential learning or fatigue effects.

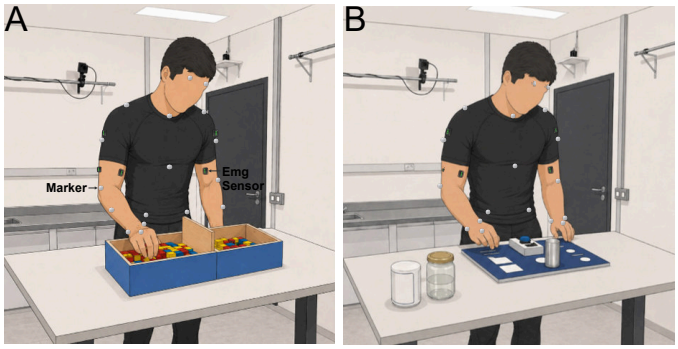

Fig. 1. Experimental setup for the simultaneous acquisition of kinematics and sEMG data during the standardized hand function tests. (A) Participant performing the Box and Block Test (BBT). (B) Participant performing a task from the Southampton Hand Assessment Procedure (SHAP).

C. Data Acquisition

1) Motion Capture: Kinematic data were acquired using a three-dimensional motion capture system (Vicon Motion Systems, Oxford, UK) consisting of eight infrared cameras operating at 100 Hz. A total of 39 retroreflective markers were placed on anatomical landmarks according to the full-body Plug-in Gait model [10], [11].

For this study, only markers corresponding to the head, trunk, and upper limbs were considered for the kinematic analysis (n = 23). This subset included four markers on the head, five on the trunk, and fourteen on the upper limbs, with seven markers on each side.

Marker trajectories were labeled in Vicon Nexus, and small trajectory gaps (up to 10 frames) were filled using a spline-based interpolation algorithm, ensuring signal continuity while minimizing distortion of the original trajectories.

2) Surface Electromyography: sEMG signals were recorded simultaneously with motion capture during task performance using a Delsys Trigno ™ system (Delsys Inc., Boston, MA, USA) at a sampling frequency of 2000 Hz and a resolution of 16 bits. sEMG activity was recorded from four upper-limb muscles: biceps brachii, the long head of the triceps brachii, deltoid, and trapezius. Before placing the electrodes, the skin was cleaned with alcohol to reduce skin-electrode impedance. The sensors were placed according to the recommendations of the Surface Electromyography for the Non-Invasive Assessment of Muscles (SENIAM) project [12], with the bipolar electrode pair positioned so that the line connecting both electrodes was aligned with the direction of the muscle fibers. Specifically, electrodes were positioned over the biceps brachii and triceps brachii muscle bellies, the anterior deltoid, and the upper trapezius, avoiding tendon regions and adjacent muscles.

D. Data Analysis

1) Kinematic Data Processing: Marker trajectories were smoothed using the Woltring spline filter, a generalized cross-

validation spline method commonly used in human motion analysis to reduce measurement noise while preserving the underlying signal dynamics. The level of smoothing was defined by the mean squared error (MSE) parameter, which specifies the tolerance to noise during spline fitting. An MSE value of 5 mm^2 was adopted, consistent with the expected noise level of the motion capture system [13]–[15]. The smoothed trajectories were subsequently used to calculate the kinematic variables analyzed in this study.

The coordinate systems of the segments and the definitions of the joints followed the recommendations of the International Society of Biomechanics for the upper limb [16]. Seven upper-limb joint angles were analyzed: three at the shoulder (flexion/extension, abduction/adduction, and internal/external rotation), one at the elbow (flexion/extension), and three at the wrist (flexion/extension, abduction/adduction, and rotation).

To reduce possible transient effects at the beginning and end of the recordings, the kinematic signals were trimmed before analysis. In the BBT task, the first and last 5 s of each trial were removed. In the SHAP task, the first and last second of each trial were removed.

2) Kinematic Variables: Trajectory and velocity metrics were obtained from the three-dimensional trajectories of upper-limb markers. In the dominant limb, the following markers were analyzed: RSHO (right shoulder acromion), RELB (right elbow lateral epicondyle), and RWRA (right wrist radial styloid). In the non-dominant limb, LSHO (left shoulder acromion), LELB (lateral epicondyle of the left elbow), and LWRA (radial styloid of the left wrist) were considered. These anatomical landmarks enabled characterization of arm, forearm, and hand movement during task performance.

The total distances traveled by the markers located on the shoulder, elbow, and wrist were calculated as the sum of the Euclidean distances between consecutive positions in three-dimensional space throughout each trial. The average speed was obtained by dividing the total distance traveled by the trial duration. In addition, the range of motion (RoM) for each degree of freedom was calculated as the difference between the maximum and minimum joint angles recorded during the trial. These variables were calculated for each trial and subsequently averaged across repetitions of the same experimental condition. In the BBT task, two repetitions per condition were averaged. In contrast, in the SHAP task, the variables were calculated across all subtasks and subsequently averaged per participant and joint to obtain a representative value for the task [3].

For the SHAP, the 26 subtasks were processed individually. Kinematic variables, including traveled distance, average velocity, and range of motion (RoM), as well as the sEMG features, were calculated separately for each subtask. Each subtask corresponded to a single execution, with no repeated trials. The entire available duration of each subtask after the predefined trimming procedure was analyzed. Because the subtasks had different durations, the signals were not temporally normalized or resampled to a common duration; each variable was therefore calculated using the original duration of the corresponding subtask.

3) sEMG Preprocessing: The sEMG signals were filtered using a zero-phase fourth-order Butterworth band-pass filter (10–500 Hz) to attenuate motion artifacts and high-frequency noise [12], [17]. The resulting filtered signals were then used for subsequent feature extraction. To avoid potential transients at the beginning and end of the recordings, the processed signals were trimmed before analysis. As with kinematic data, the first and last 5 s of each BBT recording were removed from the analysis, whereas the first and last 1 s of each SHAP trial were removed.

4) sEMG Feature Extraction: Features were extracted from the preprocessed sEMG signals to characterize muscle activity through complementary amplitude-, variability-, and complexity-related descriptors. To this end, four metrics were implemented: mean absolute value (MAV), sample entropy (SampEn), the coefficient of variation of the RMS signal ($\mathrm{CoV_{RMS}}$), and Willison amplitude (WAMP).

The overall amplitude of the signal was quantified using the mean absolute value (MAV) [7], defined in Equation 1, where x_i represents each sample of the sEMG signal and N is the total number of samples in the analyzed segment.

$$\mathrm{MAV} = \frac{1}{N}\sum_{i=1}^{N}|x_i| \tag{1}$$

As the sEMG amplitude was not normalised, the MAV was used solely as a descriptive measure. Direct comparisons of absolute MAV values between muscles should be interpreted with caution, as any differences may reflect anatomical factors or factors relating to the electrodes.

The temporal complexity of the sEMG signal was evaluated using sample entropy (SampEn, Equation 2). An embedding dimension $m = 2$ and a tolerance $r = 0.2 \cdot \sigma$ were used, where σ is the standard deviation of the signal [18]. In this equation, A represents the number of matches for patterns of length $m + 1$, and B represents the number of matches for patterns of length m. This measure reflects the signal's regularity, with lower values indicating more predictable patterns and higher values indicating greater temporal complexity.

$$\mathrm{SampEn}(m, r) = -\ln\left(\frac{A}{B}\right) \tag{2}$$

The amplitude variability was characterized using the coefficient of variation of the root-mean-square values of the sEMG signals ($\mathrm{CoV_{RMS}}$, Equation 3). The preprocessed sEMG signal was segmented into 200-ms windows with 50 % overlap over the entire trial duration. The RMS value was calculated for each window, yielding a sequence of RMS values throughout the trial. The 50 % overlap was used to maintain temporal continuity between consecutive windows. Here, σ_{RMS} and μ_{RMS} denote the standard deviation and mean of the RMS values across all windows in the experiment, respectively. This metric captures the variability of the signal amplitude over time.

$$\mathrm{CoV}_{\mathrm{RMS}} = \frac{\sigma_{\mathrm{RMS}}}{\mu_{\mathrm{RMS}}} \tag{3}$$

Finally, the Willison amplitude (WAMP) was calculated as the proportion of consecutive differences in the sEMG signal exceeding a predefined threshold T, defined by Equation 4, where N represents the number of samples and $f(\Delta x)$ is defined by Equation 5. The threshold T was set to 10 % of the standard deviation of each sEMG signal ($T = 0.1 \cdot \sigma$), within the low relative-threshold range recommended for amplitude-sensitive features [19]. The WAMP metric quantifies the frequency of significant amplitude changes between consecutive samples, reflecting the dynamic behavior of the sEMG signal. Higher WAMP values indicate a greater number of abrupt signal variations, which may be associated with changes in muscle activation dynamics and motor unit recruitment [20].

$$\mathrm{WAMP} = \frac{1}{N-1} \sum_{i=1}^{N-1} f(|x_{i+1} - x_i|) \tag{4}$$

$$f(\Delta x) = \begin{cases} 1, & \text{if } \Delta x > T \\ 0, & \text{otherwise} \end{cases} \tag{5}$$

E. Statistical Analysis

Data normality was assessed using the Shapiro–Wilk test before hypothesis testing. All variables satisfied the normality assumption ($p > 0.05$), and parametric tests were therefore applied.

Statistical analyses were performed to evaluate differences in upper-limb kinematic variables across the experimental conditions. The variables analyzed included the total distance traveled and the average speed of anatomical markers associated with the shoulder, elbow, and wrist, as well as the RoM in degrees of freedom.

For total traveled distance and average speed, two-way repeated-measures ANOVAs (RM-ANOVAs) were performed considering side (dominant vs. non-dominant) and anatomical marker location (shoulder, elbow, and wrist) as within-subject factors. For RoM, separate two-way RM-ANOVAs were conducted for each movement type (e.g., flexion/extension, abduction/adduction, and rotation), considering side (dominant vs. non-dominant) and joint (shoulder, elbow, and wrist) as within-subject factors.

For each task (BBT or SHAP) and for each sEMG feature (MAV, SampEn, $\mathrm{CoV}_{\mathrm{RMS}}$, and WAMP), a two-way repeated-measures analysis of variance (RM-ANOVA) was employed, considering side (dominant vs. non-dominant) and muscle (biceps, triceps, deltoid, and trapezius) as within-subject factors. When a significant interaction between the factors was identified, post hoc comparisons with Bonferroni correction were performed. In the absence of a significant interaction, main effects were interpreted.

For the functional indices obtained in each task (BBT or SHAP), paired comparisons were performed between the dominant and non-dominant hands using paired Student's t-tests.

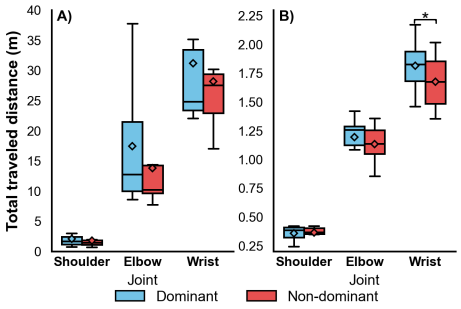

Fig. 2. Total traveled distance of the markers at the shoulder, elbow, and wrist during the Box and Block Test (BBT) (A) and the Southampton Hand Assessment Procedure (SHAP) (B). Boxplots show data from the dominant (blue) and non-dominant (red) limbs.

The significance level was set at $p < 0.05$. Effect sizes were calculated as partial eta squared (η_p^2) [21] and interpreted as small ($0.01 < \eta_p^2 < 0.06$), medium ($0.06 \leq \eta_p^2 < 0.14$), or large ($\eta_p^2 > 0.14$) [22]. All results are reported as mean ± standard deviation. Given the number of complementary kinematic and sEMG outcomes investigated, the statistical analyses were considered exploratory.

III. Results

A. Kinematic Characterization

Marker traveled distances for both the BBT and SHAP tasks are shown in Fig. 2. The total traveled distance significantly differed across marker locations in the BBT task ($p < 0.001$, $\eta_p^2 = 0.89$, Fig. 2A), with the lowest values at the shoulder, followed by the elbow, and the highest at the wrist. No significant effect of limb side was found ($p = 0.109$, $\eta_p^2 = 0.37$), and no significant side-by-marker-location interaction was observed ($p = 0.227$, $\eta_p^2 = 0.22$).

For the SHAP task (Fig. 2B), the analysis of total traveled distance revealed a significant main effect of marker location ($p < 0.001$, $\eta_p^2 = 0.98$). In addition, a significant effect of side was observed ($p = 0.043$, $\eta_p^2 = 0.59$), as well as a significant interaction between side and marker location ($p = 0.010$, $\eta_p^2 = 0.60$). Post hoc comparisons revealed a significant difference between limbs only at the wrist marker ($p = 0.035$).

The average speed of the markers at the shoulder, elbow, and wrist was assessed during the BBT and SHAP tasks, and the results are presented in Fig. 3. In the BBT task, the analysis revealed a significant main effect of marker location ($p < 0.001$, $\eta_p^2 = 0.89$), showing an increase in average speed from the shoulder to the wrist. Neither a significant effect of side ($p = 0.102$, $\eta_p^2 = 0.38$) nor a significant side-by-marker-location interaction ($p = 0.212$, $\eta_p^2 = 0.23$) was found.

For the SHAP task, the analysis of average speed revealed a significant main effect of marker location ($p < 0.001$, $\eta_p^2 = 0.996$). In addition, a significant effect of side was observed ($p = 0.005$, $\eta_p^2 = 0.82$), as well as a significant interaction between side and marker location ($p = 0.009$, $\eta_p^2 = 0.61$). Post hoc analysis of the interaction revealed significant differences between limbs only at the wrist marker ($p = 0.010$).

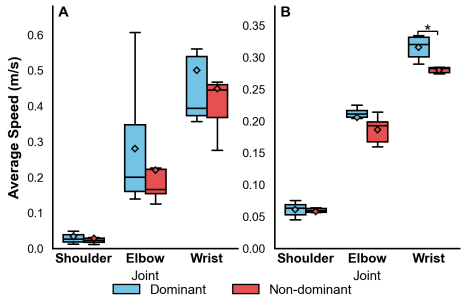

Fig. 3. Average speed of the markers at the shoulder, elbow, and wrist during the Box and Block Test (BBT) (A) and the Southampton Hand Assessment Procedure (SHAP) (B). Boxplots show data from the dominant (blue) and non-dominant (red) limbs.

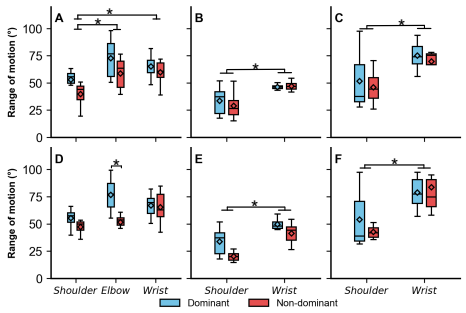

Fig. 4. Range of motion (RoM) during the Box and Block Test (BBT) and the Southampton Hand Assessment Procedure (SHAP). Panels A and D represent flexion/extension (Flex/Ext), panels B and E represent abduction/adduction (Abd/Add), and panels C and F represent rotation movements. Panels A–C correspond to the BBT task, whereas panels D–F correspond to the SHAP task. Boxplots show dominant (blue) and non-dominant (red) limbs. Diamonds indicate mean values.

Figure 4 shows the RoM associated with the degrees of freedom at each joint. In the BBT, the flexion/extension (Flex/Ext) movement (Fig. 4A) had a significant main effect of joint ($p = 0.002$, $\eta_p^2 = 0.66$). Post hoc comparisons revealed differences between the elbow and shoulder ($p = 0.004$), and between the shoulder and wrist ($p = 0.037$). For abduction/adduction (Abd/Add) movements (Fig. 4B), a significant main effect of joint was identified ($p = 0.026$, $\eta_p^2 = 0.59$), with post hoc comparisons showing differences between the shoulder and wrist ($p = 0.026$). For rotation (Fig. 4C), a significant main effect of joint was also found ($p = 0.009$, $\eta_p^2 = 0.71$), with post hoc comparisons indicating differences between the shoulder and wrist ($p = 0.009$). No significant main effects of side were found for RoM during the BBT (Flex/Ext: $p = 0.098$, $\eta_p^2 = 0.39$; Abd/Add: $p = 0.230$, $\eta_p^2 = 0.23$; Rotation: $p = 0.340$, $\eta_p^2 = 0.15$), and no significant side-by-joint interactions were observed (Flex/Ext: $p = 0.238$, $\eta_p^2 = 0.21$; Abd/Add: $p = 0.075$, $\eta_p^2 = 0.44$; Rotation: $p = 0.963$, $\eta_p^2 < 0.01$).

Conversely, for the SHAP task, the RoM associated with Flex/Ext (Fig. 4D) exhibited a significant main effect of side ($p = 0.015$, $\eta_p^2 = 0.65$) and joint ($p < 0.001$, $\eta_p^2 = 0.69$), along with a significant interaction between side and joint ($p = 0.012$). Post hoc analysis of the interaction showed that the difference between limbs was significant only at the elbow joint ($p = 0.021$). For Abd/Add (Fig. 4E), significant main effects of side ($p = 0.010$, $\eta_p^2 = 0.70$) and joint ($p = 0.002$, $\eta_p^2 = 0.81$) were found, with no significant interaction ($p = 0.561$). For rotation (Fig. 4F), a significant main effect of joint was identified ($p < 0.001$, $\eta_p^2 = 0.87$), with no significant effects of side ($p = 0.469$) or interaction ($p = 0.318$).

B. sEMG Characterization

For MAV, the BBT task (Fig. 5A) showed no significant muscle-by-side interaction ($p = 0.455$, $\eta_p^2 = 0.13$), whereas significant main effects were observed for both side ($p = 0.037$, $\eta_p^2 = 0.54$) and muscle ($p < 0.001$, $\eta_p^2 = 0.64$). However, post hoc comparisons for the main effect of muscle did not reveal significant pairwise differences after correction for multiple comparisons (all $p \geq 0.051$). In the SHAP task (Fig. 5B), MAV values showed no significant muscle-by-side interaction ($p = 0.920$, $\eta_p^2 = 0.03$) and no main effect of side ($p = 0.246$), but revealed a significant main effect of muscle ($p < 0.001$, $\eta_p^2 = 0.78$). Post hoc comparisons showed that, independently of limb side, the biceps brachii differed significantly from the triceps brachii ($p = 0.001$) and trapezius ($p = 0.003$).

In the BBT task, the SampEn values (Fig. 5C) showed no significant muscle-by-side interaction ($p = 0.258$, $\eta_p^2 = 0.20$) and no main effect of side ($p = 0.091$). However, a significant main effect of muscle was found ($p < 0.001$, $\eta_p^2 = 0.90$), indicating that SampEn values differed across muscles independently of side. Post hoc comparisons revealed higher SampEn values for the trapezius compared with the biceps brachii ($p < 0.001$), triceps brachii ($p = 0.008$), and deltoid ($p = 0.003$). In contrast, in the SHAP task (Fig. 5D), a significant muscle-by-side interaction was observed ($p = 0.034$, $\eta_p^2 = 0.37$), along with a significant main effect of muscle ($p < 0.001$, $\eta_p^2 = 0.79$), while the effect of side was not significant ($p = 0.328$). Post hoc comparisons showed that the trapezius had higher SampEn values than the biceps brachii in both limbs (dominant: $p = 0.004$; non-dominant: $p = 0.029$), as well as higher values than the deltoid ($p = 0.019$) and the triceps brachii ($p = 0.046$), only in the non-dominant limb.

The $\mathrm{CoV_{RMS}}$ analysis in the BBT task (Fig. 5E) revealed a significant main effect of muscle ($p < 0.001$, $\eta_p^2 = 0.89$), with no significant muscle-by-side interaction ($p = 0.404$, $\eta_p^2 = 0.15$) or main effect of side ($p = 0.646$). Post hoc comparisons showed that the trapezius muscle had significantly lower $\mathrm{CoV_{RMS}}$ values than the biceps brachii ($p < 0.001$) and the deltoid ($p < 0.001$), independently of limb side. In the SHAP task (Fig. 5F), however, a significant muscle-by-side interaction was found ($p = 0.004$, $\eta_p^2 = 0.51$), along with a significant main effect of muscle ($p < 0.001$, $\eta_p^2 = 0.72$) and no effect of side ($p = 0.777$). Post hoc comparisons indicated that, in the dominant limb, the trapezius muscle exhibited lower $\mathrm{CoV_{RMS}}$ values than the biceps brachii ($p = 0.032$) and the deltoid ($p = 0.004$). In contrast, in the non-dominant limb, $\mathrm{CoV_{RMS}}$ of the trapezius muscle was lower than that of

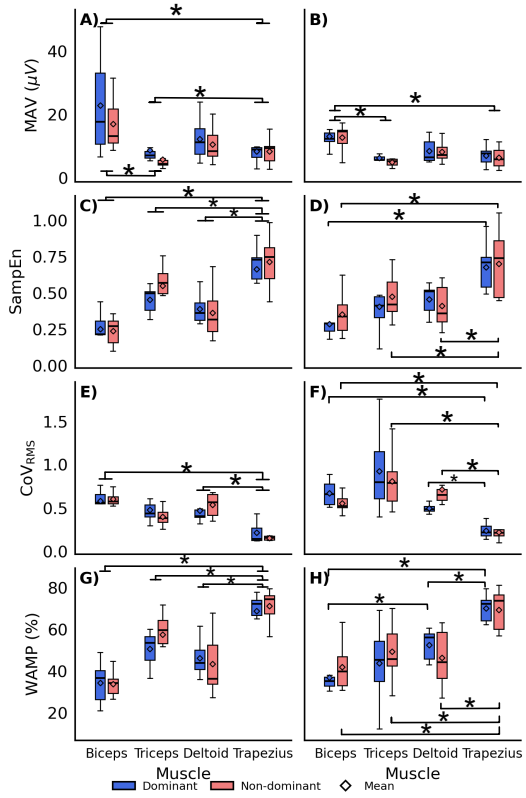

Fig. 5. Surface electromyographic (sEMG) characterization across muscles and tasks. Boxplots represent the distribution of MAV (A–B), SampEn (C–D), $\mathrm{CoV_{RMS}}$ (E–F), and WAMP (G–H). For each feature, the left panel shows the Box and Block Test (BBT) and the right panel shows the Southampton Hand Assessment Procedure (SHAP). Blue and red colors indicate dominant and non-dominant limbs, respectively. Asterisks indicate significant pairwise differences between muscles ($p < 0.05$).

the biceps brachii ($p < 0.001$), the deltoid ($p = 0.004$), and the triceps brachii ($p = 0.018$).

For WAMP, the BBT task (Fig. 5G) showed no significant muscle-by-side interaction ($p = 0.376$, $\eta_p^2 = 0.16$), nor a significant main effect of side ($p = 0.143$, $\eta_p^2 = 0.32$), whereas a significant main effect of muscle was observed ($p < 0.001$, $\eta_p^2 = 0.94$). Post hoc comparisons revealed that the trapezius muscle differed from the biceps brachii ($p < 0.001$), deltoid ($p < 0.001$), and triceps brachii ($p < 0.001$). For the SHAP (Fig. 5H), a significant muscle-by-side interaction was observed ($p = 0.005$, $\eta_p^2 = 0.50$). In addition to a significant main effect of muscle ($p < 0.001$, $\eta_p^2 = 0.80$). The main effect of side was not significant ($p = 0.637$, $\eta_p^2 = 0.04$). Post hoc comparisons revealed that the trapezius muscle differed from the biceps brachii (dominant: $p < 0.001$; non-dominant: $p = 0.002$) and the deltoid (dominant: $p = 0.007$; non-dominant: $p = 0.005$) in both limbs. A difference between the trapezius and triceps brachii was observed only in the non-dominant limb ($p = 0.030$). Additionally, a difference between the biceps brachii and deltoid was observed in the dominant limb ($p = 0.043$).

C. Functional assessment indices

Functional assessment indices obtained from the BBT and SHAP tasks are presented in Table I. The BBT scores were higher for the dominant limb compared with the non-dominant limb; however, no significant differences were observed between sides ($p = 0.126$, Cohen's $d_z = 0.67$). Similarly, SHAP scores were slightly higher for the dominant limb, with no significant differences between the dominant and non-dominant limbs ($p = 0.352$, Cohen's $d_z = 0.38$).

TABLE I
FUNCTIONAL TEST INDICES

Functional test	Dominant	Non-dominant
Box and Block Test	74 ± 6.69	71 ± 7.60
Southampton Hand Assessment Procedure	94 ± 2.08	92 ± 3.95

IV. DISCUSSION

This study investigated the neuromechanical properties of proximal and distal upper-limb segments during the BBT and SHAP, two functional motor tasks used to assess hand dexterity. To this end, both tests were characterized through kinematic analysis of the shoulder, elbow, and wrist joints, together with a multi-feature analysis of sEMG signals from upper-limb muscles.

Our results indicate that both tasks (BBT and SHAP) exhibited similar movement patterns, characterized by greater displacement and velocity of the wrist marker than of the elbow and shoulder markers. This similarity stems from both tasks involving reaching and grasping actions that require transporting and manipulating objects [1]. To perform these movements, the proximal joints primarily contribute to positioning and stabilizing the upper limb in space. In contrast, the distal joints are more directly involved in hand orientation, fine motor adjustments, and interaction with the object [1], [8]. Similar patterns have been described in the literature, namely, greater involvement of the distal joints during reaching and object-manipulation tasks [23].

In the BBT task, the contribution of each joint to the movement pattern varied by degree of freedom (flexion/extension, abduction/adduction, and rotation), and distal joints exhibited greater RoM than proximal joints, while distal markers showed higher speeds than proximal markers. However, we did not observe significant differences between the dominant and non-dominant limbs in total distance traveled, average speed, or RoM. This suggests that the repetitive and relatively stereotyped nature of the BBT may contribute to similar movement patterns on both sides [24]. Since the task consists of repeated reaching and grasping movements with limited variability, the observed movement patterns may be influenced primarily by the task's mechanical demands rather than by limb dominance [23].

In contrast, the SHAP showed different neuromechanical properties, with significant differences between the dominant and non-dominant limbs, particularly at the wrist joint. These findings suggest that differences between limbs may become

more evident as task complexity increases. Unlike the BBT, which involves repetitive movements, the SHAP comprises 26 subtasks that require different types of grasping, object manipulation, and movement transitions [2]. It is likely that the greater variability of motor actions in the SHAP, together with the complexity of some tasks, increases the demands on finer motor control and movement adaptation [25]. This is especially true in the distal segments that interact with objects. Under these conditions, lateralized motor strategies may become more pronounced, with limb dominance playing an important role in movement execution. Therefore, our results suggest that upper limb lateralization may be task-dependent and may become more evident during functionally complex activities [9], [26].

The sEMG features captured distinct properties of muscle activation during functional upper-limb tasks. The MAV showed significant muscle-dependent effects; however, post hoc comparisons were less consistent. Since this metric primarily reflects the overall intensity of muscle activation [17], [27], the results suggest that the functional tasks evaluated required a relatively homogeneous level of muscular effort across various muscles, possibly due to the coordinated and simultaneous nature of the reaching, grasping, and manipulation movements present in the BBT and SHAP tasks. Additionally, the lack of sEMG amplitude normalization may have contributed to the variability observed in the MAV values and, consequently, to the inconsistencies in the post hoc comparisons. Although normalization is recommended to improve the comparability of sEMG amplitudes across muscles and participants, selecting an appropriate normalization procedure for dynamic functional tasks remains challenging because no single method is universally applicable across movement conditions [28].

The temporal complexity of the sEMG signals, as measured by SampEn, was significantly higher in the trapezius than in the other muscles examined (biceps brachii, triceps brachii, and deltoid). This finding is physiologically consistent, as the trapezius, a muscle involved in stabilizing the shoulder and scapula, may require continuous fine-tuning to maintain postural control during movement, which could be reflected in greater signal irregularity [29]. Furthermore, we observed that the trapezius exhibited relatively low $\mathrm{CoV}_{\mathrm{RMS}}$ values, indicating lower variability in sEMG amplitude over time. In contrast, the biceps brachii and triceps brachii muscles showed greater amplitude fluctuations, despite exhibiting less complex activation patterns. This distinction suggests different functions during task performance. While the biceps brachii and triceps brachii are directly involved in the generation and modulation of movement-related forces, the trapezius appears to provide a more constant level of activation associated with shoulder position and upper limb support during task performance [30].

The WAMP analysis reinforced the functional distinction between stabilizing muscles and those more actively involved in movement execution. The trapezius muscle exhibited the most distinctive pattern in this measure, with more frequent changes in its activation amplitude. Together with the SampEn and $\mathrm{CoV}_{\mathrm{RMS}}$ findings, this result suggests that trapezius activation was characterized by a relatively constant overall amplitude accompanied by frequent local adjustments. These findings are consistent with a distinct pattern of trapezius muscle activity during functional tasks, characterized by continuous modulation of the recorded sEMG signal. In contrast, the biceps brachii and triceps brachii exhibited distinct activation profiles that were more closely related to movement execution during the task. Taken together, these findings suggest that combining multiple sEMG features enables a more comprehensive characterization of muscle activation during functional tasks.

An important point is that both tasks showed muscle-dependent differences in sEMG activity, but the structure of these responses differed across tasks. In the BBT, the absence of significant interactions across most metrics suggests that myoelectric activity was primarily driven by muscle-specific effects, with limited evidence of limb-dependent modulation. In contrast, the SHAP showed significant muscle-by-side interactions, indicating that muscle activation depended on the combination of muscle and limb. Therefore, although both tasks may share a general organization related to the functional role of each muscle, the SHAP appears to reveal task-specific and limb-dependent modulations in myoelectric activity.

Taken together, the kinematic and sEMG results enabled a more comprehensive characterization of upper-limb function during object manipulation tasks [31]. Kinematic analysis revealed greater displacement and average speed of the wrist marker than of the shoulder and elbow markers. At the same time, sEMG analysis showed functional differences among the evaluated muscles, suggesting distinct contributions to movement generation and postural maintenance. Although the BBT and SHAP functional indices showed higher values for the dominant side, no statistically significant differences were observed between sides. These results suggest that, while functional indices provide a global measure of performance during the evaluated tasks, differences associated with laterality may primarily emerge at the level of motor control strategies, which are not necessarily reflected in overall functional scores. In contrast, kinematic and sEMG variables allowed the identification of specific movement characteristics and muscle activation patterns, providing complementary information about the neuromotor control mechanisms involved during functional task execution. These findings reinforce the importance of combining kinematic and sEMG information to investigate motor control during functional tasks, as movement organization cannot be fully captured by joint variables or global measures of muscle activation alone [18].

Some limitations should be acknowledged: the sEMG analysis was performed on only four upper-limb muscles, and the sample comprised a small number of healthy participants. Despite these limitations, the approach enabled kinematic and sEMG characterization of functional upper-limb tasks. Future studies could expand on this analysis by including other muscle groups and different clinical populations.

V. Conclusion

This study characterized the kinematic and sEMG properties of functional upper-limb tasks by analyzing the BBT and SHAP in healthy individuals. The results revealed differences in movement features between the two tasks, particularly in the involvement of distal joints and the effects of handedness during more functionally complex and cognitively demanding tasks. Furthermore, sEMG characteristics revealed distinct patterns of muscle activation during task performance. Taken together, these findings contribute to a better understanding of motor behavior during object manipulation and demonstrate that kinematic and sEMG analyses extend the information provided by functional test indices, which primarily reflect overall task performance. By revealing task-specific movement patterns, joint-related characteristics, and muscle activity patterns, these neuromechanical measures provide a more comprehensive characterization of functional upper-limb performance. Given the small sample size (n = 8), the present findings should be considered exploratory.

***Abstract*—Portable and handheld electrospinning devices enable the in situ deposition of polymeric nanofiber meshes for wound care, but require the integration of a compact, low-power high-voltage supply with a controlled infusion system. A structured narrative search of IEEE Xplore, Scopus, Web of Science, PubMed, and ScienceDirect through July 2026 retained 43 studies for qualitative comparative synthesis. The literature was analyzed across three complementary axes: biomedical, material, and process requirements; the architectures and performance of portable and handheld devices; and high-voltage topologies, with emphasis on Cockcroft–Walton multipliers and flyback-based supplies. Reported devices show increasing integration and biomedical validation; however, recurring limitations include incomplete electrical specifications, limited flow control and battery autonomy, and scarce electrical-safety data. The comparison indicates that Cockcroft–Walton multipliers remain attractive for extreme miniaturization, whereas flyback-based supplies are more frequently reported in electrospinning and provide transformer isolation together with high voltage gain. Repurposed cathode-ray-tube flyback transformers may support low-cost proof-of-concept prototyping, but their lack of traceable specifications and lot-to-lot reproducibility limits clinical translation. Galvanic isolation alone is insufficient to establish clinical suitability; output regulation, stored-energy and current characterization, component standardization, and regulatory validation remain priorities.**

I. Introduction

Tissue injuries – damage to the skin from physical, thermal, chemical, or mechanical injury, or from underlying disease – are broadly classified as acute or chronic; chronic lesions, arising from conditions such as diabetes, impose a considerable burden on healthcare systems [1]. Whereas acute injuries often heal through intrinsic repair, extensive or full-thickness lesions require supporting materials that promote the migration and infiltration of reparative cells [2].

Wound healing is a complex process comprising several overlapping stages: hemostasis, inflammation, proliferation, and remodeling. A crucial step in tissue lesion treatment is dressing application, aimed at protecting the wound from external risk factors while accelerating the healing process. An ideal dressing should: (i) absorb excess exudate, (ii) prevent infection, (iii) maintain moisture at the lesion site, (iv) facilitate gas exchange, (v) be biocompatible and biodegradable, (vi) avoid adhering to the wound while remaining easy to remove, and (vii) induce angiogenesis and tissue remodeling [1].

Electrospinning is a versatile and low-cost technique for producing fibers with diameters ranging from nanometers to micrometers by stretching a charged polymer jet under a high-voltage electric field [3]. Electrospun nanofibers have emerged as a promising technology for meeting the wound-dressing requirements described above, particularly in the fabrication of 2D and 3D meshes. These structures offer the unique ability to be tuned in diameter, porosity, alignment, overlap, and surface functionalization, allowing precise control of cell migration – a control that is crucial for improving the repair and regeneration of tissues as diverse as nerve, skin, cardiac, vascular, and musculoskeletal tissue [2]. Electrospun nanofibers have additionally been widely studied as wound dressings owing to their high porosity and large surface area, properties that inhibit pathogen growth at the lesion site while facilitating the exchange of gaseous and liquid molecules [1].

Applying nanofibers directly onto a lesion in situ requires portable devices that overcome the bulk and mains dependence of benchtop equipment [22], [24]. Such devices need a compact, low-power high-voltage (HV) supply together with an infusion system delivering the solution at a controlled, reproducible flow rate – which directly affects Taylor-cone stability and fiber morphology [24], [26]. Compact, low-cost high-voltage sources are therefore a central design priority.

Research groups have proposed portable or handheld electrospinning platforms and, in parallel, a diverse array of high-voltage generation strategies to power them, ranging from Cockcroft–Walton (CW) voltage multipliers to flyback converters. These two lines of research – the biomedical characterization of the resulting nanofibers and the power electronics that render portable devices feasible – are, however, seldom reviewed jointly. This narrative review integrates the biomedical process requirements, the portable electrospinning

architectures, and the high-voltage power-supply design constraints, in order to identify the trade-offs that currently limit clinical translation. Section II describes the review methodology. Section III reviews the biological, physical, and chemical characterization of electrospun nanofibers for biomedical use, together with the physics governing jet formation and the analytical techniques used to characterize the resulting fibers. Section IV surveys the state of the art of portable and handheld electrospinning devices. Section V compares the high-voltage power-supply topologies reported for this class of device. Section VI discusses the feasibility of a flyback-based topology in terms of cost, safety, and component availability. Section VII summarizes the main open challenges, and Section VIII concludes the paper.

II. Review Methodology

This work is a narrative review with a structured and transparent search strategy. IEEE Xplore, Scopus, Web of Science, PubMed, and ScienceDirect were searched up to July 2026 using combinations of "portable/handheld electrospinning," "in situ wound dressing," "high-voltage power supply," "flyback converter," and "Cockcroft–Walton multiplier." Studies were included when they described a portable electrospinning device, its biomedical validation, or a high-voltage topology applicable to low-power electrospinning; foundational references on nanofiber characterization and jet physics were retained for background. After screening, 43 studies were retained for qualitative comparative synthesis. Given the heterogeneity of the devices and the frequent absence of standardized electrical data, the synthesis is qualitative and comparative rather than a quantitative meta-analysis.

III. Characterization of Electrospun Nanofibers

The performance of an electrospun mat as a wound dressing or drug-delivery vehicle depends on biological, physical, and chemical properties tuned jointly during electrospinning. This section summarizes recent findings and the underlying jet physics, kept concise so as to prioritize the portable-device comparison of Sections IV–VI.

A. Biological Characterization and Chemical Functionalization

An ideal wound dressing must absorb excess exudate, prevent infection, maintain a moist environment, and promote angiogenesis and tissue remodeling, while remaining biocompatible and biodegradable [6]; electrospun nanofibers can meet these requirements, in large part through improved fibroblast migration [2]. Therapeutic agents are incorporated either directly during electrospinning or by post-treatment, and this functionalization largely dictates biomedical performance [7]: antibiotics and silver or gold nanoparticles confer antimicrobial activity, including against multi-drug-resistant bacteria, while anti-inflammatory drugs such as dexamethasone or ibuprofen provide sustained, localized delivery. Representative primary studies illustrate the range of outcomes: doxycycline-loaded polybutylene adipate-co-terephthalate (PBAT)/gelatin meshes functionalized with an arginine-glycine-aspartate (RGD) peptide prevented *S. aureus* and *P. aeruginosa* infection [12]; pH-responsive coaxial fibers co-delivered lidocaine and curcumin for staged release [13]; hyaluronic acid/silk core–shell fibers with zinc oxide were active against *E. coli* and *S. aureus* [14]; chitosan/poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) fibers loaded with cephradine reached an encapsulation efficiency above 70% with sustained 48 h release in methicillin-resistant *S. aureus* (MRSA)-infected wounds [15]; a bilayered polycaprolactone/poly(vinyl alcohol) (PCL/PVA) system co-releasing LL-37 and vascular endothelial growth factor (VEGF) improved both bactericidal activity and epidermal regeneration in vivo [16]; and graphene-oxide composites enhanced bactericidal efficacy and reepithelialization, with optimal loadings yielding healing rates above 90% in murine models [11]. Loading strategy and fiber morphology are not independent, however: chrysin-loaded PCL–chitosan fibers, for example, increased in diameter from 191 to 313 nm as drug concentration rose [21].

B. Polymer and Solvent Selection

Polymers for biomedical use must meet criteria of biodegradability, safety, biocompatibility, moderate hydrophilicity, and adequate mechanical strength, and may be natural or synthetic [1]. Natural polymers such as chitosan, cellulose, collagen, and silk are valued for their biocompatibility and additional biological activity, but are comparatively costly and harder to process; synthetic polymers such as polylactic acid (PLA), poly(ethylene oxide) (PEO), and polyvinylpyrrolidone (PVP), together with PVA and PCL, offer tunable mechanical and degradation characteristics and are frequently blended with natural polymers to combine both advantages [8]. Solvent selection governs solution homogeneity and jet behavior: low-molecular-weight polymers tend to produce beads rather than fibers owing to limited chain entanglement, solvent volatility sets the jet solidification rate, and solvent dielectric constant modulates the electrostatic repulsion between surface charges [9], [19]. Commonly used solvents include alcohols, dichloromethane, chloroform, dimethylformamide (DMF), tetrahydrofuran (THF), acetone, dimethyl sulfoxide (DMSO), hexafluoroisopropanol (HFIP), and trifluoroethanol. Although aqueous electrospinning is well established for water-soluble polymers such as PVA and PEO, water's high surface tension and relatively slow evaporation can narrow the stable processing window; co-solvents or adjustments in temperature, distance, and flow rate may therefore be required depending on the polymer system [9].

C. Physical Characterization and Process Parameters

The electrospinning process is highly sensitive to a set of solution, process, and environmental parameters, whose optimization is crucial to achieving the desired fiber morphology, diameter, and mechanical properties [9]. Table I summarizes the effect of the main parameters reported in the literature.

TABLE I
EFFECT OF KEY ELECTROSPINNING PARAMETERS ON FIBER DIAMETER AND MORPHOLOGY.

Category	Parameter	Reported effect
Solution	Polymer concentration / M_w	Higher concentration or molecular weight increases chain entanglement, increasing fiber diameter; below a threshold, beads form instead of fibers [19].
	Surface tension	Higher surface tension raises the critical electric field and may promote bead formation or jet instability; its effect on fiber diameter is formulation-dependent [9].
	Conductivity	Higher conductivity increases surface charge density, accelerating stretching and reducing diameter, at the cost of increased Coulombic repulsion [9].
Process	Applied voltage	Higher voltage increases charge density and stretching, reducing diameter; excessively high voltage can raise flow rate and increase diameter again [17], [19].
	Flow rate	Higher flow rate increases fiber diameter and pore size; excessive flow leads to dripping and bead-on-string defects. Response-surface analysis identifies flow rate as the dominant parameter for mechanical properties [20].
	Tip-to-collector distance	Greater distance allows more time for jet stretching and solvent evaporation, reducing fiber diameter [17].
Environmental	Temperature	Higher temperature reduces solution viscosity and intermolecular Coulomb forces, reducing fiber diameter [9].
	Relative humidity	High humidity causes surface condensation and fiber wrinkling; very low humidity accelerates solvent evaporation at the needle tip, causing clogging [9].

Representative operating windows reported for portable or bench-characterized setups illustrate this parameter space: Haik et al. (2017) applied 25 kV at a 20 cm working distance, a 4.5 mL/h flow rate, and a 0.7 mm needle tip [25]; Mouthuy et al. (2015) operated at a fixed 20 cm distance with voltage adjustable between 0 and 14 kV and flow rate between 0 and 10 mL/h, tuned individually for each polymer solution [24]; and a parametric bench study using a polyacrylonitrile (PAN)/DMF solution at 10% (w/v) evaluated needle diameters of 0.45–0.80 mm and voltages of 15, 20, and 25 kV at a fixed 140 mm distance and 500 μL/h flow rate, obtaining fiber diameters as low as 364 $\pm$ 63 nm at 15 kV with a 0.55 mm needle [17]. A response-surface optimization of a PCL skin scaffold identified flow rate as the dominant parameter affecting both Young's modulus and tensile strength, ahead of polymer concentration and voltage [20], while a broader survey across cellulose- and chitosan-based biopolymers confirmed that fiber diameter increases with both solution concentration and applied voltage regardless of the specific polymer family [19]. Together, these results confirm the trends summarized in Table I and underscore that, for a portable device, the flow rate and the applied voltage must be co-regulated within a comparatively narrow, solution-specific window in order to sustain a stable Taylor cone.

D. Physics of Jet Formation and the Taylor Cone

The physical principle underlying nanofiber generation consists of electrically charging a polymer solution at the needle tip. The applied field must overcome the surface tension of the solution, deforming the pendant droplet into the characteristic conical shape known as the Taylor cone, from whose apex a charged jet is ejected toward the grounded collector [2], [4]. As the applied voltage increases, charge accumulates at the droplet surface until, at a critical voltage V_c, the electrostatic pressure $\rho_e = \epsilon E^2/2$ overcomes the capillary pressure $\rho_c = 2\gamma/r$ dictated by the Young–Laplace equation, where ϵ is the dielectric constant of the surrounding medium, E is the electric field intensity, γ is the surface tension, and r is the needle's internal radius. The critical voltage can be estimated by the semi-empirical relation

$$V_c^2 = \frac{4H^2}{h^2}\left(\ln\left(\frac{2h}{R}\right) - 1.5\right)(1.3\pi R\gamma)(0.09) \qquad (1)$$

where H is the needle-to-collector distance, h is the needle length, and R is the needle's external radius; the factor 1.3 derives from $2\cos(49.3^\circ)$, the semi-vertical half-angle at which the cone reaches equilibrium [2], [4]. Equation (1) is empirical and dimensionally inhomogeneous: its numerical constants (with $(1.3)(0.09) \approx 0.117$ matching the classical semi-empirical form) require the stated mixed units, namely H, h, and R in centimeters, γ in dyn/cm, and V_c in kV. It should therefore be treated as an order-of-magnitude design estimate rather than an exact physical law.

Once ejected, the jet initially follows a straight path – the near-field region – over a length sufficient to suppress the Rayleigh instability that would otherwise break it into droplets. Beyond this segment, the jet undergoes a whipping (bending) instability that stretches it by up to four to five orders of magnitude within tens of milliseconds, reaching drawing rates of up to 10^6 s^{-1} [2]. Under the whipping-instability model, the terminal jet diameter can be estimated as

$$d_t = \left(\gamma\varepsilon\frac{Q^2}{I^2}\frac{2}{\pi(2\ln\chi - 3)}\right)^{1/3} \qquad (2)$$

where γ is the surface tension, ε the permittivity of the surrounding medium, Q the volumetric flow rate, I the current carried by the jet, and χ the dimensionless wavelength of the whipping instability. Unlike Eq. (1), Eq. (2) is dimensionally consistent and is evaluated in SI units (γ in N/m, ε in F/m,

Q in m^3/s, I in A, and d_t in m); it is the analytical result derived by Fridrikh et al. for the terminal jet diameter and should likewise be treated as an idealized estimate [2], [5]. As the solvent evaporates, the jet solidifies; slower solidification allows longer stretching and thinner fibers, while residual surface charge tends to limit the achievable deposited mat thickness to roughly 0.5–1 mm [2]. For a portable device, this picture translates into a practical constraint: the needle-to-collector distance, the needle geometry, and the flow rate must be chosen jointly with the achievable output voltage of the supply in order to sustain a stable cone rather than an unstable, dripping, or multi-jet regime.

E. Post-Fabrication Characterization

Once fabricated, electrospun mats are characterized along morphological, mechanical, structural, chemical, and thermal dimensions – most commonly by scanning and transmission electron microscopy, tensile testing, X-ray diffraction, Fourier-transform infrared (FTIR) and Raman spectroscopy, and thermal analysis by differential scanning calorimetry and thermogravimetry [1], [10]. Porosity is particularly relevant: the high, interconnected porosity of these meshes governs exudate drainage and gas exchange, and is quantified by mercury or capillary-flow porosimetry per ASTM standards [6]. In vitro, fibroblasts and stem cells cultured on such meshes show no cytotoxicity and improved infiltration, migration, and proliferation [18].

IV. Portable and Handheld Electrospinning Devices: State of the Art

An electrospinning apparatus consists, essentially, of a high-voltage power supply, a mechanism for controlling the flow of the polymer solution, and a collector [10], as illustrated conceptually in Fig. 1. In benchtop equipment, all three subsystems are large, mains-powered units; portable devices must, instead, miniaturize each of them while preserving process stability. Table II summarizes representative portable and handheld electrospinning devices reported in the literature, together with their reported operating parameters and biomedical validation where available; it constitutes the core comparative contribution of this review.

Xu et al. (2015) reported one of the first battery-operated handheld apparatuses, replacing the syringe pump with a hand-actuated mechanism and a compact high-voltage module, enabling operation without a fixed electrical connection [22]. Mouthuy et al. (2015) combined an EMCO F101 high-voltage converter with a linear-actuator syringe pump under microcontroller control, powered by ten NiMH AA cells for about two hours [24]. Zhao et al. (2020) demonstrated a self-powered melt-electrospinning device reaching 20 kV from a hand-cranked or battery input, targeted at in situ wound dressing [23]. Haik et al. (2017) assessed the clinical feasibility of a handheld device – a precursor of the commercial SpinCare™ system – on a porcine wound model [25]. Owida et al. (2022) built an integrated, low-cost platform from off-the-shelf and open-hardware components at roughly US$202, against

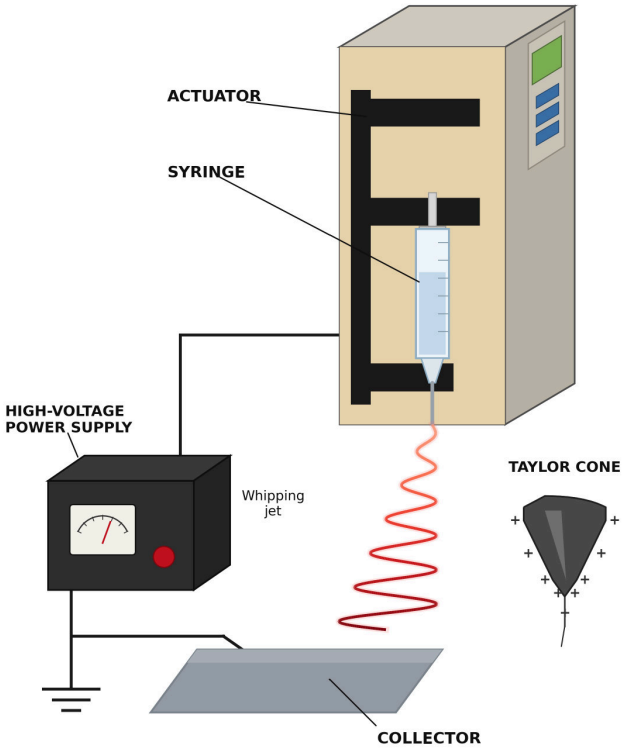

Fig. 1. Conceptual diagram of a portable electrospinning apparatus, common to the devices summarized in Table II: the battery-driven HV supply charges the syringe-dispensed polymer solution, which forms a Taylor cone at the needle tip; the resulting jet undergoes a whipping instability (coiled path) before depositing solid nanofibers on the grounded collector.

US$17,000–60,000 for commercial benchtop systems [26], underscoring cost as a first-order design constraint.

Cruz et al. (2025) introduced a glove-mounted, needleless device, stepping a 1 V input up to 50 kV via a miniaturized diode-capacitor ladder, producing cannabidiol-loaded microfibers validated on porcine skin [27]. Desai et al. (2026) presented "Fiber Gun," an integrated handheld system with high-voltage supply, syringe pump, stepper motor, and a 12 V battery, reporting over 10 h of operation and 100–151 nm fibers [28]. Cai et al. (2026) reported a hand-held multi-process printer combining photo-crosslinking extrusion, spraying, and electrospinning under wireless control, validated in rat and porcine wound models [29]. These devices show a trend toward tighter integration and lower input voltages, achieved by moving voltage multiplication or extra fabrication modes into the miniaturized platform.

Two patterns emerge from Table II. First, there is a persistent trade-off between output-voltage range, regulation quality, and cost: commercial HV modules offer stable, well-documented performance at higher cost, whereas self-built oscillator- or converter-based stages reduce cost but require in-house characterization of output voltage and ripple. Second, and more critical for translation, the reported limitations recur across designs: flow delivery is frequently hand-actuated or

TABLE II
REPRESENTATIVE PORTABLE/HANDHELD ELECTROSPINNING DEVICES: REPORTED OPERATING PARAMETERS, BIOMEDICAL VALIDATION, AND MAIN REPORTED LIMITATION. NR: NOT REPORTED.

Reference	Output voltage	Flow rate	Distance	HV topology	Power source	Biomedical validation	Main limitation
Xu *et al.*, 2015 [22]	NR	NR	NR	Compact HV module	Battery	NR	Hand-actuated; no regulated flow
Mouthuy *et al.*, 2015 [24]	0–14 kV	0–10 mL/h	20 cm	F101 converter (EMCO)	10× NiMH AA	Bench characterization	∼2 h runtime; no in vivo data
Zhao *et al.*, 2020 [23]	20 kV	NR	10 cm	Oscillator + voltage doubler	Self-powered/battery	In situ wound dressing (targeted)	Melt process; limited biological data
Haik *et al.*, 2017 [25]	25 kV	4.5 mL/h	20 cm	Commercial HV module	Battery	Porcine wound model	Feasibility only; proprietary module
Owida *et al.*, 2022 [26]	NR	NR	NR	Low-cost off-the-shelf HV module	Battery/mains	NR	No biomedical validation
Cruz *et al.*, 2025 [27]	50 kV	NR	NR	Miniaturized CW ladder	Wearable/glove battery	Porcine skin model	Microfiber scale; single drug
Desai *et al.*, 2026 [28]	NR	NR	NR	Integrated HV module	12 V battery	In vivo wound healing	Early access; few formulations
Cai *et al.*, 2026 [29]	NR	NR	NR	Multi-process (spin/spray/extrude)	Battery, wireless control	Rat and porcine wound models	Higher system complexity

only coarsely regulated; battery autonomy is short; and, above all, biomedical validation rarely advances beyond proof-of-concept or small-animal and porcine models, while quantitative electrical-safety data are essentially absent. The most recent platforms [27]–[29] improve integration and lower the input voltage, yet none reports the leakage-current or dielectric-strength characterization that clinical use would demand. These recurring gaps – regulated low-power delivery, longer autonomy, and documented electrical safety – frame the power-supply comparison developed in the following section.

V. HIGH-VOLTAGE POWER SUPPLY TOPOLOGIES FOR PORTABLE APPLICATIONS

Generating a stable output in the range of 10–30 kV from a low-voltage battery, while keeping the supply compact and light, constitutes the central power-electronics challenge of portable electrospinning. Two topologies dominate the literature on portable and low-cost high-voltage sources: the Cockcroft–Walton voltage multiplier and the flyback converter.

A. Cockcroft–Walton Voltage Multiplier

The CW multiplier, originally proposed for particle acceleration [30], cascades diodes and capacitors driven by an AC source to multiply the peak input voltage without a high-turns-ratio transformer (Fig. 2). It has been used as a compact high-voltage DC source for capacitor-bank charging in a tokamak [31], as a high-gain DC-DC converter for impulse loads [32], in a transformer-less 0.1/12 kV matrix converter with low-ripple input current and reduced device stress [33], and in a transformer-less high step-up converter that avoids the impractical duty ratios of a conventional boost stage [34].

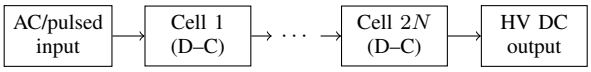

Fig. 2. Conceptual block diagram of a Cockcroft–Walton voltage multiplier. Each diode–capacitor cell transfers approximately one peak-input increment; an ideal N-stage (i.e., $2N$-cell) multiplier therefore approaches an unloaded output on the order of $2N\,V_{\mathrm{peak}}$. The practical output is lower, being reduced by load current, output ripple, and stray capacitance.

While the CW multiplier offers a modular, transformerless path to high voltage gain, its principal drawbacks for a handheld application are threefold: the number of discrete diode-capacitor cells required to reach tens of kilovolts; the increase in output impedance and voltage ripple as the cell count grows; and the absence of intrinsic galvanic isolation between the low-voltage input and the high-voltage output, unless an isolated driving stage is added beforehand. The device of Cruz et al. (2025) confirms that a CW-type ladder can nonetheless be miniaturized [27].

B. Flyback Converter

The flyback converter is a buck–boost-derived, transformer-isolated topology that stores energy in the transformer core during the switch-on interval and delivers it to the secondary during the switch-off interval. Because the transformer provides galvanic isolation by design, and a single transformer can be wound with a very high turns ratio, the flyback topology is the one most widely reported as the preferred choice for compact, low-power, high-voltage sources in electrospinning applications.

Aung et al. (2019) built a zero-voltage-switching (ZVS) flyback high-voltage supply for electrospinning, motivated by the high cost of commercial units [35]. Hapidin et al. (2017) used

a series-configuration Mazzilli ZVS flyback for needleless electrospinning [36], and Parkash et al. (2021) implemented a flyback high-voltage supply for nanofiber production [37]. Yusro and Kadarisman (2022) reported a low-cost setup with adjustable flow rate and voltage for biomedical fibers [38], while Muthi'ah et al. (2020) obtained 11–20 kV from a 12 V input with a Mazzilli ZVS driver, illustrating the high, low-cost gain of a repurposed flyback transformer [39].

Beyond electrospinning, Barsoum and Stanley (2015) found the flyback the most suitable approach for a small, simple, low-cost high-voltage supply [40]; Liu and Dong (2015) reported a 0–30 kV AC-input boost-doubler supply [41]; Manur et al. (2024) proposed a load-invariant, wireless-power-transfer high-voltage supply reaching 5 kV at 88% efficiency [42]; and Tang et al. (2017) presented a symmetric cascaded pulsed supply with reduced device voltage stress [43].

C. Comparative Discussion

Table III summarizes the trade-offs between the CW multiplier and the flyback converter for a portable, battery-powered electrospinning application.

The electrospinning-specific literature converges toward the flyback topology [35]–[39], whereas CW multipliers appear mostly in generic high-voltage or pulsed-power work [31]–[34], the wearable device of Cruz et al. showing that the CW family remains relevant when extreme miniaturization is the priority [27]. The ripple comparison in Table III is qualitative, since a rigorous one would require fixing switching frequency, load, output capacitance, control scheme, and equivalent impedance – rarely reported on a common basis. Subject to this caveat, the convergence toward the flyback, together with its inherent galvanic isolation, makes it the most frequently reported candidate for portable applications and motivates the feasibility discussion below.

VI. Feasibility of a Flyback-Based Stage: Cost, Safety, and Component Considerations

Building on the above, this section assesses – without proposing a specific design – the feasibility of a flyback stage repurposed from a cathode-ray-tube (CRT) television transformer, a strategy already reported for electrospinning [35]–[37], [39]. Such transformers are typically self-rectified: the high-voltage secondary embeds a rectifier diode and delivers pulsed DC directly, without an external multiplier. They can be energized by different switching arrangements, including single-switch converters and resonant ZVS drivers [39]. Figure 3 gives a simplified functional representation, emphasizing energy conversion and galvanic isolation rather than a particular switching topology.

From a cost and availability standpoint, CRT flybacks are discarded in considerable numbers as CRT displays are decommissioned, rendering them essentially free or very low-cost, in marked contrast with commercial high-voltage modules such as the EMCO F101 employed by Mouthuy et al. [24]. From an electrical standpoint, the flyback transformer isolates the high-voltage secondary from the low-voltage primary. Flyback

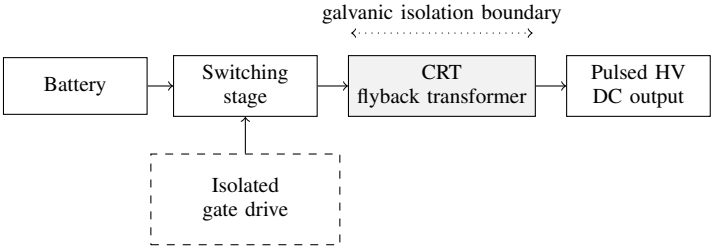

Fig. 3. Simplified functional diagram of a CRT flyback-based high-voltage stage. The switching stage is represented generically, while the transformer provides galvanic isolation between the low-voltage primary circuit and the high-voltage output.

operation can facilitate current limitation by controlling the energy transferred per switching cycle; however, the maximum output current and stored energy must be experimentally verified for each design.

Two important caveats must, however, be stated. First, galvanic isolation is a potentially safety-enhancing design feature, but it is insufficient by itself to establish suitability for clinical use. Establishing medical safety would additionally require leakage-current measurement, short-circuit-current characterization, dielectric-strength and insulation testing, and analysis of behavior under fault conditions – none of which follows automatically from the presence of an isolation transformer. Second, repurposed CRT flyback transformers may be suitable for low-cost proof-of-concept prototypes; however, their lack of traceable specifications and lot-to-lot reproducibility limits their suitability for clinical translation, which would instead call for a professionally specified and qualified high-voltage component. This absence of standardized documentation is one of the central challenges discussed in the following section.

VII. Challenges and Future Directions

Despite this convergence, several challenges remain. First, component standardization: designs relying on generic or salvaged flyback transformers lack public datasheets, so each group must bench-characterize its own units [35], [37]. Second, output regulation: low-cost flyback and CW sources typically run open-loop or with coarse duty-cycle control; closed-loop feedback on the output voltage itself – rather than the primary-side duty cycle – remains underexplored, and could exploit the critical-voltage relation of Eq. (1) to set an adaptive target per solution. Third, regulatory validation: clinical translation, as in the SpinCare™ case [25], demands leakage-current, short-circuit, and dielectric-strength testing well beyond a benchtop prototype, an area still sparsely reported. Finally, miniaturization versus output power: shrinking the HV stage and battery draw while sustaining a stable Taylor cone across solution viscosities remains an active problem for both topology families [27], [31], [42].

VIII. Conclusion

This review examined portable electrospinning devices for biomedical use along three axes: the characterization of the

TABLE III
COMPARISON OF HV TOPOLOGIES FOR PORTABLE ELECTROSPINNING.

Criterion	**Cockcroft–Walton multiplier**	**Flyback converter**
Galvanic isolation	Not inherent; requires an isolated driving stage	Inherent, provided by the transformer
Component count	Grows with the number of cells (diodes + capacitors)	Single magnetic component plus switch and driver
Cost	Low per cell, but rises with voltage target	Very low when repurposing salvaged CRT transformers
Output ripple	Application-dependent: set by switching frequency, load current, per-cell capacitance, and equivalent output impedance; tends to grow with cell count and load	Application-dependent: set by switching frequency, output capacitance, load, and control scheme; not intrinsically lower and must be evaluated per design
Reported use in electrospinning	Mostly generic HV applications [31]–[34]; miniaturized specifically in [27]	Directly reported for electrospinning [35]–[39]

resulting nanofibers and the physics of Taylor-cone jet formation; the state of the art of portable and handheld devices; and the high-voltage electronics that make them portable. While Cockcroft–Walton multipliers remain attractive for extreme miniaturization, flyback-based supplies are more frequently reported in electrospinning. Repurposed CRT flyback transformers represent a low-cost option for proof-of-concept prototyping, but their lack of traceability and reproducibility limits clinical translation. Integrating process requirements, device architectures, and power-supply constraints, we highlight the trade-offs that currently constrain clinical adoption. Galvanic isolation and low cost, though advantageous, do not by themselves establish clinical suitability; addressing component standardization, closed-loop regulation, and regulatory validation – including systematic electrical-safety testing – should guide the translation of these prototypes into clinically viable in situ applicators.

Abstract* -The Langendorff method of isolated heart perfusion is a well-established ex vivo surgical technique in cardiovascular biological and pharmacological research. However, the accuracy of clinical trials is often limited by the oscillations and variability inherent in the manual control of homeostatic parameters. This research presents the development and benchtop validation of an automation platform applied to the Langendorff method., designed to ensure the rigorous stability of critical variables during cardiac arrhythmia trials, such as atrial fibrillation. The proposed modular architecture is based on the transposition of industrial automation technologies to the laboratory environment, using a Programmable Logic Controller (PLC WEG TPW03) vertically integrated with Elipse E3 SCADA data acquisition and supervision software. The PLC operates deterministically and with low latency to control temperature and actuate peristaltic pumps and solenoid valves, managed via Ladder logic. Preliminary fluid dynamic and thermal validation tests demonstrated that the system, using on-off thermal control on the test bench, stabilized the fluid temperature at a median of 37°C (IQR = 0.10°C; σ-sigma = 0.0699°C), exhibiting statistical superiority over the manual method ($p = 4.15 \times 10^{-7}$). Thermal control via a PID loop embedded in the PLC is proposed for future implementation directly on the aortic cannula. Coronary flow was precisely regulated and maintained within the physiological range with a median of 23.5 mL/min (IQR = 0.52 mL/min; σ-sigma = 0.39 mL/min), validating the alignment of the control with the predictive allometric model for leporine specimens. Benchtop results confirm that the platform's robustness and determinism eliminate human operational errors and ensure methodological reproducibility, validating the physical-operational control infrastructure as an indispensable preparatory step for future applications in actual biological assays.

Keywords* - Laboratory automation, Langendorff system, cardiac arrhythmia, temperature control, automated perfusion, biomedical engineering, supervisory system.

I. INTRODUCTION

The isolated heart perfusion method remains a widely used approach in cardiovascular and pharmacological research [1]. Its applicability can be continuously optimized through the development of new protocols for automated monitoring systems [2]. Historically, few organ-based experiments have been as extensively utilized as the Langendorff isolated heart preparation. Initially, this technique was applied to basic cardiac biology studies; subsequently, it was adopted to test the effects of various drugs on coronary vasculature, muscle contraction, and heart rate [1]. Currently, many researchers employ this method to investigate the heart, aiming to develop new treatments that can protect it from ischemia and other forms of injury [3].

Advances in biophysical and biochemical recording techniques over recent decades have transformed the landscape of experimental research. The integration of automated acquisition and control systems enables the simultaneous monitoring of multiple parameters with high precision and reproducibility [2]. This technological leap, combined with the improved cost-effectiveness of modern systems, offsets the limitations inherent in isolated models, allowing for an in-depth analysis of complex phenomena—such as atrial fibrillation (AF)—in controlled environments.

The development of cardiac arrhythmia leads to alterations in the heart's normal rhythm affecting the atria, causing the organ to beat rapidly and irregularly rather than contracting in a coordinated fashion, which impairs efficient blood pumping [3]. The overall prevalence of AF is known to reach approximately 2.9% of the global population. Therefore, the precise identification and quantification of the mechanisms underlying the generation and maintenance of AF are essential for better stratifying the pathology and enhancing the efficacy of treatment guidelines [4].

Automation is of great importance across various sectors of society, driving significant technological advancements and improving process efficiency and reproducibility [2]. In biomedical research, it reduces the occurrence of operational errors by minimizing human factors—such as fatigue, distractions, and performance fluctuations during the workday, thereby enabling continuous, precise control of the variables involved [2].

Automation also facilitates compliance with established standards or procedures by providing detailed process records [2]. This research addresses the development of an experimental testbed for the automation of cardiovascular assays, aiming for strict control of critical variables in the study of cardiac arrhythmia. The system is based on adapting industrial automation technologies to the laboratory environment, vertically integrating a PLC with SCADA software. Using Ladder logic, the PLC operates deterministically and with low latency to control temperature and actuate peristaltic pumps and solenoid valves. In the current bench tests, reservoir temperature was maintained using a dedicated On-Off controller, with the implementation of the PID control loop directly in the PLC reserved for a later stage of development.

The proposed automation for the Langendorff-style perfusion system relies on three critical aspects: control, monitoring, and data acquisition. The system will regulate nutrient supply, volume, flow rate, and temperature during the experiment, playing a significant role in research related to cardiac arrhythmia and atrial fibrillation. Consequently, this research proposes the development and validation of an automation infrastructure for an experimental perfusion module. The objective is to measure the technological precision of the hardware and software in a controlled benchtop environment, with the understanding that this study validates the operational performance of the automated

control system, serving as a physical foundation for future biological validation in atrial fibrillation assays.

II. MATERIALS AND METHOD

A. Evaluation of Current Technology

This section contextualizes available commercial technologies and outlines the biological scenario for the platform's future application. It highlights that the experiments described involving actual rabbit hearts and complex optical/electrical mapping systems represent the methodological goal for which this system is intended. However, the scope of this research is strictly limited to benchtop validation (without the use of animals), employing water as the test fluid to verify the feasibility and precision of the automation by integrating industrial automation technologies into the laboratory environment.

The technological benchmarking encompassed the main global solutions, ranging from conventional manual architectures to high-precision integrated systems, as described below:

• Radnoti (USA): Configured as a manual glass-built platform, based on classic physiological principles. Pressure control is dependent on the hydraulic load (height of the liquid column), and thermal stability is maintained by a water bath with manual thermostatic adjustment. The system does not have integrated feedback loops or automated digital recording mechanisms.

• emka Technologies (France): Presents an integrated solution focused on software processing (IOX2) for real-time acquisition and analysis. Although it allows for protocol programming and automated switching of solutions via solenoid valves, hardware control is dependent on the software layer, lacking industrial programmable logic controllers (PLCs) or SCADA supervisory systems.

• Harvard / Hugo Sachs Elektronik (USA/Germany): Utilizes the patented S2P2C (Solid State Physiological Perfusion Circuit) technology, which replaces conventional glassware with solid Perspex blocks with machined internal channels. This architecture favors laminar flow and offers superior thermal insulation. Operational control is semi-automatic, based on the SCP (Servo Pressure Controller) module, which employs electronic feedback to switch between pressure or constant flow modes. Data acquisition is managed by the ISOHEART software, which is responsible for decoding the analog signals from the transducers and converting physical variations (such as pressure, temperature, and flow) into hemodynamic and contractility parameters in an integrated manner. Using the system's transducers, the software continuously monitors aortic perfusion pressure (PAP) and coronary flow (CF), allowing for precise assessment of vascular resistance and coronary autoregulation under constant flow or pressure regimes.

• AD Instruments (Australia): Modular platform optimized for bio acquisition, structured on Power Lab hardware and LabChart software. The system prioritizes the fidelity of the physiological signal through the direct perfusion core, which positions pressure, flow, and temperature transducers adjacent to the aortic cannula, minimizing the dead volume that could dampen the captured waves. This proximity ensures the direct recording of aortic perfusion pressure (PAP), an analog electrical signal that translates the force exerted by the fluid at the entrance of the coronary system for the calculation of vascular resistance, and coronary flow (CF), which measures in real time the volume of fluid infused into the organ per minute. Flow control is performed by the STH module, which achieves a nominal thermal accuracy between ±0.02°C and 0.05°C. However, the absence of deterministic architecture (PLC) and industrial supervision systems limits the validation of real-time statistical capability.

• A viable alternative is the implementation of the Langendorff system, using independent modules in parts, adapting to local needs for specific lines of customized research, resulting in systems with lower operational costs when compared to ready-made commercial solutions. The Heart Lab at UFABC adopted this customized development strategy for its research line. For cardiac mapping, the experimental protocol uses a rabbit heart to capture electrical and optical signals under sinus rhythm and atrial fibrillation. Invasive electrical signals are obtained directly from the epicardium using a multi-electrode array, while non-invasive signals are recorded by electrodes arranged in a hexagonal tank that simulates the impedance of the human torso. After digital filtering of these electrical signals to attenuate noise, optical signals are acquired by panoramic fluorescence using the Di-4-ANBDQPQ dye and three high-speed cameras. The integration of these data allows the projection of isopotential maps and the calculation of activation fronts and conduction velocities on the 3D geometry of the organ. Another analysis, using fast Fourier transform spectral analysis, identifies the dominant frequency, differentiating the regularity of sinus rhythm from the high spatiotemporal complexity characteristic of atrial fibrillation. The scope of this research is limited exclusively to the physical and functional validation of the automated test bench using water, serving as an indispensable preparatory step for future biological assays.

B. Specification of the new system

Comparative analysis of commercial technologies focused on the Langendorff model prioritizes the acquisition of physiological signals, presenting limitations regarding robustness and industrial determinism.

This research project presents the development of an automated experimental bench module for cardiac perfusion, based on the transposition of industrial automation concepts to the laboratory environment.

The proposed architecture is based on the vertical integration between dedicated control hardware and supervisory software. This approach ensures that the processing of critical variables occurs independently of fluctuations in the host computer's operating system.

As a result, a robust and deterministic platform is obtained, capable of ensuring the precision and reproducibility requirements necessary for the feasibility and standardization of biological assays.

The feasibility of this operational stability and the fulfillment of high scientific rigor criteria are based on five structural technological pillars:

•Industrial SCADA Architecture (Elipse E3): Implements a centralized supervision layer unprecedented in Langendorff

systems. Through an integrated Human-Machine Interface (IHM), the system provides complete parameter control, full traceability, and automated data logging in a structured environment.

•Deterministic Control via Programmable Logic Controller (PLC) model (WEG TPW03): It has 24 digital inputs and 16 outputs, a total of 40 I/O points. The use of a PLC ensures hard real-time control. This architecture eliminates computational latencies inherent in conventional acquisition software, resulting in high experimental reliability and operational stability. The PLC was programmed using Ladder logic via dedicated TPW PCLINK software, which uses relay logic with contacts and coils following the IEC 61131-3 standard[2]. It will control the operation of 5 peristaltic pumps: 1 12VDC (Voltage Common Collector) pump, operating current ranging from 0.25A to 1A, with an average flow rate greater than or equal to 70mL/min, model Kamoer NKP-DC-B10B, applied for dosages that require refined resolution of smaller volumes, due to its reduced flow dynamics, and 4 24VDC peristaltic pumps, current ranging from 3A to 5A, with an average flow rate greater than or equal to 2000 mL/min, model Watson Marlow 313 D, intended for rapid pumping of larger volumes due to their high flow rate.

- The temperature control monitoring for the proposed research was planned in two complementary stages to ensure the thermal stability of the perfusion solution, accounting for the distinction between the benchtop validation performed and future developments. The first approach for the current validation involves basic control and maintenance of the reservoir temperature (water bath) using a commercial digital controller, model XH-W3001. This device operates in a closed-loop (on-off) mode, activating a 750W electric heating element to stabilize the water bath temperature within the desired physiological range. The second approach consists of a proposal for future work to introduce thermal monitoring directly at the critical point of the circuit. For this, the proposal to be tested is to fix a waterproof DS18B20 temperature sensor directly to the aortic inlet cannula of the ex vivo organ. The signals generated by this sensor are transmitted in real time to the PLC, which executes a Proportional, Integral and Derivative (PID) control algorithm. This approach allows the system to identify and compensate for the caloric losses that occur along the fluid path between the reservoir and the heart, ensuring that the nutrient solution reaches the myocardial tissue at the ideal physiological temperature and free from oscillations.

- Statistical Validation: The project introduces statistical analysis to verify the quality of the process. Measuring temperature and flow parameters. These indices attest that the process is statistically capable and controlled, increasing the scientific rigor and reproducibility of the tests. The Figure below shows the Langendorff proposed system.

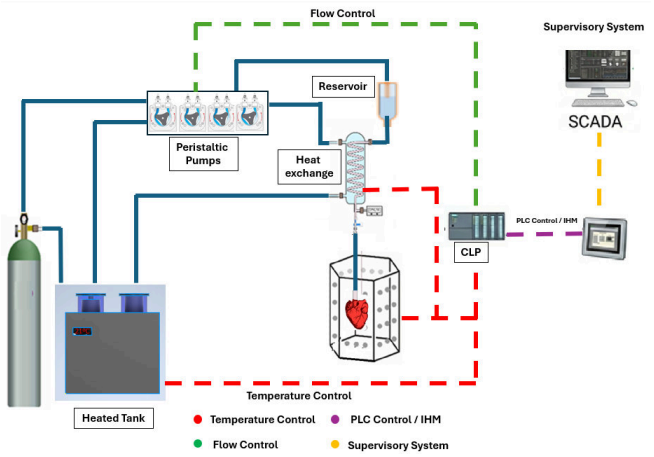

Fig. 1. Architecture of the automated experimental perfusion system

C. Development and validation

Platform validation was conducted on the benchtop by physically simulating the dynamic variables of the perfusion process—temperature, volume, and flow rate—using water as the test fluid. The testing focused strictly on the functional and thermo-fluid-dynamic verification of the automation system (PLC/SCADA), serving as a preparatory step prior to biological or hemodynamic validation using the isolated-organ Langendorff model.

The peristaltic pump drives, sized for the automated delivery of nutrients and medications, were validated using water as the test fluid. This enabled an assessment of the automated multivariable control of the fluidic circuit, ensuring the stability and precision required for the subsequent application of the protocol in biological assays.

The design of the benchtop tests was based on the hemodynamic and thermal parameters standardized by Dhein [5] for the ex vivo experimental model using rabbits, which typically has an average weight of 1.6kg and a cardiac mass between 8 and 9 g. Under these biological conditions, the reference coronary flow (CF) has an operating range of 22 to 25mL/min according to Dhein[5]. Perfusion pressure acts as an indirect indicator of coronary vascular resistance. To ensure experimental accuracy, coronary flow must be normalized as a function of cardiac mass, as demonstrated by the equation below[6]. This equation can be used to adjust the correct flow.

$$CF = 7.43 \times HW^{0.56} \quad (1)$$

Where CF represents the ideal coronary flow (mL/min) and HW corresponds to the heart mass (g). Applying the above equation and considering three different masses: 8.0g, 8.5g and 9.0g, we obtain the respectively CF as presented in Figure below. Allowing to obtain the linear allometric curve validation for CF.

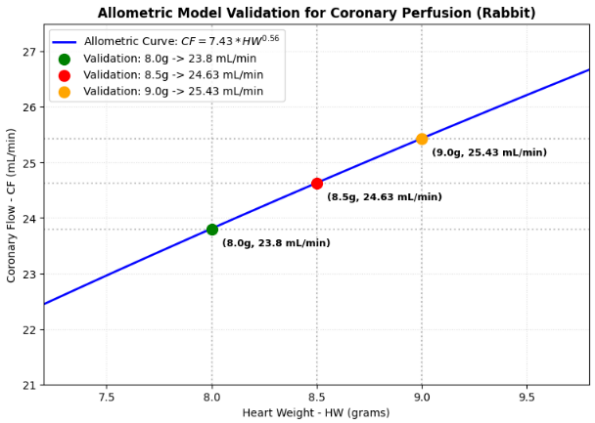

Fig. 2. Validation curve of the allometric model for determining ideal coronary flow as a function of weight

Under these biological conditions, the reference CF recommended in the literature presents a baseline operating range of 22 to 25mL/min[6], which validates the alignment of the mathematical model with the physiological behavior of the organ.

D. Methodology / test procedures

The validation of the automated dosing system was divided into three distinct, sequential and complementary phases, isolating the mechanical factors from the thermodynamic ones:

1) Volumetric and flow calibration tests of the peristaltic pumps: To conduct the tests, it is necessary to perform volumetric and flow rate calibration of the pumps. This test is carried out to evaluate mechanical precision. The repeatability of the obtained data formed the basis for the timing calculations and the parameterization of the counting blocks within the PLC logic.

Purging and Homogenization Procedure: Before starting any series of measurements, the purging cycle is manually activated using physical pushbuttons integrated into the control panel. This procedure ensured the complete elimination of residual air bubbles in the lines and the homogeneous filling of the flexible hoses, mitigating measurement errors. With the aid of graduated beaker to receive the liquid, the quantity in mL to be discarded was observed.

Low Flow Protocol for Kamoer NKP-DC-B10B 12VDC Microdosing Peristaltic Pump: The actuator was continuously activated to measure the time required to reach the fixed volume of 50mL, the graduated value found and noted on the beaker. The test was replicated 50 consecutive times to mitigate random errors. The time taken was recorded using a digital stopwatch, achieving an average of 31.25s. To calculate the flow rate (Q – mL/min), volume (V – mL) over time (t – s), the following flow rate formula was applied:

$$Q = V / t \quad (2)$$

Resulting in Q = 1.6mL/s or 96mL/min (average of readings)

Due to its high resolution and precision in small volumes, this actuator was indexed in the PLC logic for the controlled infusion of concentrated drugs and nutrients. Water was used in this test.

• High Flow Rate Protocol using a Watson Marlow 313 D 24VDC Main Circuit peristaltic pump: the same procedure as the first pump was performed, repeating the sampling for 50 consecutive repetitions with the same target volume (50mL). The average filling time is 1.88 s, and the resulting Q = 26.5 mL/s or 1590mL/min (average of readings).

2) Fluid Thermal Control and Stability Test (Water Bath): Once the mechanical flow rates were calibrated and validated, an independent protocol was implemented to evaluate the thermodynamic behavior of the system, focusing on heat exchange capacity and fluid stabilization at the target physiological temperature of 38°C (critical parameter established by Dhein[5][8] for the ex vivo rabbit model).

Procedure: The four circular glass reservoirs containing water with were immersed in a water bath inside a reservoir simulating different nutrients. The power electrical circuit consists of a 750W tubular electric resistance driven by a 127VAC industrial electromechanical contactor, its switching managed by a model XH-W3001 digital temperature controller. Continuous monitoring of the fluid temperature is performed by means of a sensor coupled to the controller as an RTD (resistance temperature detector) thermocouple. The controller compares the measured temperature with the desired temperature (setpoint) which is pre-defined at 38.5°C. With the temperature set in the controller, the contactor will be activated only when the controller determines that its output should be turned on, switching a supply voltage to activate the contactor, thus turning on the resistance. As soon as the temperature reaches 38.5°C, the controller determines that its output should be switched off, opening the contactor contacts and switching off the electrical resistance.

Monitoring: Temporal data were collected from the fluid at ambient temperature until it reached the setpoint of 37°C to 39°C, so that an average of 38°C was maintained, with the temperature adjusted for the process. The data was collected by activating the low-flow microdosing peristaltic pump, measuring the temperature with a Vonder brand portable digital probe thermometer with a temperature range of -50°C to 300°C, taking 50 samples directly in the beaker for reading. The temperature control system took 40 minutes to reach a temperature of 40°C, adjusting its temperature, and then it stabilized at 39°C at its setpoint.

3) Testing of systemic integration and reproducibility tests (PLC-IHM): The test can evaluate the reliability of the closed automation loop, the integration of the PLC with the supervisory system.

Procedure: Through the interface developed in the Easy Builder Pro software installed on the IHM, you can operate by inserting random and standardized volumetric values for each operational test of the peristaltic pumps, carrying out operational tests of the peristaltic pumps. The PLC processed the input volumes, internally converted the signals using the previously calculated flow constants 1.6 mL/s and 26.5 mL/s and activated the respective digital outputs to drive the pumps.

Measurement: The final volumes collected at the output of the automated system were checked in a graduated beaker

to perform the measurement in mL at a temperature established above.

In terms of thermal performance, the literature shows that the Krebs-Henseleit solution (perfusion) must reach the cranial portion of the aorta while maintaining a strict temperature of 37°C. Since thermal losses along the fluid circuit require the solution to be pre-heated indirectly in a water bath, adjusted between 41.5°C and 42°C, continuous monitoring at the aortic cannula inlet is mandatory. This approach is being developed with the aim of introducing thermal monitoring directly at the critical point of the fluid circuit to be tested using a waterproof DS18B20 temperature sensor directly on the aortic inlet cannula of the heart. The signals generated by this sensor will be transmitted in real time to the PLC, which executes a PID control algorithm. This approach will allow the system to identify and compensate for the caloric losses that occur along the fluid's path between the reservoir and the heart, ensuring that the nutrient solution reaches the myocardial tissue at the ideal physiological temperature and free from fluctuations.

The operating interface and experiment management were centralized in an IHM, developed specifically for monitoring process variables under the Elipse E3 SCADA platform. This system integrated the functions of supervision, control, and data acquisition, working together with the PLC to manage the dosing routines and thermal control of the assay in a coordinated manner.

E. Statistical Analysis and Experimental Validation

Validation of the automated system was carried out through benchtop tests, reproducing operational parameters in a controlled manner and without the presence of animals. The trials were divided into two constituent groups: the control group, operated via manual method, and the experimental group, conducted by the automated system. To ensure statistical robustness, a sample of 50 readings per group (n=50) was adopted, allowing a comparative analysis between the two groups.

The processing and statistical analysis of experimental data were carried out using a dedicated Python program, simulated on Google Collab.

Initially, data distribution was assessed using the Shapiro-Wilk normality test. To confirm whether thermal and hemodynamic variability follows the Gaussian distribution. The criterion was the value of $p>0.05$, which validated or applied parametric tests, thereby ensuring that the system operates in a predictable and controlled manner.

Once the normality of the data was confirmed ($p>0.05$), one-way analysis of variance (ANOVA) was applied to Compare the means and variability between the control and experimental groups.

To assess stability over a given period, repeated measures ANOVA were used, comparing readings at different time intervals (T1, T2, T3), where the null hypothesis (H0: $p>0.05$) indicates the maintenance of system stability[8].

The boxplot graph used the median as the central line; the value divides the data set in half. In the body of the boxplot, it is delimited by the 1st Quartile (Q1-25%) at the base and the 3rd Quartile (Q3-75%) at the top.

III. RESULTS AND DISCUSSION

A. Thermal Monitoring and Control

The thermal monitoring analysis was performed in real time and continuously, ensuring the variable was maintained within an operating range between 36.5°C and 37.5°C.

The statistical analyses, performed in a Python environment, consolidated the system's performance metrics. The boxplot diagram presented in figure below shows the comparative accuracy profile between the control and experimental groups, highlighting the marked reduction in data dispersion obtained through the automated system[8].

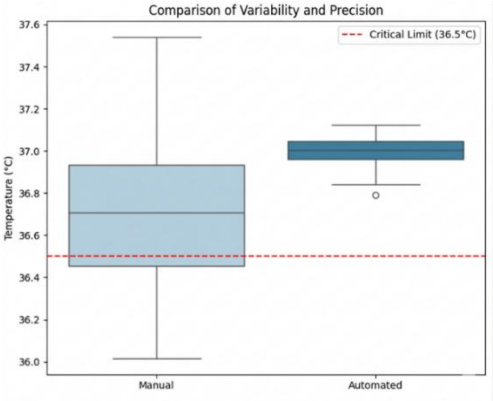

Fig. 3 - Statistical analysis of experimental temperature data

The experimental data measured for the automated method confirmed temperature stabilization at a median of 37°C, with an interquartile range (IQR) of 0.10°C. This narrow dispersion reflects the concentration of 50% of the central readings, with a standard deviation of 0.0699°C. The Gaussian distribution was validated by the normality test ($p = 0.2616$). The analysis of variance (ANOVA) confirmed the statistical distinction between the manual and automated methods ($p = 4.15 \times 10^{-7}$), while the temporal stability test ($p = 0.7172$) demonstrated the absence of drift in the system over time.

B. Coronary Flow Monitoring and Control

To ensure accuracy in perfusion control, the automated system operates under a control loop to maintain coronary flow between 22 and 25mL/min.

To validate the efficiency of the automated system, a lower specification limit (LSL) of 21mL/min was established, a level below which myocardial oxygenation becomes insufficient, and an upper specification limit (USL) of 26mL/min to prevent the risk of endothelial injury and edema formation. The system's operating point was set at 23.5mL/min, aiming to guarantee ideal stability for the experimental model.

Statistical analyses of the experimental data, processed in Python, consolidated the performance metrics presented in the box plot in the figure below, highlighting the precision comparison between the control and experimental groups and emphasizing the lower dispersion in the automated system [8].

Analysis of the measured experimental flow revealed a normal distribution of readings, validated by the normality test ($p = 0.742$). The system achieved stabilization within the desired central range, with a median of 23.5mL/min, an interquartile range (IQR) of 0.52mL/min, and a standard deviation of 0.39mL/min, demonstrating high precision in volumetric delivery. Analysis of variance (ANOVA) confirmed a statistically significant difference compared to the manual method ($p < 0.0001$).

Regarding temporal behavior, repeated-measures ANOVA confirmed overall baseline stability over extended periods ($p > 0.05$), demonstrating the absence of long-term operational drift. However, high-temporal-resolution analyses detected short-term transient fluctuations ($p < 0.05$) attributable to the intrinsic pulsatile dynamics of the peristaltic pumping mechanism.

Although these transient oscillations remain within acceptable physiological limits (lower and upper physiological limits), their identification provides a clear rationale for future system refinements, such as the implementation of pulsation dampeners and continuous closed-loop control algorithms.

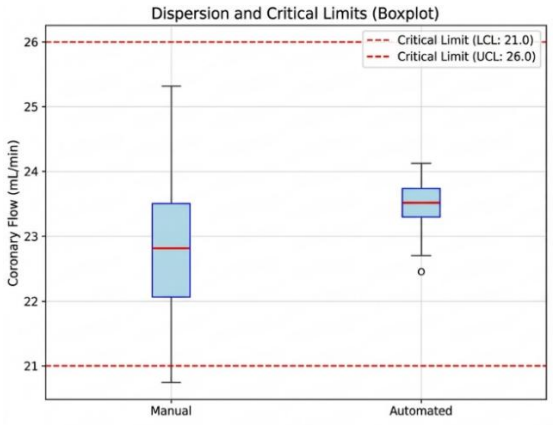

Fig. 4 - Statistical analysis of experimental flow data

The preliminary bench tests carried out can prove the feasibility of applying industrial automation concepts to the Langendorff system. The separation between the SCADA supervision layer (Elipse E3) and the real-time control executed by the PLC eliminated computational latencies typical of general-purpose operating systems. In fluid dynamics, the automated dosing routines and multivariable control ensured precision in the volumetric calibration of the peristaltic pumps.

In thermal control, the automated system stabilized the temperature of the solutions with Gaussian behavior and low dispersion (IQR = 0.10ºC and sigma(σ) = 0.0699ºC), showing statistical superiority over the manual method ($p = 4.15 \times 10^{-7}$). However, although coronary flow showed a significant reduction in variability compared to manual management, fluid dynamics revealed transient fluctuations and temporal instability ($p < 0.05$).

These results indicate the need for future refinement through dedicated continuous control algorithms and validate the proposal to integrate a thermal sensor directly into the aortic inlet cannula to mitigate caloric losses in the circuit. The developed platform establishes itself as a highly deterministic, reproducible, and low-cost alternative, offering cardiovascular research a robust tool for the standardization of ex vivo assays.

Therefore, benchtop tests were parameterized to reproduce this critical scenario, evaluating the ability of the PID algorithm embedded in the PLC to mitigate the ambient thermal gradient and maintain the target of 37°C at the aortic inlet under the stipulated flow rates (22 to 25mL/min).

The operation interface and experiment management were centralized in a Human-Machine Interface (HMI) developed specifically to monitor process variations within the Elipse E3 SCADA platform. This system integrates supervision, control, and data acquisition functions, working in conjunction with the PLC to coordinate the management of dosing routines and thermal control during the test.

IV. CONCLUSION

This study presents a review of major Langendorff systems, highlighting their key advantages and disadvantages. Based on this survey, a new system is proposed that utilizes a deterministic architecture based on a Programmable Logic Controller (WEG TPW03 PLC) integrated with Elipse E3 SCADA supervisory software.

This configuration enables greater precision and reproducibility in controlling critical ex vivo perfusion variables, eliminating the computational latencies inherent in commercial platforms that rely on conventional operating systems. As an initial validation, bench tests were conducted to confirm the efficiency of the industrial automation platform when applied to a laboratory setting; results demonstrated superior thermal and fluid-dynamic stability and a significant reduction in parameter variance compared to manual operation.

Volumetric calibration tests validated the precision of the peristaltic pumps against the allometric model for rabbit hearts. Thermodynamic control of the setup—operating in an on-off mode via secondary hardware—stabilized the temperature with low dispersion (IQR = 0.10°C and sigma-σ = 0.0699°C), demonstrating statistical superiority over the manual method ($p = 4.15 \times 10^{-7}$). Although coronary flow control reduced overall variability ($p < 0.0001$), the identification of transient fluctuations informs future developments in the Langendorff system's automation design; these plans include implementing a PID algorithm linked to a DS18B20 sensor placed directly on the aortic cannula to mitigate heat loss.

Thus, the platform establishes itself as a high-fidelity, low-cost automation solution for rigorous variable control, fully validated in both physical and technological terms to support—in future stages—complex biological protocols involving physiological signal acquisition and optical/electrical mapping.

CONFLICT OF INTEREST

There is no conflict of interest; this study simply presents a more reliable response to existing treatments, improving their accuracy.

ABSTRACT

Ultrasound phantoms require materials with acoustic properties close to those of the target tissues. This study characterized the speed of sound (SoS) in six plastisol specimens, three Soft and three Ultra. Twenty readings per specimen were obtained using through-transmission at 1 MHz. The analysis included descriptive statistics, Type A uncertainty evaluation, nested ANOVA, and Welch's t-test on specimen averages. The average SoS was 1602.34 m/s for Soft and 1473.05 m/s for Ultra. ANOVA detected no difference between formulations ($p = 0.142$), but provided evidence of variability among specimens within formulations ($p < 0.001$). The average SoS values for Soft and Ultra were numerically close to reference values for non-adipose and adipose tissues, respectively. Between-specimen variability and the small number of specimens limit generalizability and comprehensive uncertainty evaluation. The findings provide an exploratory characterization and inform the standardization of fabrication and measurement procedures for phantom applications.

Keywords - plastisol, ultrasound phantom, speed of sound, measurement uncertainty.

I. INTRODUCTION

Ultrasound phantoms are physical models used in the development, calibration, and evaluation of ultrasound systems, enabling controlled testing without exposing patients. For these purposes, a tissue-mimicking material must have acoustic properties consistent with those of the target tissue and sufficient stability to yield reproducible results [1]–[4].

The speed of sound affects time of flight (ToF) and the spatial localization of reconstructed interfaces. Its value depends on the properties of the medium and the measurement conditions; experimental characterization therefore requires careful comparison with biological tissue reference values [5], [6].

Ultrasound imaging systems calculate depth using an assumed speed of sound. A discrepancy between the actual and assumed speeds can cause axial scaling errors and affect focusing. Matching the speed of sound in a phantom to that of the represented tissue is therefore relevant to both geometric fidelity and equipment performance assessment [1], [3].

Plastisol, a dispersion of polyvinyl chloride particles in plasticizers, can be processed to achieve different degrees of flexibility and molded into various geometries. These features support its investigation as a material produced in Brazil for phantom fabrication [2], [4], [7]. Its use requires assessing both the dispersion of readings and the consistency of results across specimens.

This study aimed to characterize the SoS of Soft and Ultra formulations, estimate variability within and between specimens, and compare their average SoS values with biological tissue references.

II. THEORETICAL BACKGROUND

A. Speed of sound in tissues and tissue-mimicking materials

The speed of sound depends on the relationship between the elastic properties and density of the medium. In soft tissues, differences in water, lipid, protein, and collagen content give rise to characteristic ranges: lipid-rich tissues tend to have lower speeds, whereas tissues with higher protein or connective tissue content exhibit higher values [5], [6].

SoS depends jointly on density and the elastic properties of the medium. Flexibility alone does not determine longitudinal wave speed. Differences between formulations or specimens therefore cannot be attributed solely to density or flexibility without additional measurements [4]–[6].

Biological tissue references were used for descriptive comparison, accounting for differences in temperature, measurement method, and specimen preparation, without assuming that these references are free of uncertainty [5], [6].

B. Plastisol for phantom fabrication

Plasticized PVC materials combine flexibility with ease of molding. Formulation, homogenization, heating, bubbles, and cooling can affect their properties [4], [7]. Comparisons across specimens must also consider potential contributions from the measurement procedure.

Numerical proximity in SoS is an initial consideration when evaluating a tissue-mimicking material. Attenuation, acoustic impedance, backscattering, homogeneity, and temporal stability also influence phantom response; SoS alone does not establish acoustic equivalence with a tissue [3], [4].

III. MATERIALS AND METHODS

A. Study design and specimens

Three Soft specimens (S1–S3) and three Ultra specimens (U1–U3) were evaluated, with 20 thickness readings and 20 SoS readings per specimen. The specimen was the unit of comparison between formulations, and readings were treated as observations within each specimen. Inference between formulations assumes independent preparations. A fabrication batch effect was not estimated separately.

B. Fabrication

Approximately 100 g portions of plastisol were weighed using an Adventurer ARA520 balance (Ohaus, Brazil), homogenized for 30 min, and placed in a desiccator for 30 min. Microwave (Philco, model PM023E/127V) heating was performed at the 50% power setting, with an initial 90 s cycle followed by a 40 s cycle and, when necessary, a 15 s cycle. Heating was stopped near 150 °C to avoid signs of degradation; the material was then poured into molds and cooled.

Heating in successive cycles allowed the temperature to be monitored. For Soft, the additional 15 s cycle was used when necessary; for Ultra, the temperature limit was reached after the 40 s cycle. The formulations were processed separately, following the sequence of weighing, homogenization, bubble removal, heating, and cooling. Figure 1 identifies the six specimens evaluated.

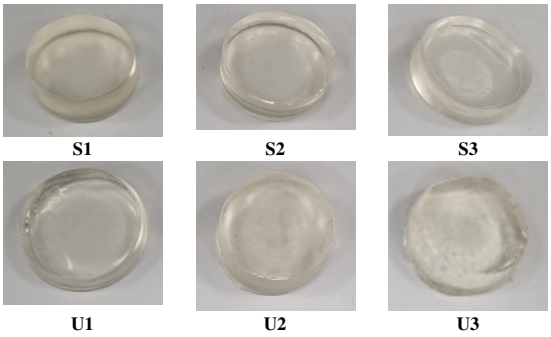

Figure 1 - Soft (S1–S3) and Ultra (U1–U3) plastisol specimens.

C. Thickness and speed of sound measurements

Thickness was measured using a 500-172-30B digital caliper (Mitutoyo, Brazil). Acoustic measurements were performed at the Ultrasound Laboratory of COPPE/UFRJ in a glass tank containing distilled water, with temperature monitored near 24 °C. The setup comprised an AFG3021 signal generator (Tektronix), a 200 MHz WaveSurfer 3024 oscilloscope (Teledyne LeCroy), two 1 MHz Panametrics/Olympus transducers with a 0.70–1.30 MHz frequency band, and an MTH-1362W thermometer (Minipa).

Thickness readings were taken to represent dimensional variations within each specimen. During acoustic acquisitions, the transducers were aligned on opposite faces and kept in contact with the material. Bath temperature was monitored throughout the experimental sequence. The effect of contact pressure on thickness was not quantified.

Excitation consisted of a five-cycle sinusoidal burst at 1 MHz and 10 Vpp. The received signal was recorded on the oscilloscope and processed in LabVIEW with the standard substitution method [2]. The designation v_{PD} refers to SoS obtained along the direct path between the transducers; PD derives from the Portuguese term *percurso direto* (direct path). The internal equations and documentation of the ToF estimation algorithm, delay compensation, and use of thickness readings in the calculation are unavailable. No specific arrival-time detection method is therefore attributed to the routine. The analysis used the available SoS outputs, without reprocessing the signals. Figure 2 shows the through-transmission setup.

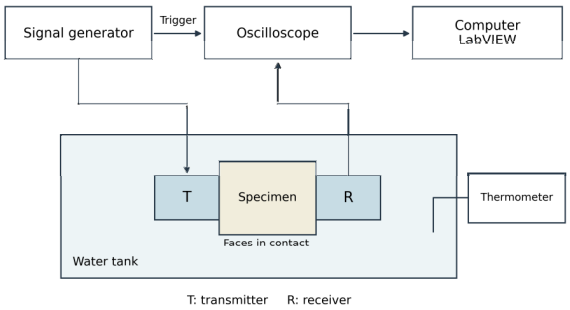

Figure 2 - Through-transmission setup. Adapted from Maggi [2].

D. Statistical analysis and uncertainty evaluation

For each specimen, the average, standard deviation (SD), coefficient of variation (CV), minimum, and maximum were calculated, and the Shapiro-Wilk test was applied to the readings. The Type A standard uncertainty of the average and the corresponding expanded uncertainty were estimated as [8]:

$$u_A = \frac{s}{\sqrt{n}};\ U_{95,A} = t_{0.975;\,n-1} \times u_A.$$

Here, s is the SD and n is the number of observations. For 20 readings, ν = 19 and k = 2.093. For the average across three specimens, the SD of specimen averages was divided by √3, with ν = 2 and k = 4.303. The 95% confidence intervals (95% CIs) rely on the t-distribution and independent observations at the relevant level; their coverage is approximate when these assumptions are not met.

The estimates u_A and $U_{95,A}$ describe the statistical contribution at the level analyzed. They do not constitute a complete uncertainty budget: calibration and resolution, thickness and its potentially shared contribution across readings, temperature, coupling, and internal processing were not fully evaluated. The lack of documentation for the routine prevents reconstruction of input uncertainty propagation. The uncertainty of the average across specimens also does not describe the dispersion expected for a future specimen.

Nested ANOVA was applied with material as a fixed effect and specimen nested within material as a random effect. Each variance term was calculated as the sum of squares divided by its degrees of freedom (SS/df). The material test used the specimen(material) term as its denominator; the between-specimen test used the within-specimen term. Welch's t-test on the three specimen averages per formulation was used as a sensitivity analysis for unequal variances. The results are exploratory because of the small number of specimens and limited assessment of assumptions; specimen-level Shapiro–Wilk tests do not assess normality of the between-specimen effects. Variance components were estimated from the ANOVA variance terms separately for each material. The intraclass correlation coefficient (ICC) was calculated as the ratio of between-specimen variance to total estimated variance. The significance level was α = 0.05.

Comparison with the values compiled by Mast [5] used difference magnitudes: $D = |\overline{c} - c_{ref}|$ and $D_{rel} = 100 \times \frac{D}{c_{ref}}$. No equivalence testing or statistical inference against tissue values was performed because the references are point values. Mass, volume, and density were not measured systematically before and after fabrication; their contributions to SoS could not be isolated.

IV. RESULTS

A. Descriptive statistics and within-specimen dispersion

Specimen averages ranged from 1410.49 to 1667.03 m/s, and CVs ranged from 1.28% to 3.99%. S2 had the greatest dispersion (SD = 63.19 m/s; CV = 3.99%), which is relevant to applications requiring precise SoS values. CVs were below 2.3% for the other specimens. The Shapiro–Wilk test indicated a departure from normality for S2 (W = 0.881; p = 0.018); failure to reject normality for the other specimens does not establish a normal distribution. Table I summarizes the 20 SoS readings for each specimen.

Table I - Descriptive statistics of SoS by specimen

ID	CV (%)	Average ± SD (m/s)	Min.–max. (m/s)
S1	1.28	1667.03 ± 21.28	1629.42–1698.49
S2	3.99	1582.55 ± 63.19	1467.19–1667.03
S3	1.33	1557.44 ± 20.69	1515.03–1593.57
U1	1.64	1598.00 ± 26.13	1551.49–1656.52
U2	1.91	1410.49 ± 26.87	1369.43–1471.69
U3	2.28	1410.64 ± 32.11	1349.26–1459.91

Note: 20 readings per specimen. S = Soft; U = Ultra; SD = standard deviation; CV = coefficient of variation.

Table II presents the Type A uncertainty evaluation for each specimen average and the corresponding 95% CI.

Table II - Type A uncertainty evaluation by specimen

ID	u_A	$U_{95,A}$	95% CI of average
S1	4.76	9.96	1657.07–1676.99
S2	14.13	29.57	1552.98–1612.12
S3	4.63	9.69	1547.75–1567.12
U1	5.84	12.23	1585.77–1610.23
U2	6.01	12.58	1397.92–1423.07
U3	7.18	15.03	1395.62–1425.67

Note: values in m/s; u_A = Type A standard uncertainty; $U_{95,A} = k \cdot u_A$, with k = 2.093 and v = 19. CIs are based on t; coverage is approximate for S2.

B. Comparison between materials and variance components

The average SoS of the Soft specimens was 1602.34 m/s, compared with 1473.05 m/s for the Ultra specimens. The Soft − Ultra difference was 129.30 m/s, equivalent to 8.78% of the average SoS of the Ultra specimens. Dispersion among specimen averages was greater for Ultra.

At the specimen level, $U_{95,A}$ ranged from 9.69 to 29.57 m/s for Soft and from 12.23 to 15.03 m/s for Ultra. For the average across three specimens, it was 142.63 m/s and 268.82 m/s, respectively. The increase reflects between-specimen variability and the larger t-factor associated with only two degrees of freedom. Table III summarizes the averages for each formulation, using specimens as the units of analysis.

Table III - Average SoS and dispersion of specimen averages

Material	Average ± SD	u_A	95% CI of average
Soft	1602.34 ± 57.42	33.15	1459.71–1744.97
Ultra	1473.05 ± 108.21	62.48	1204.23–1741.86

Note: three specimens per material. SD = standard deviation of specimen averages; u_A = SD/√3. Values in m/s; 95% CIs use k = 4.303 and v = 2.

ANOVA detected no material effect [F(1,4) = 3.342; p = 0.142], but provided evidence of variability among specimens within formulations [F(4,114) = 123.175; p < 0.001]. Welch's test yielded a consistent result [t(3.04) = 1.828; p = 0.164], with a 95% CI for the Soft − Ultra difference from −93.98 to 352.57 m/s. Inclusion of zero does not establish equivalence between formulations. Table IV presents the nested ANOVA results.

Table IV - Nested ANOVA of SoS

Source	df	SS	SS/df	F; p
Material	1	501522	501522	3.342; 0.142
Specimen (material)	4	600261	150065	123.175; < 0.001
Within specimen	114	138888	1218	—

Note: df = degrees of freedom; SS = sum of squares; SS and SS/df are in (m/s)². F and p are dimensionless.

The between-specimen component accounted for 66.4% of the estimated variance in Soft and 93.5% in Ultra. These percentages locate variability within the experimental design but do not distinguish fabrication effects from measurement contributions that persist within each specimen.

Table V presents the variance components for each material as SDs and their relative contributions. ICC is dimensionless and does not represent measurement accuracy.

Table V - Variability components and ICC

Component	Soft	Ultra
Between-specimen SD (m/s)	56.70	108.03
Within-specimen SD (m/s)	40.31	28.50
Between-specimen variance (%)	66.4	93.5
Within-specimen variance (%)	33.6	6.5
ICC (dimensionless)	0.664	0.935

Note: component SDs are in m/s; percentages refer to total estimated variance. The between-specimen SD is derived after subtracting the within-specimen contribution from the variance of specimen averages and therefore differs from the SD in Table III.

C. Comparison with biological tissues

For Soft, the smallest absolute relative differences were found for liver (0.46%), connective tissue (0.66%), skin (0.78%), and skeletal muscle (1.41%). For Ultra, they were found for fat (0.33%) and adipose tissue (1.59%).

Table VI compares formulation averages with human tissue references using absolute differences and absolute relative differences.

Table VI - Absolute differences from tissue reference values

Tissue	c_{ref}	Soft D; D_{rel}	Ultra D; D_{rel}
Adipose tissue	1450	152.34; 10.51	23.05; 1.59
Fat	1478	124.34; 8.41	4.95; 0.33
Breast	1510	92.34; 6.12	36.95; 2.45
Skeletal muscle	1580	22.34; 1.41	106.95; 6.77
Liver	1595	7.34; 0.46	121.95; 7.65
Connective tissue	1613	10.66; 0.66	139.95; 8.68
Skin	1615	12.66; 0.78	141.95; 8.79

Note: c_{ref} is in m/s; D = absolute difference in m/s; D_{rel} = 100D/c_{ref}, in %. Values from Mast [5]. "Fat" and "adipose tissue" retain the fat and adipose entries drawn from different sources in that compilation.

V. DISCUSSION

The average SoS values for Soft were numerically close to reference values for non-adipose tissues, whereas those for Ultra were close to adipose tissue references. This descriptive comparison guides further investigation of the materials but does not establish equivalence or demonstrate that flexibility determines SoS.

A formulation average does not guarantee the suitability of each specimen. For Ultra, U1 had an average SoS of 1598.00 m/s, whereas U2 and U3 had averages of 1410.49 and 1410.64 m/s. The proximity of the group average to the fat reference must therefore be considered alongside between-specimen dispersion. Furthermore, the references compiled by Mast [5] include tissue speeds measured at 37 °C or *in vivo*, whereas plastisol was measured near 24 °C; no temperature correction was applied.

The numerical difference between formulations was not statistically resolved, given the between-specimen variability and small number of specimens. The analysis accounted for readings nested within specimens, but generalizability depends on independent preparations and the model assumptions. A larger between-specimen variance component does not establish that fabrication caused the observed differences.

The greater dispersion in S2 is consistent with a possible contribution from limited repeatability of the procedure, including coupling, alignment, and ToF estimation. This explanation remains a hypothesis because the data do not distinguish these contributions from spatial variations in the material. Dispersion was therefore described quantitatively, without assigning a qualitative magnitude category. S2 was retained in the analysis, with its SD and Type A contribution explicitly reported.

Repeated readings quantify observed dispersion but do not reveal potential shared biases. The results characterize the outputs obtained under the study conditions; they do not constitute independent metrological validation of the routine or estimates supported by a complete uncertainty budget.

The absence of systematic mass, volume, and density measurements limits interpretation of effects. Future studies should include independently prepared batches, multiple specimens per batch, mass, volume, and density measurements at defined fabrication stages, local thickness measurements, and repeated acquisitions at defined positions. The ToF routine should also be documented and verified against an appropriate reference.

Such a design would allow the effects of formulation, batch, and measurement procedure to be distinguished more precisely. Characterization of other acoustic properties and temporal stability would complement the assessment of the materials for phantom applications.

VI. CONCLUSION

The Soft and Ultra specimens had average SoS values of 1602.34 and 1473.05 m/s, respectively, with no statistically detected difference between formulations. The between-specimen variance component predominated. Comparison with tissue references identified numerical proximities useful for initial material selection, without establishing equivalence or the suitability of each specimen. S2 dispersion was incorporated into the analysis; limited repeatability is a possible explanation, not a demonstrated cause. The findings inform the standardization of fabrication and measurement procedures and future validation of the materials and measurement procedure.

***Abstract*—**
Lab automation is increasing, improving efficiency, traceability and remote experimentation, however it is unevenly accessible. Small and medium labs support themselves on open-source 3D printed equipment for reliability and customization.
3D printing for liquid handling automation has a crucial challenge, removing leakage to get an electronically controlled micropipette to work.
This work proposes a model apt for the automated manipulation of cell cultures through 3D printing assisted by uncomplicated heat treatments.
To read volumes in microliters, digital imaging is used and the results show a reliable new open-source tool for micrometric volume control in labs.

Keywords*— *Automation, 3D printing, Biomaterials, Micropipette, Liquid Handler.

I. Introduction

Lab automation is the next step for improving efficiency and traceability, mainly used in North America, Europe and Asia while efforts in the rest of the world represent only 7% of the industry [1] Fig. 1.

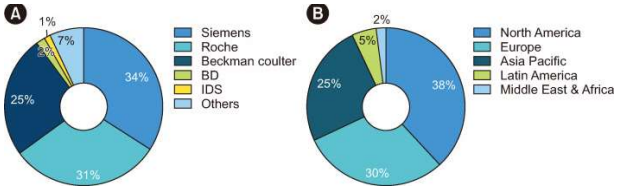

Fig. 1. Cake graphs for world distribution of the lab automation industry.

This disparity is more noticeable in public institutions and small enterprises, where technological adoption has the most resistance, even though these sectors are a potential customer base [1].

DIY (do it yourself) manufacturing allows smaller research teams to adopt and customize current technologies while still allowing replicability and automation due to the considerable number of labs adopting a similar methodology [2].

3D (three dimensional) printing is a promising technology that could allow us to create lab equipment to be shared globally [3].

During this work, 3D printers also served as a model of study for the adoption of an emerging technology fostering scientific work.

Liquid handling automation for lab use began developing at the start of the century and its usage in research doubled following the 2019 pandemic [4].

However, there is a gap in current research regarding standardization and flexible 3D printable designs, as the current devices use proprietary technology or require manual swapping of handheld universal micropipettes as will be shown in the current designs section.

This work intends to serve as the base for an automated 3D cell culture system; however, it is of widespread use for precise liquid management in any science project.

The result is the creation of an electronically controlled printable 3D micropipette using disposable syringes and stepper motors in contrast with current models to improve accessibility and maintain repeatability.

In this work we will:

1. Study current proposals for lab automation regarding pipetting (Sec. II).
2. Determine the optimal polymers and manufacturing processes (Sec. III).
3. Formulate a mathematical model for the micropipette (Sec. IV).
4. Create an electronically controlled micropipette prototype (Sec. V).
5. Design a replicable test to evaluate the micropipette's performance (Sec. VI).
6. Evaluate the pipette's performance for its adoption in lab environment and future uses (Sec. VII)

II. Current Designs

Every author mentioned in this section successfully solved a problem they encountered and designed ingenuous models for their specific use.

The goal of studying them in this work is to focus on their strengths to create a general micropipette that could spread lab automation adoption.

Current solutions can be divided into two groups, the ones that utilize manual micropipettes [5], [6] and the ones that implement proprietary volume control tools [7]-[11].

Using manual micropipettes presents a challenge to automation, because human intervention is needed to adjust precise volumes. Whilst proprietary volume control tools complicate widespread adoption by decreasing availability and repairability [12].

A. Manual pipette automation

The idea behind these models is to create a platform capable of moving a micropipette to pre-established coordinates triggering the pipette to suction or deposit a manually fixed volume, making repetitive tasks easier [5].

Another popular approach is adapting more familiar and available technologies, such as 3D printing and manual pipettes to automate liquid handling tasks [6]. Fig 2.

These modes enable replicability and take advantage of preexisting standardization, fostering open-source usage [12].

CBEB ©2026 IEEE

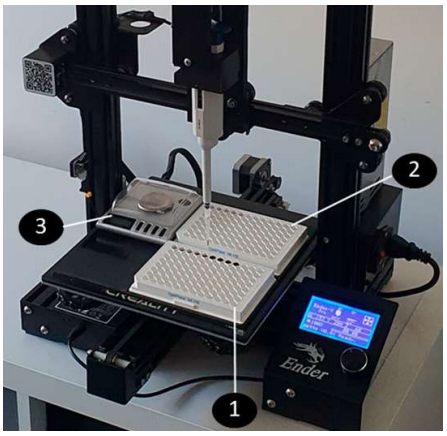

Fig. 2. Manual pipette mounted to a 3D printer [6]

B. *Proprietary volume control*

Privately developed technologies are more suitable for commercialization, but they lack standardization and flexibility due to corporate confidentiality, challenging repeatability for experimentation, in exchange, these models tend to offer tailored solutions for their consumers [7].

For example, the one-off automated cell culture system from Kyoto University [8] designed for automatic proliferation of stem cells, this system uses a robotic arm and different modules to replace human intervention.

Opentrons's liquid handling robot OT-2 is one of the most successful commercial models; it has an open software API and platform to share protocols and even semi-open hardware [7]. However, their pipetting technology is proprietary [9]. As the only manufacturers it is not viable to replicate their hardware and adopt their open software. Fig 3.

Fig. 3. Opentrons OT-2 liquid handler platform. [7]

Proprietary technologies can also be integrated into open-source 3D printable models, which improves repeatability if the proprietary hardware is sold in the region.

This compromise benefits researchers for highly specialized uses, the PHIL [10] or Sidekick [11] robots.

Phil was created to fit in a Nikon Ti-Eclipse microscope, and uses 3D printed peristaltic pumps, which are reliable at dispensing but not as much for suction [10].

Sidekick uses solenoid driven displacement pumps which are highly reliable although slightly less available worldwide [11].

C. *3D printing micropipettes*

Creating open tools for lab use goes beyond simply reducing costs, oftentimes it favors customization, streamlines the experimentation and provides the ability to share models globally for feedback [12].

Regarding 3D-printed micropipettes, the existing models deal with the mobile parts by using a syringe, this streamlines the printing process by preventing possible leaks while preserving repeatability and availability on a worldwide scale [13] Fig. 4.

Fig. 4. 3D printed micropipettes using disposable syringes [13]

After analyzing the current proposals, we can identify a clear need for an open-source standardized volume control system that can improve automation and worldwide replicability.

In addition, our proposal can be retrofitted to the systems that depend on manual micropipettes to simplify its adoption.

We can look at a brief comparison of the cases. Table 1.

TABLE I. CURRENT DESIGNS

Name	Automated volume control	Open-source design	Can use the automated pipette	Allows controlled suction
OTTO [5]	No	Yes	Yes	Yes
3D Printer system [6]	No	Yes	Yes	Yes
OT-2 [7]	Yes	Partial	No	Yes
Kyoto U [8]	Yes	No	Yes	Yes
PHIL [10]	Partial	Yes	No	No
Sidekick [11]	Partial	Yes	No	No

III. BIOMATERIALS AND 3D PRINTING

A. *Biocompatible polymers*

FDM (fused deposition modelling) 3D printers heat up a polymer filament and extrude it by moving on a flat plane to "draw" the layers that make up the volume of a digital object [14]

For life sciences, the use of polymers in general must consider biocompatibility, meaning the material must enable normal cell function, surface migration and proliferation, as well as be tolerated by the immunological cells [15].

One of the most complete studies on polymers used in life sciences was made before 3D printing popularized in the field but still includes melting temperatures due to the required sterilization processes [16].

A valid concern is that even if the polymers are biocompatible in the surface, the generation of microplastics can affect the cells, as it has been proven that their presence weakens the cellular membrane [17].

So, we will look for polymers suitable for FDM printing that do not degrade with disinfection. We will include UV (Ultra-Violet) light, chemical and heat and pressure conditions that ensure disinfection [16], [18], [19]. Table 2.

TABLE II. POSSIBLE POLYMERS

	PLA	ABS	TPU	PETG	Nylon UV/T	PC
Extrusion Temp. (°C)	130 – 180	200 – 230	~ 200	220 - 260	230 – 270	~300
Deforming Temp. (°C)	~ 60	~ 100	~ 70	80 – 90	80 – 120	>100
Ethanol (70%) resistance	No	Single event	Yes	Yes	Yes	Yes
Chlorine (0.5%) resistance	No	Single event	No	Yes	Yes	Single event
Formalde - hyde (10%) resistance	No	Single event	Single event	Yes	Yes	Yes
UV – B resistance	No	Single event	No	Single event	Yes	Yes
UV – C resistance	No	No	No	No	Single event	Yes

Where single event sterilization means it withstands the procedure once, making them single use.

The only materials that could resist standard sterilization due to temperature limits are PC (Polycarbonate) and certain Nylon UV tolerant varieties.

For disinfection, PETG (Polyethylene Terephthalate Glycol) resists chemical sterilization and can withstand cycles of UV-B radiation, however, it tends to deteriorate it overtime [17].

The problem with PC is it´s high fusion temperature, mid-range 3D printers are not designed to reach 300 °C.

The most promising filaments will be the PETG or UV tolerant Nylon, like PA6-CF [18].

We will use PETG-CF in a Creality Ender 3V3 printer due to availability, CF being carbon fiber, which increases slightly the melting temperature [20], [21].

B. 3D printing methodology

There are slight differences between modern 3D printers and their filaments, so a CAD model needs to be "sliced" (i.e., instructions to create the volume layer by layer [18]) selecting the correct model of 3D printer inside the software. Table 3.

Z-wobble (f) and layer shifting (c) appear to be hardware related with no direct solution, but the rest can be adjusted [18]. Fig. 5.

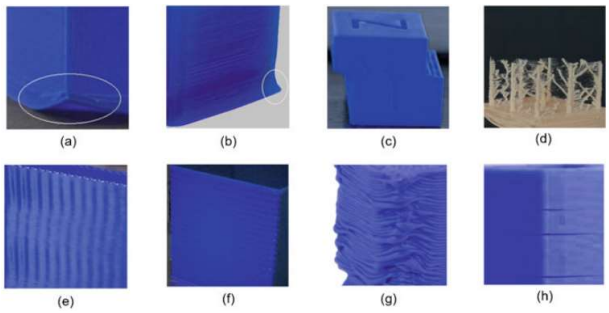

Fig. 5. Common 3D printing mistakes [18]

TABLE III. COMMON 3D PRINTING PROBLEMS [18]

Problem	Cause	Solution
Warping (a)	Thermic contraction detaches the piece from the base.	Heat up the base and avoid cold air around the piece.
Elephant's foot (b)	Melting in the base layers.	Cool down the base.
Stringing (d)	Plastic residue sticking to the tip.	Reduce tip temperature and extrusion rate.
Ringing (e)	Mechanical vibrations or air breezes affect the printing.	Fastening and isolating the 3D printer.
Curling (g)	Heat from the tip deforms lower layers.	Reduce tip temperature or cool down the piece.
Layer separation (h)	The extruded polymer isn't hot enough for another layer to stick.	Heat up the tip and avoid cold air around the piece.

Aside from this common 3D printing problems, there is also a prevalent challenge in avoiding leakage when working with fluids [11], [18], [22].

We analyzed three methodologies to avoid leaks to determine the optimal printing conditions for PETG-CF [20], [21], [23]:

- 0.16 mm layer height, as thin layers fuse easier.
- 90% Infill and 110% Extrusion rate, to overflow the borders and ensure minimal air bubbles.
- 4 Outer and Inner walls, pairing parallel walls reduces heat deformation and air bubbles.
- 50 mm/s printing speed, this is a moderate speed for most printers, which avoids unexpected vibrations.

C. After-printing treatment

Thermal treatments are common for manufacturing, however with FDM there is a possibility of deforming the polymer, so a new method has been developed, salt mold annealing [24], [25 (Unpublished)].

This methodology is used to improve the mechanical properties by reducing internal imperfections, but as a side effect it also allows us to fuse any possible leakage. Fig. 6

These essays use spectroscopy to show there is no chemical reaction happening, it is only PETG getting to its glass transition state and internally rearranging.

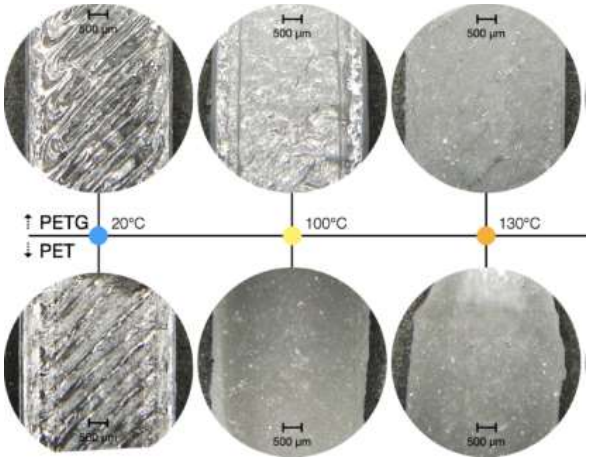

Fig. 6. Microscopic imaging of annealed polymers [25]

To avoid deformations from heat variation we will employ an 80 °C salt annealing process for 60 minutes, fount effective even if not ideal in both studies.

IV. Numerical Modeling

A. *Defining the function*

We will take Brennan et al.'s approach and use disposable syringes to control the volume [13], however, to avoid cross contamination and improve control we will use a flexible membrane [26]

This is the proposed model, it accepts both 200 µL and 10 µL pipette tips and connects to the syringe using medical grade disposable silicon tubes which have a fixed volume.

In this model the pipette has two chambers, the first one created by the mobile syringe, the silicon tube and the upper half of the pipette. Fig. 7.

The second one was created by the lower half of the pipette, the pipette tip holder and the universal pipette tips.

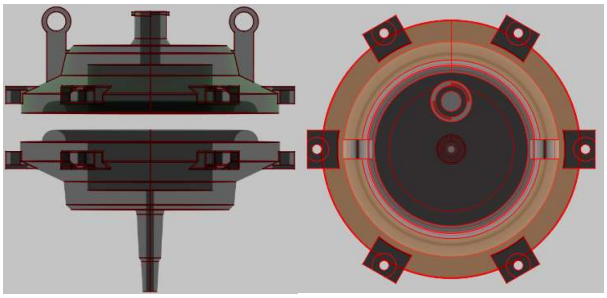

Fig. 7. Proposed pipette working for dispensing and suction.

Both halves of the pipette are separated by the flexible membrane, which is made from latex condoms after considering their global availability and standardization [27].

This membrane is characterized before [28] and after [29] vulcanization, as well as before packaging, in all cases the surface area presents homogenous elastic resistance up to 200% strain. This usage does not surpass this limit, so the surface behaves like a 2D Hooke's law spring.

Considering a 3mL syringe beginning at 1.5 mL, a 1 mm internal radius and our model's dimensions, we get a volume of 6.96 mL for the upper half (V1) and a volume of 5.35 mL for the lower half (V2). Fig. 8.

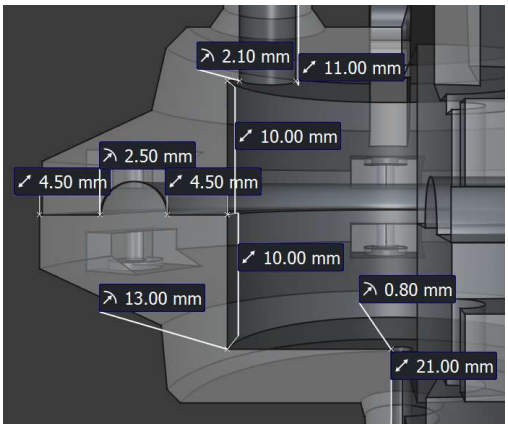

Fig. 8. Measurements from the proposed model

The small curve between the pipette parts ensures the gripping of the flexible membrane, it is held airtight by six M2 screws like a watertight watch.

Under the system's conditions we can consider the air to behave like an ideal gas [27] in two chambers Fig. 9.

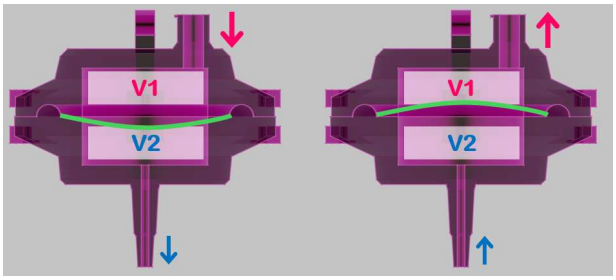

Fig. 9. 2D representation of the model's function, with the flexible membrane in green and air interacting trough it (V1 and V2)

$$PV=nRT \quad (1)$$

Considering a closed isothermal system with initial pressure, we can use Boyle's law (2 and 3).

$$P_o * V_0 = P_1 * V_1 \quad (2)$$

$$V_1 = (P_o * V_0) / \Delta P \quad (3)$$

The pressure varies as the volume compresses or expands because of the membrane's resistance (3).

Total pressure (P_T) will be the sum of external pressure (P_e) and the membrane's resistance pressure (P_m) leading to a change (4).

$$P_T = P_e + P_m \quad (4)$$

Unlike Beroz and Hart, our model's membrane has a lineal behavior for our range of displacements [29], [30].

$$P_m = K * \Delta V_{(P)} \quad (5)$$

We consider the displaced volume ($V_{(P)}$) directly as x because the scale in disposable syringes indicates volume from displacement (regular pistons use area * displacement).

$$\Delta V_{(P)} = x \quad (6)$$

Now that we have the main variable, we can substitute our defined values into Boyle's volume equation (3):

$$V(x) = (P_o * V_0) / (P_e + K* x) \quad (7)$$

Our initial (P_o) and external (P_e) pressures are both the atmospheric pressure at our altitude, the initial volume will be 6.96 mL based on our model, and K varies slightly with each disposable membrane used. Fig. 10.

$$V(x) = (P_{atm} * 6.96\ mL) / (P_{atm} + K* x) \quad (8)$$

Finally, to get the volume change (ΔV) we must consider the initial volume (7). Fig. 11.

$$\Delta V = V_0 - V(x) \quad (9)$$

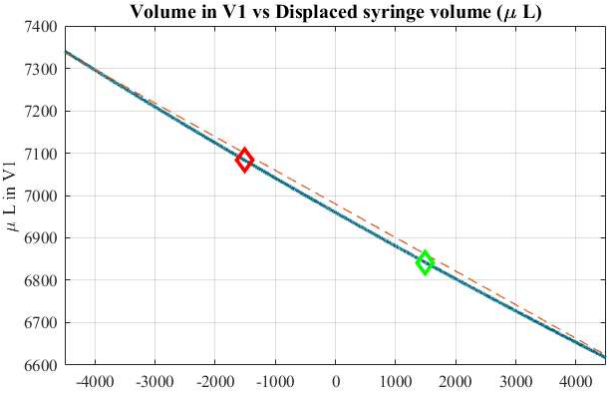

Fig. 10. Graph of V(x) according to equation 8 made, the red and green diamonds represent the physical minimum and maximum values for the syringe, and the orange dotted line exemplifies lineal behavior.

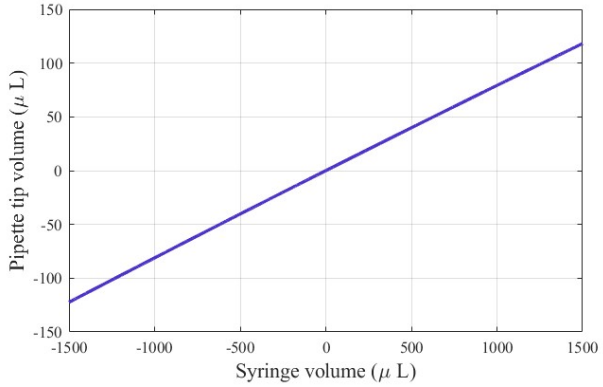

Fig. 11. This graph shows the final volume change according to equation 9, using the local barometric pressure (77 kPa) and a membrane stiffness ratio of 0.9 Pa / μL.

V. Printing the Pipette

The entire model uses a 3D printed platform to hold the syringe and the stepper motor in place.

During this stage of development, we use open loop control, the linear actuator uses a captive screw so the amount of steps can be accounted for reliably.

The 3D model for the pipette was designed independently from the motor platform to allow users to customize the control mechanism for their own needs, but our control model is also available if needed. Fig. 12.

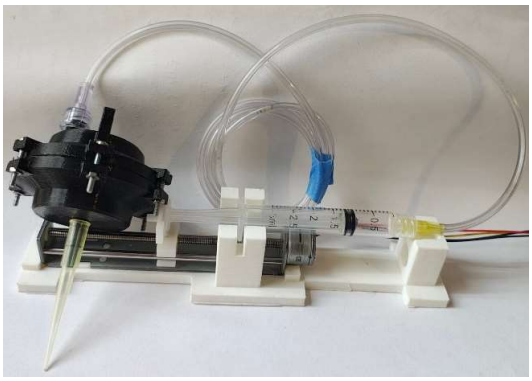

Fig. 12. 3D printable pipette and control system

The heat treatment done to the 3D pipette to avoid leakage differed from studied methodologies due to the uneven salt crystal sizes. Fig. 13.

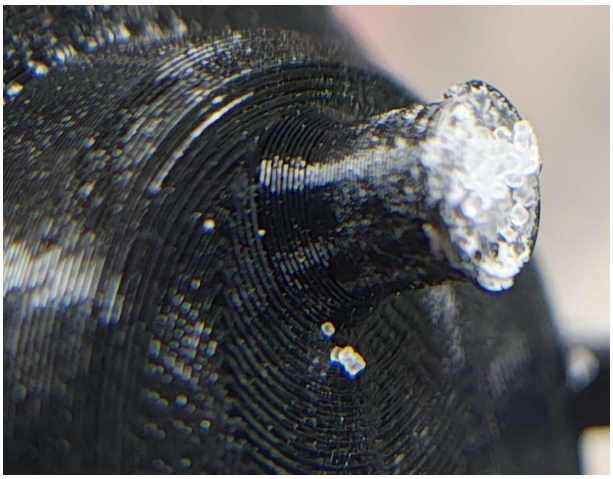

Fig. 13. Salt crystals and pulverized salt in the tip of the 3D printed pipette before salt annealing

To counteract this problem and ensure the least deformation in crucial spots pulverized salt was added where the pipette connects to the silicon tube.

Also, accounting for deformation the inside of the pipette was filled with salt and assembled with aluminum foil instead of the flexible membrane. Fig. 14.

Fig. 14. Aluminum foil placed into the pipette before salt annealing.

The resulting piece still shows the original filament positions, however, due to the heat treatment, layers joined together resulting in shallower, blurrier lines on the surface. Fig.15.

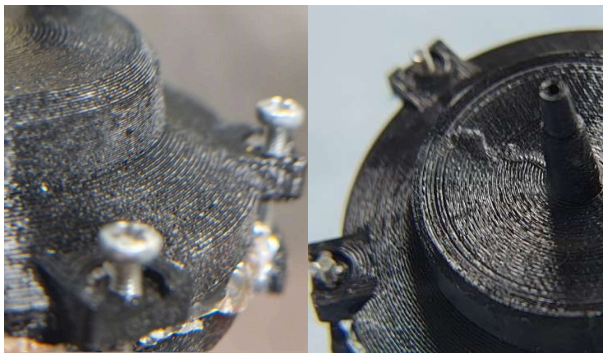

Fig. 15. 3D printable pipette post- salt annealing

VI. Testing the Pipette

To evaluate the pipette´s volume control accurately we resort to measuring the volume of each drop of water using digital imaging [30] using MATLAB. Fig. 16.

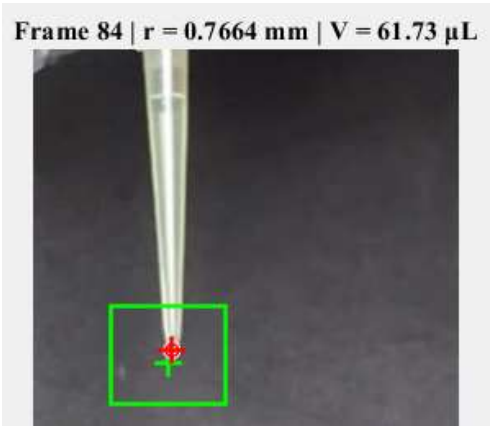

Fig. 16. MATLAB imaging program used to determine drop volume.

The program is simple, first it detects the tip and then it looks for a circle in that direction, we used the tip to determine the conversion from pixels to millimeters.

Footage will be captured from a smartphone camera, so, to avoid image deformation, we will keep a fixed 12 cm distance from the lens to the pipette's tip.

The phone's camera has a f/2.0 aperture and 3x optical zoom recording at 60 frames per second.

The volume will be controlled by the TB6600 stepper driver connected to an ESP32.

The controlled volume is determined by the amount of steps the stepper motor gives.

This number can vary depending on the dimensions of the disposable syringe, so it will be transformed into volume lineally by taking the maximum and minimum values for a 3mL disposable syringe Fig 17.

For reference, 50% of the syringe will be 0 so we have both positive and negative displacement like in our mathematical model.

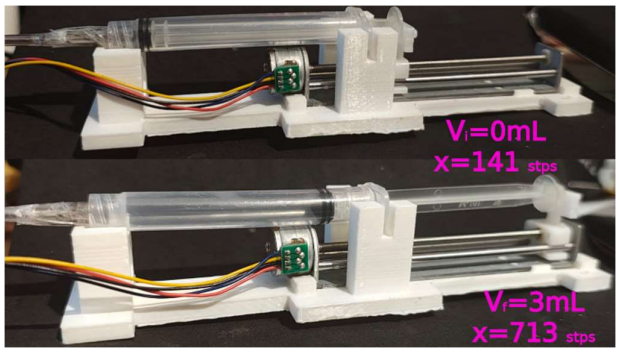

Fig. 17. Syringe max and min values.

To validate if the mathematical model is correct, we need to demonstrate that the membrane performs in a completely elastic deformation.

For this test the stepper motor will advance at a fixed speed by delaying each step 1 millisecond, thus we can analyze the syringes retraction (suction) and compression (expulsion).

After the first test (5 cycles of suction and expulsion). We will wait eight hours to repeat the same test to analyze the membrane's deformation and see if the elastic model still corresponds to the mathematical model.

VII. Results

From this experimentation model and advancing the linear actuator at a constant speed we can obtain the volume control graph in MATLAB for the droplets Fig. 18.

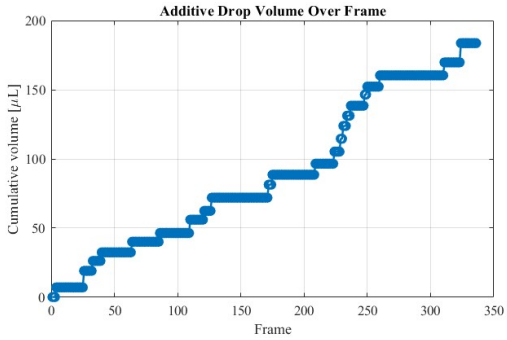

Fig. 18. Graph of total volume overtime as the syringe empties.

If we compare the theoretical graph [Fig. 15] to our obtained graph the only changing factor would be the membrane's stiffness, however behavior was not completely lineal.

As more tests were done it became clear that the membrane loosens overtime, needing compensation or diminishing the final range Fig. 19.

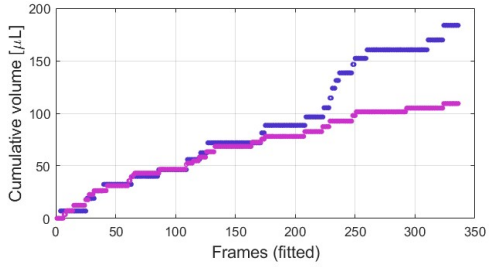

Fig. 19. Graph of total volume overtime as the syringe empties for test 1 and test 2 using the same membrane.

Finally, we can compare both tests to the mathematical model and analyze the R value to see if they correlate Fig. .

According to the R value from test 2, the membrane is no longer accurately represented by the mathematical model.

However, with a fresh membrane we get an R value above 0.95, making the mathematical model reliable for this case. Fig. 20.

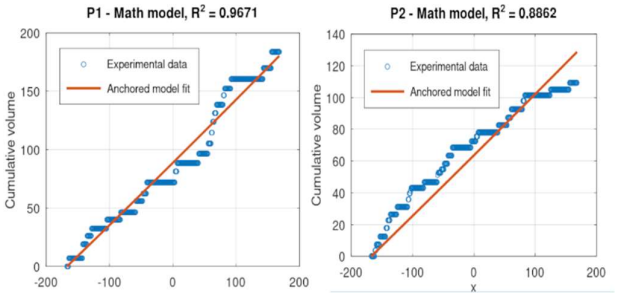

Fig. 20. Graphs of empirical values vs mathematical models with R squared values.

In conclusion, this 3D printable model can reliably control micrometric volumes only under ideal conditions (Thermically treated, with brand new membranes and with no degradation from repeated sterilization).

However, it does offer a base in which open-source development can be fostered by replicability and ease of access.

The design deals with leakage, one FDM's strongest challenge, by implementing manufacturing technologies from different fields like drone aeronautics and vastly available reliable and sterile materials like disposable syringes and condoms for its use in the biomedical sector.

To encourage replicability, we make available the 3D printable models and the MATLAB code.

Regarding further work we look forward to researchers wanting to experiment with this pipette into their own liquid handlers, as well as more sophisticated, closed loop control approaches using it to get more accurate volume conversions.

In our specific case, this pipette will be applied for the automation of hanging-drop 3D cell cultures, and we are looking for a programmer to create an open-source API to control it remotely.

Another approach to the API would be to integrate it into preexisting open software liquid handlers like OTTO [8] if we get to collaborate in their efforts.

For those who want to improve this proposal in material engineering aspects we encourage the development of flexible membranes designed specifically for micro pipetting or other creative approaches. We used condoms for their worldwide availability, but other solutions might make the system more reliable.

***Abstract*—Parkinson's disease (PD) is the second most common neurodegenerative disorder worldwide, and rigidity affects most diagnosed individuals. Although a cardinal symptom, rigidity assessment remains largely subjective, relying on the ordinal MDS-UPDRS scale and susceptible to inter-rater variability. This study presents a biomechanical and usability assessment of an active wrist orthosis designed to objectively quantify wrist rigidity. The device performed standardized passive flexion-extension movements on 30 participants (15 PD, 15 healthy controls) while recording current, force, and angular displacement. Twelve biomechanical features were correlated with MDS-UPDRS Item 3.3 rigidity scores using Spearman correlation. As an exploratory, interpretable complement, a multiple linear regression model with second-order interaction terms was fitted to relate these features to the rigidity score. Usability was evaluated with the System Usability Scale (SUS) and the Short Flow State Scale (SFSS). Flexion-phase features showed moderate, statistically significant correlations with Item 3.3, while signal-variability features showed moderate negative correlations. In this exploratory analysis, a parsimonious three-interaction-term model reached an adjusted coefficient of determination of about 0.57 and an in-sample expanded accuracy near 73 percent, within one point of the clinical score. The overall mean SUS score of about 85, classified as excellent, confirmed strong device acceptance in both groups. These findings support the use of the orthosis as an objective and user-friendly tool for PD rigidity assessment.**

***Index Terms*—Parkinson's disease, wrist rigidity, active orthosis, MDS-UPDRS, usability, SUS**

I. Introduction

Parkinson's disease (PD) is a progressive neurodegenerative disorder and the second most common neurodegenerative condition worldwide, affecting an estimated 6.1 million people globally, with only Alzheimer's disease being more prevalent [1]. Its prevalence doubled between 1990 and 2015, driven by population aging [1], and rose by 274% from 1990 to 2021, with projections indicating continued acceleration [2]. In Brazil, PD represents a significant and growing public health burden, particularly given the country's demographic transition toward an older population.

The four cardinal motor signs of PD are frequently summarized by the acronym TRAP: Tremor, Rigidity, Akinesia (or bradykinesia), and Postural instability [3]. Despite advances in neuroimaging and biomarker research, PD diagnosis remains predominantly clinical, based on medical history and physical examination, introducing subjectivity and the potential for diagnostic inaccuracy. Diagnostic error rates ranging from 15% to 24% have been reported even in specialized centers [4].

Among the motor symptoms, rigidity is especially relevant in clinical practice. It is present in 83–89% of PD patients [5] and is defined as an increased resistance to passive joint movement that is independent of movement velocity and constant throughout the range of motion. Two subtypes are

recognized: “lead pipe” rigidity, characterized by a uniform, sustained resistance, and “cogwheel” rigidity, in which intermittent catches are superimposed on the underlying muscle tone [5]. Rigidity is influenced by both neural components (basal ganglia dysfunction, altered supraspinal drive) and non-neural components (viscoelastic properties of muscle and connective tissue), which contributes to the complexity of its quantification [5], [6].

Wrist rigidity, in particular, is highly disabling. The wrist joint is essential for daily activities such as eating, writing, and personal hygiene. Impaired wrist mobility reduces independence and quality of life [7], making its accurate measurement a priority for both therapy and monitoring. Furthermore, rigidity is a key outcome measure in clinical trials evaluating dopaminergic therapy and deep brain stimulation (DBS), where subtle changes in muscle tone must be reliably detected.

Currently, the gold standard for rigidity assessment is the Movement Disorder Society–Unified Parkinson’s Disease Rating Scale (MDS-UPDRS) [8], which revised the original UPDRS [9]. Its Part III, Item 3.3 evaluates rigidity at the neck, upper limbs, and lower limbs on a 0–4 ordinal scale. Although widely adopted, this instrument is inherently semi-quantitative and susceptible to inter- and intra-rater variability, with inter-rater disagreement of up to 20% reported [5]. The ordinal and subjective nature of the scale limits its sensitivity in detecting small but clinically meaningful changes in rigidity, particularly for monitoring disease progression or treatment response in longitudinal settings.

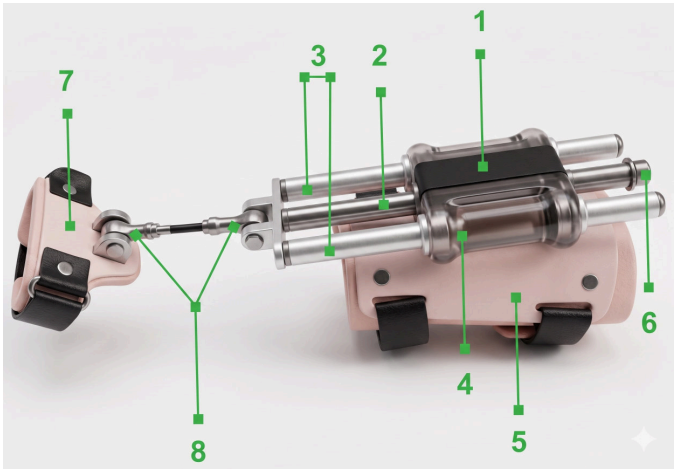
To overcome these limitations, several instrumented methods for objective rigidity quantification have been proposed. Devices such as the Bionics Institute Rigidity Device (BiRD) [6] and the PDMeter [10] perform automated passive joint movements and record biomechanical parameters, demonstrating the feasibility of objective rigidity measurement. However, few such devices have undergone simultaneous evaluation of clinical correlation with the MDS-UPDRS and usability in PD patients, both of which are needed before such tools can be adopted clinically.

This study reports a biomechanical and usability assessment of an active wrist orthosis developed at the Nucleus of Innovation and Technological Assessment in Health (NIATS/UFU). The orthosis performs standardized passive wrist flexion-extension movements and records biomechanical signals from which quantitative features are extracted. We quantified Spearman correlations between orthosis-derived features and MDS-UPDRS Item 3.3 rigidity scores, fitted a regression model relating these features to the clinical rigidity score, and assessed device usability via the SUS and SFSS in both PD and healthy control (HC) groups. A companion study used the same device for automatic PD-versus-control classification with machine learning [11]; here we instead examine how orthosis-derived measures agree with clinical rigidity scores and how usable the device is, treating the regression model as an exploratory, interpretable step and not a validated predictor.

II. Materials and Methods

A. Device Description

The active wrist orthosis used in this study (patent BR1020140232826) was developed in the NIATS laboratory as a custom instrumented tool for objective measurement of rigidity in PD. Weighing 850 g, the system is actuated by a Faulhaber DC linear servomotor (LM 2070-080-11, Faulhaber, Schönaich, Germany) driven by a high-precision controller (MCLM 3006 S RS, Faulhaber). The device performs passive flexion and extension of the participant’s wrist, and quantifies rigidity by measuring the motor’s current consumption, which is proportional to the resistive force exerted by the wrist joint during imposed movement. Fig. 1 illustrates the main structural components of the orthosis.



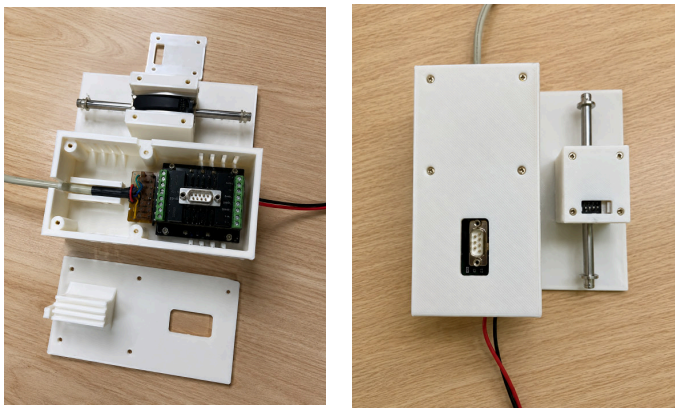


Fig. 1: Active wrist orthosis. (1) Actuator; (2) Actuator’s cylindrical shaft; (3) Auxiliary cylindrical shafts; (4) Actuator casing; (5) Forearm attachment structure; (6) Safety displacement limiter; (7) Hand coupling structure; (8) Spherical joints.

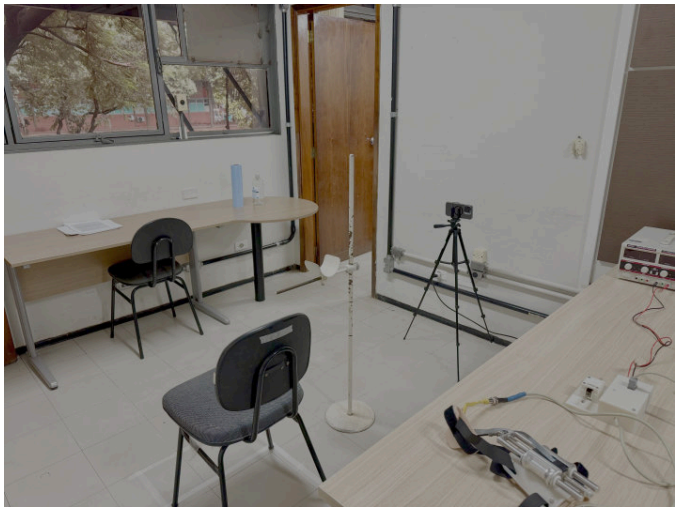
The electronic control unit consists of a Faulhaber MCLM 3006 S RS motion controller and the linear actuator, both housed in a custom 3D-printed PLA enclosure. The controller communicates via RS-232 and is programmed using Faulhaber Motion Manager 6 software. Signal acquisition was managed by the Faulhaber software running on a host PC, which communicated with the MCLM 3006 S RS controller over an RS-232/USB converter cable at 38,400 bps. ASCII commands defined the actuator trajectory as bidirectional displacement of $\pm$ 4,500 encoder increments from the neutral wrist position, at 100 increments/s with no commanded acceleration. Each acquisition produced one CSV file per set, containing time (ms), shaft position (increments), and motor current (mA). Motor current was used as the proxy for the resistive torque generated by the wrist, since it is proportional to the force exerted by the LM 2070-080-11 actuator through a fixed electromechanical constant.

Fig. 2 shows the opened housing revealing the control electronics.

(a) (b)

Fig. 2: (a) Aerial view of the MCLM 3006 S RS microcontroller and the LM 1247-060-01 actuator fixed in their respective housings. (b) Top view of the closed base. Note: the photographed unit corresponds to an earlier prototype of the housing assembly; the actuator used in the present study is the upgraded LM 2070-080-11 model.

Data collection took place in a standardized room with floor and chair markings to ensure reproducible positioning across sessions. The setup included a fixed chair, an adjustable forearm support for the assessed limb, a matched support for the contralateral arm, the orthosis with its dedicated power supply, disinfection materials, and a tripod-mounted smartphone (iPhone 14 Pro Max, Apple Inc., Cupertino, CA, USA) placed perpendicular to the sagittal plane of the assessed wrist to record the movement. Participants were positioned within the floor-marked area, with both forearms on their supports and the assessed wrist in a neutral pronation-supination position. Color-based markers were placed on the anatomical landmarks tracked by the lateral video. Fig. 3 shows an overview of the data collection environment.



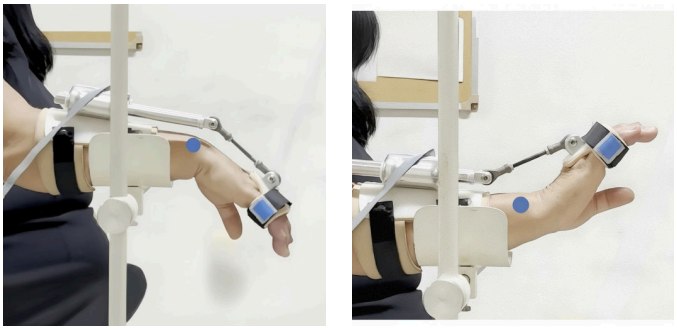


Fig. 3: Data collection setup including the chair, forearm supports, active wrist orthosis, and tripod-mounted smartphone.

Angular displacement of the wrist was estimated using a computer vision-based tracking system with color-based markers and the Kinovea® software (version 2025.1.1). This approach replaced the physical goniometer used in earlier validation studies [12], reducing equipment bulk and improving participant comfort. The orthosis was positioned on the participant's forearm 6 cm from the ulnar styloid process, following established biomechanical alignment recommendations [11]. Signals were acquired at a sampling rate of 166.67 Hz; video was recorded at 60 fps and interpolated to 166.67 Hz using cubic spline interpolation [11]. Fig. 4 shows the experimental setup with the orthosis fitted to a volunteer at maximum flexion (a) and maximum extension (b).

B. *Participants*

Following approval from the Research Ethics Committee of the Federal University of Uberlândia (CAAE: 84004924.1.0000.5152), 30 participants provided written informed consent and were enrolled: 15 with a confirmed PD diagnosis (PD group) and 15 neurologically healthy controls (HC group), matched by age and sex. Table I summarizes the demographic and clinical characteristics. Inclusion criteria for the PD group required a formal clinical diagnosis by a movement disorder specialist. Exclusion criteria for all participants included any other neurological condition, joint disease, or painful condition that could affect wrist movement. PD participants were evaluated in the OFF-medication state. In PD participants, the most affected limb (identified using MDS-UPDRS Item 3.3) was used for orthosis placement; in HC participants, the dominant hand was assessed.

Both groups were well-balanced for age, sex, and overall health profile, with no significant between-group differences in demographic variables. Within the PD group, the Motor Examination (Part III) score indicated mild-to-moderate motor impairment, with rigidity present in 14 of the 15 participants and broadly distributed across the 0–10 range of the Item 3.3 subscore.

TABLE I: Clinical and Demographic Characteristics

Item	HC	PD	Total
Gender – Male	8	8	16
Gender – Female	7	7	14
Age (years)	62.00 ± 5.21 (50–69)	62.07 ± 5.68 (53–72)	–
MDS-UPDRS Part III (Motor)[1]	–	20.93 ± 9.70	–
Rigidity Subscore (Item 3.3)[1]	–	4.53 ± 2.29	–
Total	15	15	30

[1] Part III: Motor Examination (3.1–3.18).
Gender values are counts; Age and MDS-UPDRS scores are mean ± SD.

C. Data Collection Protocol

Participants were seated with the forearm resting horizontally on a padded support, with the orthosis secured 6 cm proximal to the ulnar styloid process following established biomechanical alignment recommendations. The wrist was maintained in a neutral pronation-supination position throughout the protocol. Prior to data acquisition, a standardized 30-second passive stretching routine was applied in each direction (flexion and extension) to reduce viscoelastic stiffness and standardize initial joint conditions. Participants were verbally instructed to remain relaxed and not to resist or voluntarily react to the device's movement, allowing the actuator to act passively on the joint. Data collection commenced only after the researcher confirmed full participant familiarization. Each participant completed three consecutive sets of 10 passive wrist flexion-extension cycles, with 2-minute rest intervals between sets to prevent fatigue-related confounds. Electrical current (mA), time (s), and linear displacement were recorded continuously throughout each cycle at 166.67 Hz.

D. MDS-UPDRS Clinical Assessment

PD participants underwent evaluation of MDS-UPDRS Part III, Item 3.3 (neck and limbs rigidity, five sub-items a–e), conducted by two trained raters blinded to each other's scores. When the difference between raters' total motor scores exceeded five points, a consensus procedure was applied [13], [14]. The final score was computed as the mean of the two evaluations. Both the total motor score (Part III, maximum 132) and the rigidity subscore (Item 3.3, maximum 20) were used in subsequent analyses.

E. Feature Extraction

Twelve biomechanical features were extracted from the conditioned orthosis signals (1–16 Hz band-pass filtering and z-score standardization). As the features are used here only as relative descriptors for correlation and regression, they are treated as dimensionless quantities. The first pair, $C_{Extension}$ and $C_{Flexion}$, is the area under the current-time curve, a charge-like measure of the cumulative current during extension and flexion respectively. $W_{Extension}$ and $W_{Flexion}$ are the area under the force-angle curve, a work-like measure of the mechanical effort, while $FR_{Extension}$ and $FR_{Flexion}$ describe the force rate, obtained from the slope of the force-angle linear regression. The remaining features capture statistical properties of the signal: MAV denotes the mean absolute value, with MAVFD and MAVSD denoting the same measure applied to the first and second signal differences. The set is completed by PEAK, RANGE, and STD.

F. Correlation and Prediction Model

Correlation and regression analyses were restricted to the PD group, since MDS-UPDRS scores are defined only for these participants, and comprised 45 movement sets (three consecutive sets from each of the 15 PD participants). Spearman's ρ was computed between each feature and two clinical scores (MDS-UPDRS Part III and Item 3.3), with a significance level of 0.05. For the prediction model, the twelve features were combined with 66 second-order interaction terms, yielding 78 candidates that were evaluated via stepwise forward selection with an entry threshold of $p < 0.05$. Performance was assessed through R^2, adjusted R^2, RMSE, and Expanded Accuracy (tolerance ± 1 point), all computed on the fitting sample. The twelve-feature linear regression served as the internal baseline against which the optimized stepwise model was compared; formal external validation (e.g., k-fold cross-validation against a constant-mean predictor) is reserved for future work, consistent with the underlying thesis [15].

G. Usability Assessment

Device usability was assessed using two validated instruments administered to all participants immediately after the data collection protocol.

The System Usability Scale (SUS) [16] is a ten-item questionnaire rated on a five-point Likert scale ranging from 1 for strongly disagree to 5 for strongly agree, with items alternating between positively and negatively phrased statements. For scoring, odd-numbered items contribute the score minus one, while even-numbered items contribute five minus the score; all contributions are then summed and multiplied by 2.5 to yield a final value on a 0–100 scale. According to Bangor et al. [17], scores $\geq$68 are considered acceptable, $\geq$71 good, and $\geq$80.3 excellent. The validated Brazilian Portuguese version was used in this study.

The Short Flow State Scale (SFSS) [18] is a nine-item instrument that evaluates the psychological state of flow during task performance. Each item is rated on a five-point Likert scale, and the final score corresponds to the arithmetic mean of the responses, ranging from 1 to 5. The nine dimensions assessed are challenge-skill balance, action-awareness merging, clear goals, unambiguous feedback, concentration on task, sense of control, loss of self-consciousness, time transformation, and autotelic experience. Both instruments were administered in paper form immediately after device removal, with the researcher available for clarification.

III. Results

A. Sample Characterization

Groups were well-matched by age and sex (HC: 62.00 ± 5.21 years; PD: 62.07 ± 5.68 years; independent t-test, $p > 0.05$). Each group comprised eight men and seven women.

Within the PD group, the Mann-Whitney test revealed no significant difference in motor scores between sexes, and the Spearman analysis showed no significant correlation between age and motor severity, confirming a homogeneous and well-characterized sample.

B. MDS-UPDRS Scores

The PD group presented a mean total motor score of 20.93 with a standard deviation of 9.70, ranging from 11 to 42, which indicates mild-to-moderate motor impairment. The rigidity subscore corresponding to Item 3.3 reached a mean of 4.53 with a standard deviation of 2.29 and a median of 4.0, with scores ranging from 0 to 10. Rigidity was present in 14 of the 15 PD participants, one of whom scored 0 on Item 3.3 at the time of assessment, yielding a clinically meaningful spread of rigidity severity for the correlation analysis. No significant differences emerged between male and female subgroups for either score, and age showed no significant correlation with clinical severity.

C. Spearman Correlation Analysis

No feature showed a significant correlation with the total motor score of Part III, a result consistent with the broad and multi-symptom nature of this aggregate measure. In contrast, five features demonstrated significant moderate correlations with the rigidity-specific Item 3.3, as detailed in Table II. The strongest positive associations were observed for the flexion-phase variables $C_{Flexion}$ and $W_{Flexion}$, with Spearman coefficients of 0.408 and 0.342 and corresponding p-values of 0.005 and 0.022. The signal variability descriptors STD, MAVSD, and MAVFD, in turn, showed moderate negative correlations, reflecting the attenuated signal variability that characterizes rigid movement.

TABLE II: Spearman Correlations: Orthosis Features vs. MDS-UPDRS

Feature	ρ (Part III)	p	ρ (Item 3.3)	p
$C_{Flexion}$	0.238	0.115	0.408*	0.005
$W_{Flexion}$	0.210	0.165	0.342*	0.022
STD	−0.176	0.247	−0.326*	0.029
MAVSD	−0.281	0.062	−0.320*	0.032
MAVFD	−0.280	0.062	−0.320*	0.032
RANGE	0.081	0.597	0.270	0.073
PEAK	0.104	0.495	0.238	0.115
$C_{Extension}$	0.092	0.546	−0.144	0.346
$FR_{Extension}$	0.060	0.698	0.113	0.460
$W_{Extension}$	0.075	0.627	0.015	0.923
MAV	0.072	0.638	−0.055	0.721
$FR_{Flexion}$	0.037	0.810	−0.043	0.778

* $p < 0.05$. No correction for multiple comparisons applied (exploratory analysis).

Fig. 5 displays the full correlation profile across all features, with the magnitude of Spearman's ρ shown on the horizontal axis. Bars extending to the right of the origin indicate positive associations with rigidity, while bars to the left indicate negative associations; bars crossing the dashed thresholds at $\rho = \pm 0.3$ identify the five features that reached statistical significance and are highlighted in darker shading.

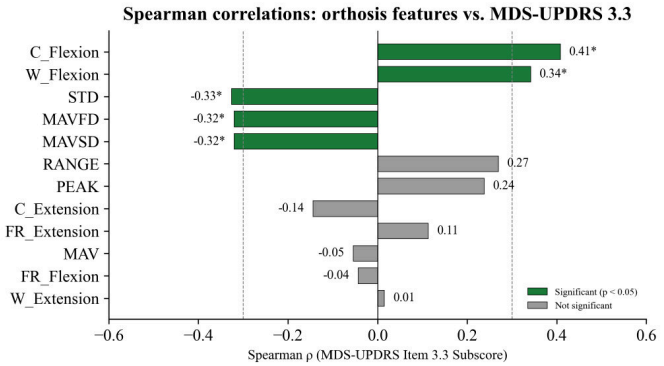

Fig. 5: Spearman correlation coefficients (ρ) between orthosis biomechanical features and MDS-UPDRS Item 3.3 (rigidity subscore). Dark bars indicate statistically significant correlations ($p < 0.05$). Dashed lines mark the $\rho = \pm 0.3$ threshold for moderate correlation.

D. Mathematical Prediction Model

Building on the correlations identified in the previous section, an exploratory stepwise selection refined the predictor set to three second-order interaction terms that proved most informative: MAVFD×STD, STD×$FR_{Flexion}$, and MAVSD×$C_{Flexion}$. To assess whether this parsimonious formulation preserved predictive performance, the resulting optimized model was compared against the internal twelve-feature baseline, with both configurations summarized in Table III. The reported metrics correspond to model fit on the complete sample and should be interpreted accordingly.

TABLE III: Regression Model Performance – Rigidity Score Prediction

Metric	Base Model (12 feat.)	Optimized (3 interact.)
R^2	0.682	0.603
R^2 adj	0.563	**0.574**
RMSE (points)	1.250	1.396
Expanded Accuracy (±1 pt)	75.56%	73.33%

The comparison shown in Table III reveals that the optimized model uses only three interaction terms instead of twelve features, yet its adjusted R^2 (0.574) slightly exceeds the baseline's (0.563), with comparable clinical accuracy. Its RMSE (about 1.40 points, near 7% of the 20-point maximum) is slightly higher than the baseline's 1.25 – a modest cost in raw error for a simpler, more interpretable model. STD appears in two of the three selected interactions, suggesting that signal variability adds information beyond the movement descriptors alone.

E. Usability Assessment

The overall SUS mean reached 84.83 with a standard deviation of 7.28, a value classified as "excellent" according to Bangor et al. [17]. Both groups individually surpassed the 80.3 excellence threshold: PD group 83.33 ± 7.66 (median 85;

range 72.5–97.5); HC group 86.33 $\pm$ 6.81 (median 90; range 70–95). The Mann-Whitney U test revealed no significant between-group difference ($p > 0.05$), indicating that PD-related motor impairments did not meaningfully affect technology interaction. Every individual SUS score in both groups exceeded the acceptable threshold of 68, and the majority surpassed the excellence threshold of 80.3, reflecting uniform device acceptance (Fig. 6).

SFSS scores confirmed a moderate-to-high flow state during device use in both groups (PD: 4.03 $\pm$ 0.26; HC: 4.38 $\pm$ 0.29; on a 1–5 scale; values are between-subject means $\pm$ SD). Both groups reached a high flow level, with the HC group showing a slightly higher mean (a 0.35-point advantage), suggesting that PD participants experienced somewhat lower, though still high, engagement during the protocol. Fig. 7 displays the SFSS score distribution across groups.

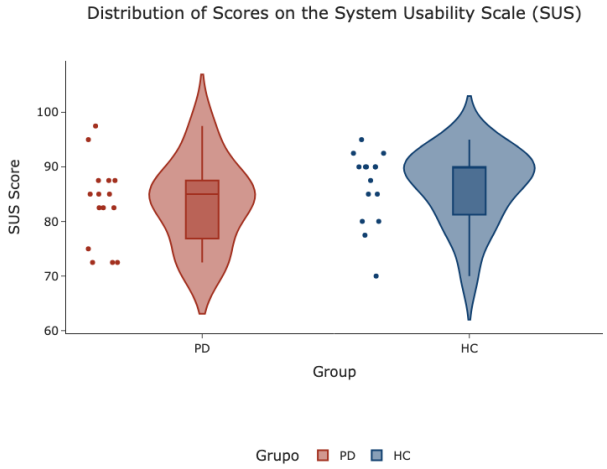

Fig. 6: Distribution of SUS scores by group. Boxes show the interquartile range; dots represent individual scores.

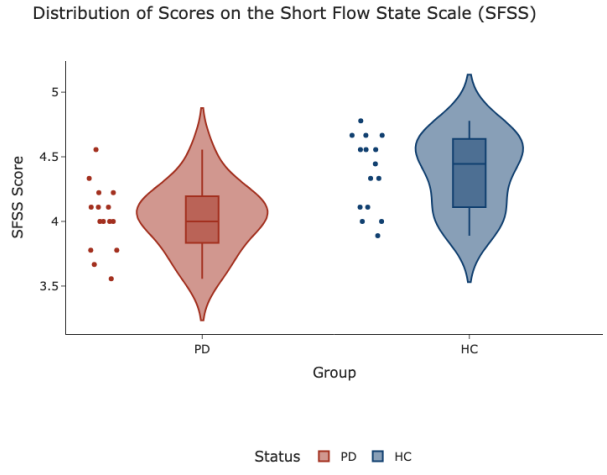

Fig. 7: Distribution of SFSS scores by group. Boxes show the interquartile range; dots represent individual scores.

IV. Discussion

The biomechanical measurements from the wrist orthosis correlated significantly with clinician-rated rigidity in Parkinson's disease, and the device was perceived as highly usable by both patients and healthy controls.

The correlations were selective: the orthosis features associated significantly with MDS-UPDRS Item 3.3, but not with the total motor score of Part III. Part III aggregates tremor, bradykinesia, postural instability, and other signs, which dilutes the rigidity-specific signal the device captures. Item 3.3 isolates the resistance to passive movement that the orthosis quantifies. The same selectivity was reported by Perera et al. [6] with the BiRD device, indicating that instrumented rigidity tools are more sensitive to rigidity-specific clinical items than to composite motor scores.

The strongest positive associations were observed for the charge-like flexion integral ($C_{Flexion}$, $\rho = 0.408$) and the work-like flexion integral ($W_{Flexion}$, $\rho = 0.342$). Both quantify, in relative terms, the cumulative current and mechanical effort required to overcome wrist resistance during flexion, mirroring the resistant force clinicians assess during passive movement. The negative correlations of STD, MAVFD, and MAVSD have a clear biomechanical basis: a rigid joint produces a more uniform force profile during passive movement. As rigidity increases, the wrist offers more constant resistance to the imposed motion, lowering the standard deviation and the derivative-based descriptors.

This flexion-phase specificity is reinforced by an independent group-level analysis reported in the underlying thesis [15], in which the only three features that differed significantly between PD and HC participants were all flexion-phase descriptors: $C_{Flexion}$ ($p = 0.003$), $W_{Flexion}$ ($p = 0.006$), and $FR_{Flexion}$ ($p = 0.015$). Two of them, $C_{Flexion}$ and $W_{Flexion}$, are precisely the features that track rigidity severity in the present analysis. The flexion phase therefore carries information both about group membership and about the degree of clinical impairment, which converges on the same conclusion from two independent directions.

The optimized prediction model suggests that wrist rigidity, as measured by Item 3.3, is better captured by feature interactions than by individual features. STD appears in two of the three selected interaction terms (MAVFD$\times$STD and STD$\times FR_{Flexion}$), indicating that signal variability modulates the dynamic movement descriptors, accounting for a sizeable share of the clinical rigidity variance in this sample, with an adjusted R^2 of 0.574. On the fitting sample, the model has a root mean squared error of about 1.40 points and an expanded accuracy of 73.3%, with its rounded estimate landing within one point of the clinician's score in about three of four cases. As these metrics are not cross-validated, they should be read as exploratory rather than as evidence of out-of-sample predictive performance.

The mean SUS score of 84.83 is encouraging, given the motor and cognitive difficulties that often complicate technology use in PD. An "excellent" rating in this population [17]

likely reflects the ergonomic refinements made across device iterations – above all, replacing the physical goniometer with computer-vision tracking. The 3.0-point PD–HC difference in mean SUS (86.33 versus 83.33) indicates that the device is accessible across functional levels. The SFSS scores point the same way: both groups reported a high flow state, with PD slightly below controls (4.03 versus 4.38 on a 1–5 scale). The small difference fits the higher motor and cognitive load in PD, but the still-high scores show that the device kept users engaged.

This study has limitations. The sample of 30 participants limits statistical power, and the correlation analysis was exploratory, without correction for multiple comparisons. The absence of test-retest reliability data and longitudinal assessments restricts conclusions about device sensitivity to disease progression or to therapy. Larger, stratified cohorts with longitudinal follow-up are needed to extend these findings. Each participant contributed three movement sets sharing the same clinical score, so the observations were not fully independent and the correlation and regression results should be read as exploratory. The reported R^2, adjusted R^2, and RMSE reflect model fit on the full sample rather than out-of-sample performance; future work will use per-subject aggregation or mixed-effects modeling with k-fold cross-validation against a constant-mean baseline, as discussed in the underlying thesis [15].

V. Conclusion

The active wrist orthosis serves as an objective complement to clinical rigidity assessment in PD. Flexion-phase features, namely the relative charge-like ($C_{Flexion}$) and work-like ($W_{Flexion}$) integrals, correlated moderately and significantly with MDS-UPDRS Item 3.3, while showing no significant association with the total motor score, confirming measurement specificity. An exploratory three-interaction-term regression model related these features to the clinical rigidity score ($R^2_{adj} = 0.574$; 73.3% expanded accuracy within one point), in line with values reported for the BiRD [6] and PDMeter [10] devices, and suggests that feature interactions deserve attention in future predictive models. PD patients and healthy controls rated the device as excellent in usability (SUS = 84.83) and reported a moderate-to-high flow state during use (SFSS = 4.20 on a 1–5 scale), supporting clinical deployment. The orthosis is therefore an objective, user-friendly tool for quantifying rigidity in PD, with potential use in diagnostic support and longitudinal monitoring.

Acknowledgment

The present work was carried out with the support of the Ministry of Science, Technology, and Innovation (MCTI); Federal Institute of Education, Science, and Technology Goiano (IF Goiano); National Council for Scientific and Technological Development (CNPq); Coordination for the Improvement of Higher Education Personnel (CAPES); and Foundation for Research Support of the State of Minas Gerais (FAPEMIG). ***Resumo*—A análise fractal tem sido amplamente empregada na biomecânica para investigar a complexidade presente em sinais associados à marcha humana. Entretanto, fatores relacionados à aquisição e ao processamento dos sinais, como a frequência de amostragem e a presença de ruído, podem influenciar diretamente a estabilidade das métricas obtidas. O objetivo deste estudo foi investigar a influência dessas características sobre o desempenho dos algoritmos Correlation Dimension (D_2) e Multifractal Detrended Fluctuation Analysis (MF-DFA). Foram analisados sinais biomecânicos de marcha provenientes de jovens, idosos não caidores e idosos caidores, submetidos a diferentes frequências de amostragem, velocidades e níveis de ruído branco gaussiano. Os resultados demonstraram que ambos os algoritmos foram influenciados pelas modificações impostas aos sinais, porém apresentaram comportamentos distintos quanto à robustez e sensibilidade. A Correlation Dimension mostrou maior sensibilidade à redução da frequência de amostragem, enquanto o MF-DFA apresentou maior influência das interações entre velocidade e ruído. Os achados fornecem subsídios para a utilização mais consistente de métricas fractais em estudos biomecânicos e clínicos.**

***Index Terms*—Marcha humana, Dimensão fractal, Correlation Dimension, MF-DFA, Complexidade, Biomecânica**

I. Introdução

A marcha humana representa um sistema dinâmico complexo cuja variabilidade emerge da interação entre mecanismos neuromotores, sensoriais e biomecânicos. A compreensão dessa variabilidade tem sido amplamente explorada por meio de métodos não lineares capazes de caracterizar a complexidade presente nos sinais biomecânicos, conforme discutido por Lopes e Betrouni [7].

Entre os métodos mais utilizados destacam-se a Correlation Dimension (CD), baseada na reconstrução do espaço de fase, e o Multifractal Detrended Fluctuation Analysis (MF-DFA), fundamentado na análise das propriedades multifractais das séries temporais. Esteller et al. [8] demonstram a relevância da análise por algoritmos de dimensão fractal e das diferenças associadas aos métodos utilizados. Embora ambos sejam amplamente empregados em estudos biomecânicos, ainda existe limitada compreensão sobre sua robustez frente às alterações frequentemente presentes nos sinais experimentais.

A frequência de amostragem e a presença de ruído representam dois fatores capazes de modificar significativamente a estrutura temporal dos sinais, podendo influenciar diretamente as estimativas fractais obtidas. Nesse contexto, Mehdizadeh [5] investigou a influência do ruído sobre métodos de análise não linear, enquanto Souza et al. [6] avaliaram a influência da adição de ruído em sinais biomecânicos da marcha. Dessa forma, torna-se importante compreender como diferentes algoritmos respondem a essas modificações.

O objetivo deste estudo foi investigar a influência da frequência de amostragem e do ruído branco gaussiano sobre o desempenho dos algoritmos Correlation Dimension e MF-DFA aplicados a sinais biomecânicos da marcha humana.

II. Materiais e métodos

A. Participantes

Foram analisados dados provenientes de um estudo experimental conduzido pelo Laboratório de Biomecânica da Universidade Federal de Goiás (UFG). A amostra foi composta por jovens saudáveis (J), idosos não caidores (INC) e idosos caidores (IC).

O estudo experimental que originou os dados foi previamente aprovado pelo Comitê de Ética em Pesquisa da Universidade Federal de Goiás (UFG), sendo todos os procedimentos realizados em conformidade com as normas éticas para pesquisas envolvendo seres humanos. Todos os participantes foram incluídos no estudo mediante consentimento livre e esclarecido..

B. Aquisição dos Dados

Os sinais biomecânicos foram adquiridos por meio de um sistema tridimensional de captura de movimento com frequência original de amostragem de 120 Hz durante protocolos de marcha realizados em diferentes velocidades, 80PWS,

100PWS e 120PWS, (Preferred Walking Speed) correspondentes a 80%, 100% e 120% da Velocidade de Caminhada Preferida.

As séries temporais analisadas foram obtidas a partir do marcador posicionado sobre o processo espinhoso da décima vértebra torácica (T10). Esse ponto anatômico é amplamente utilizado em estudos biomecânicos como representação da dinâmica do tronco durante a locomoção, por estar localizado em uma região central do segmento torácico e apresentar estreita relação com os mecanismos de controle postural e estabilidade da marcha. Dessa forma, as métricas fractais avaliadas neste estudo refletem a complexidade associada ao comportamento dinâmico do tronco humano durante a marcha.

C. Processamento dos Sinais

Os sinais originais foram submetidos a duas formas de degradação controlada:

- redução da frequência de amostragem para 60 Hz e 30 Hz;
- adição de ruído branco gaussiano com relações sinal-ruído de 50, 40, 30, 20 e 10 dB.

D. Correlation Dimension

A Correlation Dimension foi calculada a partir da reconstrução do espaço de fase, conforme os fundamentos propostos por Grassberger e Procaccia [1] e Takens [2], utilizando atraso temporal obtido pelo primeiro mínimo da informação mútua e dimensão de imersão estimada pelo método dos falsos vizinhos mais próximos.

E. MF-DFA

O algoritmo Multifractal Detrended Fluctuation Analysis (MF-DFA), proposto por Kantelhardt et al. [3] e posteriormente detalhado por Ihlen [4], foi aplicado para caracterizar as propriedades multifractais das séries temporais biomecânicas. O método avalia o comportamento de escala das flutuações após a remoção de tendências em múltiplas escalas temporais, permitindo estimar correlações de longa duração e caracterizar a estrutura multifractal dos sinais analisados.

F. Análise Estatística

Os resultados foram analisados por meio de análise de variância (ANOVA) de medidas repetidas, utilizando o software JASP e adotando nível de significância de p¡0,05. Foram avaliados os efeitos principais e as interações entre os fatores velocidade da marcha, frequência de amostragem, nível de ruído e grupo, de acordo com as condições experimentais analisadas. As análises foram realizadas separadamente para os parâmetros obtidos pela Correlation Dimension (CD) e pelo Multifractal Detrended Fluctuation Analysis (MF-DFA), permitindo avaliar a influência das modificações impostas aos sinais sobre cada método.

Para a avaliação da influência da frequência de amostragem, foram consideradas as condições de 120, 60 e 30 Hz, juntamente com as diferentes velocidades de marcha e os grupos avaliados. Para a avaliação da influência do ruído, foram considerados os diferentes níveis de relação sinal-ruído aplicados aos sinais, permitindo analisar os efeitos do ruído e suas interações com a velocidade da marcha e o grupo.

Na análise da Correlation Dimension em função da frequência de amostragem, as diferenças identificadas entre as frequências foram posteriormente avaliadas por comparações pós-hoc. Adicionalmente, foram calculados coeficientes de correlação de Pearson (r), utilizando a condição de 100% PWS e 120 Hz como referência, com o objetivo de avaliar a associação entre os resultados obtidos nas diferentes condições experimentais. A incerteza das estimativas de correlação foi avaliada por meio de intervalos de confiança de 95% (IC95%), calculados utilizando a transformação z de Fisher.

III. Resultados

A. Influência da Frequência de Amostragem na Correlation Dimension

A análise da Correlation Dimension demonstrou efeito significativo da frequência de amostragem, indicando que alterações na resolução temporal modificam os valores estimados pela métrica. Em contraste, a velocidade e o grupo não apresentaram efeitos principais significativos. Entretanto, foram identificadas interações entre frequência e grupo e entre velocidade e frequência, demonstrando que o efeito da resolução temporal depende das condições analisadas. A interação entre velocidade, frequência e grupo não apresentou significância estatística. Os resultados completos são apresentados na Tabela I.

A Figura 1 permite visualizar esse comportamento na condição de 100% PWS. Os idosos caidores (IC) apresentaram maior variação dos valores de Correlation Dimension entre as frequências, com valores médios de aproximadamente 2,249 em 30 Hz, 2,167 em 60 Hz e 2,203 em 120 Hz. Em contraste, INC e J apresentaram trajetórias mais regulares, com redução gradual dos valores à medida que a frequência aumentou. Essa diferença entre as trajetórias é compatível com a interação significativa entre frequência e grupo observada na ANOVA, embora as diferenças apresentadas graficamente devam ser interpretadas como tendências descritivas.

A análise de correlação apresentada na Figura 2 complementa esses resultados ao avaliar a preservação do padrão da Correlation Dimension em relação à condição de referência de 100% PWS e 120 Hz. Mantendo-se 100% PWS, os grupos INC e J apresentaram coeficientes de Pearson próximos da unidade mesmo após a redução para 60 e 30 Hz, indicando elevada correspondência com os resultados obtidos em 120 Hz. Dessa forma, embora a frequência tenha influenciado significativamente a magnitude da Correlation Dimension, a relação entre os resultados permaneceu amplamente preservada nesses grupos.

O grupo IC apresentou maior variação, com correlações de aproximadamente 0,60 em 60 Hz e 0,79 em 30 Hz. Esse comportamento também foi observado na Figura 1 e pode estar relacionado, ao menos parcialmente, ao menor tamanho amostral desse grupo, que pode aumentar a variabilidade das

estimativas. Essa interpretação, entretanto, deve ser considerada com cautela, não sendo possível atribuir exclusivamente ao tamanho da amostra as diferenças observadas.

A Figura 2 também demonstra influência importante da velocidade da marcha sobre a preservação do padrão da métrica. Nos grupos INC e J, a alteração da velocidade produziu reduções acentuadas da correlação com a referência, mesmo quando a frequência permaneceu em 120 Hz. Esse comportamento foi particularmente evidente no grupo J, que apresentou correlações negativas nas condições de 80% PWS. Assim, embora a velocidade não tenha apresentado efeito principal significativo na ANOVA, a análise de Pearson indica que modificações na condição de marcha podem alterar a correspondência dos resultados com a referência.

Em conjunto, as Figuras 1 e 2 mostram aspectos complementares da resposta da Correlation Dimension. A Figura 1 evidencia alterações na magnitude da métrica associadas à frequência, enquanto a Figura 2 demonstra que essas alterações não necessariamente resultam em perda da correspondência com a condição de referência. Dessa forma, a Correlation Dimension apresenta sensibilidade quantitativa à frequência de amostragem, mas também relativa robustez quanto à preservação do padrão dos resultados, especialmente nos grupos INC e J.

Do ponto de vista metodológico, esses resultados reforçam a importância da resolução temporal na aplicação da Correlation Dimension. A redução da frequência diminui a densidade de pontos disponíveis para a reconstrução do espaço de fase e pode modificar a representação geométrica da dinâmica do sistema. Embora os elevados coeficientes de correlação indiquem que frequências inferiores podem preservar parte importante do padrão da métrica, a aquisição em 120 Hz permanece recomendável quando disponível, por preservar maior resolução temporal e reduzir a possibilidade de perda de informação.

Assim, os resultados indicam que frequência de amostragem e velocidade influenciam propriedades distintas da Correlation Dimension. A combinação da ANOVA, da análise dos valores médios e das correlações permite caracterizar de forma mais abrangente a resposta da métrica às modificações impostas aos sinais biomecânicos.

B. Influência do Ruído na Correlation Dimension

O fator ruído apresentou efeito significativo sobre a Correlation Dimension. Entretanto, não foram observadas diferenças significativas associadas aos grupos analisados, às velocidades de marcha ou às interações entre os fatores experimentais. Esses resultados indicam que a Correlation Dimension é influenciada pela degradação do sinal, porém essa influência ocorre de maneira relativamente homogênea entre as diferentes populações avaliadas. Os resultados completos da análise estatística são apresentados na Tabela II

C. Influência da Frequência de Amostragem no MF-DFA

Para o MF-DFA foram observados efeitos significativos da velocidade de marcha, da frequência de amostragem e

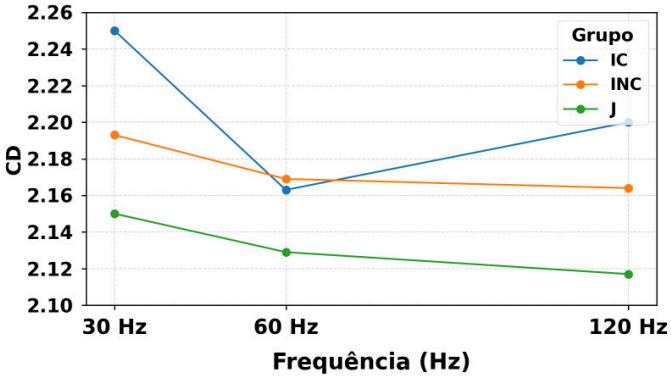

Figura 1. Valores médios da Dimensão de Correlação (CD) em função da frequência de amostragem na condição de 100% PWS para os grupos de Idosos Caidores (IC), Idosos Não Caidores (INC) e Jovens (J). Os valores representam a média com margem de erro considerada de $\pm 3\%$ para interpretação.

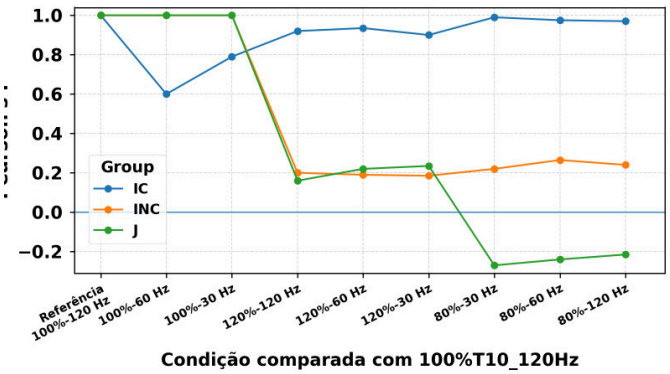

Figura 2. Coeficientes de correlação de Pearson (r) comparando as diferentes condições com a referência 100%T10_120Hz para os grupos IC, INC e J. As estimativas foram avaliadas considerando intervalo de confiança de 95% (IC95%), calculado pela transformação z de Fisher.

da interação entre velocidade e frequência. Não foram identificadas diferenças significativas envolvendo os grupos ou interações que incluíssem o fator grupo. Os resultados sugerem que o comportamento multifractal dos sinais é influenciado principalmente pelas condições experimentais relacionadas à execução da tarefa e pela resolução temporal dos dados. Os resultados completos da análise estatística são apresentados na Tabela III.

A representação dos valores médios do MF-DFA em função da frequência de amostragem, considerando a condição de 100% PWS, permite visualizar de forma mais detalhada a influência da resolução temporal sobre os valores obtidos pelo método (Figura 3). Observa-se uma tendência progressiva de aumento do MF-DFA com o aumento da frequência de amostragem em todos os grupos avaliados. Em 30 Hz, os valores permaneceram próximos de 0,97–0,98, aumentando para aproximadamente 1,26–1,28 em 60 Hz e atingindo valores próximos de 1,45–1,47 em 120 Hz. Dessa forma, a tendência observada graficamente é consistente com o efeito significativo da frequência de amostragem identificado pela análise

estatística.

Além do aumento progressivo da métrica, a Figura 3 demonstra que a alteração observada entre 30 e 60 Hz é visualmente mais acentuada do que aquela observada entre 60 e 120 Hz. Esse comportamento indica que a relação entre a frequência de amostragem e os valores obtidos pelo MF-DFA não apresenta uma variação proporcional entre todos os níveis analisados. Entretanto, essa diferença na magnitude das variações deve ser interpretada de maneira descritiva, uma vez que a análise apresentada não permite estabelecer, apenas pela representação gráfica, que a alteração entre 30 e 60 Hz seja estatisticamente superior àquela observada entre 60 e 120 Hz.

Outro aspecto relevante apresentado na Figura 3 é a elevada proximidade entre as trajetórias dos grupos de idosos caidores (IC), idosos não caidores (INC) e jovens (J). Apesar de pequenas diferenças nos valores médios em cada frequência, os três grupos apresentam praticamente o mesmo padrão de resposta, caracterizado pelo aumento sistemático do MF-DFA entre 30, 60 e 120 Hz. A proximidade e o comportamento aproximadamente paralelo das trajetórias são consistentes com a ausência de interação significativa entre frequência e grupo observada na análise estatística, sugerindo que a influência da frequência de amostragem sobre o MF-DFA ocorreu de maneira relativamente uniforme entre as populações avaliadas.

Esse resultado também contribui para diferenciar o efeito associado à resolução temporal daquele relacionado às características dos grupos. Considerando que não foram identificados efeitos significativos envolvendo o fator grupo, enquanto a frequência apresentou efeito significativo, as alterações observadas na Figura 3 estão predominantemente associadas às modificações impostas à frequência de amostragem. Nesse sentido, dentro das condições avaliadas, a resposta do MF-DFA parece apresentar maior dependência das características temporais do sinal do que das diferenças entre as populações analisadas.

A dependência observada em relação à frequência de amostragem pode estar relacionada à própria natureza do MF-DFA, uma vez que o método caracteriza o comportamento das flutuações do sinal ao longo de múltiplas escalas temporais. A redução da frequência de amostragem diminui o número de pontos disponíveis na série temporal e modifica sua resolução temporal, podendo alterar a representação das flutuações utilizadas na estimativa dos parâmetros multifractais. Consequentemente, sinais analisados em frequências distintas podem produzir diferentes estimativas mesmo quando provenientes de uma mesma condição experimental. A tendência apresentada na Figura 3 reforça, portanto, a importância da padronização da frequência de amostragem em estudos que utilizem o MF-DFA para caracterização de sinais biomecânicos.

Embora a Figura 3 represente especificamente a condição de 100% PWS e demonstre elevada similaridade entre os grupos nessa velocidade, a interação significativa entre velocidade e frequência identificada pela ANOVA indica que a influência da resolução temporal sobre o MF-DFA também depende da velocidade de marcha considerada. Dessa forma, a tendência apresentada em 100% PWS não deve ser generalizada isoladamente para as demais velocidades avaliadas. Em conjunto, os resultados demonstram que a interpretação dos parâmetros obtidos pelo MF-DFA deve considerar simultaneamente a frequência de amostragem e as condições de execução da tarefa, uma vez que alterações nesses fatores podem modificar a caracterização multifractal dos sinais e, consequentemente, influenciar comparações entre diferentes protocolos experimentais.

D. Influência do Ruído no MF-DFA

O MF-DFA apresentou o comportamento mais complexo entre todos os cenários avaliados. Foram observados efeitos significativos para velocidade, ruído, interação entre veloci-

dade e grupo, interação entre velocidade e ruído e interação tripla entre velocidade, ruído e grupo. Por outro lado, a interação entre ruído e grupo não apresentou significância estatística, indicando que a influência direta do ruído ocorreu de forma semelhante entre os grupos, embora suas interações com a velocidade tenham produzido respostas distintas. Esses resultados demonstram que o MF-DFA apresenta elevada sensibilidade às alterações impostas ao sinal e às condições experimentais da marcha. Os resultados completos da análise estatística são apresentados na Tabela IV

E. Discussão

O presente estudo investigou a influência da frequência de amostragem e da adição de ruído branco gaussiano sobre o desempenho da Correlation Dimension (D_2) e do Multifractal Detrended Fluctuation Analysis (MF-DFA) aplicados a sinais biomecânicos. De modo geral, os resultados demonstraram que ambos os métodos são influenciados pelas características dos sinais, porém apresentam comportamentos distintos frente às modificações introduzidas, evidenciando a importância das condições de aquisição e processamento na interpretação das métricas fractais.

Na Correlation Dimension, a frequência de amostragem apresentou efeito significativo. Embora não tenham sido observadas diferenças entre 120 e 60 Hz, a redução para 30 Hz produziu alterações significativas, indicando maior influência sobre a estimativa da métrica em reduções mais acentuadas da resolução temporal. Esse comportamento pode estar relacionado à reconstrução do espaço de fase, uma vez que a redução da frequência diminui a quantidade de informações temporais disponíveis e pode modificar a distribuição geométrica dos pontos que constituem o atrator reconstruído, considerando os princípios de reconstrução descritos por Takens [2].

A Figura 1 permite visualizar esse comportamento na condição de 100% PWS. Enquanto INC e J apresentaram trajetórias relativamente regulares entre 30, 60 e 120 Hz, o grupo IC apresentou maior variação entre as frequências, com comportamento não monotônico. A divergência entre essas trajetórias é compatível com a interação significativa entre frequência e grupo, indicando que a influência da resolução temporal sobre a Correlation Dimension não ocorreu de maneira completamente uniforme entre as populações analisadas.

A análise de correlação apresentada na Figura 2 complementa esses resultados ao comparar as diferentes condições experimentais com a referência de 100% PWS e 120 Hz. Quando a velocidade foi mantida em 100% PWS, INC e J apresentaram coeficientes próximos da unidade mesmo após a redução para 60 e 30 Hz. Assim, embora a frequência tenha produzido alterações significativas na magnitude da Correlation Dimension, a correspondência com a condição de referência permaneceu elevada nesses grupos.

O grupo IC apresentou maior variação, com correlações de

aproximadamente 0,60 em 60 Hz e 0,79 em 30 Hz. Esse comportamento, também observado na Figura 1, pode estar relacionado parcialmente ao menor tamanho amostral desse grupo, que aumenta a influência das características individuais sobre as estimativas. Entretanto, essa interpretação deve ser considerada com cautela, não sendo possível atribuir exclusivamente ao tamanho da amostra as diferenças observadas.

A Figura 2 também evidencia influência da velocidade sobre a preservação do padrão da Correlation Dimension. Nos grupos INC e J, a alteração para 120% ou 80% PWS reduziu consideravelmente as correlações com a referência, mesmo quando a frequência permaneceu em 120 Hz. Esse comportamento foi particularmente evidente no grupo J, que apresentou correlações negativas nas condições de 80% PWS. Embora a velocidade não tenha apresentado efeito principal significativo na ANOVA, esses resultados indicam que modificações na condição de marcha podem alterar a correspondência dos resultados individuais sem necessariamente produzir um deslocamento sistemático de sua magnitude média.

Em conjunto, as Figuras 1 e 2 demonstram que a Correlation Dimension apresenta sensibilidade quantitativa à frequência de amostragem, mas também relativa preservação do padrão em diferentes resoluções temporais, principalmente em INC e J. Considerando, entretanto, o efeito significativo da frequência e a dependência da reconstrução do espaço de fase em relação à resolução temporal, a aquisição em 120 Hz permanece metodologicamente recomendável quando disponível, por preservar maior quantidade de informação do sinal original.

Em relação ao ruído branco gaussiano, a Correlation Dimension apresentou alterações significativas associadas à degradação do sinal, porém não foram identificadas interações significativas envolvendo grupo ou velocidade. Esse resultado sugere uma influência relativamente homogênea do ruído nas condições analisadas. A introdução de componentes aleatórios pode modificar a distribuição dos pontos no espaço de fase e, consequentemente, interferir na estimativa da dimensionalidade, comportamento compatível com a influência do ruído sobre análises não lineares discutida por Mehdizadeh [5] e com os resultados apresentados por Souza et al. [6] em sinais biomecânicos da marcha.

O MF-DFA apresentou comportamento distinto. Na análise da frequência foram identificados efeitos significativos da velocidade, da frequência e da interação entre velocidade e frequência, sem interações significativas envolvendo o grupo. Esses resultados indicam que os parâmetros multifractais foram influenciados principalmente pela resolução temporal e pelas condições de execução da tarefa.

A Figura 3 evidencia esse comportamento na condição de 100% PWS. Os três grupos apresentaram aumento progressivo dos valores do MF-DFA com o aumento da frequência, partindo de aproximadamente 0,97–0,98 em 30 Hz, aumentando para 1,26–1,28 em 60 Hz e atingindo aproximadamente 1,45–1,47 em 120 Hz. As trajetórias permaneceram próximas e aproximadamente paralelas, comportamento compatível com o efeito significativo da frequência e com a ausência de interação significativa entre frequência e grupo.

A alteração observada entre 30 e 60 Hz apresentou magnitude visualmente maior do que entre 60 e 120 Hz, sugerindo maior influência de reduções mais acentuadas da resolução temporal. Essa tendência deve, entretanto, ser interpretada de forma descritiva. A dependência do MF-DFA em relação à frequência pode estar associada à própria natureza do método, uma vez que a caracterização das flutuações em múltiplas escalas temporais depende da quantidade e da distribuição temporal dos pontos disponíveis na série, conforme os fundamentos apresentados por Kantelhardt et al. [3] e Ihlen [4].

Embora a Figura 3 represente especificamente 100% PWS, a interação significativa entre velocidade e frequência demonstra que a influência da resolução temporal sobre o MF-DFA também depende da condição de marcha. Dessa forma, os resultados obtidos nessa velocidade não devem ser generalizados diretamente para as demais condições, reforçando a necessidade de considerar conjuntamente as características do sinal e da tarefa biomecânica.

Na análise do ruído, o MF-DFA apresentou efeitos significativos para velocidade e ruído, além de interações entre velocidade e grupo, velocidade e ruído e entre velocidade, ruído e grupo. Esses resultados demonstram maior dependência das combinações entre os fatores experimentais. Essa sensibilidade pode estar relacionada à natureza multifractal do método, que caracteriza a organização das flutuações em múltiplas escalas temporais e, consequentemente, pode responder de forma mais pronunciada às alterações simultâneas na execução da tarefa e na qualidade do sinal, considerando as características do método descritas por Kantelhardt et al. [3] e Ihlen [4].

A maior sensibilidade observada para o MF-DFA não deve ser interpretada necessariamente como menor desempenho. Essa característica pode representar uma limitação quando o objetivo é obter uma métrica robusta às alterações de aquisição e processamento, mas também pode favorecer a identificação de modificações na organização temporal dos sinais. Assim, sensibilidade e robustez devem ser consideradas de acordo com a finalidade da análise.

A comparação entre os métodos demonstra que eles caracterizam propriedades distintas da dinâmica dos sinais. A Correlation Dimension está associada predominantemente à geometria do atrator reconstruído, conforme os fundamentos de Grassberger e Procaccia [1], enquanto o MF-DFA caracteriza a organização das flutuações em múltiplas escalas temporais, conforme descrito por Kantelhardt et al. [3] e Ihlen [4]. Dessa forma, as diferenças observadas frente à frequência, velocidade e ruído são compatíveis com as distintas propriedades avaliadas pelos algoritmos.

Do ponto de vista metodológico, os resultados reforçam que métricas fractais obtidas sob diferentes protocolos de aquisição devem ser comparadas com cautela. Alterações na frequência de amostragem e na qualidade do sinal podem modificar os valores estimados e interagir com as condições experimentais, tornando importante a padronização dos protocolos de aquisição e processamento. A escolha entre Correlation Dimension e MF-DFA deve, portanto, considerar a propriedade dinâmica que se pretende investigar e as características dos

sinais disponíveis.

Dessa forma, os métodos podem ser considerados complementares na caracterização da complexidade dos sinais biomecânicos. A utilização conjunta dessas abordagens permite associar informações relacionadas à geometria da dinâmica reconstruída às características temporais e multiescalares das flutuações, contribuindo para uma análise mais abrangente da dinâmica da marcha humana.

F. Agradecimentos

Os autores agradecem ao Programa de Pós-Graduação em Engenharia Biomédica da Universidade Federal de Uberlândia, ao Laboratório de Bioengenharia e Biomecânica da Universidade Federal de Goiás e às instituições de fomento que contribuíram para a realização desta pesquisa.

***Resumo*—A ausência de membros inferiores decorrente de amputações transfemorais é uma das principais causas de redução da mobilidade funcional, comprometendo o equilíbrio e o conforto biomecânico. As próteses convencionais de baixo custo distribuídas na rede pública apresentam limitações severas no amortecimento inicial da marcha devido a rigidez excessiva e ao comportamento mecânico, resultando em assimetrias significativas. O projeto propõe o desenvolvimento de uma prótese de pé e tornozelo fundamentada no uso de metamateriais mecânicos e manufatura aditiva para otimizar a absorção de impacto. Através da parametrização de metaestrutura auxeticas reentrantes, projetou-se um dispositivo com gradientes de rigidez adaptáveis. Os resultados obtidos via simulação por elementos finitos e ensaios experimentais de compressão demonstraram que a geometria de 0,4mm suportou cargas de até 5800N. Os resultados do modelo revelaram uma correlação de 88,9% entre a força estimada (4098N) e a força experimenta (3643 N) para uma deformação de 15,6%. Concluiu-se que a precisão obtida e a viabilidade econômica (R$ 186,54) têm uma tendencia possível da eficácia da proposta na atenuação de assimetrias de marcha.**

***Index Terms*—Prótese Modular de Tornozelo e Pé, Marcha Humana, Manufatura Aditiva, Absorção de impacto, Caracterização Mecânica.**

I. Introdução

A perda de membros inferiores representa um desafio crítico de saúde pública no Brasil. Dados da Sociedade Brasileira de Angiologia e de Cirurgia Vascular (SBACV), extraídos do Sistema Único de Saúde (SUS), indicam a realização de mais de 282 mil amputações entre janeiro de 2012 e maio de 2023, comum uma média alarmante de 85 procedimentos diários em 2022 [1]. Este cenário exige tecnologia assistivas que restaurem a independência funcional e mitiguem o comprometimento da fase de apoio terminal e o retorno de energia ineficiente

As limitações das próteses rígidas convencionais residem na incapacidade de reproduzir a resposta dinâmica não linear do complexo pé-tornozelo natural. Tais dispositivos falham na absorção de impacto gerando sobrecargas compensatórios que resultam em assimetrias de marcha crônicas. Dispositivos de alto desempenho, embora eficazes, possuem custo proibitivo para a maior parte da população, especialmente para adolescentes em fase de crescimento e idosos.

Apesar do avanço da engenharia, a realidade tecnológica das próteses de membros inferiores para grande parte da população ainda é marcada por limitações especialmente os dispositivos de baixo custo distribuídos em sistemas públicos, no qual baseiam-se em designs que utilizam materiais tradicionais e estruturas passivas de alta rigidez. Em modelos clássicos o uso de núcleos rígidos é incapaz de reproduzir as variações dinâmicas não lineares do complexo pé-tornozelo humano ao longo das diferentes fases de marcha [2].

Essa característica de "tamanho único" ou rigidez padrão gera um problema crítico na ausência de ajustes individualizados para diversas características biomecânicas únicas de cada indivíduo como a diferença entre massa corporal, idade, estatura e necessidades personalizadas que agravam a adapta-

O presente trabalho foi realizado com o apoio da Financiadora de Estudos e Projetos (Finep) – Contrato nº 01.25.0458.00 (0339/24). Os autores agradecem à Finep pelo suporte financeiro e institucional que possibilitou a realização desta pesquisa.

bilidade especialmente do público adolescente e idoso. A falta dessa personalização compromete a estabilidade e a eficiência funcional, uma vez que o dispositivo não consegue mimetizar a absorção de impacto necessária no contato inicial [3].

Como consequência dessa baixa adaptabilidade, o usuário desenvolve assimetrias de marcha significativas. O uso de sistemas rígidos sem amortecimento dinâmico exige do corpo a realizar compensação musculoesqueléticas que resultam em dores crônicas e doenças degenerativas ao longo prazo [4]. Portanto, existe uma lacuna tecnológica entre os dispositivos acessíveis e a necessidade biomecânica de uma marcha simétrica e confortável, justificando a busca por novos materiais e geometrias customizáveis.

O objetivo deste trabalho é projetar e caracterizar mecanicamente em bancada uma sola protética de pé e tornozelo baseada em metaestrutura auxética reentrante fabricada por manufatura aditiva, avaliando a rigidez ajustável do perfil celular, a concordância entre a previsão numérica e o ensaio de compressão, e o custo de material da solução proposta. A avaliação biomecânica da marcha e a validação clínica com usuários não fazem parte do escopo deste estudo.

II. Metodologia

A. Fundamentação Biomecânica e Materiais

A locomoção Humana exige que o pé e o tornozelo atuem como um sistema dinâmico de dissipação e restituição de energia. Durante a fase de Loading Response (LR), é imperativo que a estrutura promova a atenuação de impacto para proteger o membro residual. Na fase de propulsão, a rigidez deve ser suficiente para a transmissão eficiente de carga.

A escolha da metaestrutura auxética reentrante fundamenta-se em seu coeficiente de Poisson negativo. Sob compressão vertical, as paredes celulares contraem-se lateralmente, resultando em um aumento da densidade local e maior resistência ao impacto. Para a construção modular, o TPU 95A foi selecionado para a sola devido à sua resiliência e capacidade de amortecimento, enquanto o PETG foi adotado nas partes estruturais por sua estabilidade dimensional e resistência mecânica superior. A interface entre os materiais foi projetada com um encaixe do tipo “cauda de andorinha” (dovetail), garantindo a integridade mecânica para interferência e influenciado diretamente as condições de contorno das análises estruturais.

Os carregamentos adotados nas análises numéricas e nos ensaios preliminares foram definidos com base em referencias biomecânicas da macha humana e nos princípios gerais da ISSO 10328:2916, norma destinada à avaliação estrutural de próteses de membros inferiores.

B. Modelagem Geométrica e Simulação Numérica

A célula unitária auxética foi parametrizada no software Siemens NX, permitindo a construção de uma sola com gradiente de rigidez. A simulação numérica via Finite Element Analysis (FEA) foi conduzida no Ansys Workbench 2025R2, utilizando o modelo Bilinear isotropic Hardening para representar a não linearidade constitutiva do TPU 95A, os parâmetros inseridos incluíram uma tensão de escoamento de 42 MPa e um módulo de elasticidade tangente de 960 MPa, conforme caracterização de sólidos celulares e o TPU 95A foi modelado com densidade de 1,24 g/cm³ e coeficiente de Poisson de 0,35 [7].

As condições de contorno foram estabelecidas com foco na precisão do comportamento. Carregamento: Aplicou-se uma carga de 50 N sobre um módulo representativo da metaestrutura conforme ilustrado na Figura 1 lado A, cuja área é de 135,412 mm², correspondente a uma pressão de 369 kPa. Esta carga corresponde a uma célula unitária que ocupa 1,22% da área total da sola, escalonando matematicamente para o suporte das cargas observadas no ensaio experimental de compressão. Ressalta-se que a carga simulada e a carga do ensaio não são diretamente equivalentes: a comparação apresentada na Seção III foi obtida por escalonamento proporcional de área, admitindo-se distribuição uniforme dos esforços entre as células — hipótese simplificadora que, dado o caráter não linear da geometria, não é rigorosamente válida e não foi verificada experimentalmente. Malha e Configurações: Utilizou-se um refinamento de malha de 0,8 mm e a ativação da opção Large Deflection, essencial para capturar as grandes deformações e a reconfiguração geométrica das paredes auxéticas antes do platô de densificação gerando a malha da Figura 1 lado B. Foi utilizado auto time stepping com 25 substeps iniciais, mínimo de 10 e máximo de 100. Tentativas de refinamento adicional da malha não atingiram convergência, de modo que não foi realizado estudo formal de convergência. Restrições: A face superior foi modelada como suporte fixo, simulando o acoplamento por interferência à estrutura principal.

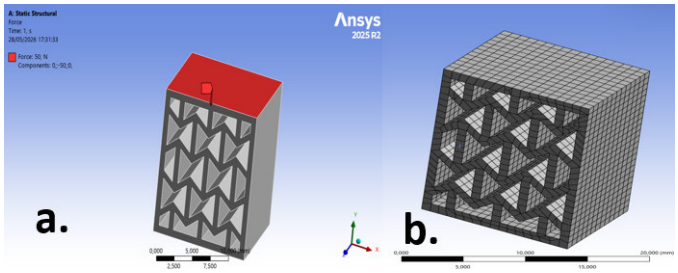

Figura 1. Configurações pré-simulação sendo o lado A - configuração das condições de contorno e o lado B - resultado da malha gerada pelo ANSYS.

C. Manufatura Aditiva e Parametros de Impressão

A fabricação foi realizada via FDM (Fused Deposition Modeling) utilizando uma impressora Bambu Lab A1 e P1S equipadas com bico de 0,4 mm. Foram selecionados dois materiais distintos, PETG para as partes estruturais (corpo principal, pé e tornozelo) pela tenacidade e estabilidade dimensional e a estrutura metamaterial da sola TPU 95A para a sola por sua elevada capacidade de recuperação elástica. Adotou-se altura de camada de 0,16 mm, com primeira camada de 0,20 mm e largura de linha entre 0,42 mm e 0,45 mm conforme a região da peça. A orientação das peças na mesa foi definida de modo a alinhar as camadas de deposição favorável

à direção predominante dos esforços, minimizando o risco de delaminação intercamadas.

- PETG: Bico extrusor a 223 °C e mesa a 80 °C, com 5 perímetros de parede para resistência mecânica e preenchimento tipo gyroid de 30% com ancoragem de 400% e comprimento máximo de âncora de 20 mm; seis camadas sólidas superiores em padrão monotônico; velocidades de 30 mm/s na parede externa, 80 mm/s na parede interna e 45 mm/s nas superfícies superiores.
- TPU: Bico extrusor a 250 °C e mesa a 60 °C com velocidade reduzida em 10 mm/s na primeira camada para assegurar a adesão interlaminar e precisão da célula auxética; paredes externa e interna a 70 mm/s e 80 mm/s; preenchimento a até 270 mm/s; limitação de vazão volumétrica em 3 mm³/s para reduzir instabilidades de extrusão típicas de materiais flexíveis. A impressão consumiu 156,9g de filamento em 12h 42min para o retropé.

D. Caracterização Mecânica Experimental

A caracterização mecânica foi conduzida por ensaios de compressão em máquina universal MTS 810. Foram produzidos três corpos de prova em TPU 95A, um para cada geometria avaliada — auxético de 0,4 mm, auxético de 0,6 mm e perfil combinado (Figura 2) —, todos fabricados com os parâmetros descritos na Seção II-C. As amostras, de 15 mm de altura, foram posicionadas entre as placas de compressão com alinhamento controlado, de modo a minimizar efeitos de carregamento excêntrico, e comprimidas até um deslocamento máximo de 8 mm com uma taxa de deslocamento de 8 mm/min. Adotou-se um corpo de prova por geometria, sem repetições; consequentemente, os valores reportados correspondem a observações individuais e não permitem estimativa de dispersão entre amostras. As amostras não foram submetidas a condicionamento controlado de umidade e temperatura previamente ao ensaio.

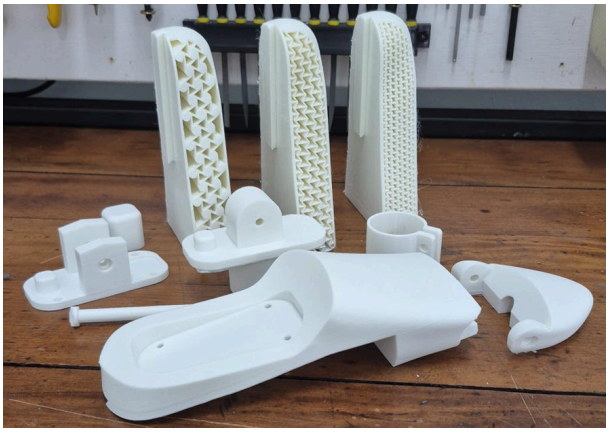

Figura 2. Prótotipo desmontado com todas as peças feitas em manufatura aditiva.

III. Resultados e discussão

Os ensaios experimentais em máquina MTS 810 caracterizam as respostas mecânicas dos três perfis distintos. Os dados obtidos estão sintetizados na Tabela I.

Tabela I
Resultado dos ensaios de compressão dos diferentes perfis.

Ensaio de compressão dos corpos de prova		
Perfil	Força Máxima (N)	Tensão Máxima (MPa)
Auxético 0,4 mm	∼5760	∼40
Auxético 0,6 mm	∼2450	∼17
Combinado	∼2800	∼19

O perfil auxético de 0,4 mm demonstrou o maior suporte de carga, suportando uma força máxima de aproximadamente 5760 N e com uma tensão máxima de 40 MPa. Em contrapartida, o perfil de 0,6 mm e combinado apresentaram um desempenho intermediário quando comparado ao perfil de 0,4 mm. Observou-se um comportamento não linear nas curvas de força-deslocamento, típico de sólidos celulares [8] com aumento progressivo da inclinação associado à densificação das células (Figura 3), sem colapso estrutural abrupto. Ressalta-se que os ensaios foram de compressão uniaxial sobre perfis isolados e não reproduzem as condições de carregamento combinado previstas nos ensaios estáticos da ISO 10328, referência que deve ser adotada em etapa posterior para qualificação do dispositivo montado.

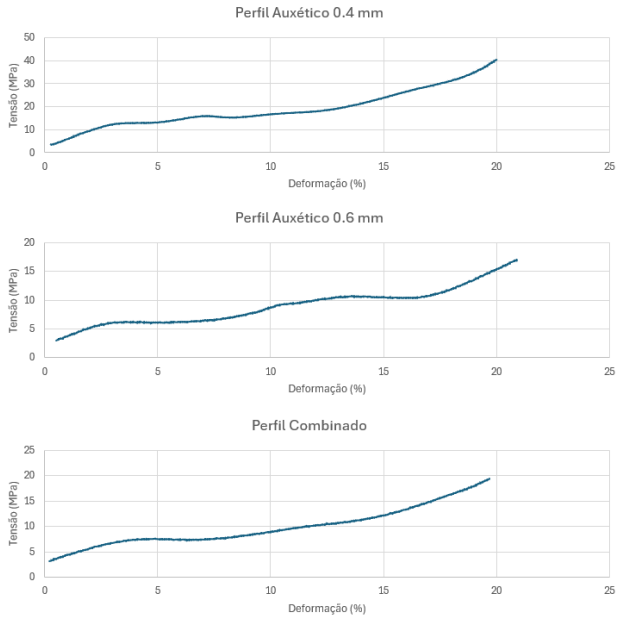

Figura 3. Curva tensão x deformação dos 3 peris auxeticos ensaiados e zonas de platô.

A comparação entre o modelo numérico e o ensaio experimental revelou que a simulação previu uma força de 4098 N para uma deformação de 15,6%, enquanto o ensaio físico

registrou 3643 N para o mesmo nível de deformação. Este resultado tem uma correlação de 88,9%, demonstrando o possível uso de elementos finitos para a predição do desempenho de metaestruturas impressas em 3D utilizando a tecnologia de impressão por Modelagem por Deposição Fundida (FDM) utilizando o modelo Bilienar Isotropic Hardening para prever o desempenho do protótipo.

A simulação ainda demonstrou que a estrutura auxética reentrante em TPU possui elevada capacidade de deformação controlada. Sob uma carga de 50N, o modelo apresentou um deslocamento máximo de 2,34 mm, o que apresenta 15,6% da altura total da amostra. A análise da energia de deformação atingiu 0,0419 mJ ao final da simulação, indicando a capacidade da geometria em armazenar e redistribuir energia.

A. Viabilidade Economica e Implicações Clinicas

O custo direto de fabricação do protótipo foi quantificado em R$ 187,66, decomposto em R$ 51,05 de materiais (0,157 kg de TPU a R$ 150,00/kg e 0,344 kg de PETG a R$ 80,00/kg), R$ 6,61 de energia elétrica (7,34 kWh a R$ 0,90/kWh) e R$ 130,00 de componentes comerciais (mola de inox do tornozelo e duas molas de torção dos dedos), a preços de mercado no período de execução do trabalho. Esse valor não inclui mão de obra, depreciação do equipamento, pós-processamento ou adaptação individualizada, itens que compõem o custo total de disponibilização do dispositivo ao usuário. Registra-se ainda que a mola inicialmente projetada em aço AISI 304 não atendeu ao critério de fadiga de Goodman (1,608 contra o limite de 0,77) para os dados de entrada adotados — força entre 500 N e 1000 N, deflexão de 15 mm e 3×10^6 ciclos conforme a ISO 10328; o projeto foi, portanto, alterado para aço SAE 1070, resultando em fator de segurança de 1,5 sob carregamento cíclico.

Este baixo custo de produção possui implicações clínicas diretas para o cenário brasileiro. A acessibilidade financeira é fundamental para adolescentes em fase de crescimento, que necessitam de substituições frequentes da prótese devido a alterações antropométricas. A modularidade e o baixo custo permitem que o sistema de saúde forneça dispositivos com amortecimento dinâmico a uma fração do preço das próteses de fibra de carbono importadas.

Ao comparar as outras opções no mercado, o conceito tecnológico apresentado evidencia a vantagem no custo-benefício conforme a Tabela II.

B. Comparativo com o Estado da Arte: Pé SACH

O pé SACH (Solid Ankle Cushion Heel) é utilizado como padrão de referência utilizado amplamente pelo SUS tendo sua construção com núcleo de madeira rígido e revestimento em poliuretano conforme ilustrado na Figura 4, sem qualquer articulação mecânica ou mecanismo de retorno de energia. Sua rigidez linear e a ausência de comportamento não-linear de amortecimento tornam-no incapaz de mimetizar a resposta dinâmica do complexo pé-tornozelo humano ao longo da fase da marcha [5].

Tabela II
COMPARATIVO ENTRE O CUSTO DE MATERIAL E COMPONENTES DO PROTÓTIPO E PREÇOS DE REFERÊNCIA DE DISPOSITIVOS COMERCIAIS (VALORES EM R$, BASE DE PREÇOS DO PERÍODO DE EXECUÇÃO DO TRABALHO; NÃO INCLUEM SERVIÇOS DE ADAPTAÇÃO).

Dispositivo	**Custo Estimado**	**Tipo de Amortecimento**	**Personalização**
Pé SACH convencional (SUS)	R$ 269,50 (reposição SUS) / R$ 200 ∼ R$380 (varejo)	Passivo, linear, núcleo rígido	Não
Pé SACH Ottobock 1S66 (importado)	R$ 1.299,09	Passivo, linear	Não
Próteses em fibra de carbono (ESR)	R$ 3.000 ∼ 15.000	Retorno de energia	Parcial
Protótipo (TPU/PETG)	R$ 187,66	Não linear, auxético, gradiente de rigidez	Sim

Do ponto de vista biomecânico, o pé SACH apresenta assimetria interlaterais significativas durante o ciclo de marcha, com redução da força de reação vertical no lado protetizado e incapacidade de simular a flexão plantar natural.

Contrapondo essa deficiência do pé de SACH, o protótipo apresentado, por meio do gradiente de rigidez das metaestruturas auxéticas reentrantes, oferece uma resposta mecânica não linear (Figura 3) que mimetiza a densificação progressiva do tecido adiposo plantar humano, potencialmente podendo contribuir na eventual redução de assimetrias de marcha. Ressalta-se que essa comparação é qualitativa e apoiada em dados de literatura, sendo necessário o estudo e ensaios clínicos para validar a hipótese acima posteriormente.

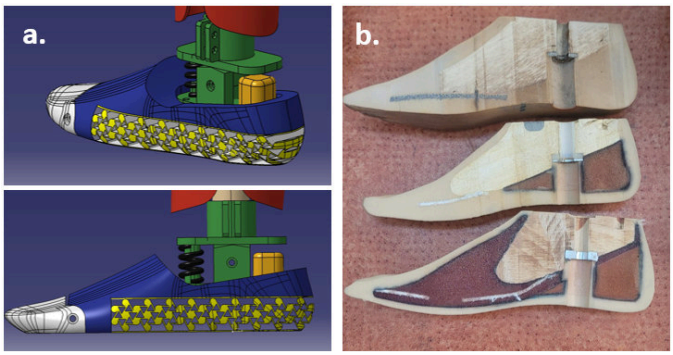

Figura 4. Comparação entre o prototipo (A) e o pé de SACH (B).

O pé SACH convencional não oferece mecanismo de ajuste de rigidez e por conta disso adolescentes em fase de crescimento tendem a mudar a sua massa corporal e biomecânica [6]. Sendo assim, a manufatura aditiva via FDM permite que o perfil auxético seja reimpresso e substituído com custo margi-

nal irrisório comparado aos custos atuais, aderindo diretamente as necessidades do sistema público brasileiro e ocupando essa lacuna tecnologia.

C. Limitações do Estudo

Este trabalho limita-se à caracterização mecânica em bancada de perfis celulares isolados, com um corpo de prova por geometria e sem repetições, o que impede estimativa de dispersão. As propriedades do TPU 95A empregadas no modelo numérico provêm de literatura e de ficha técnica, sem caracterização em tração do lote impresso. O refinamento adicional da malha não convergiu, de modo que não há estudo formal de convergência. O modelo de contato entre paredes celulares foi definido sem atrito e é válido apenas até o instante do primeiro toque entre elementos, não representando o deslizamento, as interferências adicionais nem a densificação subsequente. A comparação entre modelo e ensaio apoia-se em escalonamento proporcional de área, hipótese não válida em rigor para uma geometria de resposta não linear. Não foram realizados: condicionamento controlado das amostras; medição de armazenamento e retorno de energia; ensaios de fadiga e de carregamento cíclico; avaliação de envelhecimento ambiental e degradação polimérica; análise instrumentada de marcha, medição de pressão plantar ou avaliação funcional com usuários; nem ensaios comparativos diretos, sob condições equivalentes, com pés SACH ou com dispositivos de armazenamento e retorno de energia. Em decorrência dessas limitações as implicações clínicas discutidas devem ser entendidas como hipóteses de projeto.

IV. Conclusão

Os resultados obtidos indicam a viabilidade técnica de uma sola protética de pé e tornozelo baseada em metaestrutura auxética reentrante em TPU/PETG fabricada por manufatura aditiva, caracterizada em condições de bancada. Os perfis ensaiados apresentaram comportamento não linear com região de platô e densificação, característico de sólidos celulares, e rigidez ajustável pela espessura de parede da célula unitária, o que constitui a principal contribuição do trabalho: a caracterização experimental de uma geometria celular ajustável com potencial de aplicação em próteses de baixos custos.

Os principais achados técnicos destacam: Desempenho Estrutural: O perfil auxético de 0,4 mm demonstrou ser configuração mais eficiente, suportando cargas de até 5.760 N com uma tensão de 40 Mpa, superando as exigências típicas de carga para o ciclo de marcha humana sem apresentar deformação permanente. Concordância do Modelo: o desvio de 11,1% observado entre a simulação por elementos finitos e o ensaio na máquina MTS 810, em um único ponto de comparação, sugere que o modelo Bilinear Isotropic Hardening representa adequadamente a ordem de grandeza da resposta do TPU 95A na geometria estudada. A confirmação dessa capacidade preditiva depende da comparação de curvas completas para as diferentes geometrias, com repetições, e não é estabelecida por este resultado isolado.

Do ponto de vista socioeconômico, o protótipo apresentou um custo estimado de R$ 187,66 reais, valor drasticamente inferior às próteses comerciais de alto desempenho. Essa acessibilidade é fundamental para o cenário brasileiro e para o Sistema Único de Saúde (SUS), especialmente para o público adolescente, que demanda substituições frequentes devido ao crescimento antropométrico.

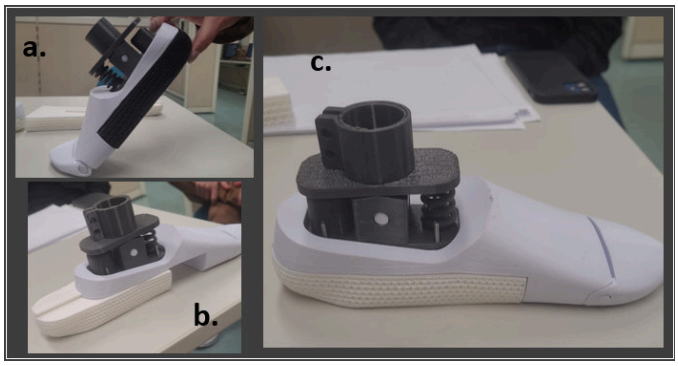

Figura 5. Prototipo em 3 vista sendo (A) demonstração do movimento da frente do pé, (B) subistituição do perfil auxetico, (C) prototipo completo.

Trabalhos futuros devem contemplar a caracterização em tração dos materiais efetivamente impressos, o estudo de convergência de malha e a comparação de curvas força-deslocamento pareadas para todas as geometrias, com repetições e reporte de erro e de modos de falha; a medição de armazenamento e retorno de energia; e a construção de bancada específica para os ensaios previstos na ISO 10328, incluindo fadiga dinâmica, visando à qualificação para uso clínico prolongado, além da análise da degradação polimérica sob exposição ambiental. Concluída a etapa de bancada e montado o dispositivo completo, a avaliação com usuários exigirá ensaios de segurança, aprovação por comitê de ética em pesquisa e adaptação individualizada por profissional habilitado, permitindo então a análise instrumentada da marcha, a medição de pressão plantar e a comparação funcional direta com pés protéticos comercialmente disponíveis, incluindo SACH e dispositivos ESR.

Uso de IAG

Em conformidade com a Portaria CNPq n° 2.664/2026, os autores declaram o uso da ferramentas de IAG nas seguintes etapas e finalidades: revisão de redação e padronização do estilo do texto (GPT-5.6, Notebook LM e Perplexity AI); busca de artigos para a revisão de literatura (Claude, Gemini e Sonar 2). A ferramenta não foi utilizada para gerar dados, resultados ou conclusões; não é listada como autora; e todo o conteúdo produzido com seu auxílio foi verificado e revisado pelos autores, que se responsabilizam integralmente pelo conteúdo final.

***Abstract*— Simultaneous control of multiple servomotors is a challenge in the development of Socially Assistive Robots (SAR) with a high number of degrees of freedom. In this work, we compare two PWM architectures for servo control in pediatric SAR: (1) the software-based Time-Division Multiplexing (TDM) technique, implemented and validated in hospital field trials on the TIGRÃO robot since 2005, and (2) the dedicated PCA9685 integrated circuit, evaluated for the BORIS robot project. Timing analysis was conducted using an 8-channel logic analyzer at 24 MHz, comparing both approaches under equivalent operating frequency conditions (33 Hz). The results demonstrate that the actual TDM update frequency is 33 Hz, differing from the nominal value of 50 Hz, without compromising the robot's expressive performance. The effective resolution analysis, performed at the 33 Hz test frequency, reveals that TDM operates with 180 steps entirely within the servo's useful range (0.5–2.5 ms), while the PCA9685 uses approximately 270 of the 4096 available steps at 33 Hz, an effective resolution gain of 1.5 times; at the 50 Hz frequency planned for BORIS's servo operation this gain rises to 2.3 times (410 effective steps). The use of multiple PCA9685 units requires an external oscillator to ensure synchronization between ICs. Both solutions demonstrated feasibility for SAR applications, with PCA9685 being the chosen solution for BORIS as it fully frees the processor for other critical tasks.**

Keywords—socially assistive robotics; servomotors; PWM; time-division multiplexing; PCA9685; pediatric SAR; HRI

I. INTRODUCTION

The development of socially assistive robots has grown continuously in order to support different groups, including the elderly [1] hospitalized children [2] e and individuals with autism spectrum disorder (ASD) [3], presenting designs and human-robot interaction (HRI) [4] that range from anthropomorphic [5], to abstract and zoomorphic [6], under autonomous [7], pre-programmed [8] or telepresence [9] control strategies. Among these, the Wizard of Oz (WOZ) method stands out in clinical contexts by allowing the specialist to control the robot covertly and in real time [10]; this approach simulates autonomous social intelligence for users and ensures that responses are strictly empathetic, dynamic, and adapted to the current limitations of purely autonomous systems [6, 11].

In 1993 in Japan, the PARO robot was developed [12], inspired by a harp seal pup, with the purpose of providing therapeutic support to the elderly and individuals with cognitive impairment; it began to be commercialized in 2005, and in 2009 it was certified by the Food and Drug Administration (FDA) as a "biofeedback medical device." The robot was designed to be soft and cuddly, incorporating servomotors to control head, flipper, and eye movements, enabling the simulation of realistic emotional responses, favoring the establishment of affective bonds, and promoting user well-being [12].

In 2004, Aldebaran Robotics launched NAO, a medium-sized, autonomous, and programmable humanoid robot. Since then, NAO has been used in various research areas, including SAR with children with ASD. However, it is a platform that requires high investment, and its programming is not trivial [13].

Huggable was developed at the MIT Media Lab with the aim of socially interacting with children in hospital settings, and can be used for pain distraction, entertainment, and to inform them about upcoming medical procedures. The robot has the appearance of a cute and friendly teddy bear. Its structure comprises 12 degrees of freedom, enabling expressive and animated movements. It is also equipped with capacitive sensors, which allow it to respond to tactile stimuli, maintaining natural interaction [14].

TIGRÃO robot project [15] began development in 2005, becoming fully functional with its 37 servomotors (DoFs), executing movements from pre-recorded positions by the end of 2006. Its mission as a SAR began in 2010, when its WOZ capability was expanded with the integration of a joystick for head and mouth control, demonstrating its effectiveness as a SAR as a supportive playful therapeutic technology, aligning with global efforts to mitigate the stress and fear inherent to pediatric hospitalization [16], alidating the potential of SAR as a provider of well-being in highly sensitive clinical environments.

TIGRÃO robot was developed with the core concept that it should be simple to explain and reproduce. Thus, to explain its electronic structure, we use a description tool known as the Hardware Diagram, shown in Fig. 1, in which at the center, a PIC18F452I/P microcontroller operates at 20 MHz. It receives signals from five buttons/switches for quick access to poses stored in memory, three analog signals from the joystick, connection to external pose-storage memory via I^2C bus, USART serial communication signals for WOZ operator control, the internal PWM output for controlling the illumination of a frosted acrylic panel with red LEDs placed on the robot's cheek, and has twelve digital connections to the PWM signal multiplexing block [17], through which the software manages the PWM outputs, operating under Time-Division Multiplexing (TDM) [18].

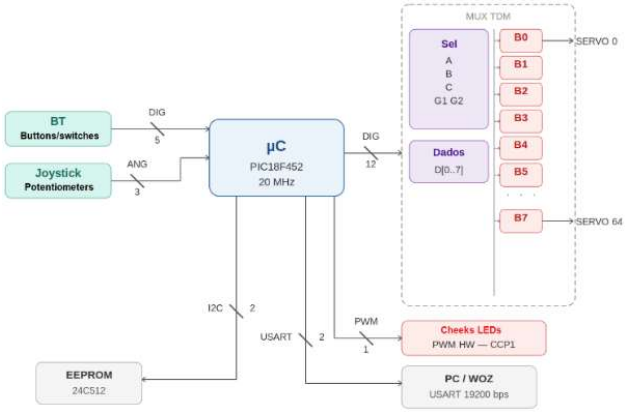

Fig. 1. Hardware Diagram of the TIGRÃO Robot

Since TIGRÃO robot requires at least 37 independent PWM signals (37 degrees of freedom - DoFs) to move its lower and upper limbs and all mobile parts of the head, it was necessary to expand the microcontroller's pin count. This task was accomplished through the TDM time-division I/O multiplexing circuit, increasing the physical capacity of digital signal outputs, mainly the PWM signals for the servos. The TIGRÃO mechanical structure was entirely built from flat, laser-cut aluminum sheets, with brass bushings and pins, resulting in an approximate weight of 13 kg, difficult to support even with the 20 kg HS805 motors used at that time, so it was decided to mount it onto an aluminum profile frame.

Inspired by the TIGRÃO robot, development of a new SAR began in 2026: BORIS (Buddy Operated Robot for Imagination and Stories), with at least 29 degrees of freedom (DoFs), in addition to sensors and haptic interfaces. It has the characteristics of a Siberian Husky dog and is being developed to be cute and huggable, intended primarily for use with hospitalized children during storytelling. It builds on almost 20 years of lessons learned from the TIGRÃO project, and its purpose is to go beyond a socio-emotional comfort tool and become an active physiological regulation agent.

BORIS robot is being fully designed to be built via 3D printing, which will facilitate its dissemination as a SAR development platform. Its electronic structure consists of five specialized microprocessor-based NODES, as shown in the robot's block diagram in Fig. 2. All of these modules are internal and communicate via a high-speed RS485 backbone (BORIS Bus daisy chain) and an RF network, both high-speed [19]. Some of the nodes have an SD card for synchronized data storage, allowing data retrieval and subsequent scientific evaluation. The microprocessors used in the NODES can be swapped for other models in the event of new research or the development of new models.

The microprocessors chosen for the BORIS robot project have two cores, and the primary strategy is to offload these cores by using as many hardware resources as possible. This created the need to replace software-based PWM signal generation and the previously developed I/O multiplexing structure with a dedicated hardware architecture. Accordingly, the first point considered was the possibility of using the microprocessor's internal hardware resources, which provide sixteen available PWM signals; however, this would limit the possibility of swapping microprocessors, would leave insufficient GPIO pins available on some modules, and would hinder future expansions. Therefore, the use of the PCA9685 integrated circuit was considered, which was originally designed to control sixteen PWM outputs for LEDs via I^2C, with a 12-bit resolution (4096 steps) and a guaranteed constant frequency across all sixteen outputs (24 Hz to 1526 Hz).

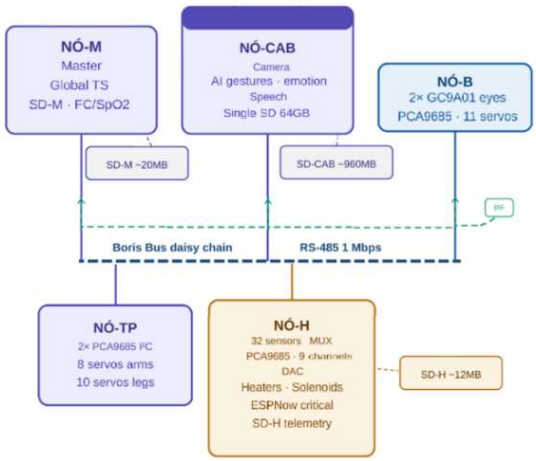

Fig. 2. Diagram of the BORIS Robot NODES.

The second point, in addition to I/O capacity and its respective load considerations, is that a SAR requires the latency between position changes of the facial servomotors to be less than 100 to 150 ms. This technical requirement is justified by the temporal dynamics with which the human brain decodes canine emotional expressions. Neurophysiological studies show that high-amplitude responses to dog emotions (such as aggressiveness or happiness) occur within a window of 100 ms to 150 ms [20]. Mechanical delays exceeding this neurological window would result in lethargic, unnatural behavior that breaks the consistency of realism and pushes the perception of the robot into the uncanny valley, an effect that is especially severe for moving entities [21].

Therefore, the efficient generation of PWM signals to control and synchronize multiple servomotors and haptic actuators remains a significant hardware challenge in the development of socially assistive robots (SAR). To address this challenge and ensure that the new platform meets real-time interaction requirements, the study described in this paper aims to compare two servomotor control techniques: software-based Time Division Multiplexing (TDM), currently used in the TIGRÃO robot, and the dedicated PCA9685 integrated circuit, proposed for the BORIS robot. This comparison is necessary to validate whether the dedicated integrated circuit can ensure the critical requirements of sub-150 ms latency and synchronization, without overloading the main microprocessors, and also to identify the most efficient approach that will determine BORIS's electronic architecture, ensuring the robot can deliver realistic, immediate emotional responses required for effective clinical intervention.

II. METHODOLOGY

To investigate the best PWM signal generation technique for the BORIS robot, we defined a strategy to temporally compare the two hardware solutions chosen for this purpose, namely the discrete I/O multiplexer and the dedicated PCA9685 integrated circuit. Since these are two very distinct

hardware solutions with very different techniques, we used a sequence of information common to both: the time between sending commands and the start of PWM signal generation at the outputs.

Another important analysis concerns the servomotor models used in the TIGRÃO robot project and those intended for use in the BORIS project, one being analog and the other digital, since each may have a different response in interpreting the PWM signals received.

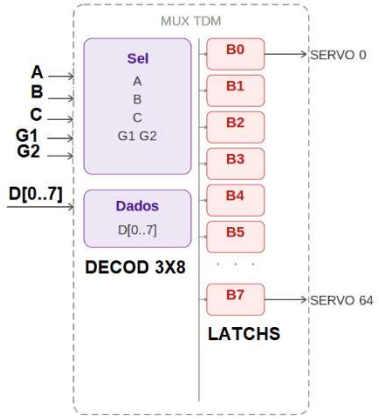

Fig. 3. PWM Output Multiplexing Board Circuit in block diagram.

To analyze the signals, an 8-channel logic analyzer with USB interface and a sampling frequency of 24 MHz was used, together with the Logic 2 software, which enables measurement of digital signals as well as monitoring and decoding of the I²C bus of the PCA9685. In addition to the logic analyzer, adapters were developed to connect the bank outputs of the TIGRÃO robot multiplexing board to the protoboard in order to facilitate connections, considering that the measurements do not require the servomotors to be in operation, nor any intervention with operator control or activation of a demonstration mode, since the outputs are constantly updated.

For the PCA9685 hardware test, four identical off-the-shelf Shield boards were used (Fig. 4.C), unmodified and mounted on the same protoboard as the TIGRÃO robot signal adapters, with I²C addresses configured from 0x40 to 0x43. The clock (SCL) and data (SDA) signals were connected in parallel and routed to an ARDUINO UNO. The input channels of the logic analyzer were connected to the selection signals and to the multiplexer bank outputs; it is not necessary to connect the SEL_G signal, since it is set to a high level as soon as the PIC18F452 microcontroller is configured, and the SEL_GA and SEL_GB signals remain continuously enabled in hardware, as shown in Fig. 3. TABLE 1 presents the configuration adopted for connecting the signals to the logic analyzer channels.

In the first test, the goal was to obtain the output signals from the TIGRÃO multiplexer, verifying, from the binary combinations of the selection signals, the moment at which the bank outputs begin their PWM cycles, connecting the logic analyzer channels according to TABLE 1. Once the signal acquisitions were performed, the interval between the configuration of the banks by the MUX selection signals and the start of the PWM cycle of the related output was measured.

TABLE 1. LOGIC ANALYZER CONNECTIONS.

LOGIC ANALYZER	MUX	PCA9685
SEL_0	SEL_A	SCL
SEL_1	SEL_B	SDA
SEL_2	SEL_C	0x40 – Servo 1
CHANNEL 3	Bank 0 – SR0	0x40 – Servo 9
CHANNEL 4	Bank 1 – SR8	0x41 – Servo 1
CHANNEL 5	Bank 2 – SR16	0x41 – Servo 9
CHANNEL 6	Bank 3 – SR14	0x42 – Servo 1
CHANNEL 7	Bank 4 – SR32	0x42 – Servo 9

After the first test was completed, the connector at the logic analyzer inputs was repositioned, now connecting the I²C bus and the outputs of the Shield boards to the input channels. Firmware versions for the ARDUINO UNO, which controls the PCA9685 units via the I²C bus, was recorded so as to simulate the same 8-output bank behavior as the TDM in each I²C transaction; that is, the PCAs was configured so that writing the position value of the 16 servos on each board is loaded in two transmissions to the same slave address on the I²C bus, first for outputs 1 to 8 and then 9 to 16, simulating the effect of loading one bank of 8 servomotors at a time, as in the multiplexer.

The test bench integrating the TIGRÃO robot with its PWM output multiplexing board, its connection cables to the protoboard, the PCA9685 Shield boards, and the logic analyzer are shown in Fig. 4.

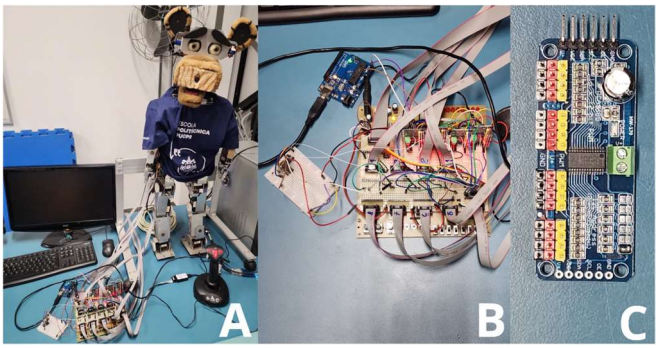

Fig. 4. Protoboard test setup for PWM signal evaluation. A. overall view; B. protoboard view; C. view of the PCA9685 board.

Initially, a write test was performed on all outputs of each PCA to confirm that everything is functioning correctly, and only afterward will signal acquisition begin, following the same timing measurement procedure used for TDM signal capture. In the case of the PCA9685, time measurement starts at the START of the I2C transmission frame and ends at the start of the PWM cycle of the related output. Since the PCA9685 allows all 16 PWM outputs to be sent in a single I2C transaction, the ARDUINO UNO firmware was modified for this test.

To perform the tests, a sequence was created that first resets all outputs of all PCA9685 units to zero, and after a delay, loads values for 8 and 16 outputs, depending on the test being performed. The signal capture procedure was carried out with a change in the connections between the logic analyzer and the PCA9685 Shield boards, following the configuration in TABLE 2.

TABLE 2. LOGIC ANALYZER AND PCA9685 – SINGLE 16-CHANNEL FRAME

LOGIC ANALYZER	PCA9685
SCL	SCL

CHANNEL 3	0x41 – Servo 1
CHANNEL 4	0x42 – Servo 1
CHANNEL 5	0x43 – Servo1
CHANNEL 6	Not used
CHANNEL 7	Not used

III. RESULTS

After collecting the signals from the TIGRÃO robot PWM multiplexing board, it was confirmed that the values implemented in its time-division multiplexing PWM generation technique are highly efficient. Although the multiplexer hardware has eight 8-bit banks (64 PWM outputs), the firmware of the PIC18F452 microcontroller limits activation to six banks, resulting in 48 updated PWM outputs, although only 37 are currently in use.

Another verification concerned the frequency of the generated PWM signal, which is 33 Hz, differing from the classic value typically used for servomotor control, normally 50 Hz. Since the TIGRÃO robot servomotors are analog, this frequency difference surprisingly causes no undesirable instability effect in their operation, allowing us to infer that they are more tolerant. Based on this observation regarding PWM frequency, and to maintain rigor in the analyses, the frequency of the PCA9685 units was changed to 33 Hz.

From the standpoint of the servomotors used in TIGRÃO robot (analog), each output bank's eight pins are set high as soon as the bank is selected as output within the ISR, followed by a fixed initial window (1000 to 1160 µs, depending on the bank) during which digital and, where applicable, analog inputs are read; this window is intentionally dimensioned in firmware so that its duration remains consistent across banks despite their different processing loads. Only after this window does the 180-step counting loop begin, with a fixed 4 µs resolution per step (720 µs total), during which each output individually falls to a low level once the step count exceeds its programmed position — this transition is what encodes the commanded pulse width. This 4 µs step resolution was dimensioned for the servos available in 2005 and safely exceeds the electromechanical deadband of every evaluated servo model (1 to 10 µs, depending on technology and era, TABLE 3), ensuring that the smallest programmable position change is always detected. An analog servo with an 8–10 µs deadband does not react to pulse variations smaller than this threshold, regardless of the controller's resolution, as shown in TABLE 3.

TABLE 3. SERVOMOTORS, DEADBAND, AND RESOLUTION

Model	YEAR	Technology	Deadband	Actual resolution
Hobbico CS-60	2005	Classic analog	8–10 µs	1,5°–2,0°/step
Hitec HS-805BB	2005	High-power analog	8 µs	0,8°–1,5°/step
SG90 TowerPro	2005	Micro analog	5 µs	0,8°–1,2°/step
MG90S	2026	Modern analog	5 µs	0,5°–1,0°/step
MG996R	2026	High-frequency digital	1–2 µs	0,44°/step (PCA bottleneck)

Timing measurements for the TDM technique were validated across n = 1435 complete bank cycles captured from a single continuous 44.25 s logic-analyzer session on the robot's original hardware and firmware, in use since the beginning of this study, summarized in TABLE 4 ("Boca ON/OFF" refers to whether the head-joystick analog reading was active). Banks without active analog input handling showed standard deviations (SD) on the order of tens of nanoseconds across all repetitions, indicating deterministic, hardware-level timing. Banks with conditional analog input reading showed two distinct, individually low-variance timing states corresponding to whether the joystick control was active, rather than measurement noise.

TABLE 4. BANK TIMING STATISTICS (SEL_G PULSE WIDTH, N = 1435 CYCLES)

Bank	State	n	Mean ms)	SD (ms)
0	Boca OFF	959	3.6231	0.01263
0	Boca ON	477	3.6199	0.00031
1	Boca OFF	959	3.6660	0.00002
1	Boca ON	477	3.6970	0.00821
2	dormant	1435	3.6662	0.00002
3	dormant	1435	3.6662	0.00002
4	no AD	1435	3.6666	0.00001
5	no AD	1435	3.6666	0.00001

Fig. 5 illustrates the actual behavior of the TDM technique operating on the TIGRÃO robot hardware, where it is possible to observe the logic selection signals Sel_0, Sel_1, and Sel_2 activated in sequence, and for each of their combinations, banks BANK0 through BANK4 being selected. The logic analyzer inputs were positioned on the first output bit of each bank (Q1 of the 74LS573), considering that the update of the 8 bits of the banks occurs simultaneously, since they are parallel registers; thus, it is possible to verify the moment at which the PWM signal begins its duty cycle at a high level in each bank. The markers from the start of a PWM pulse in one bank to the start of the subsequent bank indicate the delay time between the outputs of one bank and the next, which is 5 ms, the exact time of the timer interrupt call, and considering that there are six banks, the resulting period is 30 ms.

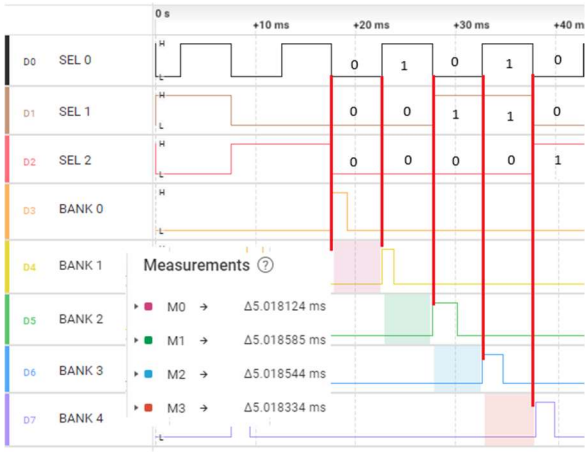

Fig. 5. Signal obtained from the logic analyzer for the TDM technique.

During the preliminary tests with the PCA9685 units, each with its own address and loading outputs in the classic manner, i.e., one output per I²C transaction, and using their internal clock generators, the synchronization problem between the outputs of one PCA relative to another became clearly evident, in addition to the variation in output frequency of each unit, as shown in Fig. 6. To mitigate the frequency variation problem, an external oscillator was developed.

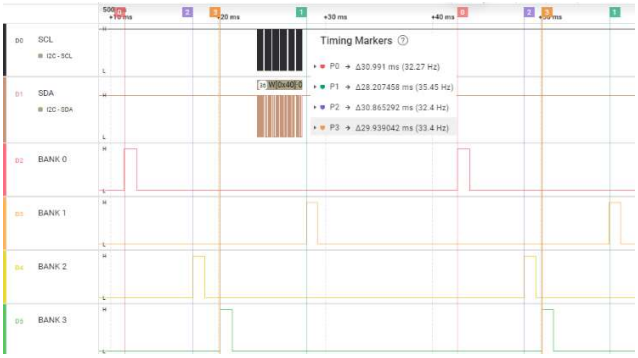

Fig. 6. Outputs of the Shield boards with internal oscillator and classic loading.

Since the Shield boards have the PCA9685 external clock input pin connected to GND through a via on the PCB, an intervention was performed using a drill bit to isolate the via from the GND plane on the bottom side of the board, and a wire was soldered to connect the external clock input pin to the developed clock generator. The external clock generator is a crystal oscillator with a frequency of 11.0592 MHz, based on inverting logic gates. This frequency value was chosen because it allows the best division ratio for the PCA outputs to operate at a precise PWM frequency of 50 Hz for the project; in this study, it was configured to operate at 33 Hz. The implemented oscillator circuit is shown on Fig. 7.

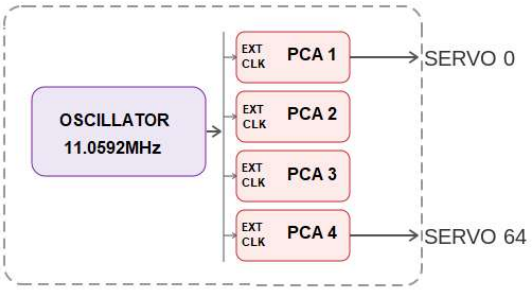

Fig. 7. External oscillator circuit and connection of the PCA9685 units in block diagram.

After implementing the clock generator circuit and confirming its operation together with the Shield board modifications and their connections to the external clock input pin, all PCA9685 units passed the individual basic tests and were connected to operate in a synchronized manner, allowing the acquisitions to be performed again.

A very important piece of information about PCA9685 concerns the update of the duty cycle of its outputs. Once a new value is loaded into the output registers, it only becomes available at the outputs after two conditions are met: the arrival of the STOP signal of the I²C transaction related to its address, and the next start of the PWM cycle. The times related to the update of the PCA9685 outputs after the arrival of the STOP signal of its I²C transaction were around 8 µs, and this procedure occurs regardless of the operating mode, whether loading a value for a single output, for blocks of 8 outputs (Fig. 8), which was one of our test objectives, or for 16 outputs (Fig. 9).

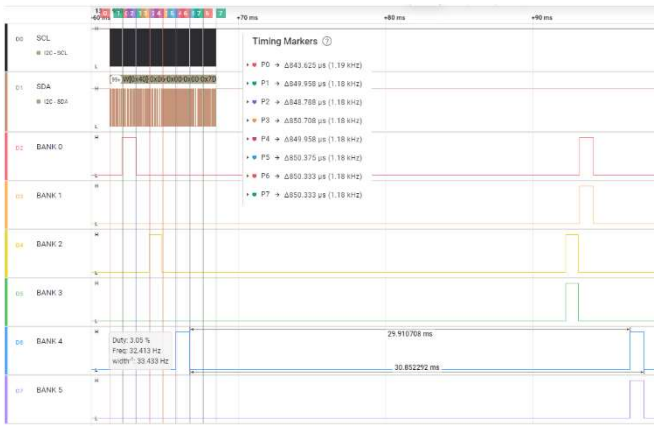

Fig. 8. Update times of the 8-output banks of the PCA9685 after receiving the channel stop signal.

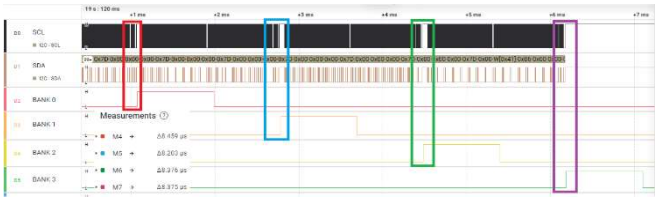

Fig. 9. Update times of the 16 outputs of the PCA9685 after receiving the channel stop signal.

One very important point that caught significant attention was the behavior observed when simulating operation in banks of 8 servos. As an example, Fig. 8 illustrates that when the I²C transaction for bank 0 ends (outputs 1 to 8 of the PCA at address 0x40), 8 µs after the STOP bit signal, the PWM

period of the entire PCA begins (the frequency is the same for all outputs), and loading of bank 1 (outputs 9 to 16 of the PCA at address 0x40) then begins; however, the PWM cycle of these outputs will only start at the beginning of the next PWM cycle of that PCA. This effect can be observed in all banks – PCAs in Fig. 8.

Since the ARDUINO UNO was being used for the tests, the source of the problem was identified as related to the size of its I²C buffer in the library, which allowed transmission of only 32 bytes per I²C transaction — coincidentally updating the positions of 8 outputs — with the second I²C transaction completing the remaining 16 outputs. The methodology originally specified the Arduino UNO for these acquisitions, however, upon identifying the limitation, the team switched to the ESP32devkit, redoing the data collection accordingly — all figures presented in this section (Fig. 8, Fig. 9, and Fig. 10) were captured using the ESP32devkit. Resuming the tests to evaluate the 16-output bank configuration, it was observed that, although the PCA9685 outputs have being updated and the I²C packets could be seen on the logic analyzer, the ATMEGA328 microcontroller kept writing two separate 32-byte packets for the outputs, instead of the expected 64 bytes that should appear in a single I²C transaction, since each position/output uses 4 bytes.

The solution would be to modify the standard library used or to change the microprocessor. We chose to migrate the test firmware to the ESP32devkit, which has up to 128 bytes of buffer, solving the buffer size problem, allowing the definition of 8- or 16-output updates per PCA9685, and bringing the hardware closer to the final version. Another change was made to increase the I²C bus frequency to 400 kHz, since with the ARDUINO UNO it operated at 100 kHz. With these changes, we solved the problem of writing 16 outputs (64 bytes) in a single I²C transaction, and the acquisitions for writing 16 outputs per transaction were repeated (Fig. 10).

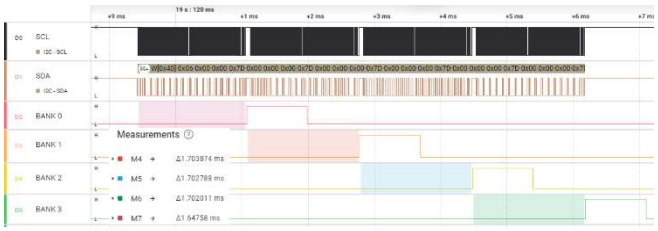

Fig. 10. Update times of the PCA9685 outputs measured from the start of the pulse of the previous PCA output – 16 outputs.

The procedure to measure this interval consisted of loading all 16 outputs of the PCAs with a value of 0, then starting the loading of duty cycle values for all 16 outputs of each PCA as well. Once the I²C transaction begins and the first STOP related to the PCA address occurs, the PWM cycle for that PCA begins for all 16 outputs. This procedure is repeated for each PCA slave on the bus.

IV. DISCUSSION AND CONCLUSION

Although the TIGRÃO robot is controlled by an 8-bit microcontroller, it still represents a major achievement of its development team, since its architecture is simple and discrete, based on performing multiple functions within each 5 ms window generated by a timer interrupt, optimizing the hardware to the maximum beyond what has already been described. Readings from 64 analog channels and 64 digital inputs were implemented using the same existing TDM selection signals, since these already had a planned destination: receiving signals from the WOZ operator suit, developed with potentiometers to capture the movements of arms, shoulders, legs, and other joints.

The scope of this study is limited to characterizing PWM signal generation. Treating the PWM signal generation electronics as a black box, its output does not interfere with the functioning of the servomotor and its attached mechanics since the same characteristics of the generated control signal are maintained, thereby ensuring an equivalent mechanical response regardless of the generation architecture used. Direct mechanical validation with load is beyond the scope of this comparison and is recommended as future work.

BORIS robot project inherits the concept of the Operator Suit, but now with current MPU technology, haptic feedback, and other features, aiming to offer greater interaction and realism for the operator, greater control of the robot, and the capture of scientific data for future evaluation. The behavioral implications of these technical improvements — including their effect on perceived expressiveness and child engagement — will be evaluated in the clinical trials of the BORIS project.

In TIGRÃO robot project, TDM operates with 180 steps, 100% within the useful range. At 33 Hz frequency used in this comparison, the PCA9685's 4096 total steps yield approximately 270 effective steps within the servo's useful operating range (0.5 ms to 2.5 ms), a 1.5× gain over TDM. At the 50 Hz frequency planned for BORIS's servo operation this effective count rises to approximately 410 steps, a 2.3× gain. In both cases, the PCA does not use its total counter range, but rather the effective steps that fall within the servo's commercial useful operating range.

Evaluating synchronization for the control of multiple servomotors, when using several PCA9685 units, the use of an external oscillator circuit must be considered to improve output synchronization and mitigate the drift effect caused by internal oscillators. This effect becomes concerning in a case similar to TIGRÃO, which requires 37 servomotors (DoFs). In the case of TDM, this problem does not occur, since the time base is the same for all banks, with only a 5 ms offset between banks in the TIGRÃO project, which could be reduced as the bank update rate is improved.

Traditional software-based PWM generation on a general-purpose microcontroller timer interrupt is inherently limited in channel count — the reference application note for this technique reports up to 24 PWM channels using its supplied code sample, with the demonstrated example implementing ten channels [18]. Microcontrollers such as the ESP32 offer up to 16 dedicated hardware PWM outputs [24], which can compromise the number of pins available for a project's other needs; the ATMEGA2560, in turn, has 54 digital pins, of which 15 can be configured as PWM outputs [25]. The microcontroller used in TIGRÃO project in 2005, however, was the PIC18F452, which has only two internal hardware modules for PWM generation [26]. TDM technique implemented in its architecture is therefore essentially discrete time-division multiplexing logic, using only 13 pins (2 control, 3 selection, 8 data) to drive external pin-expansion

hardware for up to 64 outputs. This output-expansion hardware could be migrated to a modern FPGA, drastically reducing the physical board space. Furthermore, the FPGA opens the possibility of implementing a dedicated multichannel PWM generation peripheral analogous to the PCA9685, with a configurable interface such as SPI, I²C, or even parallel as currently used, with position resolution defined by the design. However, the adoption of FPGAs in SAR projects must take into account the high cost of the devices, the complexity of the development tools (synthesis, simulation, programming), and the significant learning curve for the development team, factors that can be decisive in projects with limited resources, lower levels of education, or in a rapid prototyping phase.

In TIGRÃO robot, the facial expression servomotors are grouped in banks 0 and 1, ensuring that all are updated within a fixed 5 ms window, a hardware design parameter that remains well below the audiovisual asynchrony detection thresholds reported in the literature [22], and therefore imperceptible in HRI. This margin is preserved in BORIS robot, since transmitting the 16 outputs in a single I²C transaction allows practically all head servos to be updated within a comparably short interval, consistent with the same perceptual margin [23].

With its 37 degrees of freedom (DoFs) distributed among the head, upper limbs, and lower limbs, the TIGRÃO robot still represents a major achievement in the field of pediatric hospital-use SAR.

The comparative analysis between the TDM and PCA9685 techniques directly addresses the study's proposed objective, validating the hardware architecture for the BORIS robot. The results show that, although both solutions are effective for SAR development while keeping latency below 150ms, their application must be carefully analyzed, evaluating the context and functionality of each, and especially the technical knowledge required to implement them. TDM technique in the TIGRÃO robot was built entirely with discrete components, with the timer interrupt service routine (ISR) managing — not monopolizing — bank selection and PWM timing every 5 ms. Based on cycle-accurate analysis of the compiled instruction listing, the ISR remains active for approximately 3.4 to 3.8 ms per 5 ms bank period (69% to 75%), comprising a fixed initial window for digital and analog input handling followed by the 180-step comparison loop; the remaining 25% to 31% of each period is available to the main loop for joystick reading, serial menu commands, and EEPROM pose storage. In the case of the PCA9685, the load on the microprocessor is limited to I²C transactions, not to mention the reduction in the number of physical connections used.

Therefore, for the BORIS project, the intention is to use the PCA9685 based on the data collected during this study, since it proved to be the right path for innovation, in addition to meeting the goal of keeping the microprocessor nearly 100% free for other tasks — which does not invalidate the TDM technique, the alternative chosen in 2005, when a component with the flexibility and features of the PCA9685 was not yet available, and implementation with programmable logic was beyond the reach of the development team at the time.

***Abstract*— This study applied the Generalized Wavelet Coherence Analysis (GWCA) technique, proposed by Espen Ihlen (2014), to investigate whether variability in hip–knee joint coupling during gait in elderly fallers and non-fallers is associated with falls, compared with young adults. Kinematic data were collected from 30 young adults, 17 older non-fallers, and 13 older fallers during treadmill walking at three speeds: preferred walking speed (PWS), 120% PWS, and 80% PWS. Participants performed three 1-minute trials at each speed in random order. Data from 16 reflective markers were used to compute hip and knee joint angles across four gait phases (first double support, single support, second double support, and swing), from which sagittal-plane coordinative variability was calculated. All participants exercise regularly at least three times a week. Kinematic data from 16 markers were used to calculate hip and knee joint angle values for four gait phases (first double stance, single stance, second double stance and swing), from which coordinative variability was calculated, in the sagittal plane. Results showed that GWCA distinguished gait patterns between elderly fallers and non-fallers. Exploratory ROC analysis further indicated that selected GWCA-derived parameters had potential to discriminate between elderly fallers and non-fallers, supporting their potential relevance for fall-related gait assessment. Significant speed effects were observed, with greater variability at 80% and 120% PWS, mainly indicating knee dominance over the hip.**

***Index Terms*— wavelet coherence analysis, older adults, aging, falls, gait**

I. Introduction

Population aging has become one of the main demographic transformations in Brazil[1]. According to recent estimates from the Brazilian Institute of Geography and Statistics (IBGE), the country has approximately 213.4 million inhabitants, with more than 34 million people aged 60 years or older, representing nearly 16% of the total population. Demographic projections indicate that this proportion will continue to increase over the coming decades, leading to a substantial rise in age-related health conditions[2]. Falls are among the most frequent adverse events affecting older adults, with approximately 28–30% of this population experiencing at least one fall annually[3]. Besides their impact on mobility, independence, and quality of life, falls account for a considerable number of hospitalizations and generate a substantial economic burden on the Brazilian public health system due to emergency care, surgical procedures, rehabilitation, and long-term treatment. Consequently, strategies aimed at identifying factors associated with fall risk and improving early detection have become increasingly important in the context of an aging population.

The gait can be described as a cyclical movement of body parts [4]. The coordination between segments provides a measure of the relative timing and magnitude of movement coordination variability measures the varied movement patterns that an individual uses during locomotion [5], [6]. Coordination variability represents the range of movement strategies that an individual can employ while walking [7], [8], [9].

Wavelet is a transient waveform of finite duration [10]. Generalized Wavelet Coherence Analysis (GWCA) combines wavelet coherence techniques with a matrix-based correlation method to estimate correlation coefficients among multiple joints simultaneously. The method divides the signal into smaller segments and analyzes them at different scales, allowing evaluation within short time windows [11]. The wavelet transform operates by decomposing a signal into multiple time-scale components, allowing each segment of the data to be analyzed at a resolution that is appropriate for its corresponding frequency content. In practice, the signal is examined within localized time windows using a reference function, commonly referred to as the

mother wavelet. High-frequency components are obtained by applying contracted versions of the mother wavelet, whereas low-frequency components are represented through its dilated forms, enabling the simultaneous investigation of both transient and long-duration signal characteristics [12]. The correlation between two signals is then computed across different time scales, producing time-frequency contour maps that provide a detailed representation of their dynamic relationship. From these analyses, an overall instantaneous correlation coefficient (Rt) is calculated, representing the global wavelet-based correlation between the paired signals throughout the analyzed period [11]. However, the discriminative potential of GWCA-derived coordination variability for distinguishing older adults with and without a history of falls remains insufficiently explored. Therefore, this approach may provide clinically relevant information for the assessment of fall-related gait alterations.

Based on this approach, the present study aimed to estimate coordination variability using the GWCA method between the hip and knee joints in three distinct groups—young adults, older adults without a history of falls(non-fallers), and older adults with a history of falls (fallers)—while they walked on a treadmill at different speeds. We hypothesized that (1) young people present greater coordination variability in relation to the other groups, that (2) the joint variability calculated by the GWCA technique for elderly non-fallers will be greater than that of fallers and (3) that the higher the speed greater the joint variability will be in all groups.

II. Material and Methods

A. Subjects

Thirty young adults (23.90 ± 5.05 years), 17 older non-fallers (64.68 ± 3.74 years), and 13 older fallers (68.35 ± 7.41 years) participated in this study. Older participants were classified as fallers if they reported three or more falls in the previous year. The protocol was approved by the local Research Ethics Committee (1.003.935–2018), and all participants provided written informed consent.

B. Protocol

Kinematic data were collected using sixteen retroreflective markers placed according to the Vicon Plug-in-Gait lower limb model and recorded with a 3D motion capture system (10 infrared cameras, 100 Hz). Signals were filtered using a fourth-order zero-lag Butterworth low-pass filter (8 Hz) and processed with custom MATLAB routines (R2025b). The preferred walking speed (PWS) was determined following a previous protocol [13], and participants performed three one-minute treadmill trials at 80%, 100%, and 120% of the PWS, in random order, with one-minute rest intervals.

The hip-knee joint pair was analyzed using 20 strides per trial, with time series normalized to 100 points. Analysis was performed in the sagittal plane, and the gait cycle was divided into first double support (0–10%), single support (11–50%), second double support (51–60%), and swing (61–100%) phases [14], [15].

Using Generalized Wavelet Coherence Analysis (GWCA), contour plots were obtained from instantaneous correlation coefficients (R_t) between joint angles at different time scales [11]. For each phase, the median R_t generated two maximum (Rmax) and two minimum (Rmin) values, representing respectively the double support phases (stronger coordination) and the single support and swing phases (weaker coordination). The Rmax and Rmin parameters were selected to characterize the highest and lowest coordination values within each gait phase, thereby capturing phase-specific variations in hip–knee coordinative variability.

C. Statistical analysis

The repeated measures analysis of variance (ANOVA)with mixed design was used to compare the three groups and the main effect of speed, followed by a post-hoc test with Bonferroni correction in the cases where the main or interaction effect was significant. Statistical analysis wasperformed using SPSS software, version 23 (SPSS Inc., Chicago, IL, USA), with a significance level set at $\alpha < 0.05$.

Additionally, an exploratory Receiver Operating Characteristic (ROC) analysis was performed to assess the discriminative capacity of GWCA-derived parameters between elderly fallers and non-fallers. The ROC analysis was restricted to gait phases and walking-speed conditions in which significant group effects were identified in the mixed ANOVA, and the area under the curve (AUC), 95% confidence interval, sensitivity, specificity, and optimal cutoff value based on the Youden index were calculated.

III. Results

Fig. 1 presents the GWCA contour maps for the hip-knee joint signals at scales from 1/20 to 1/5 of the average stride time for walking speeds of 80%, 100%, and 120% of the preferred walking speed (PWS). In these maps, red areas indicate stronger intra-articular coupling, according to the color scale. The figure suggests that young participants exhibited greater variability than the older groups.

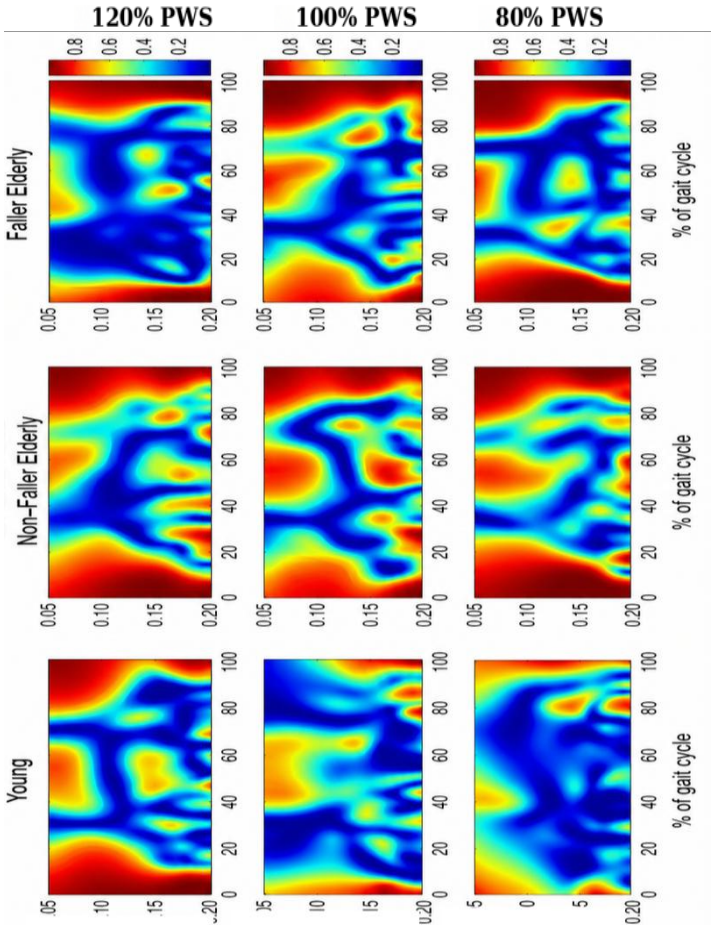

Fig. 1 Contour plotter for Hip-Knee joint signs, for scales from 1/20 to 1/5 of the average stride time.

To quantitatively characterize the wavelet coherence patterns, the median value of the instantaneous correlation coefficient (Rt) is computed for each phase of the gait cycle. Four representative values are extracted: two peak values (Rmax), corresponding to the first and second double-support phases, and two minimum values (Rmin), associated with the single-support and swing phases. The Rmax values indicate the gait events at which intersegmental coordination reaches its highest level, whereas the Rmin values identify the phases characterized by reduced coupling intensity between the analyzed signals.

The Fig. 2 show averages of coordinative variability of Rt, evaluated by GWCA, for the Hip-Knee joint pair at speeds 80% of PWS, PWS and 120% of PWS. From the Figure 2, it is possible to identify that in most situations' older non-fallers people (black curves) presented higher values of coordinative variability, followed by fallers people (red curves), and young people (dashed blue curve), this is not in line with hypothesis 1. Therefore, the graphical results suggest that gait speed may influence coordinative variability in a phase-dependent manner rather than producing a consistent monotonic increase in Rt. Accordingly, these findings provide partial graphical support for hypothesis 3, which should be interpreted in conjunction with the statistical analysis.

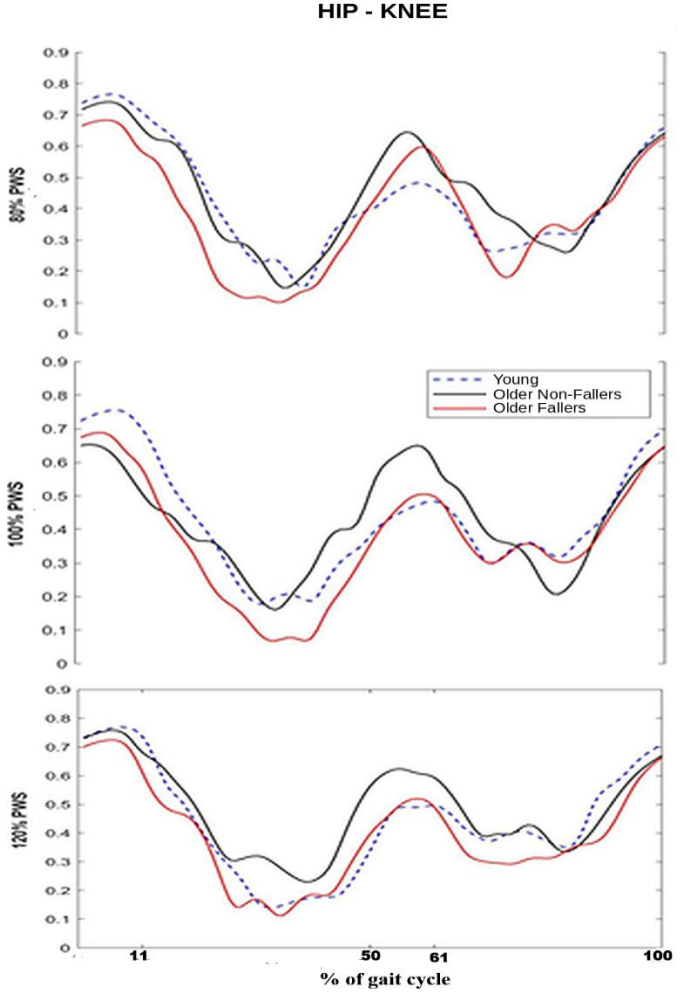

Fig. 2 Averages of coordinative variability, evaluated by GWCA, for the Hip-Knee joint pair at speeds 80% of PWS, PWS and 120% of PWS.

The statistical analysis (p-values) of the variability of $Rmax$ and $Rmin$ is presented in Table 1 below and was evaluated with a mixed repeated measures analysis (mixed ANOVA) and significance level $p < 0.05$.

TABLE I. VARIABILITY OF R_{max} and R_{min} FOR HIP-KNEE PAIR.

Effect	Phases of Gait	80%PWS	100%PWS	120%PWS
Group	***FDS***	NS	0.23	p< 0.001
	SS	NS	NS	p< 0.001
	SDS	0.039	NS	NS
	SG	NS	NS	**NS**
		Young	**Elderly Non-Fallers**	**Elderly Fallers**
Speed	***FDS***	p< 0.001	p< 0.001	p< 0.001
	SS	NS	p< 0.001	p< 0.001
	SDS	0.030	NS	NS
	SG	p< 0.001	NS	NS

Analysis of Repeated Measures (ANOVA). FDS = First Double Support; SS = Single Support; SDS = Second Double Support; SG = Swing.

Significant group-related differences were identified during the FDS phase, with higher Rt values observed in elderly non-fallers compared to elderly fallers. Significant group-related differences were identified in the FDS phase at 120% PWS ($p < 0.001$), with elderly non-fallers presenting higher Rt values than elderly fallers. A significant group effect was also observed in the SDS phase at 80% PWS ($p = 0.039$). Additionally, a significant group effect was found in the SS phase at 120% PWS ($p < 0.001$). Concerning walking speed, the young group showed significant differences between 120% and 80% of the preferred walking speed (PWS) in the FDS, SDS, and SG phases. In contrast, among elderly fallers, significant differences were detected only in the SG phase.

To further investigate the potential discriminative capacity of GWCA-derived coordinative variability between elderly fallers and non-fallers, an exploratory ROC analysis was performed. The analysis was restricted to gait phases and walking-speed conditions in which significant group effects were identified in the mixed ANOVA. Specifically, Rmax at the FDS phase at 120% PWS, Rmax at the SDS phase at 80% PWS, and Rmin at the SS phase at 120% PWS were evaluated for their ability to discriminate between elderly fallers and non-fallers. For each parameter, the area under the ROC curve (AUC), 95% confidence interval, sensitivity, specificity, and optimal cutoff value based on the Youden index were calculated. This exploratory analysis was intended to assess the potential discriminative value of GWCA-derived coordinative variability for identifying individuals with a history of falls, rather than to establish its predictive ability for future falls.

IV. Discussion

In terms of group, there were significant differences in the SDS phase with the Rt values of the non-falling elderly being higher than that of the falling elderly. The significant statistical differences between the Rt of the SDS phase for elderly non-fallers in relation to fallers may reflect a greater requirement for inter-articular coordination of the impulsion lower limb to accelerate the center of mass in gait progression compared to the lower limb of

impact on the ground that slows down the movement of the center of mass immediately after the heel touches the ground [16]. Therefore, age-related decline in inter-joint coordination only in these phases may indicate deficiencies related to push-off coordination [11]. These findings are consistent with previous evidence that older adults with a history of falls may exhibit altered inter-joint coordination and reduced ability to appropriately regulate lower-limb movements during critical phases of gait[17].

Regarding walking speed, significant differences were observed primarily between the slowest (80% PWS) and fastest (120% PWS) conditions. In the young group, these differences were evident during the first double-support (FDS), second double-support (SDS), and swing (SG) phases, whereas in older fallers significant changes were identified only during the FDS and SG phases. Similar findings have been reported in previous studies investigating gait modulation in young and older adults, indicating that locomotion at speeds below the preferred walking speed requires greater adjustments in lower-limb coordination than walking at faster speeds relative to PWS [7], [18]. These adaptations may reflect the increased neuromuscular demand required to preserve gait stability and maintain forward progression when the natural walking rhythm is altered[19].

Since the hip and knee joints play a fundamental role in controlling body support, propulsion, and limb advancement throughout the gait cycle, modifications in their coordination pattern are expected when walking speed changes[20]. In particular, the double-support phases require accurate coordination to ensure a smooth transfer of body weight between limbs, whereas the swing phase is characterized by precise control of limb advancement and preparation for the subsequent heel contact[21], [22]. The observed differences in *Rt* across walking speeds may represent adaptive strategies adopted to preserve dynamic stability while maintaining efficient locomotor performance.

The exploratory ROC analysis provides an additional perspective on the potential discriminative value of GWCA-derived coordinative variability between elderly fallers and non-fallers. The parameters selected for this analysis were those that showed significant group effects in the mixed ANOVA, namely Rmax during the FDS phase at 120% PWS, Rmax during the SDS phase at 80% PWS, and Rmin during the SS phase at 120% PWS. The observed ROC performance suggests that alterations in hip–knee coordinative variability may have potential to distinguish older adults with and without a history of falls. These findings are particularly relevant because the identified parameters were obtained under different walking-speed conditions and gait phases, suggesting that the discriminative behavior of inter-joint coordination may depend on the specific locomotor demands imposed by the task. However, given the exploratory nature of the analysis and the use of a cross-sectional classification based on fall history, these results should not be interpreted as evidence that GWCA-derived parameters can predict future falls.

This study focused exclusively on hip–knee coordination in the sagittal plane, future investigations should incorporate analyses of additional planes of motion and other lower-limb joint couplings to provide a more comprehensive understanding of the biomechanical adaptations associated with aging and fall risk.

V. Conclusion

The present study analyzed coordinative variability during gait between the hip–knee joints in young adults, older non-fallers, and older fallers, using the Generalized Wavelet Coherence Analysis (GWCA) technique, which demonstrated sensitivity to changes in intra-articular coordination of this joint pair. The exploratory ROC analysis further indicated the potential of selected GWCA-derived parameters to discriminate between older fallers and non-fallers, suggesting that coordinative variability may have potential as a complementary marker for fall-related gait assessment. However, further prospective studies with larger samples are needed to confirm these findings and investigate their applicability to future fall-risk assessment. Future studies should investigate the influence of physical activity, muscle strength, and a wider range of walking speeds on hip–knee coordinative variability.

***Abstract*—Operator trust governs whether part of a physical task can be handed to a robot: too little and the robot is underused, too much and the risk of collision rises. Estimating trust during the interaction depends on datasets that pair trust labels with recorded signals, and the field has not agreed on what to record or how. Through a documented search we retained eight collections that report a trust measurement in a physical task, comparing them on setting, mechanical coupling, instrument, time scale, recorded signals, and data availability. Each cell records whether its entry is documented, absent from the recorded signals, unreported, or without a referent in that setting. The first result concerns the settings rather than the measurements: only three of the eight place the operator in contact with the robot, and sustained contact occurs in one. Five gaps follow. No common protocol fixes the instrument or the time scale. A single trust score is often copied onto many observations and the model then tested on randomly drawn folds; the one study reporting both splits sees accuracy fall from 0.92 to 0.45 once participants are held out. No collection records force or torque, leaving its relation to trust untested rather than ruled out. Anonymization is never varied within a collection. The measured construct differs across collections, and only two of the eight are openly deposited. Four priorities follow: report the instrument, the sampling point, how the score was propagated, and how the evaluation folds were drawn; record force, torque, and trust on one clock under controlled loads; label one cohort at more than one time scale; and vary anonymization as a controlled factor.**

***Index Terms*—human-robot interaction, physical collaboration, trust, datasets, measurement.**

I. Introduction

The arrival of collaborative robots outside isolated industrial cells has moved the research focus from physical safety toward operator trust, now treated as a condition for their effective use and adoption [1], [2]. When trust is too low, the operator underuses the robot; when it is too high, the risk of collision and harm grows [3]. This matters most in physical human-robot interaction (pHRI), where the human and the robot share the workspace and often the same object, so a misjudged action carries an immediate physical cost. A robot that could track trust as the interaction unfolds could adjust to it, but it must first be measured, and that is where the difficulty begins. Trust cannot be read off directly, only inferred from what the operator reports and from the objective signals the interaction leaves behind. Estimating it therefore depends on data that pairs these signals with trust labels, and increasingly on learning models trained over such data. This makes curated pHRI datasets the foundation on which trust estimation rests. Yet the field has not agreed on what to record or how, and the datasets that exist reflect that disagreement.

Trust is not measured the same way across studies, and the differences start with the task. The collections reviewed here range from explicit handover [4] and shared-load transport [5] to co-located placement [3], object placement with a handover at failure recovery [6], shared-workspace assembly [7], [8], supervisory monitoring [9], and tasks reproduced in mixed or virtual reality [10], [11]. The physical coupling, the failure modes, and the signals available to an observer differ across these settings, so a trust measurement in one is not directly comparable to a trust measurement in another.

The clearest divergence is in the measurement instrument. The questionnaire is still the most common tool, but no single instrument is standard for pHRI, and the available scales were built for different purposes. Two scales come from the automation literature and rate reliance on a machine in general [12], [13]; two were developed for robots and rate the robot's perceived trustworthiness as a partner [14], [15]; another separates a cognitive judgment of the system from an affective attitude toward it [16]. Studies frequently assemble their own item sets from several of these scales; Alhaji et al. draw single items from five different questionnaires [10]. Two studies can therefore both report trust while operationalizing different constructs, and because the questionnaire records a single point in a process that changes over time [1], [8], results rarely transfer from one dataset to another.

The objective and physiological side is just as varied. Trust in pHRI is read from self-report, from observable behavior, and from physiological signals [17]. Physiological signals complement the questionnaire because they track the operator's internal state continuously and involuntarily, registering shifts in arousal, attention, and effort between the discrete moments a questionnaire samples and beyond what the participant reports. Across the collections reviewed here the recorded channels include raw video, eye tracking and gaze, body pose, facial expression and emotion, and central, muscular, cardiac, and autonomic physiology [4], [7], [9]. No two collections record the same combination, and there is no agreed answer to which signals a trust dataset should contain.

The contribution of this paper is a mapping of the trust data collected for physical collaboration onto a common set of mea-

surement parameters, read as a coverage matrix whose empty cells mark the gaps. We describe what has been collected rather than measure it against an ideal. A systematic review of trust assessment in HRI already covers how individual studies measure trust [1]. What is missing is a comparison at the level of the collections themselves, along the parameters that decide whether one dataset can be read against another, including whether its data can be obtained at all. Two further features separate the matrix from a narrative comparison. The retrieval that produced the set is stated, so the boundary of the set is reproducible, and each cell carries the status of its entry, so an absence attributable to a silent publication is not read as an absence of the signal itself. We split the parameters across two tables to keep the comparison readable. Table I covers the environment, the mechanical coupling, the task, robot, sample size, instrument, time scale, induced failures, and data availability, and Table II the objective signal modalities. Figure 1 shows three of the tasks. Section II sets the search, the scope, the terminology, and the cell coding, Section III describes the parameters, Section IV reads the matrix, its data volume, and its internal divergences, and Section V discusses the open problems. The reading begins with a result about the settings rather than the measurements: physical contact occurs in a minority of the collections gathered under the heading of physical collaboration.

II. Search, Scope, Terminology, and Coding

Search protocol. Candidate records were retrieved from IEEE Xplore and Scopus, searched over title and abstract. Two query branches were used: one combining trust with human-robot and a term for released data, run as two separate queries for *dataset* and for *database*, and one combining trust with a term for physical or contact-based interaction (physical human-robot, handover, or collaborative robot). On IEEE Xplore these three queries returned 22, 5, and 117 records; on Scopus, restricted to Computer Science and Engineering, the two branches returned 75 and 521 records. These are unfiltered return counts rather than counts after title/abstract screening: records were screened against the criteria below, and the reference lists of the retained records and of a systematic review of trust assessment in HRI [1] were followed for further candidates. Screening and coding were carried out by the first author and checked by the second. This is a targeted retrieval and not a systematic review: it is reported so that the boundary of the set is reproducible, not so that the set can be read as exhaustive.

Inclusion and exclusion. We restrict the scope to tasks in which the operator and the robot act on the same objects in one workspace, with or without contact: contact tasks, co-manipulation, shared load, object handover, and co-located work on shared parts. Contact is therefore a parameter we record, not a condition of entry, which is what makes the reading in Section IV possible. Robots acting as purely social or conversational agents fall outside this scope, since the nature of trust and the available signals differ from physical contact [1]. We include a record when its central task is of this kind and it reports some measurement of trust, whether by questionnaire, scale, or behavior-derived label. We exclude records that measure only adjacent constructs such as affect, comfort, stress, or cognitive load, even in physical tasks [18], [19], and conversational assistance scenarios [20].

The set is small by construction. We keep the works that set out to measure trust in a physical collaboration and that document the task, the instrument, and the recorded signals in enough detail to place them on the matrix, several of which were published specifically to release a trust dataset [4]–[6]. We leave aside studies where the trust data is incidental, undocumented, or not provided as a labeled target, since these cannot be read along the same parameters. The pattern therefore describes the collections that meet these criteria rather than the field in full.

Terminology. The sources label comparable arrangements differently, so we fix a vocabulary and apply it in place of the source wording. *Physical collaboration* covers any task in which the operator and the robot act on the same objects in one workspace. Within it, the *coupling* takes four values: *sustained*, when the two hold a common object or contact point for a whole repetition; *transfer only*, when contact exists at a handover and not otherwise; *none (co-located)*, when they act on the same parts without touching at the same time; and *none (no contact)*, when the robot is monitored or rendered rather than touched. A parenthetical qualifier after a coupling value names the phase of the task in which that contact occurs, and narrows the window rather than adding a fifth value. The *environment* is *real*, *mixed reality* when a virtual robot is rendered into a real workspace, or *virtual reality* when the whole scene is rendered. Where a source uses more than one of these terms for one setting, Table I records the value that follows from the definitions above. We use pHRI for the field, and *collection* for any of the eight records placed on the matrix, whether or not its data is documented as obtainable.

Cell coding. Every cell of Tables I and II carries the status of its entry. A cell that names a task, instrument, sensor, or number is documented in the cited publication, which is the level of evidence for the matrix as a whole: the entries state what the sources report, not what we verified in the data. Absences are separated into three cases. The mark *n.rec.* applies where the source enumerates its recording setup and the modality is not in that enumeration; reading an enumeration as complete is an assumption of ours rather than a statement by the authors. The mark *n.r.* applies where the source does not report the parameter at all, so its value is unknown, and in the availability column it marks the collections that state no route to the data. The mark *n/a* applies where the parameter has no referent, as with an interaction force in a task without contact. The distinction matters because an absence of the first kind is a property of the collection and one of the second kind is a property of its documentation.

III. The Coverage Parameters

Each parameter is a measurement axis established in the trust literature, listed with the reference that grounds it, and is

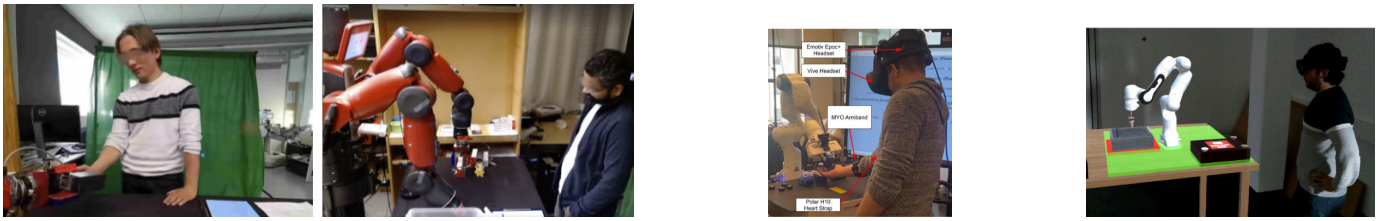

Figure 1. Physical tasks across three collections. **Left:** a human and a Baxter robot fill a shelf by exchanging objects (REFLEX [6]). **Center:** an instrumented handover with a real Franka Emika robot, the operator wearing EEG, EMG, ECG, and eye-tracking sensors (TrustBase [4]). **Right:** a battery disassembly task in *mixed reality*, where the Franka Panda and workpieces are virtual, rendered in the operator's head-mounted display rather than physically present (Alhaji et al. [10]). Images reproduced from the respective papers.

Chauhan et al. [11]	n/a	n.rec.	n.rec.	n.rec.	Valence, arousal (EEG-derived)	EEG (Emotiv EPOC X)	EDA, temp., HRV

F/T: force and torque. AU: facial action unit. BVP: blood volume pulse. ch: channels. ECG: electrocardiography. EDA: electrodermal activity, also reported as GSR (galvanic skin response). EEG: electroencephalography. EMG: electromyography. fNIRS: functional near-infrared spectroscopy. HR: heart rate. HRV: heart rate variability. IMU: inertial measurement unit. temp.: skin temperature.

kept only when it varies across the collections. The parameters fall into six groups, split across Tables I and II.

Context. The environment, the task, the robot, and the number of participants (N) fix the setting in which trust is observed. They are not coverage claims, but N belongs to the minimum information expected of a measurement study, and the task and robot fix the physical regime.

Instrument and time scale. The instrument separates validated scales, ad hoc items, and behavior-derived labels; the time scale separates post-session, per-trial, and continuous labels, the last of which no collection in the set supplies. Validated trust scales for HRI exist [14], [15], and the same literature notes that a questionnaire misses variation within a task, which is what motivates real-time measurement [1], [3],

[8]. The instrument and the time scale are not independent, since a scale administered at one point per session cannot resolve a change inside the session.

Failure induction. This parameter records whether the collection deliberately manipulates trust, most often by provoking robot failures or violations, but also by varying a trust-relevant factor such as robot speed [5]. Trust is easier to observe around such manipulations; the effect of failures on real-time trust and the effect of a faulty robot on cooperation are established results [10], [21], [22].

Mechanical coupling. When the human and the robot are mechanically coupled, through a shared object or a contact point, forces and torques are exchanged at that point, and controllers already read them as the most direct available measure of the mechanical interaction [23], [24]. Whether they also carry information about an operator's trust is a separate question, taken up in Section V. Coupling of this kind is not present in every setting the literature places under physical collaboration, and it bounds the window in which an interaction force exists at all, so we record it as a parameter of its own.

Captured signal modality. This group separates force and torque from visual and physiological signals. Video, gaze, pose, and skin conductance are indirect indicators of the operator's state, and we keep the distinction from the mechanical channel as a parameter rather than folding the two together.

Availability. This parameter records whether the source documents a route to the data, since a collection that reports a measurement without releasing it constrains what a later study can reuse. It separates an open deposit, a statement that the data is available on request, an announcement with no deposit, and silence.

IV. The Coverage Matrix

Tables I and II bring the eight collections together. The two studies of the same cohort are kept as a single row because they share task and manipulation across two venues [7], [8].

Four patterns stand out. First, and in the coupling column rather than in any measurement: only three of the eight settings place the operator in contact with the robot, and only one holds the two on a shared load for a whole repetition. A set assembled under the heading of physical collaboration turns out to contain physical contact in a minority of its cases. No row names a force or torque sensor, which follows in part from this, since in five of the eight settings there is no common mechanical path on which such a sensor could read. Second, the instrument column is widely scattered: a validated scale [5], a single item [4], a multi-factor questionnaire [10], an item embedded in a satisfaction scale [6], a preference-based label [3], the Muir survey [9], and a validated scale adjusted by a single dynamic item [11]. Two instruments recur, the Trust Perception Scale-HRI [5], [11] and items from the Muir survey [9], [10], and in each case the two collections that share them differ in the sampling point or in how the items were assembled. The time scale is equally scattered, from a label taken per interaction or per trial to one taken per round, per phase, or per task iteration, with no dominant choice and no collection labeling trust continuously. Third, the objective modalities are scattered as well: visual and physiological signals are common, no two collections share a combination, and the most direct channel appears in none.

Fourth, the amount of data differs as sharply as its type, which Table II does not show. Cohort size runs from eleven to sixty-five, as the N column records, and cuts against the density of signal per participant. Small cohorts tend to carry dense signals and larger cohorts sparser ones, and none is both large in participants and rich in modalities. For training or evaluating a model, what matters is the number of trust labels rather than the raw signal volume, and this number is often small: a per-round or per-task label yields on the order of one to a few hundred labeled instances even when the underlying streams are large [6], [9]. The benchmark movement set is the sharpest case: roughly 950 task repetitions of 60 Hz kinematics across 17 IMUs are labeled by only two trust scores per participant, one per task, on the order of forty trust labels for the whole set [5].

Reading the matrix by cell status adds a fifth pattern: part of what looks like coverage is a property of the documentation rather than of the data. Two collections are deposited openly [5], [6], two state that the data is available from the authors on request [10], [11], and one announces a release without a deposit [9]; the remaining three report a measurement without documenting any route to it, so the matrix is in part a map of published studies rather than of retrievable material. The absences in the F/T column are of two kinds, five settings where the signal has no referent and three where it does but is not listed, and only the second is a design choice a later collection could reverse. Sample sizes are not uniformly defined either, since TrustBase describes its contents as 65 user studies in one place and as 65 participants in another [4]. The largest divergence sits inside one row: the two publications on a single cohort sample trust with different instruments at different rates, a 12-item survey per reliability block [7] and a single seven-point item per trial [8], so even one cohort does not fix an instrument or a time scale.

V. Gaps and Open Problems

The scarcity of contact just described, together with the empty cells of Tables I and II, points to five directions, each grounded in the collections reviewed here or in the adjacent literature. They are stated as gaps in this set, not as properties of the field as a whole.

No common measurement protocol. With the instrument and time-scale columns this scattered, two collections are rarely comparable: what one measures with a validated scale, another records as a single item or as a stated preference between trajectories. This matches the limitation that reviews attribute to the dominance of the questionnaire [1]. A practical step is to report which instrument was used, at what point in the task, and how the resulting score was propagated to the recorded signals, so that datasets can be read against one another, rather than to impose a single scale on the field.

One label, many observations. Trust is recorded once or twice per session. The signals meant to reveal it are recorded many times per second. To train a model, the single score has to be copied onto every observation it is supposed to cover, and that copying is not a preprocessing detail: it asserts that trust held constant across the whole interval, and it produces many near-identical examples that carry one label. Three of the collections do this, in different ways, counting the model trained on the benchmark movement set [25]. A five-point rating given after a four-minute task is copied onto every overlapping thirty-second window drawn from that task [9]. A per-task score is copied onto every one-second sample of physiology [11]. A questionnaire score is split at the sample median, and in the variant with the highest reported accuracy the training set keeps only the first five repetitions of the low-trust participants and the last five of the high-trust ones, on the assumption that trust rises within a session [25]. A fourth avoids the propagation, averaging each indicator over one task iteration, but its label is a stated preference between two trajectories rather than an absolute trust value, as the authors note, and its reported accuracy is computed after the 210 real comparisons are expanded to 840 by synthetic sampling [3].

The copying matters at evaluation. When folds are drawn at random, consecutive observations from the same participant fall on both sides of the split, and a model can score well by recognizing the participant rather than the trust level. One study reports both splits on the same data and the same architecture: accuracy is 0.92 and 0.90 with random folds, and 0.45 and 0.55 once the validation participants are held out [25]. Elsewhere in the set, a classification accuracy of 0.975 under ten-fold cross-validation [9] and a regression R^2 of 0.985 under five-fold cross-validation [11] are reported, neither described as participant-wise, and whether those folds separated participants cannot be told from the text. One of these targets a model personalized to an individual baseline, where validating within a participant is defensible; the qualification is that the figure then describes consistency within a session rather than detection of trust. Trust has no external ground truth against which the difference could be settled. Reporting how the folds were drawn, together with a majority-class baseline, would separate the two readings at no experimental cost. Until the measurement is standardized, such results are best read as evidence that a signal correlates with the label built from it, and the step from there to a robot adjusting its speed or proximity online is larger than the accuracies suggest.

No force and torque channel. None of the eight collections records force or torque, and the coupling column shows that the absence is not evenly distributed. In five of the eight settings there is no interaction force to record. The mixed- and virtual-reality tasks have no physical contact [10], [11], in the shared-workspace and supervisory settings the robot delivers parts to the operator's side of the workbench or is only monitored [7]–[9], and in the chemical-mixing task the operator holds one beaker while the robot pours into it from another, so the two never share a contact point [3]. Where contact does occur it is confined to the instant of transfer, at the handover itself [4] and at the failure-resolution step in which the operator places an object into the gripper [6]. Only the transport task of the benchmark movement set holds the human and the robot on the same load for the duration of a repetition, each carrying one end of a textile piece [5], and there only the human kinematics were logged. That coupling runs through a compliant textile, which transmits tension rather than the full wrench, so even the one available case bounds what the channel could carry.

For the settings with real contact the absence is not a technical limitation: handover failure-detection datasets already record force, torque, and gripper position [26], and trust has already been used to modulate impedance in co-manipulation [27], so the signal is both collectable with hardware these setups already run and usable by the controllers already in the loop. Trust also changes what the operator does physically [1], so a mechanical trace, if one exists, may surface in quantities these controllers already read [23], [24].

Any such trace would be superimposed on the mechanical response of the task itself, since the same forces are set by the payload, the commanded trajectory, the robot's impedance, external disturbances, and the operator's biomechanics, and any of these can change the measured wrench while trust does not [23], [24]. A study of this channel would therefore have to hold those conditions constant across trust conditions, or model them, before a difference in force could be attributed to trust, and a null result under such controls would be as informative as a positive one. The gap is therefore twofold. The signal is absent from these collections, and the setting in which it would carry the most information is itself nearly absent, so whether the mechanical channel carries trust information as a recorded signal paired with trust labels remains untested rather than ruled out.

Anonymization as an unused variable. How visible a participant is, from identifiable video to an anonymized silhouette, has been studied at length in computer vision, where it trades off against the utility of the data [28]–[30]. This trade-off falls directly on the trust-relevant channels: the facial expression, gaze, and body-pose signals that these collections record as indicators of the operator's state are the same signals that identify the participant, so anonymizing the data degrades precisely the cues a trust model reads. Blurring and similar traditional methods lower model performance, more so for the full body, while synthesis-based methods recover much of the loss [28]. The same trade-off shows up in keypoint detection, instance segmentation, and face detection, and re-identification often still succeeds when recognition rates are low [29]. No pHRI trust collection in this set varies this level of visibility. Only the collections that record raw video could be anonymized at all (Table II), and the few that do fix a single level, while the benchmark movement set, recording only IMU-derived skeleton kinematics, is anonymous by construction [5]. The set spans both endpoints of the axis but never varies it inside one collection, even though the level chosen decides whether the data can be shared at all. The trade-off above was measured for models trained on the anonymized data; for vision-language

models applied zero-shot, where no retraining absorbs the distortion, the effect of the anonymization level on a trust judgment is unstudied.

Fragmented construct and environment. The physical collaboration literature is split across constructs: several signal-rich datasets measure affect, comfort, stress, or cognitive load rather than trust [18], [19], which leaves trust labels in physical collaboration scarce. The environment varies too: some studies use a real robot, some mixed reality [10], some virtual reality [11], so the condition of physical collaboration is itself not held constant, as the environment and coupling columns of Table I record. The measured construct and the collection environment are part of the protocol that is still missing.

VI. Conclusion

This paper compared eight collections for physical human-robot collaboration by how each one measures trust. They were retrieved through a documented search, placed on a coverage matrix built from measurement parameters drawn from the trust literature, and read cell by cell with the status of each entry recorded. Physical contact occurs in three of the eight arrangements and sustained contact in one, so the condition the field is named after is largely absent from the data it has collected. The collections are individually rich, yet this set does not share a way to measure trust. Instruments range from validated scales to single items and preference-based labels, and time scales from post-session to per-trial, with none continuous, so two collections are rarely comparable, and in one case the two publications on a single cohort do not agree with each other. Visual and physiological signals are common but never co-occur across collections; no collection reports force or torque, only three of the eight settings put the operator in contact with the robot at all, and the sustained coupling under which that channel would be most informative is present in one setting only, so its relation to trust is untested and would in any case have to be separated from the payload, trajectory, and disturbance components of the same signal; and the level of participant anonymization is fixed rather than varied. The amount of data is uneven as well, and the count that matters for training a model, the number of trust labels, stays low even when the raw streams are large. That scarcity is then absorbed by copying one score across many observations, a step that also breaks the usual way of testing a model. Only two of the eight are openly deposited and three document no route to their data at all, so part of the matrix describes published studies rather than reusable material. The construct and the collaboration environment are fragmented too, since some collections substitute affect or comfort for trust and others replace real contact with mixed or virtual reality.

Laying these collections on one matrix gives a compact reading of what trust data for physical collaboration is documented and where it runs out, so that a new study can be positioned against the gaps rather than against a single prior work. Four experimental priorities follow from the empty cells, in the order in which each unblocks the next. First, a reporting protocol: state the instrument, the point in the task at which trust is sampled, how that score was propagated to the recorded signals, how the evaluation folds were drawn, and the route to the data, since without it the remaining three cannot be compared across studies. Second, a collection that records force, torque, and trust labels on a common clock under sustained contact, with the payload and the commanded trajectory held constant across trust conditions, so that a mechanical trace of trust can be looked for and, if absent, reported as absent. Third, labels at more than one time scale within one cohort, which is the only design that shows whether a per-session and a per-trial measurement of trust track the same quantity. Fourth, an anonymization level varied as a controlled factor within a single collection, which would measure its cost to a trust judgment, including for vision-language models applied zero-shot, where no retraining absorbs the distortion. The fifth gap, the fragmentation of construct and environment, is not a separate experiment but a consequence of the first: once the instrument, the sampling point, and the setting are reported in a common form, collections that measure different things can at least be told apart before they are compared. A journal extension will widen the scope beyond the parameters used here, toward other dimensions of trust and uncertainty in physical interaction and a larger, more systematic body of collections.

***Abstract*—This work describes the use of a field oriented control (FOC) model to improve the performance of external-rotor Permanent Magnet Synchronous Motors towards the development of robotic rehabilitation devices. The proposed system encompasses the design of an external-rotor permanent magnet synchronous motor, a dedicated motor driver, and a FOC algorithm, constituting the actuator module upon which a complete robotic rehabilitation platform can be built. The simulation results demonstrate that FOC produces lower torque ripple than six-step commutation under equivalent operating conditions, supporting its adoption as the control strategy for applications requiring smooth and precise torque delivery.**

***Index Terms*—Upper-Limb Rehabilitation, FOC, Control Systems, Embedded Software.**

I. Introduction

The loss or impairment of upper limb motor function represents one of the main challenges in the field of physical rehabilitation, directly impacting individuals independence and quality of life. The World Health Organization (WHO) estimates that 2.4 billion people, with projections of 3.35 billion by 2050, require some form of rehabilitative intervention, with motor dysfunction resulting from conditions such as stroke being one of the leading causes of functional disability [1]. In this context, the restoration of mobility and functionality of the upper limbs becomes a central goal in therapeutic processes.

Conventional rehabilitation, based on repetitive and supervised exercises, faces limitations related to treatment variability, patient fatigue, and a shortage of specialized professionals. As an alternative, assistive robotics has emerged as a promising tool, enabling more consistent, intensive, and measurable therapies [2], [3]. These systems allow for the controlled application of forces and movements, as well as the acquisition of relevant data such as position, velocity, and torque, which are essential for assessing patients progress.

Among the most commonly used control strategies, Field-Oriented Control (FOC) is characterized by its ability to provide continuous, decoupled control of the motor currents, offering greater precision, superior dynamic response, and smoother torque generation—desirable characteristics in rehabilitation applications that require precise torque control and natural-like movement.

The generation of appropriate torque is a critical factor in robotic rehabilitation systems, as it directly influences physical interaction with the patient. More advanced control strategies can contribute to better adaptation to the required level of assistance, while adhering to fundamental principles of rehabilitation, such as individualization, intensity, and progression of therapeutic effort [2]. Actuators available in industry vary in configuration, some direct drive with Six-Steps as its commutation control strategy at a lower price (K-Tech MF6015) and FOC controlled actuators with reduction gear boxes (CubeMars AK10-9)

Given this context, it is important to investigate and compare the performance of different control strategies applied to robotic actuators, especially with regard to torque generation. Thus, this work aims to conduct an analysis of field-oriented control (FOC), evaluating its characteristics and implications for the performance of robotic systems, as well as the development and testing of a prototype designed for upper limb rehabilitation.

II. Literature review

A. Traditional Rehabilitation

Traditional Rehabilitation is primarily based on repetitive exercises supervised by physiotherapists and occupational therapists, aiming to restore movement, muscular strength, and functional independence. Among different strategies, task-specific training stands out as one of the most effective for upper limb rehabilitation. [5], [6]

Task-specific training is based on the repetitive execution of daily activities. It differs from motor deficit training by exploring functional abilities instead of focusing solely on muscle strengthening and increased range of motion. According to Hubbard et al., as cited by Rozevink et al., task-specific training should involve activities relevant to the patient, performed repeatedly, presented in different contexts, organized to reconstruct complete functional tasks, and accompanied by

performance feedback. These principles promote neuroplasticity and motor relearning. [5]

B. Robotic Rehabilitation

Advances in motor assistance technologies have enabled the development of robotic rehabilitation, in which electromechanical devices assist or partially perform upper limb movements during therapeutic sessions. These devices have emerged as an alternative for increasing the intensity, repeatability, and precision of rehabilitation exercises. [5]

Robotic devices for upper limb rehabilitation can be classified into two main categories: end-effector systems and exoskeletons. End-effector devices interact with the distal end of the limb, allowing for relatively free movement of the proximal joints, while exoskeletons have structures aligned with the arm joints, providing support and assistance directly to joint movements. [1]

In addition, these systems can operate in different training modes, including passive, active-assisted, assistive, and active modes. In assistive modes, the device provides supplemental torque to assist the patient's movement, while in active modes, the individual performs the movement independently, using the robot primarily as a monitoring or interaction tool. [5]

One of the main advantages of robot-assisted rehabilitation is its ability to provide a large number of repetitions with precise control over training conditions. In addition, these devices can automatically adjust the difficulty of exercises, record performance metrics, and provide real-time feedback to the user. These features encourage active patient participation and enable the implementation of individualized programs. [5]

The results presented by Rozevink et al. indicate that both robot-assisted rehabilitation and conventional task-based rehabilitation are effective in improving upper limb function after stroke. In the subacute phase, assistive devices yielded superior results in reducing motor deficits, whereas in the chronic phase, the benefits were similar to those obtained with conventional therapy. [5]

The Figure 1 represents the MIT-Manus, one of the designs for upper limb rehabilitation and the one that inspired the work. The MIT-Manus and H-Man are both end-effectors and can perform activities in all training modes previously mentioned.

C. Permanent Magnet Synchronous Motor (PMSM)

The operating principle of brushless DC motors is similar to that of brushed DC motors, in which rotational motion is generated through the attraction and repulsion of magnetic poles. However, these motors differ in the way a single DC voltage is converted into a three-phase voltage.

The DC current passing through the rotor coil windings generates an electromagnet with poles. These magnetic poles of the rotor interact with the poles of the permanent magnet fixed to the stator to cause the rotor to rotate. Commutation occurs mechanically every half-turn via the electrical contacts of the brushes. Due to this physical contact, the brushes wear out over time and cause fluctuations in torque.

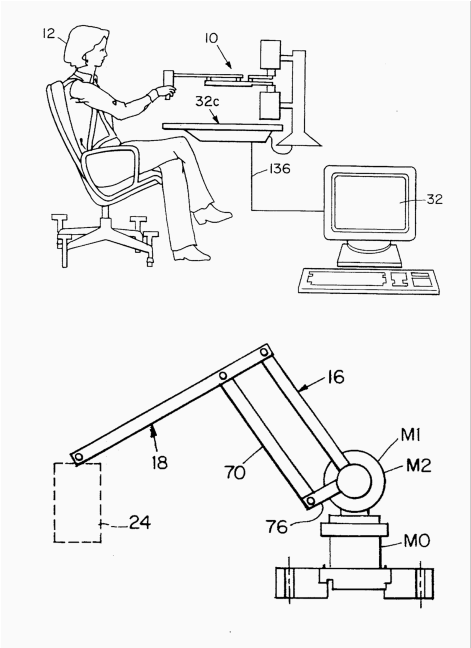

Fig. 1. Representation of the planar rehabilitation platform MIT-Manus, consisting of two actuators and a polar coordination configuration. Part of patent document US5466213A

The BLDC motor replaces mechanical commutation with electronic commutation. Compared to a brushed DC motor, permanent magnets can be installed on the rotor, while the coil windings form the stator.

BLDC and PMSM motors both operate synchronously; that is, the rotor rotates at the same speed as the stator's magnetic field. The main difference lies in the back-EMF, which determines the optimal control algorithm.

D. Field Oriented Control (FOC)

Field Oriented Control (FOC) is a control technique commonly used in induction machines and permanent magnet synchronous machines (PMSM) to achieve good control capability over the full torque and speed range. The block diagram in Figure 2 shows the architecture of the FOC control technique.

Clark and Park transforms a stationary frame abc into a rotating frame dq, the current controller consists of a PI controller for iq and id currents in the orthogonal rotating reference frame and a space vector modulator to convert a steady-state frame into a PWM signal to stator windings.

Hardware wise, the FOC uses a three-phase inverter circuit that consists of high and low power MOSFETs for each phase of the motor. The upper, lower, and no-switching states determine the phase state, keeping the motor at a constant speed. [7]–[10]

1) Clark and Park Transformation:

The Clark transformation (Equation 1) converts the time-domain components of a three-phase system into two components in a steady-state frame (Figure 3) [11].

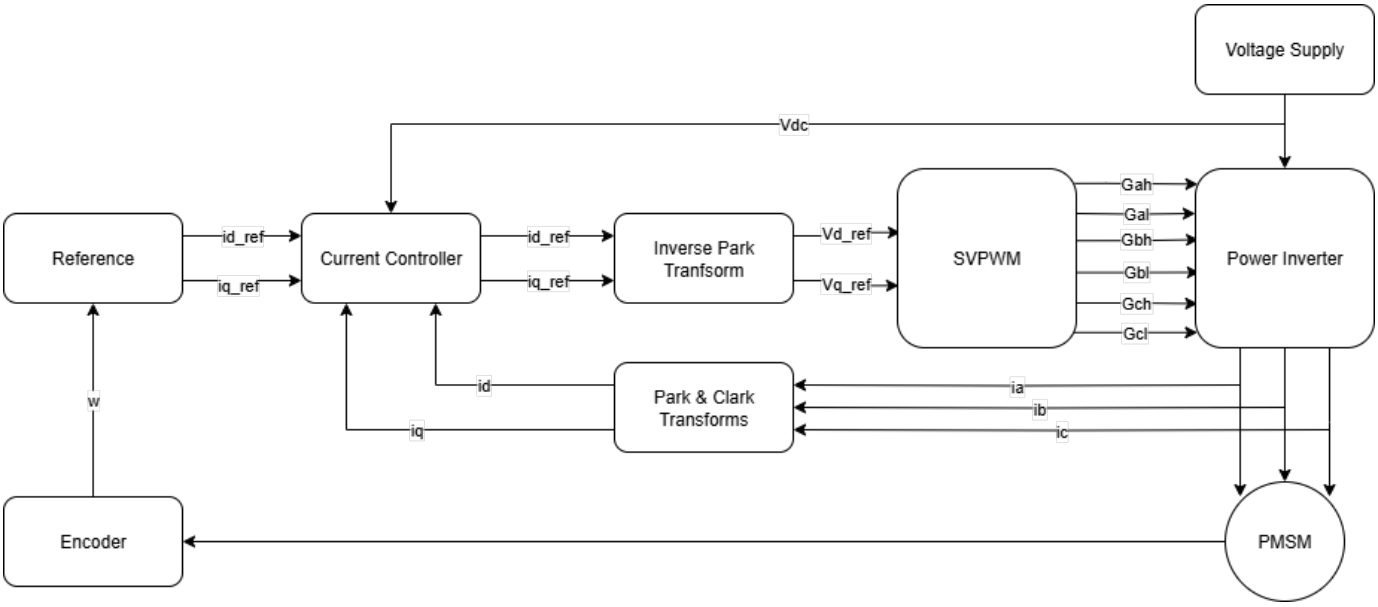

Fig. 2. Control block of Field Oriented Control architecture. Diagram made in draw.io

$$\begin{bmatrix} f_\alpha \\ f_\beta \\ f_0 \end{bmatrix} = \frac{2}{3} \begin{bmatrix} 1 & -\frac{1}{2} & -\frac{1}{2} \\ 0 & \frac{\sqrt{3}}{2} & -\frac{\sqrt{3}}{2} \\ \frac{1}{2} & \frac{1}{2} & \frac{1}{2} \end{bmatrix} \begin{bmatrix} f_a \\ f_b \\ f_c \end{bmatrix} \tag{1}$$

For a balanced system with motors, the zero-sequence component is always zero (Equation 2)

$$eu_a + eu_b + eu_c = 0 \;\Rightarrow\; e_{uc} = -\left(eu_a + eu_b\right) \tag{2}$$

This means that only two of the phases need to be monitored.

To put it simply (Equation 3):

$$\begin{bmatrix} f_\alpha \\ f_\beta \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \frac{1}{\sqrt{3}} & \frac{2}{\sqrt{3}} \end{bmatrix} \begin{bmatrix} f_a \\ f_b \end{bmatrix} \tag{3}$$

Where:

- f_a, f_b, and f_c are three-phase components in the abc panel
- f_α and f_β are orthogonal two-phase components in the steady-state $\alpha\beta$ frame
- f_0 is the zero in the steady-state $\alpha\beta$

Park's transformation converts the two components of the $\alpha\beta$ reference frame into an orthogonal rotating dq reference frame (Figure 3)

Aligning axis f_α with axis d (Equation 4)

$$\begin{bmatrix} f_d \\ f_q \end{bmatrix} = \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} f_\alpha \\ f_\beta \end{bmatrix} \tag{4}$$

Where:

- f_α and f_β are components of the Clark transform
- f_d and f_q are orthogonal components in the dq reference frame

2) Space Vector Modulation (SVM):

SVM is a common tool when it comes to FOC in induction motors and PMSMs. This technique is responsible for generating PWM signals for inverter commutation, which in turn controls the motor [8], [12].

Using the circuit shown above (II-D) and the logic circuit presented, each configuration results in simple space vectors that describe the magnitude and direction of the space vector.

The switching states corresponding to the basic spatial vectors (direction) and the zero vectors (magnitude) are combined to approximate a voltage vector of any magnitude, at any position, within the spatial vector hexagon. For example, for each pulse width modulation (PWM) period, the reference vector 'Uref' is calculated using a switching sequence of two adjacent spatial vectors for a specified time period and a zero vector (U7 and U8) for the remainder of the period [12].

By controlling the switching sequence and, consequently, the duty cycle, any voltage vector with varying magnitude and direction can be achieved for each PWM period. The objective of the SVM technique is to generate switching sequences that correspond to the reference voltage vector in order to obtain a continuously rotating spatial vector [12].

For each PWM period, using the voltage vector as the input reference, the SVM algorithm:

- Calculates the turn-on and turn-off times based on the reference voltage vector
- Use transition times to generate double-hump modulation waveforms
- It uses switching times to generate gate pulses suitable for the inverter switches

The waveform of the modulation signal generated by a double-hump structure maximizes the utilization of the available bus voltage (Figure 4) [12].

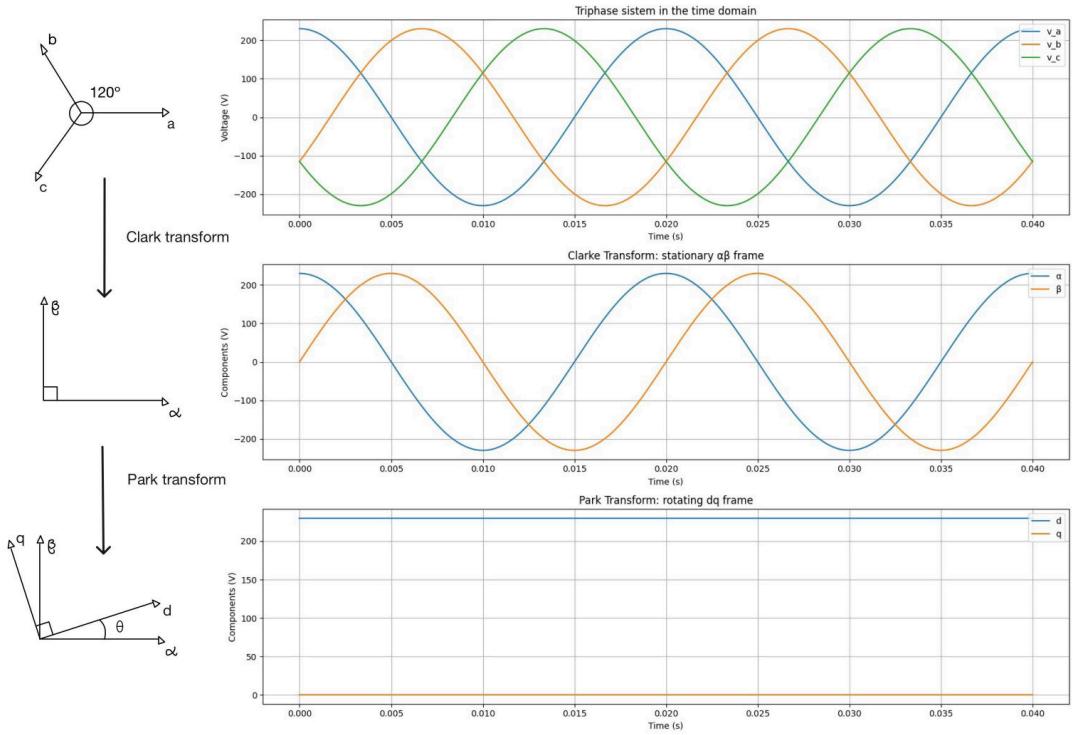

Fig. 3. Clark and Park Transforms representation in motor waveform. Made with python and GoodNotes

3) PI Current Control:

After the Clark and Park transformations, the three-phase stator currents are represented as two DC-like quantities, i_d and i_q, in the rotating reference frame. This characteristic allows for the use of conventional Proportional-Integral (PI) controllers to regulate the motor currents, since PI controllers are particularly effective at tracking constant reference signals with zero steady-state error, unlike the sinusoidal references required when controlling currents directly in the stationary abc frame.

As illustrated in the FOC block diagram (Figure 2), two independent PI loops are employed: one regulating the direct-axis current i_d and another regulating the quadrature-axis current i_q. For surface-mounted PMSMs, the reluctance torque component is negligible, so the electromagnetic torque is approximately proportional to i_q alone; the reference i_d^{ref} is therefore commonly set to zero, minimizing resistive losses whilei_q^{ref} is set according to the desired torque output. Each PI controller computes a voltage reference,v_d^{ref} and v_q^{ref}, based on the error between the reference and measured currents, which is then forwarded to the inverse Park transform and the space vector modulator (Figure 2).

It is worth noting that the d and q axes are not fully decoupled, since cross-coupling terms arising from the rotor's electrical angular speed appear in the motor's voltage equations. Although decoupling compensation terms can be added to improve dynamic performance at higher speeds, simplified implementations often neglect this coupling, relying instead on the bandwidth separation between the current loop and the mechanical dynamics of the system [8]–[10].

III. Methodology

The development of the proposed system followed a progressive approach, moving from control validation to a higher-fidelity simulation of the complete system. First, both six-step commutation and Field-Oriented Control strategies were modeled and compared in a MATLAB/Simulink environment to validate the proposed control approach and obtain reference parameters for the subsequent design stages, as detailed in Section III-A. Based on these results, a compact permanent magnet synchronous motor with an external-rotor topology was designed to provide the continuous torque required for upper limb rehabilitation, as described in Section III-B. In parallel, a dedicated motor driver was developed to execute the FOC algorithm with adequate computational and electrical performance, as presented in Section III-C. Given that physical validation of the assembled prototype was not feasible within the project schedule, a higher-fidelity simulation incorporating the identified motor and driver characteristics was employed as a substitute validation strategy, as discussed in Section III-D.

A. Simulation

The simulation phase aimed to validate the feasibility of both six-step commutation and Field-Oriented Control before proceeding to the design of the motor and driver electronics. At

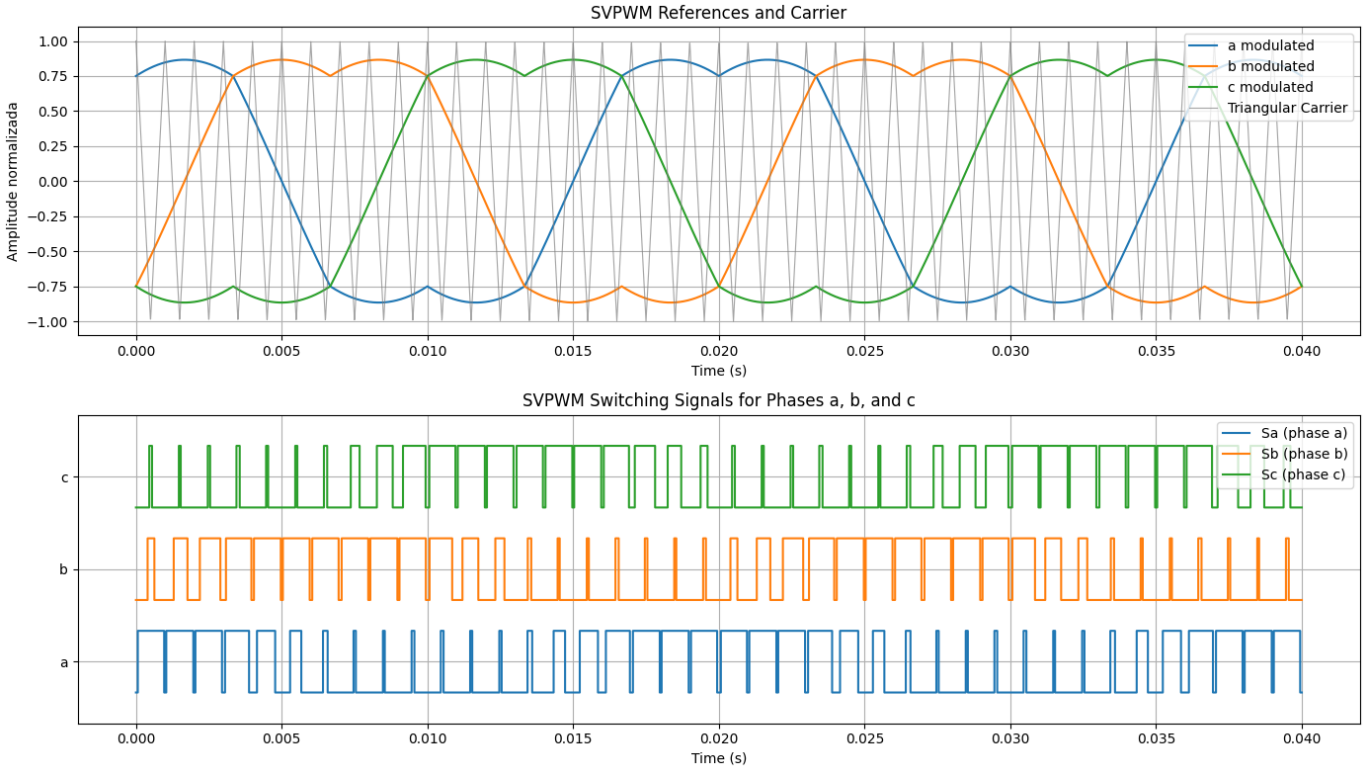

Fig. 4. Waveform and PWM output of Space Vector Modulation made in python.

this stage, since the custom motor had not yet been built, representative parameters for a generic surface-mounted PMSM (SM-PMSM) were used, consistent with the reference models adopted as a starting point for the control architecture [7], [9], [10]. These parameters were used to build a Simulink model combining blocks from the Simscape Electrical Specialized Power Systems library, which represent the power-electronics stage (three-phase inverter), and Simscape Electrical motor-control blocks, which represent the PMSM electromechanical behavior together with the Clark/Park transforms and current controllers shown in the FOC architecture (Figures 2 and 3). The resulting reference and switching signals generated by the space-vector modulator are shown in Figure 4. Both six-step commutation and FOC strategies were implemented in the same simulation environment and compared in terms of torque ripple, given its relevance for smooth, natural-like movement assistance in rehabilitation applications, as discussed in Section II-D.

B. Motor Design

Based on the parameters obtained from the simulation, a custom external-rotor (outrunner) PMSM with 14 pole pairs was designed. The out-runner topology, without the use of reduction gears, was selected to improve torque utilization at low speed without the addition of load, a desirable characteristic for rehabilitation actuators that must deliver continuous torque and backdrivability. By placing the permanent magnets on a rotating outer rotor cup around a fixed stator, the effective magnetic air-gap radius is increased, resulting in higher torque density when compared to an equivalent inrunner topology. The motor employs standard construction materials, namely copper wire for the stator windings, neodymium permanent magnets on the rotor, an aluminum structural housing, and soft magnetic steel for the stator core and rotor back-iron to efficiently channel magnetic flux.

The mechanical design was carried out in Autodesk Fusion 360, which was used for the geometric modeling and assembly verification of the rotor, stator, shaft, housing, and bearings (Figures 5 and 6). At this stage, design decisions were guided by the electrical parameters obtained from simulation and by the application requirements (continuous torque capability, compact footprint, and direct mechanical integration with the driver PCB); finite element analyzes (electromagnetic, thermal, or structural) were not performed due to hardware limitations.

C. Driver Architecture

The driver electronics were built around the STSPIN32G4, an STMicroelectronics system-in-package combining an STM32G4 microcontroller core with an integrated three-phase gate driver and motor pre-driver stage. This significantly reduced the component count of the board since most of the control and gate-driving functionality required by the FOC architecture (Figure 2) was already provided by the selected device. Power switching is performed by STL220N6F7, and rotor position feedback is provided by an AS5048A contactless

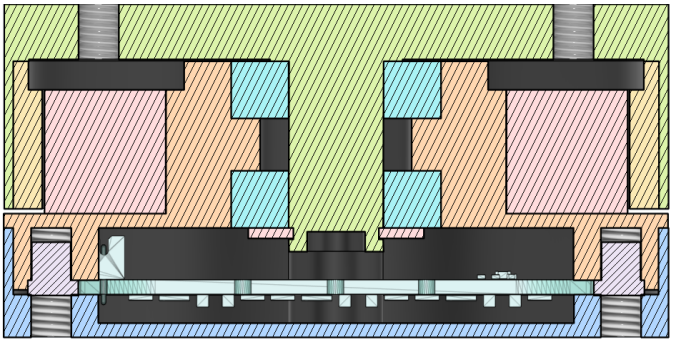

Fig. 5. CAD section analysis of the motor. Green: Rotor's case, Orange: Stator's case, Yellow: Rotor's magnetic ring, Pink: Stator, Light Blue: Bearings, Dark Blue: Driver's Case. Design and analysis made with Autodesk Fusion 360

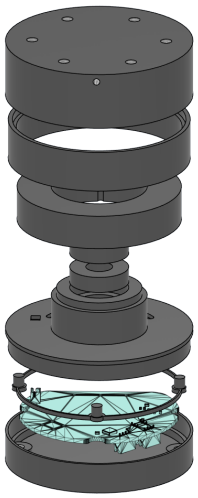

Fig. 6. CAD exploded view of the motor. Design and analysis made with Autodesk Fusion 360

14 bits magnetic rotary encoder, used as the position sensor in the current-control loop.

The printed circuit board was designed in KiCad 9 as a four-layer stack-up, with the outer layers dedicated to the ground reference and the inner layers routing the power-supply traces; digital/control circuitry and power circuitry were physically separated on the board layout to minimize switching noise coupling into the sensing and control signals. The board is supplied with a nominal input voltage of 24 V, with design operation up to a maximum of 48 V.

D. Validation

A high-fidelity simulation was conducted using the same Simulink model described in Section III-A, now updated with the parameters of the actual motor built during the design stage (Section III-B), in place of the generic representative parameters initially adopted. These parameters were identified directly from the physical motor using the ST Motor Pilot tool (v6.4.1) and the ST Motor Control Workbench, and are summarized as follows: stator resistance $Rs = 6.28\Omega$, stator inductance $L_s = 2.93$ mH, back-EMF constant $K_e = 41.89$ V/krpm, viscous friction coefficient of $16{,}06\,\mu Nms/rad$, rotor inertia of $4{,}66\,gcm^2$, 14 pole pairs, nominal current of $1.8A$, nominal DC-bus voltage of $23.35V$, and a maximum rated speed of $270rpm$. ST Motor Control Workbench provides a motor parameters extraction firmware for ST Nucleo Boards, in witch a set of values are tested inside a voltage and current range set by the user. As the motor spins the back-EMF is read and compared to the input. Motor Pilot is a graphical interface for a list of applications, such as torque, velocity and position control and open loop tests.

With the model updated to reflect the as-built system, the torque ripple comparison between six-step commutation and FOC was repeated under these conditions, allowing the conclusions drawn in the preliminary simulation to be compared against the characteristics of the real hardware developed in Sections III-B and III-C, in the absence of physical test results.

IV. Results

The torque ripple comparison between six-step commutation and Field-Oriented Control, conducted with the identified parameters of the custom motor, is shown in Fig. 7 and 8 and I. The results demonstrate that FOC produces lower torque ripple than six-step commutation under equivalent operating conditions, yielding a continuous torque output of 1 N·m. FOC also presents a faster response time when starting, causing it to overshoot, as shown in 8. This behavior is due to its characteristic alignment between the rotor end and the magnetic field. This difference is particularly relevant in the context of upper limb rehabilitation, where torque smoothness directly affects the quality of physical interaction with the patient, as discussed in Section II-D. The superior performance of FOC in this regard supports its adoption as the control strategy of choice for the proposed system, consistent with findings reported in the literature. Since the only hardware test made was in open-loop for the parameter extraction, results may vary in a closed loop test with both the motor and driver.

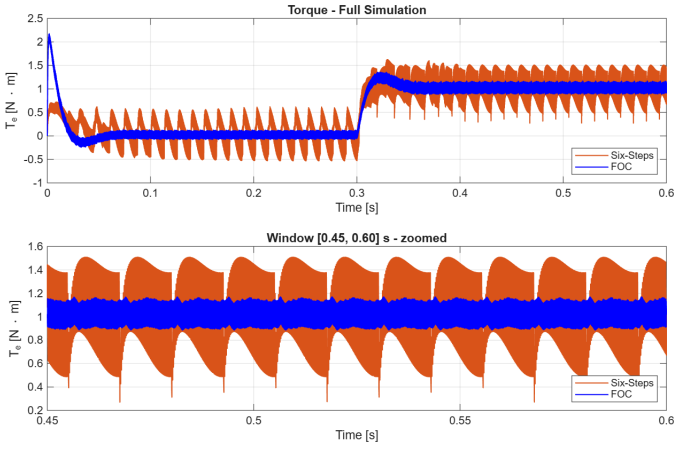

Fig. 7. Top figure shows the torque output of FOC in Blue and Six-Steps in Orange, bottom figure show a zoomed window of the same outputs

TABLE I
TORQUE RIPPLE ANALYSIS RESULTS FOR THE TWO TECHNIQUES.

Strategy	Mean[Nm]	Min[Nm]	Max[Nm]	P2P[Nm]	Ripple[%]
Six-Step	1,021	0,269	1,509	1,240	121.5
FOC	1,021	0,886	1,171	0,285	27.9

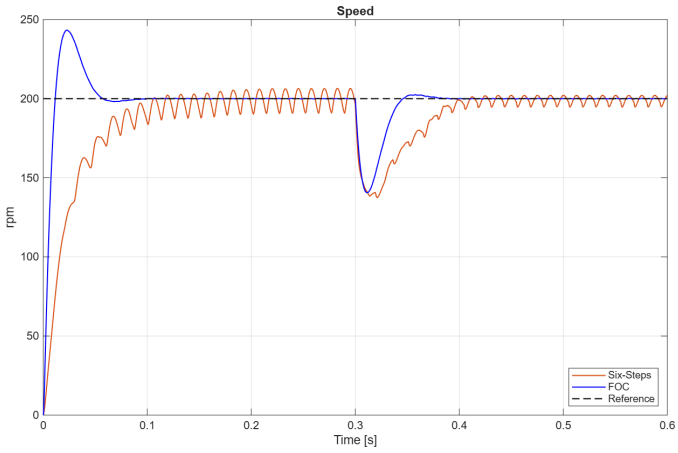

Fig. 8. Top figure shows the torque output of FOC in Blue and Six-Steps in Orange, bottom figure show a zoomed window of the same outputs

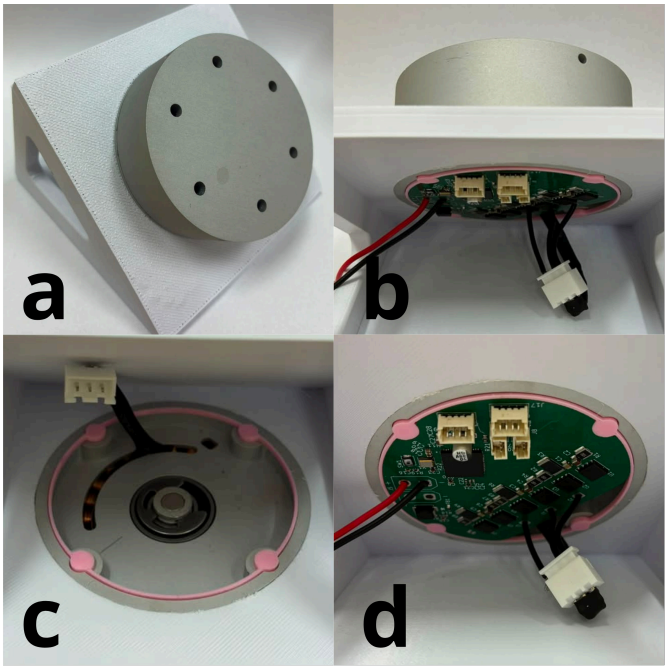

Fig. 9. a: Top view of the PMSM; b: Side view in test support; c: Bottom view; d: Bottom view with Driver attached.

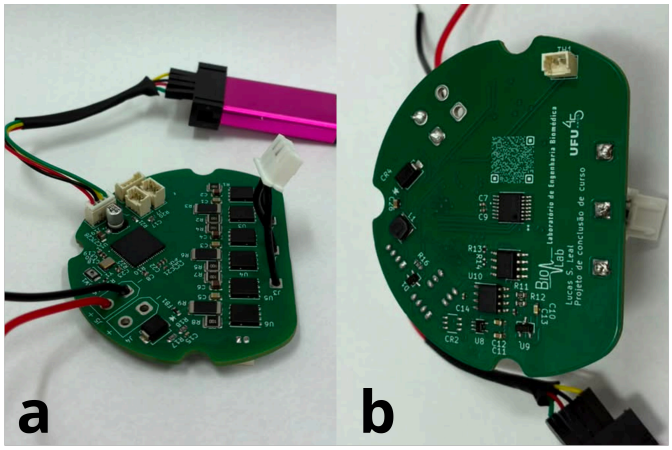

Fig. 10. a: Driver's top view with STlink; b: Driver's bottom view.

The custom external-rotor PMSM resulted in a compact actuator with a diameter of 70 mm and a height of 30.55 mm, with a total mass of 320g. These dimensions confirm the suitability of the outrunner topology for integration into a rehabilitation platform, where compactness and low weight are essential requirements. The assembled motor is shown in Fig. 9, together with the driver PCB mounted directly to its base, demonstrating the mechanical integration achieved by the design.

The manufactured four-layer driver board, shown in Fig. 10, integrates the STSPIN32G4 system-in-package, the STL220N6F7 power MOSFETs, and the AS5048A magnetic encoder interface into a compact footprint directly compatible with the motor housing. Other peripherals were also added, such as an EEPROM for storing configurations and other parameters, and a CAN communication interface. Some electrical protection was also added: SMBJ30CA for electrostatic discharge (ESD) protection in the power line; a Schottky barrier diode BAT54S for high speed switching applications, circuit protection, and voltage clamping; and ESDA5V3 for ESD protection in data lines. For temperature, both motor and driver present a slot for a thermistor, only for monitoring, no active cooling system was added to the project. The physical separation between digital and power domains on the board layout is expected to minimize electromagnetic interference on the current sensing and position feedback signals, which are critical for the stability of the FOC current loop. The board was designed to operate at a nominal supply voltage of 24 V, with the capability to support operation up to 48 V in case of usage with motors of up to 36 V, designed to present headroom for future iterations requiring higher torque output.

It is important to acknowledge that the simulation-based validation conducted in Section III-A, while sufficient to characterize the behavior of the control strategies under realistic motor parameters, does not substitute physical experimental validation. Furthermore, although FOC demonstrated a measurable reduction in torque ripple relative to six-step commutation, the perceptual relevance of this difference to the end user in a rehabilitation context remains an open question. Given the low operating speeds and the inherent compliance of the human musculoskeletal system, torque ripple at the levels produced by either strategy may fall below the threshold of clinical significance for upper limb rehabilitation quality, a hypothesis that can only be confirmed through patient-facing trials. These aspects constitute important directions for future

work, to be addressed once a fully functional prototype is available for physical testing.

V. Conclusion

This work presented the development of a FOC PMSM model to be used in the design of a robotic rehabilitation platform for upper limb motor recovery, inspired by end-effector systems such as the MIT-Manus (Figure 1). The proposed system encompasses the design of a custom external-rotor PMSM, a dedicated motor driver, and the implementation and evaluation of a Field-Oriented Control algorithm, constituting the actuator module upon which a complete rehabilitation platform can be built.

The simulation results demonstrated that FOC produces lower torque ripple than six-step commutation under equivalent operating conditions, supporting its adoption as the control strategy for applications requiring smooth and precise torque delivery. The custom motor achieved a compact form factor of 70 mm in diameter and 30.55 mm in height, with a continuous torque output of 1 N·m, and the driver integrated control, gate-driving, and position sensing functions into a single compact board.

Physical validation of the prototype remains the immediate next step, as the simulation-based approach adopted here does not fully capture real-world operating conditions. Future work includes experimental torque characterization, closed-loop performance evaluation, implementation of impedance and admittance controllers, and the integration of the actuator module into the mechanical structure of the rehabilitation platform, moving toward a complete system suitable for clinical assessment.

Acknowledgment

This work benefited from assistance with text review from other members of BioLab - UFU, as well as assistance with motor characterization, testing, and specific design-related questions. The authors would like to acknowledge the Brazilian funding agencies CAPES, CNPq and FINEP for the financial support.

***Abstract*— Advanced Heart Failure (AHF) remains a major clinical challenge, often requiring Ventricular Assist Devices (VADs) as long-term mechanical circulatory support. Despite significant improvements in survival, VAD patients remain vulnerable to adverse events, including thrombosis, power supply failures, and electromechanical malfunctions. This study presents the development of an Internet of Medical Things (IoMT)-based architecture integrating telemonitoring and geolocation functionalities to improve emergency response and patient safety. The proposed system combines an ESP32 microcontroller, INA219 monitoring sensor, GPS module, MQTT communication protocol, cloud infrastructure, and a mobile application for real-time visualization and alarm management. The architecture adopts an Event-Driven Architecture (EDA) and Discrete Event Systems concepts supported by Interpreted Petri Nets. Experimental validation demonstrated stable communication, accurate geolocation, reliable telemetry acquisition, and effective transmission of critical alerts. The proposed solution establishes a scalable framework for remote supervision of VAD patients and contributes to reducing response time during critical adverse events.**

Keywords*— *Internet of Medical Things (IoMT), Ventricular Assist Devices, Telemonitoring, MQTT, Fault Diagnosis.

I. INTRODUCTION (*HEADING 1*)

Heart Advanced Heart Failure (AHF) remains one of the leading causes of morbidity and mortality worldwide, requiring therapeutic strategies capable of improving both patient survival and quality of life. In this context, Ventricular Assist Devices (VADs) have become an established therapeutic option for patients requiring bridge-to-transplant, bridge-to-recovery, or destination therapy by providing long-term mechanical circulatory support [1], [2]. Despite significant technological advances in pump miniaturization, durability, and hydraulic performance, VADs remain susceptible to adverse events such as pump thrombosis, ventricular suction, flow obstruction, electromechanical failures, and hemodynamic instability, all of which may compromise device performance and patient safety [2], [3].

Experimental cardiovascular platforms have become essential tools for investigating the behavior of VADs under controlled laboratory conditions. These systems enable the reproduction of physiological and pathological cardiovascular scenarios, allowing researchers to evaluate device performance, validate control algorithms, investigate adverse events, and assess new monitoring strategies without exposing patients to experimental risks [4], [5]. Similarly, vascular flow phantoms have been extensively employed for Doppler ultrasound calibration, operator training, and validation of blood flow measurements by reproducing different vascular geometries and flow conditions [5]–[7].

However, most vascular phantoms reported in the literature have been designed to simulate isolated blood vessels or specific cardiovascular diseases rather than the complex hemodynamic conditions observed in patients implanted with continuous-flow VADs. Furthermore, few experimental platforms integrate a realistic cardiovascular simulator, a ventricular assist device, Doppler ultrasound assessment, multiparameter monitoring, and data acquisition into a single experimental environment [4], [8]. This limitation restricts the development of standardized protocols for evaluating implanted VADs and validating Doppler ultrasound techniques under clinically relevant operating conditions.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

To accurately reproduce the physiological behavior of patients supported by VADs, it is necessary to define a minimum set of hemodynamic and operational parameters capable of representing the interaction between the native heart and the mechanical circulatory support system. Among the most relevant parameters are the Pulsatility Index (PI), blood flow rate, hydraulic pressure, pump rotational speed (RPM), electrical current, power consumption, and Doppler-derived blood velocity profiles. These variables provide valuable information regarding preload, afterload, ventricular contractility, pump operating conditions, and the occurrence of adverse events such as ventricular suction, thrombosis, partial obstruction, and abnormal flow patterns [2], [9], [10]. Continuous monitoring of these parameters is fundamental for understanding VAD behavior and improving both experimental investigations and future clinical monitoring systems.

The development of experimental platforms capable of reproducing these complex conditions requires multidisciplinary collaboration involving biomedical engineers, mechanical engineers, clinicians, cardiovascular surgeons, and ultrasound specialists. In recent years, **co-creation frameworks** have emerged as an effective methodology for integrating knowledge from different stakeholders throughout the design and validation process of healthcare technologies. By promoting collaborative definition of functional requirements, physiological scenarios, monitoring strategies, and validation procedures, co-creation enhances the clinical relevance, usability, and technological robustness of biomedical systems [11]–[13].

Therefore, this paper proposes the development of a Doppler ultrasound circulatory system Phantom capable of simulating patients implanted with Ventricular Assist Devices through the application of a co-creation framework. The proposed platform integrates a cardiovascular hydraulic model, a prototype blood pump representing the VAD, biomedical sensors, multiparameter monitoring, and Doppler ultrasound evaluation into a unified experimental environment. The Phantom is intended to reproduce clinically relevant physiological and pathological conditions, supporting the investigation of VAD-related adverse events, the validation of Doppler ultrasound protocols, and the development of intelligent monitoring technologies for mechanical circulatory support systems.

II. Theoretical Background

A. Advanced Heart Failure and Ventricular Assist Devices

Advanced heart failure (AHF) is a progressive clinical condition associated with high morbidity and mortality, often requiring mechanical circulatory support when pharmacological therapy is no longer sufficient [1], [2]. In this context, Ventricular Assist Devices (VADs) have become an important therapeutic option for patients undergoing bridge-to-transplant, bridge-to-recovery, or destination therapy, providing continuous support to systemic circulation and improving survival rates [1], [2]. Continuous-flow VADs are currently the most widely used devices; however, their operation is associated with complex hemodynamic interactions involving preload, afterload, ventricular contractility, and pump rotational speed [9], [10].

Despite significant technological advances, VADs remain susceptible to adverse events such as pump thrombosis, ventricular suction, flow obstruction, hemolysis, and electromechanical failures, which may compromise device performance and patient safety [3], [10]. These complications highlight the need for experimental platforms capable of reproducing realistic cardiovascular conditions and enabling the investigation of hemodynamic behavior under controlled laboratory environments [4], [5]. Furthermore, continuous monitoring of parameters such as blood flow, pressure, rotational speed, power consumption, and pulsatility index is essential for understanding device performance and supporting the development of safer and more reliable mechanical circulatory support systems [9], [10].

B. Cardiovascular Simulators and Circulatory Phantom Development

Experimental cardiovascular simulators have become essential tools for the development, validation, and optimization of mechanical circulatory support devices. These platforms reproduce physiological and pathological hemodynamic conditions under controlled laboratory environments, allowing researchers to evaluate the hydraulic performance of Ventricular Assist Devices (VADs), investigate cardiovascular responses, validate control strategies, and perform repeatable experiments without exposing patients to clinical risks [4], [5]. Mock circulatory loops have also been widely employed to support device certification, surgical training, and the development of innovative biomedical technologies by providing realistic representations of systemic circulation [4], [8].

In parallel, the development of vascular and circulatory phantoms has significantly expanded the application of Doppler ultrasound in biomedical research. Unlike conventional vascular phantoms designed primarily for equipment calibration or isolated flow measurements, next-generation circulatory phantoms seek to reproduce the complex interaction between the cardiovascular system and implanted VADs by integrating hydraulic components, prototype blood pumps, biomedical sensors, and data acquisition systems [5], [6]. Such experimental infrastructures enable the simulation of physiological and pathological flow conditions, including changes in pulsatility, pressure, flow distribution, and adverse events, thereby providing a robust platform for Doppler ultrasound validation and the evaluation of intelligent monitoring technologies for mechanical circulatory support systems [5], [7], [8].

C. Doppler Ultrasound Applied to Ventricular Assist Devices

Ultrasound imaging has become one of the most versatile and widely adopted diagnostic modalities in modern medicine due to its non-invasive nature, real-time imaging capability, absence of ionizing radiation, and relatively low operational cost. Recent technological advances have significantly expanded its clinical applicability through the development of portable and handheld ultrasound systems capable of providing point-of-care imaging in hospitals, ambulances, remote locations, and emergency scenarios. The incorporation of wireless communication, integrated beamforming electronics, and compact transducers has increased system flexibility while reducing equipment size and operational complexity, thereby facilitating the dissemination of ultrasound technologies across different healthcare environments [14]. These innovations have transformed Doppler ultrasound into an essential tool for cardiovascular assessment and continuous hemodynamic monitoring.

Ultrasound consists of mechanical waves with frequencies above the upper limit of human hearing, typically ranging from 20 kHz to several hundreds of megahertz. In diagnostic imaging, clinical systems generally operate between 2 and 15 MHz, depending on the target anatomical structure and the desired spatial resolution [15], [16]. The transducer contains piezoelectric elements that convert electrical energy into acoustic waves and subsequently transform returning echoes into electrical signals after their interaction with biological tissues. Differences in acoustic impedance among tissues determine the reflected echoes, enabling the reconstruction of B-mode images that represent the internal anatomical structures [17]. When combined with the Doppler effect, ultrasound systems become capable of estimating blood flow velocity, flow direction, spectral characteristics, and turbulence by measuring the frequency shift generated by moving red blood cells [6], [15].

Doppler ultrasound has become an important complementary technique for monitoring patients implanted with Ventricular Assist Devices (VADs), since changes in Doppler waveforms reflect the interaction between the native cardiovascular system and the mechanical circulatory support device. Parameters such as blood flow velocity, pulsatility, pressure gradients, and spectral flow profiles provide valuable information regarding preload, afterload, ventricular unloading, pump operating conditions, and the occurrence of adverse events including ventricular suction, thrombosis, obstruction, and abnormal flow patterns [8]–[10]. Nevertheless, the validation of Doppler measurements under clinically realistic VAD conditions remains limited because conventional vascular phantoms generally reproduce only simplified arterial geometries and physiological flow profiles [5], [7].

Therefore, the development of a circulatory Phantom specifically designed to simulate patients implanted with continuous-flow VADs represents an important contribution to biomedical engineering research. By integrating a cardiovascular simulator, prototype blood pumps, Doppler-compatible materials, biomedical sensors, and multiparameter data acquisition, the proposed platform enables controlled reproduction of physiological and pathological hemodynamic scenarios. This experimental infrastructure is expected to support Doppler ultrasound validation, investigation of VAD-related adverse events, evaluation of intelligent monitoring strategies, and future developments in mechanical circulatory support technologies [4], [5], [8].

D. Hemodynamic Parameters for VAD Phantom Development

The development of a circulatory Phantom capable of realistically simulating patients implanted with Ventricular Assist Devices (VADs) requires the definition of a representative set of hemodynamic and operational parameters that characterize the interaction between the native cardiovascular system and the mechanical circulatory support device. Unlike conventional vascular phantoms, which are primarily designed for equipment calibration or simplified flow measurements, a VAD-oriented Phantom must reproduce physiological conditions associated with continuous-flow support, enabling the evaluation of both normal operation and clinically relevant adverse events [4], [5]. Consequently, the experimental platform should incorporate variables that adequately represent cardiovascular function, pump performance, and Doppler ultrasound behavior under controlled laboratory conditions.

Among the most important parameters is the **Pulsatility Index (PI)**, which reflects the interaction between ventricular contractility and pump operation. The PI is influenced by preload, afterload, circulating blood volume, ventricular filling, and pump rotational speed, serving as an indirect indicator of changes in cardiovascular status [9], [10]. Reductions in pulsatility may occur during ventricular suction, hypovolemia, or reduced ventricular preload, whereas elevated pulsatility may indicate increased native ventricular contribution or changes in systemic vascular resistance [10], [18]. Continuous assessment of PI, combined with flow and power measurements, has been reported as an important strategy for monitoring VAD performance and supporting clinical decision-making [19].

Additional operational parameters include **blood flow rate**, **pump rotational speed (RPM)**, **electrical current**, **power consumption**, and **hydraulic pressure**, all of which provide complementary information regarding the mechanical behavior of the circulatory support system. Variations in these parameters may indicate changes in pump loading conditions, partial inflow or outflow obstruction, thrombus formation,

mechanical degradation, or abnormal operating conditions [2], [9]. Simultaneous acquisition of these variables enables comprehensive characterization of VAD performance and contributes to the interpretation of Doppler ultrasound findings during experimental investigations.

From the hemodynamic perspective, the Phantom should also reproduce physiological and pathological flow conditions, including laminar, pulsatile, turbulent, intermittent, and retrograde flow patterns. Furthermore, the experimental platform should be capable of simulating clinically relevant adverse events such as ventricular suction, pump thrombosis, aortic valve dysfunction, stenosis, and altered ventricular loading conditions, which produce characteristic Doppler signatures and distinct hemodynamic responses [4], [8], [20]. Computational cardiovascular models and experimental simulators have demonstrated that reproducing these scenarios is fundamental for understanding device behavior and validating monitoring methodologies before clinical application [4], [20].

Finally, integrating these hemodynamic and operational parameters into a Doppler-compatible circulatory Phantom provides a comprehensive experimental environment for evaluating VAD performance. The simultaneous acquisition of hydraulic, electrical, mechanical, and ultrasound-derived variables allows the development of reliable databases for future studies involving intelligent monitoring, predictive maintenance, adverse event detection, and artificial intelligence applied to mechanical circulatory support systems. Therefore, the proposed Phantom is expected to provide a realistic and reproducible platform for biomedical research, device validation, and the advancement of Doppler ultrasound applications in patients supported by Ventricular Assist Devices [5], [11], [13].

E. Co-Creation Framework for Biomedical Device Development

The increasing complexity of biomedical technologies has stimulated the adoption of collaborative development methodologies that integrate knowledge from multiple stakeholders throughout the innovation process. In this context, **co-creation** has emerged as an important approach for the conception, design, and validation of healthcare technologies by promoting the active participation of researchers, engineers, clinicians, end users, and other specialists during product development. According to Koning *et al.* [21], the literal meaning of co-creation derives from the combination of **"co"**, meaning "together", and **"creation"**, representing the joint production of something new. This collaborative philosophy encourages the integration of complementary expertise, resulting in technological solutions that are more robust, user-centered, and aligned with clinical needs.

Although co-creation has gained increasing attention in innovation management and healthcare engineering, its practical implementation remains heterogeneous. Roser *et al.* [12] analyzed more than fifty co-creation models described in the literature and concluded that there is no universally accepted definition or standardized methodology. Depending on the application, co-creation may be interpreted either as an open innovation strategy that promotes collaboration among organizations or as a participatory design methodology focused on involving stakeholders throughout the product development process. Despite these conceptual differences, most approaches share the common objective of integrating multidisciplinary knowledge to improve innovation outcomes and reduce development uncertainties [12].

Koning *et al.* [21] proposed a meta-model that organizes the co-creation process into six sequential phases: **Identify, Analyze, Define, Design, Realize, and Evaluate**. Within this framework, the **Design** phase represents the core of the collaborative process by incorporating activities such as inviting stakeholders, sharing knowledge, combining ideas, selecting alternative solutions, and continuously refining the proposed concept. Rather than representing a strictly linear methodology, these phases constitute an iterative innovation cycle in which technical requirements, clinical demands, experimental evidence, and user feedback are progressively incorporated into the development process, increasing the maturity and reliability of the resulting technology.

In the present study, the co-creation framework provides the methodological foundation for the development of a Doppler ultrasound circulatory Phantom intended to simulate patients implanted with Ventricular Assist Devices. The framework supports the collaborative definition of clinical requirements, hemodynamic parameters, Doppler ultrasound characteristics, hydraulic architecture, sensor integration, and experimental validation procedures. The participation of researchers from biomedical engineering, mechanical engineering, cardiovascular physiology, medical imaging, and clinical practice enables the systematic integration of multidisciplinary knowledge throughout all development stages. This collaborative approach contributes to the creation of a more realistic experimental platform capable of reproducing clinically relevant physiological and pathological conditions associated with VAD-supported circulation.

Furthermore, the proposed framework extends beyond the physical development of the Phantom by supporting the specification of monitoring variables, experimental protocols, validation criteria, and future technological evolution of the platform. By combining collaborative design principles with experimental cardiovascular simulation and Doppler ultrasound evaluation, the proposed methodology is expected to improve the reproducibility, usability, and scientific robustness of the experimental infrastructure. Consequently, the co-creation framework constitutes a strategic element for developing innovative biomedical devices capable of supporting research in mechanical circulatory support, intelligent monitoring, and validation of emerging healthcare technologies [5], [21]–[13].

III. Prepare Materials and Methods

This study adopted an applied and experimental research approach to develop a Doppler ultrasound circulatory phantom for patients implanted with Ventricular Assist Devices (VADs). The proposed methodology was structured around a co-

creation framework, integrating clinical requirements, engineering design, hemodynamic simulation, IoMT-based monitoring, and experimental validation. Initially, the functional and technical requirements were identified through a literature review and consultation of current VAD technologies. Subsequently, the circulatory phantom was designed and constructed, followed by the integration of the VAD, Doppler ultrasound acquisition system, embedded monitoring architecture, and IoMT communication infrastructure. Finally, experimental tests were conducted to evaluate the hydraulic behavior of the platform, the acquisition of hemodynamic parameters, and the suitability of the phantom for Doppler ultrasound studies. **Figure 1.** Methodological framework proposed for the development of a Doppler ultrasound circulatory phantom for patients implanted with Ventricular Assist Devices (VADs). The framework is organized into five sequential stages: co-creation, phantom development, hemodynamic simulation with Doppler setup, IoMT-based monitoring, and experimental validation with data analysis. This structured workflow integrates biomedical engineering, cardiovascular simulation, Doppler ultrasound, and digital health technologies to support the design and validation of an experimental platform for VAD research.

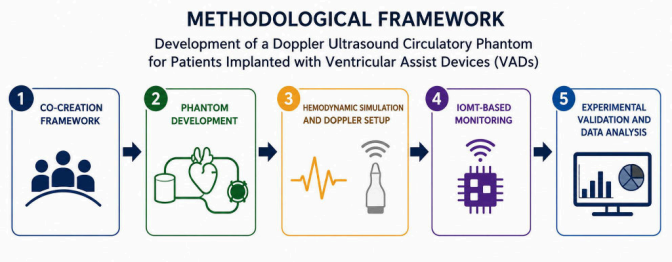

Fig. 1 Methodological framework proposed for the development of a Doppler ultrasound circulatory phantom for patients implanted with Ventricular Assist Devices (VADs).

A. System Architecture

The proposed supervisory platform was developed as a proof-of-concept Internet of Medical Things (IoMT) system for telemonitoring and geolocation of patients supported by Ventricular Assist Devices (VADs). The architecture adopts a modular layered organization that facilitates scalability, interoperability, and the future implementation of intelligent fault diagnosis algorithms.

The supervisory logic was conceived according to the principles of Discrete Event Systems (DES) and Interpreted Petri Nets (IPNs), allowing future representation of asynchronous events, alarm sequencing, and fault transitions in critical medical devices [13], [14].

The complete architecture is organized into four functional layers:

- Data Acquisition Layer
- Communication Layer
- Cloud Processing Layer
- Application Layer

The Data Acquisition Layer consists of an ESP32 microcontroller integrated with an INA219 current and voltage sensor and a NEO-6M GPS receiver. The ESP32 continuously acquires electrical variables generated by the VAD electronic emulator while simultaneously obtaining geographical coordinates from the GPS receiver. These data are processed locally and encapsulated into telemetry packets before transmission to the cloud infrastructure.

The proposed modular organization enables future integration of additional sensors and intelligent supervisory algorithms without requiring structural modifications to the overall system architecture.

B. Cardiovascular Simulators and Circulatory Phantom Development

Experimental cardiovascular simulators have become essential tools for the development, validation, and optimization of mechanical circulatory support devices. These platforms reproduce physiological and pathological hemodynamic conditions under controlled laboratory environments, allowing researchers to evaluate the hydraulic performance of Ventricular Assist Devices (VADs), investigate cardiovascular responses, validate control strategies, and perform repeatable experiments without exposing patients to clinical risks [4], [5]. Mock circulatory loops have also been widely employed to support device certification, surgical training, and the development of innovative biomedical technologies by providing realistic representations of systemic circulation [4], [8].

In parallel, the development of vascular and circulatory phantoms has significantly expanded the application of Doppler ultrasound in biomedical research. Unlike conventional vascular phantoms designed primarily for equipment calibration or isolated flow measurements, next-generation circulatory phantoms seek to reproduce the complex interaction between the cardiovascular system and implanted VADs by integrating hydraulic components, prototype blood pumps, biomedical sensors, and data acquisition systems [5], [6]. Such experimental infrastructures enable the simulation of physiological and pathological flow conditions, including changes in pulsatility, pressure, flow distribution, and adverse events, thereby providing a robust platform for Doppler ultrasound validation and the evaluation of intelligent monitoring technologies for mechanical circulatory support systems [5], [7], [8].

C. Doppler Ultrasound Applied to Ventricular Assist Devices

Doppler ultrasound is one of the most widely used non-invasive imaging techniques for evaluating blood flow dynamics and cardiovascular function. By measuring the frequency shift produced by moving blood cells, Doppler systems provide quantitative and qualitative information regarding flow velocity, flow direction, turbulence, and vascular resistance [6]. In patients implanted with Ventricular Assist Devices (VADs), Doppler ultrasound has become an important complementary tool for assessing the interaction between the native cardiovascular system and mechanical circulatory support. Variations in Doppler waveforms may indicate changes in ventricular unloading, pulsatility, flow

distribution, pump operating conditions, and the occurrence of adverse events, contributing to clinical decision-making and patient follow-up [8]–[10].

Despite its widespread clinical use, the validation of Doppler ultrasound techniques for VAD applications remains challenging because of the limited availability of experimental models capable of reproducing realistic hemodynamic conditions. Conventional vascular phantoms generally simulate simplified arterial geometries and steady or pulsatile flows but do not adequately represent the complex hemodynamic behavior observed in patients supported by continuous-flow VADs [5], [7]. Consequently, the development of a circulatory Phantom integrating a cardiovascular simulator, prototype blood pumps, Doppler-compatible materials, and multiparameter monitoring represents an important step toward improving ultrasound validation, investigating VAD-related adverse events, and supporting the development of intelligent monitoring systems. Such an experimental platform enables repeatable and controlled evaluation of Doppler signals under physiological and pathological conditions, strengthening research in biomedical engineering and mechanical circulatory support [4], [5].

D. *Validation Procedure*

The proposed IoMT platform was experimentally validated through integrated laboratory bench testing using a Ventricular Assist Device electronic emulator developed for supervisory system evaluation.

The validation procedure aimed to verify the correct operation of all functional layers of the proposed architecture, including embedded telemetry acquisition, wireless communication, cloud synchronization, geolocation services, and mobile application performance.

The experimental protocol evaluated the following performance indicators:

- Communication latency;
- MQTT connectivity stability;
- GPS positioning accuracy;
- Voltage measurement consistency;
- Current measurement consistency;
- Telemetry transmission reliability;
- Alarm notification reliability;
- Synchronization between embedded hardware and the supervisory application.

During the experimental tests, the ESP32 continuously acquired electrical measurements from the VAD emulator while simultaneously transmitting telemetry information and GPS coordinates to the cloud server. The received information was automatically processed and displayed by the supervisory mobile application, enabling real-time monitoring of the simulated device.

The adopted validation methodology follows a proof-of-concept approach commonly employed during the development of embedded IoMT systems for medical applications and was based on the experimental platform developed for VAD supervisory monitoring [16].

E. *Data Analysis*

The experimental results were analyzed qualitatively according to the operational behavior of the complete supervisory architecture. The stability of telemetry acquisition, wireless communication, cloud synchronization, GPS positioning, and graphical visualization were evaluated throughout continuous operation.

The validation focused on demonstrating the technical feasibility of integrating embedded hardware, IoMT communication, cloud services, and mobile supervision into a unified platform capable of supporting future intelligent fault diagnosis algorithms for Ventricular Assist Devices.

Although the present study was conducted using a laboratory emulator, the proposed architecture establishes a scalable technological framework for future implementation in commercial VAD systems and for the development of predictive maintenance and automated fault diagnosis strategies based on Discrete Event Systems and Interpreted Petri Nets [13], [14].

IV. RESULTS AND DISCUSSION

The proposed IoMT-based supervisory architecture was successfully implemented and validated through integrated bench testing using a Ventricular Assist Device (VAD) emulator. The experimental evaluation demonstrated the feasibility of combining telemetry acquisition, wireless communication, cloud processing, and real-time geolocation into a unified supervisory platform, consistent with the objectives established for the proof of concept. **Fig. 1** illustrates the complete architecture of the developed IoMT platform.

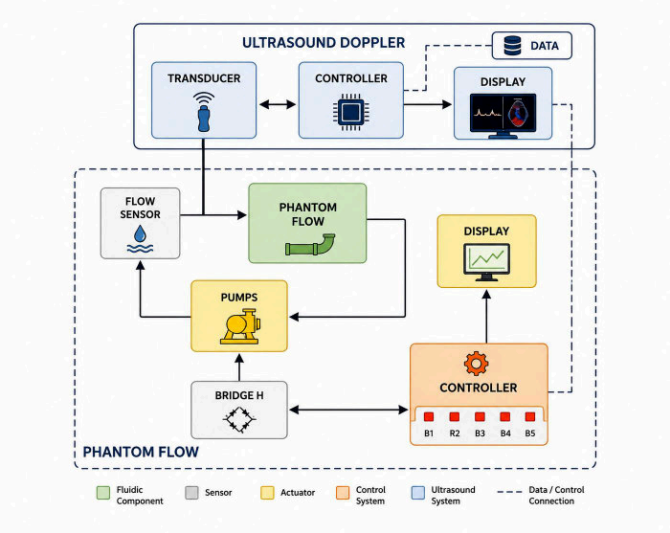

Fig. 1. The complete architecture of the developed IoMT platform

The system architecture integrates an ESP32 microcontroller, an INA219 current and voltage sensor, a

NEO-6M GPS receiver, an MQTT communication infrastructure, cloud services, and a mobile application operating under an Event-Driven Architecture (EDA). The developed platform continuously acquires electrical variables from the VAD emulator while simultaneously transmitting geographic coordinates, allowing remote supervision of both device status and patient location. These results validate the proposed architecture as a functional IoMT solution for VAD telemonitoring.

A. *Telemetry Acquisition*

Experimental tests demonstrated stable acquisition of the monitored electrical variables throughout the evaluation period. The INA219 sensor continuously measured voltage and current with consistent readings, while the ESP32 processed and transmitted the acquired information without communication interruptions.

As illustrated in **Fig. 2**, the developed prototype integrates all embedded hardware components responsible for data acquisition and communication. The experimental platform demonstrated stable operation during continuous measurements, confirming the feasibility of using low-cost embedded electronics for supervisory monitoring applications.

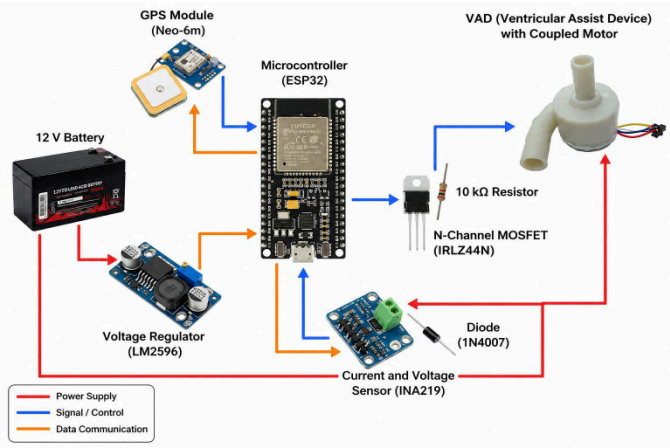

Fig. 2. The developed prototype integrates all embedded hardware components responsible for data acquisition and communication

The implemented acquisition module successfully generated periodic telemetry packets containing:

- Voltage (V);
- Current (mA);
- Device operating status;
- GPS coordinates;
- Alarm classification.

The obtained measurements remained consistent during prolonged operation, indicating that the embedded acquisition subsystem is suitable for continuous monitoring applications. Although the current implementation employs a VAD emulator rather than a clinical device, the adopted architecture can be directly extended to real LVAD controllers after appropriate hardware interface adaptation.

B. *MQTT Communication Prformance*

Communication between the embedded hardware and the cloud broker remained stable throughout the validation experiments. The publish-subscribe model based on MQTT enabled asynchronous data exchange with low communication overhead.

No packet losses capable of compromising system functionality were observed during the experimental evaluation. The communication architecture also demonstrated scalability, allowing additional sensing modules or monitoring devices to be incorporated without structural modifications.

These results confirm the suitability of MQTT for IoMT applications involving continuous telemetry of critical medical devices, where reliable low-latency communication is essential.

C. *Geolocation Validation*

The GPS subsystem successfully determined the geographic position during all outdoor validation tests. Coordinates acquired by the NEO-6M module were correctly transmitted to the cloud platform and visualized through the mobile application using Google Maps services.

The simultaneous availability of telemetry and geolocation information represents one of the principal contributions of the proposed architecture, since most currently available LVAD telemonitoring systems rely primarily on manual data entry and do not provide automatic patient localization.

The developed solution therefore enables emergency teams to identify not only abnormal operating conditions but also the patient's exact geographical location, supporting faster emergency response.

D. *Mobile Application Performance*

The supervisory mobile application successfully received, processed, and displayed all transmitted variables in real time.

As presented in **Fig. 3**, the graphical interface provides continuous visualization of the monitored parameters, including voltage, current, device status, GPS location, and alarm notifications. The Event-Driven Architecture ensures that the interface is automatically updated whenever new telemetry messages become available.

The graphical interface remained responsive throughout the validation tests, and all transmitted variables were correctly synchronized with the cloud database. The event-driven architecture allowed immediate updating of the graphical interface whenever new telemetry messages were received.

E. *Discussion*

The obtained results demonstrate that the proposed IoMT architecture is technically feasible for remote supervision of Ventricular Assist Devices.

Unlike conventional telemonitoring platforms, which generally depend on manual insertion of operational parameters, the proposed system automatically acquires electrical measurements directly from the monitored device while simultaneously providing continuous geolocation.

The combination of embedded sensing, MQTT communication, cloud services, and mobile visualization establishes the technological infrastructure required for future implementation of predictive diagnostic algorithms based on Discrete Event Systems and Interpreted Petri Nets.

Although the present study focused on proof-of-concept validation using a VAD emulator, the developed architecture constitutes an important technological step toward intelligent supervisory systems capable of supporting early fault detection, adverse event mitigation, and emergency logistics in patients supported by Ventricular Assist Devices.

Fig. 3. The graphical interface provides continuous visualization of the monitored parameters, including voltage, current, device status, GPS location, and alarm notifications Example of a figure caption.

The principal limitation of the present work is that validation was performed using an experimental emulator rather than commercially available LVAD hardware or a mock circulatory loop. Consequently, future investigations should integrate the proposed platform with physiological simulators and clinical VAD systems to evaluate its performance under realistic operating conditions.

F. Limitations of the Study

This study has several limitations that should be considered when interpreting the results. The proposed architecture was evaluated using a laboratory ventricular assist device emulator, and therefore the experiments demonstrate IoMT integration, telemetry, remote monitoring, control and geolocation functionality rather than clinical safety or patient-specific performance. Quantitative assessments of end-to-end communication latency, packet loss rate, long-term system availability, battery autonomy, alarm response time and GPS positioning error under different environmental conditions were not performed. In addition, fault-injection experiments, communication-failure tolerance, cybersecurity mechanisms, including authentication, encryption, access control and auditability, and medical interoperability were not experimentally validated. Therefore, the demonstrated results should be interpreted as proof of concept at the laboratory prototype level. Future work will include quantitative performance characterization, controlled fault-injection scenarios, cybersecurity assessment, network-failure testing and validation under increasingly realistic operating conditions prior to any clinical investigation.

V. CONCLUSION

This study presented the development and experimental validation of an Internet of Medical Things (IoMT)-based supervisory platform for telemonitoring and geolocation of patients supported by Ventricular Assist Devices (VADs). The proposed architecture integrates embedded hardware, wireless communication, cloud computing, and a mobile supervisory application into a unified platform capable of continuously monitoring electrical operating parameters while simultaneously providing real-time patient geolocation.

The proof-of-concept implementation demonstrated the technical feasibility of integrating an ESP32 microcontroller, INA219 current and voltage sensor, NEO-6M GPS receiver, MQTT communication protocol, and cloud-based services into a reliable supervisory system. Experimental results confirmed stable telemetry acquisition, consistent wireless communication, accurate geolocation, and successful synchronization between the embedded platform and the mobile application throughout the validation tests. These findings demonstrate that low-cost IoMT technologies can be effectively employed to support remote supervision of critical medical devices.

An important contribution of this work is the integration of automatic telemetry acquisition with real-time geolocation in a single supervisory architecture. Unlike conventional telemonitoring solutions that frequently depend on manual transcription of operational parameters, the proposed system automatically acquires electrical variables directly from the monitored device and transmits them to healthcare professionals through an event-driven communication infrastructure. This capability has the potential to reduce

response time during critical adverse events and improve emergency logistics for patients requiring immediate clinical intervention.

From the perspective of intelligent medical systems, the proposed architecture also establishes a technological foundation for future implementation of advanced fault diagnosis, predictive maintenance, and clinical decision-support algorithms. The modular organization adopted in this work facilitates the incorporation of Discrete Event Systems, Interpreted Petri Nets, and Artificial Intelligence techniques for automatic detection of abnormal operating conditions and prediction of adverse events.

The main limitation of the present study is that the experimental validation was performed using a laboratory VAD electronic emulator rather than a commercial ventricular assist device or a physiological mock circulatory loop. Consequently, additional investigations are required to evaluate the proposed architecture under realistic operating conditions and to validate its clinical applicability.

Future work will focus on integrating the supervisory platform with commercial VAD systems, implementing model-based fault diagnosis algorithms using Discrete Event Systems and Interpreted Petri Nets, incorporating machine learning techniques for predictive analysis of adverse events, and conducting experimental validation in physiological simulators and clinical environments. These developments are expected to contribute to safer, more reliable, and more intelligent remote monitoring systems for patients receiving long-term mechanical circulatory support.

ACKNOWLEDGMENT *(Heading 5)*

The preferred spelling of the word “acknowledgment” in America is without an “e” after the “g”. Avoid the stilted expression “one of us (R. B. G.) thanks ...”. Instead, try “R. B. G. thanks...”. Put sponsor acknowledgments in the unnumbered footnote on the first page.

***Abstract*—Camera repositioning in robot-assisted minimally invasive surgery is conventionally performed through foot-pedal clutching, forcing surgeons to interrupt instrument manipulation and increasing cognitive workload. Existing autonomous camera control approaches commonly rely on surgical instrument tracking, surgeon-specific learning, or additional wearable devices, which may limit exploratory camera motion, require personalization, or increase operational complexity. This paper presents a hands-free framework for intuitive endoscopic camera control based on real-time face-tracking. The proposed method estimates the surgeon's head orientation from facial landmarks, maps natural head movements into continuous camera motion commands, and enables independent control of the endoscopic view without interrupting the surgical workflow or requiring additional wearable hardware. Compared with the conventional pedal-based camera control strategy, the proposed approach achieved overall performance comparable to the conventional method while maintaining similar trajectory characteristics and providing statistically significant improvements in selected spatial accuracy metrics, particularly root-mean-square (RMS) deviation and angular deviation for specific participants. These results demonstrate that the proposed interface provides accurate and stable camera navigation while representing a feasible alternative to conventional endoscopic camera control.**

***Index Terms*—Robotic Surgery, Simulation and Modeling, Teleoperation, Human-Robot Interaction**

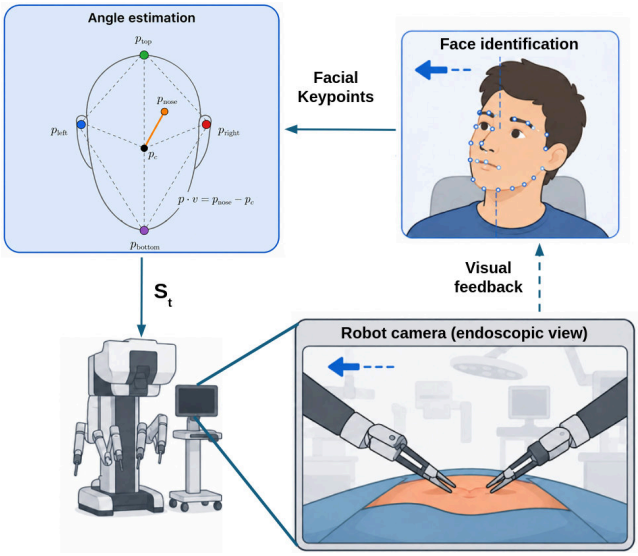

Fig. 1: Overview of the proposed framework. Head movements are tracked and translated into motion commands for the surgical robot's endoscopic camera, enabling hands-free camera control during robotic surgery.

I. INTRODUCTION

Robotic surgery has become a cornerstone approach in minimally invasive procedures [1], offering high precision while eliminating the need for conventional open interventions [2]. This technology has established applications in neurosurgery, orthopedics, urology, and many others [3]. In these systems, the surgeon typically controls the surgical manipulators and the endoscopic camera through hand-operated interfaces and foot pedals [4]. In this context, camera positioning control is a critical factor [3], [5], [6], given the inherent limitations of the surgical field of view [3]. However, current commercial platforms predominantly operate under a clutch-based control paradigm [4], which prevents the simultaneous manipulation of both the surgical instruments and the vision system.

The need to periodically interrupt the surgical procedure to reposition the camera directly disrupts the workflow. Given a restricted field of view and the dynamic nature of anatomical structures, the continuous effort to maintain an optimal frame heightens the operator's stress and cognitive load [7]–[9].To mitigate these limitations and preserve operational continuity, several autonomous camera manipulation strategies have been

proposed in the literature. These methods can be broadly categorized into: context-aware systems driven by anatomical structures, gesture and kinematic tracking approaches, and learning-based personalized frameworks [10].Within context-aware systems, Ji et al. [11] proposed the automatic detection of viewpoints to favor the visualization of critical anatomy. Regarding gesture and kinematic tracking, Pasini et al. [12] combined recurrent neural networks with forceps kinematics for automated positioning, while Elazzazi et al. [13] implemented vision control via voice commands. To capture surgical preferences, Iovene et al. [14] integrated camera movement with procedural phases and pre-mapped surgeon profiles, whereas Wagner et al. [15] developed a modular perception-interpretation-action framework that incrementally learns individual preferences into a knowledge base. Extending behavioral learning, Rivas-Blanco et al. [16] employed Learning from Demonstration (LfD) to guide an endoscopic assistant robot. Lastly, alternative hardware interfaces have been explored, such as the system by Dardona et al. [17], which leverages user head movements captured via a Head-Mounted Display (HMD).

Despite these advancements, some limitations remain unaddressed in the literature. The prevalent constraint of keeping surgical instruments strictly in focus [18], [19] restricts the surgeon's operational freedom, preventing the inspection of peripheral regions of interest without moving the active tools [3]. Learning-based and gesture-recognition systems inherently absorb the specific traits and habits of a single operator, requiring retraining to ensure interchangeability among different professionals [10]. Finally, alternative modalities that rely on additional hardware, such as HMDs or eye-trackers, could increase the user's cognitive burden [20], [21].

To overcome these limitations, this paper presents a camera control framework driven by the surgeon's head inclination and orientation via real-time face tracking, as illustrated in Fig.1. By decoupling camera motion from instrument tracking, the proposed solution restores exploratory autonomy to the surgeon, allowing independent field-of-view adjustments without cognitive drawbacks associated with wearable hardware.

II. METHODS

This section presents the methodology used to extract facial keypoints and estimate head inclination. It also describes the simulation environment used to emulate endoscopic camera movements and evaluate the proposed framework.

A. *Face-tracking*

The operator's facial pose is tracked using the MediaPipe framework [22]. After face detection, a set of facial landmarks is extracted to define a local reference plane. Since the proposed method relies solely on image information, the three-dimensional facial keypoints are represented as two-dimensional pixel coordinates. This plane is geometrically defined by four peripheral landmarks: the upper forehead region ($\mathbf{p}_{\text{top}}$) , the right ($\mathbf{p}_{\text{right}}$) and left ($\mathbf{p}_{\text{left}}$) facial extremities, and the lower chin region ($\mathbf{p}_{\text{bottom}}$), where each keypoint is

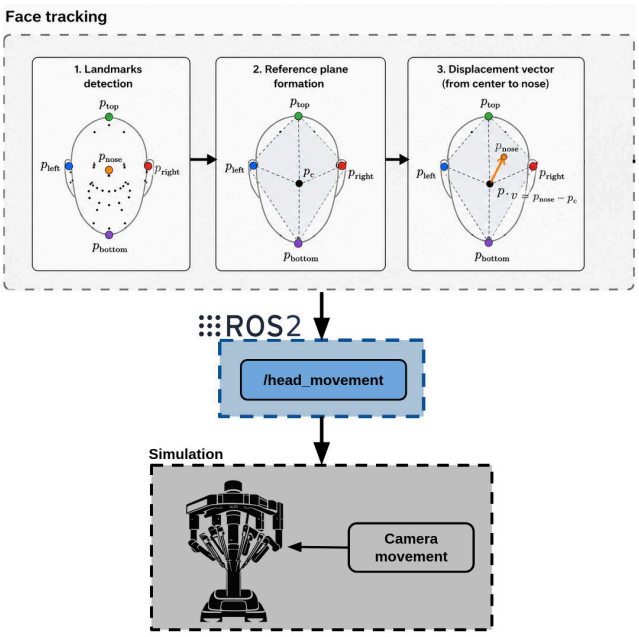

Fig. 2: Block diagram of the proposed framework. MediaPipe performs real-time face tracking to estimate the operator's head pose. Four peripheral facial landmarks are extracted to define a local reference plane, whose geometric center is computed and used as the origin of the local coordinate system. A displacement vector from the reference plane center to the nose landmark represents the head orientation through its direction and the movement amplitude through its magnitude, enabling continuous two-dimensional mapping of the operator's head motion. This information is published to a ROS2 topic, where the simulation environment subscribes and converts the received commands into endoscopic camera motion of the surgical robot.

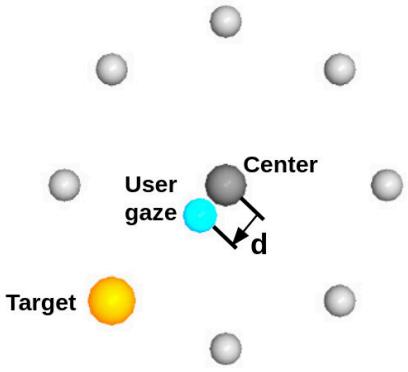

Fig. 3: Experimental environment for the target-tracking task. The sphere corresponding to the target sector is highlighted in yellow to indicate the gaze target, whereas the remaining spheres are displayed in gray. The user's estimated gaze position is represented by the blue sphere. The bidimensional length between the center and the user heead-gaze position is represented by d.

represented by a vector in $\mathbb{R}^{2\times1}$. The geometric center of this plane, denoted by $\mathbf{p}_c$, is computed according to (1) and used as the origin of the vector employed to estimate the head inclination:

$$\mathbf{p}_c = \frac{1}{4}\left(\mathbf{p}_{top} + \mathbf{p}_{bottom} + \mathbf{p}_{right} + \mathbf{p}_{left}\right) \quad (1)$$

Once the reference plane has been established, a projection vector $\mathbf{v}$ is defined by connecting the geometric center $\mathbf{p}_c$ to the landmark corresponding to the nose ($\mathbf{p}_{nose}$). This vector serves as an indicator of the face's relative displacement and is expressed by (2):

$$\mathbf{v} = \mathbf{p}_{nose} - \mathbf{p}_c \quad (2)$$

By taking $\mathbf{p}_c$ as the origin and baseline of the local coordinate system, the facial orientation and movement amplitude are directly represented by the direction and magnitude of the vector $\mathbf{v}$, respectively. Consequently, the operator's head movements are continuously mapped into a complete two-dimensional trigonometric domain. This representation provides an intuitive and omnidirectional control space, enabling unrestricted exploratory navigation of the endoscopic camera.

Finally, since dynamic head movements are inherently susceptible to involuntary tremors and high-frequency oscillations, a first-order exponential smoothing filter is applied to attenuate measurement noise and ensure the stability of the control signal. The filtering process is governed by (3):

$$\mathbf{s}_t = \alpha \cdot \mathbf{s}_{t-1} + (1-\alpha)\mathbf{v}_t \quad (3)$$

where $\mathbf{v}_t$ denotes the raw displacement vector measured at the current time step, $\mathbf{s}_t$ is the resulting filtered vector, and $\alpha \in [0, 1]$ is the exponential smoothing coefficient. The exponential smoothing coefficient α in Eq. 3 was empirically set to 0.6. A calibration step, performed at the beginning of each trial, recorded the operator's neutral head position as a baseline offset, which was subtracted from subsequent facial displacement measurements to account for individual variations in resting head pose and camera placement. To prevent unintended camera motion caused by small involuntary head movements, a deadzone threshold of 0.015 (in normalized image coordinates) was applied to the magnitude of the filtered displacement vector $\mathbf{s}_t$. The control loop operated at 100 Hz, facial landmarks were extracted from webcam frames captured at 30 fps (640×480 resolution), and the resulting camera pose commands were transmitted to the simulation environment at 30 Hz. The complete methodological workflow for facial pose estimation and kinematic mapping is illustrated in Fig. 2.

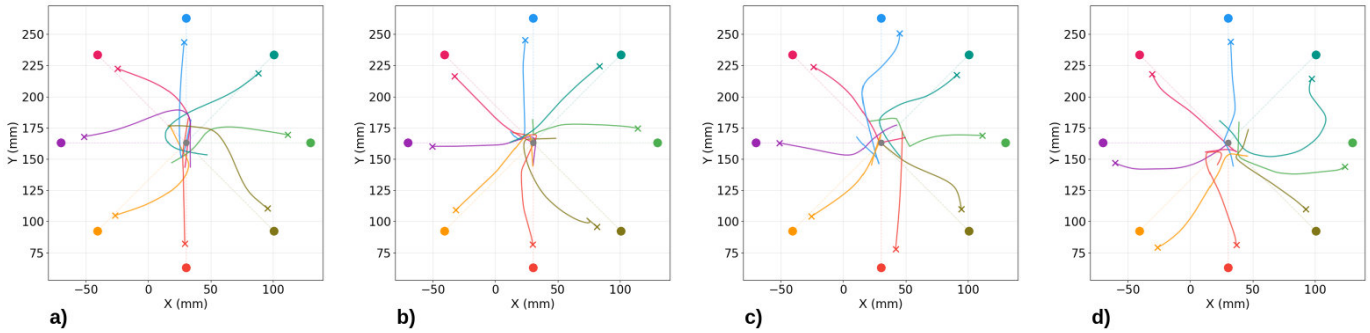
B. Simulation

The simulation of the da Vinci surgical robot, comprising its three instrument arms and the endoscopic camera, was implemented within the Asynchronous Multi-Body Framework (AMBF). AMBF was selected as it provides an open-source platform optimized for the real-time simulation of complex robotic systems, sensors, and environments, while offering baseline integration with existing da Vinci robot models [23]. Inter-process communication between the simulator and external command interfaces is handled via ROS2 topics, as illustrated in Fig. 2. Specifically, the simulator subscribes to the user's head movement orientation through ROS2 topics, translating these inputs to actuate the endoscopic camera in the corresponding direction.

III. EXPERIMENTAL EVALUATION

This section presents the experimental evaluation of the proposed system in comparison with the conventional foot-pedal-based camera control method.

The study was conducted with two volunteers, both non-surgeons, aged between 19 and 23 years. Regarding visual characteristics, one participant presented refractive errors: high myopia associated with astigmatism. Concerning familiarity with the task, only one participant had prior experience with both the simulator and camera manipulation.Both participants performed 15 trials with each of the two proposed methods.



A. Experimental Setup

All experimental evaluations and the robotic system simulation were conducted on a ASUS ROG Strix G533ZS, with a 12th Gen Intel Core i9-12900H processor, 16 GB of RAM, NVIDIA GeForce RTX 3080 GPU, and Ubuntu 24.04.4. The simulation's graphical interface was rendered on the computer screen, with 15.6" and native resolution of 2560 x 1440 px. Operator facial tracking was performed using a Logi C270 HD WebCam camera.

B. Target Tracking

This experiment was designed based on established assessment tasks used in serious rehabilitation games [24], [25]. The visual stimulus consists of a circle divided into eight sectors, as depicted in Fig.3. At the beginning of each trial, the target sector is highlighted by changing its corresponding sphere's color from gray to yellow, while the remaining spheres remain gray. To ensure system robustness and mitigate potential failures in detecting the user's focus of attention, the pixel error between the target coordinates and the actual gaze fixation point is computed. After directing their gaze toward the target, participants are required to return their visual fixation to the center of the circle.

Based on this head-movement protocol, five performance metrics are quantified. The first metric is the total execution time required for the participant to complete the gaze shift from the central target to the highlighted peripheral target. The second metric is the trajectory length, defined as the total distance traveled by the gaze between the initial and final fixation points. The third metric is the trajectory efficiency, computed by comparing the performed gaze path with the shortest possible path connecting the two targets. The fourth metric is the perpendicular root-mean-square (RMS) deviation, computed as the RMS of the perpendicular distances between each sampled gaze point and the ideal trajectory, measuring the average lateral deviation from the intended path. The fifth

(a) Method 1 (b) Method 2 (c) Method 3 (d) Method 4

Fig. 4: Target-tracking trajectories obtained for each participant during the experimental evaluation. The solid lines represent the trajectories executed by the participants while moving from the central target to the highlighted peripheral target, whereas the dashed lines denote the ideal shortest path between the two targets. The ideal trajectory served as the reference for computing the trajectory efficiency, perpendicular RMS deviation, and angular deviation metrics. images (a) and (b) correspond to User 1, using the proposed and the traditional methods, respectively. Similarly, images (c) and (d) correspond to User 2, using the proposed and the traditional methods, respectively.

TABLE I: Performance metrics for each participant using the conventional and proposed methods.

User	Time (s)	Length (mm)	Eff. (%)	RMS (mm)	Angle (°)
Conventional Method Performance					
1	1.50 ± 0.13	104.81 ± 4.68	84.80	9.00 ± 1.43	9.79 ± 2.32
2	1.49 ± 0.11	112.98 ± 4.81	86.60	11.57 ± 1.84	10.17 ± 2.05
Proposed Method Performance					
1	1.63 ± 0.14	107.92 ± 10.59	84.80	9.01 ± 3.39	8.27 ± 2.19
2	1.55 ± 0.06	109.28 ± 5.20	86.60	9.34 ± 1.71	7.95 ± 1.94

metric is the angular deviation, defined as the angle between the ideal movement vector and the net displacement vector of the executed gaze trajectory, computed using the normalized dot product.

The results for the two participants are presented in Fig.4, where the solid lines represent the trajectories followed by the participants during the experiment, while the dashed line indicates the ideal trajectory. The quantitative results for each participant are summarized in Table.I, which reports the mean values of the performance metrics described before.

IV. DISCUSSION

The participants exhibited a mean completion time of $1.593, \mathrm{s}$ using the face tracking approach, which corresponds to the displacement from the central target to a peripheral target. Compared to the traditional method involving foot-pedal clutching and manual camera positioning, the conventional approach yielded a slightly lower average completion time of $1.500, \mathrm{s}$. Statistical analysis revealed that this difference was mainly influenced by User 1 ($p = 0.0128$), whereas no statistically significant difference was observed for User 2 ($p = 0.0906$). These findings indicate that no statistically significant difference in temporal performance was found between the proposed interface and the conventional control strategy, though this should be interpreted with caution given the small sample size, rather than indicating a consistent improvement in execution time. Nevertheless, the ability to maintain visual focus on the surgical field while simultaneously issuing camera commands remains an attractive characteristic of the proposed interface, as it minimizes interruptions associated with clutch activation and manual camera adjustments.

Regarding the trajectory, the average displacement between the central and peripheral targets was $108.60, \mathrm{mm}$ for the face tracking approach, while the traditional method resulted in an average trajectory length of $108.89, \mathrm{mm}$. Statistical analysis demonstrated that no significant differences were observed for either User 1 ($p = 0.3120$) or User 2 ($p = 0.0528$), although the latter exhibited a trend toward shorter trajectories with the proposed method. These results indicate that the face tracking interface is capable of generating camera movements with spatial efficiency comparable to the conventional control strategy. In this way, maintaining equivalent path lengths suggests that head-orientation commands can be translated into camera motions without introducing unnecessary endoscope displacement. Consequently, the proposed interface preserves the efficiency of camera repositioning while providing an alternative interaction modality that does not compromise trajectory quality.

The RMS deviation calculated between the ideal trajectory and the one executed via face tracking revealed an average deviation of $9.18, \mathrm{mm}$, whereas the traditional method presented an average deviation of $10.28, \mathrm{mm}$. Although no statistically significant difference was observed for User 1 ($p = 0.9890$), User 2 exhibited a significantly lower RMS deviation with the face tracking interface ($p = 0.0019$), indicating improved trajectory consistency for this participant. To complement this metric and ensure the robustness of the proposed method, the angular deviation of the participants was computed, yielding an average of $8.11°$ for the face tracking approach and $9.98°$ for the traditional method. This reduction was statistically

significant for User 1 ($p = 0.0049$), while no significant difference was found for User 2 ($p = 0.0770$). These findings suggest that the proposed interface is capable of producing camera trajectories with at least the same level of spatial precision as the conventional technique, while providing measurable improvements in specific aspects of trajectory quality depending on the individual user. Such consistency is particularly desirable in robot-assisted surgery, where predictable camera movements directly influence instrument positioning and the surgeon's situational awareness.

These results demonstrate that the proposed face tracking interface achieves performance comparable to the conventional pedal-based camera control while providing improvements in selected spatial metrics, including RMS and angular deviation for specific participants. Although a consistent reduction in task completion time was not observed across all users, the results indicate that head-orientation commands can serve as a viable alternative modality for robotic camera control without compromising navigation efficiency. Regarding the practical integration of this face tracking algorithm into the original architecture of the Da Vinci surgical system, an increase in face rotation detection sensitivity would be required. This calibration can be achieved by tuning the parameters of Equation 3, as surgeons exhibit subtle head rotations and translations when interacting with the master console viewer.

V. CONCLUSION

This paper presented a novel framework for controlling the endoscopic camera of the Da Vinci surgical robot through real-time face tracking, replacing the conventional foot-pedal clutching and manual camera manipulation paradigm. Unlike existing approaches that rely on surgical instrument tracking, surgeon-specific training, or additional wearable hardware, the proposed method enables intuitive hands-free camera control using only the surgeon's natural head movements. This framework preserves the surgeon's ability to freely explore the surgical field without requiring simultaneous movement of the surgical instruments, thereby improving workflow continuity and reducing interruptions caused by camera repositioning. The proposed approach was assessed through a preliminary experimental evaluation, in a comparative study against the conventional camera control strategy

The results demonstrated that the proposed interface achieved overall performance comparable to the conventional method while maintaining similar trajectory characteristics and providing statistically significant improvements in selected spatial metrics, particularly RMS and angular deviation for specific participants. Although statistically significant differences were not consistently observed across all metrics and users, the findings demonstrate that face-tracking interaction constitutes a feasible and promising human-machine interface for robotic surgical systems, providing intuitive operation while preserving the accuracy and consistency required for endoscopic camera navigation.

Despite these findings, some limitations should be acknowledged. The experimental evaluation was conducted exclusively with the authors of this paper, which limits the generalizability of the findings to a broader population of surgeons and users with different levels of experience. Second, the original Da Vinci surgical console differ from those implemented in the camera-and-computer setup used in this study. In particular, the interaction dynamics of the original console may impose constraints on lateral head movements, which could affect the direct transferability of the proposed interaction paradigm to the original surgical platform.

Future work will focus on integrating the proposed framework into the original Da Vinci hardware platform and evaluating its performance with a larger number of participants. In addition, future developments will investigate multimodal interaction by combining face tracking with complementary input modalities, motivated by the growing evidence that multimodal interfaces can provide greater robustness, flexibility, and usability than unimodal interaction paradigms.

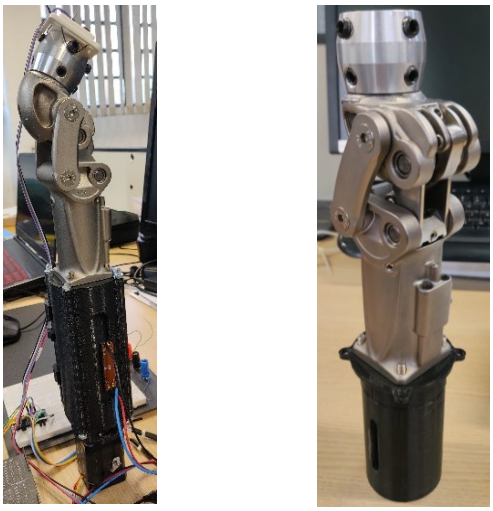
***Abstract*—For patients with lower limb disabilities, the primary goal of rehabilitation is to restore limb function, a process in which robotic knee prostheses act as a fundamental component. This paper presents the design of a mechanism adapted for the implementation of a Series Elastic Actuator (SEA) within a polycentric knee prosthesis. The proposed system utilizes a commercial polycentric knee joint, which comprises a four-bar mechanism and a pneumatic damping system. To evaluate the knee joint prosthesis, a flexion-extension cycle was executed to capture the sensor responses. During this dynamic test, distinct differences in displacement values between the two cycle phases were observed. Additionally, to test the SEA output, the knee joint was mechanically blocked with a rigid bar, enabling the measurement of signals generated exclusively by the elastic component's deformation. The testing of the elastic element demonstrated that its deformation values, relative to the drive pulses sent to the mechanism, scaled linearly. These results provide an essential foundation for the future implementation of an effective force control system on the prosthetic mechanism.**

Keywords—Knee joint prosthesis, Series elastic actuator.

I. INTRODUCTION



For individuals with lower limb disabilities, the restoration of limb function is the primary objective of physical rehabilitation, with robotic knee prostheses serving as the core functional component. These advanced prostheses enable amputees to walk by actively controlling shank posture, providing the necessary joint torque, supplying swing damping, and ensuring overall lower limb stability, thereby facilitating both physical recovery and psychological well-being. Due to its robust bionic and mechanical properties, the four-bar mechanism has been widely utilized in the design of robotic knee prostheses since the 1980s. Recently, research on four-bar robotic knees has increasingly focused on specialized locomotion functions, integrated actuation, and controlled elastic deformation. A polycentric knee mechanism is characterized by an instantaneous center of rotation that shifts its position dynamically as the knee flexion angle changes. While all polycentric devices control stability through this shifting center of rotation , there is an infinite variety of possible kinematic arrangements, each offering distinct functional characteristics.

The Series Elastic Actuator (SEA) is an alternative actuation configuration that emerged in the 1990s as a solution to robotic control challenges, specifically designed to maintain safe force levels during physical therapy and human-robot interaction. SEAs have since become a standard in force and impedance control applications. In an SEA, an elastic element is positioned in series between the mechanical transmission and the load, allowing the system to indirectly measure the applied force based on spring deformation, effectively transforming a complex force-control problem into a more manageable position-control problem. To further optimize SEA performance against disturbances caused by human biomechanical torques, advanced strategies such as optimal PID and feedforward controllers with disturbance observers have been implemented. The objective of this work is to design a mechanism specifically tailored for integrating an SEA into a polycentric knee prosthesis.

II. MATERIALS AND METHODS

A. Prosthesis Design

The experimental setup utilized a Wonderful 3F24P polycentric knee joint, which features a four-bar mechanism and a pneumatic damping system. The primary design goal was to replace the original passive system—composed of a spring and pneumatic valves—used to assist the gait cycle.

a b

Figure 1. (a) Complete assembly of the polycentric knee with the series elastic actuator. (b) Polycentric prosthetic knee.

The knee joint was modified by introducing a transmission mechanism driven by a NEMA stepper motor, which is linked to a lead screw via an elastic coupling. An extension is attached to the piston of the pneumatic damping system to transmit motion and force from the series spring assembly. This assembly is driven by a nut (8mm/rev pitch) connected to the lead screw. To optimize rapid prototyping costs during the testing phase, several custom components were manufactured using 3D printing. This compact design ensures full functionality and optimal space utilization within the knee, making it highly suitable for future developments of fully integrated lower limb prostheses.

The custom elastic device was constructed using two parallel springs with a combined elastic constant of 113 N/mm. The displacement of the internal sliding piston is recorded by a 20 kΩ sliding potentiometer. All these subcomponents are housed within a custom capsule attached to the sliding link of the polycentric knee prosthesis.

B. Specifications, Kinematics and Dynamics

For dynamic modeling, normative gait cycle torque data provided by Kirtley was applied to the kinematic model to determine the necessary force exerted by the motion system. Using a detailed CAD model, the structural efforts on the knee joint were simulated to calculate the resultant forces acting on the sliding link joint. These extracted values determined the required force along the displacement vector of the prosthetic link throughout a standard gait cycle. By correlating these force values with the displacement of the spring system, the varying elastic constants across different positions were calculated.

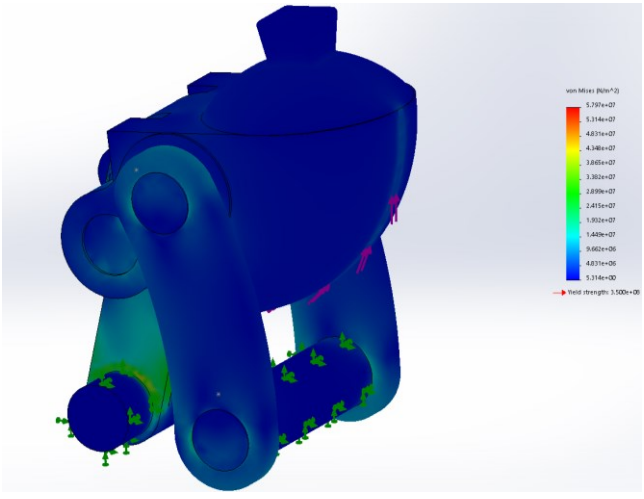

Figure 4. Forces on the prosthetic knee sliding link using FEM simulation.

The forces derived from the FEM simulation were plotted against Kirtley's normative torque data for corresponding knee joint angles. This comparison between the simulated sliding system forces (required for flexion and extension) and experimental torque values allowed for the precise determination of the electrical motor's necessary torque output.

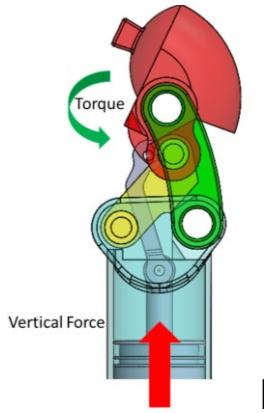

Figure 5. Vertical Force due an applied Torque schematic for static simulation.

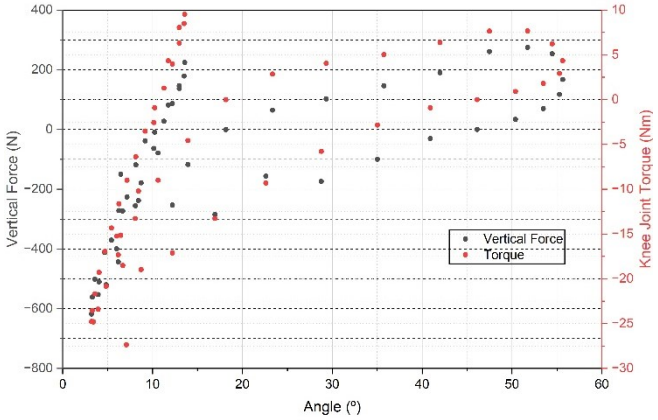
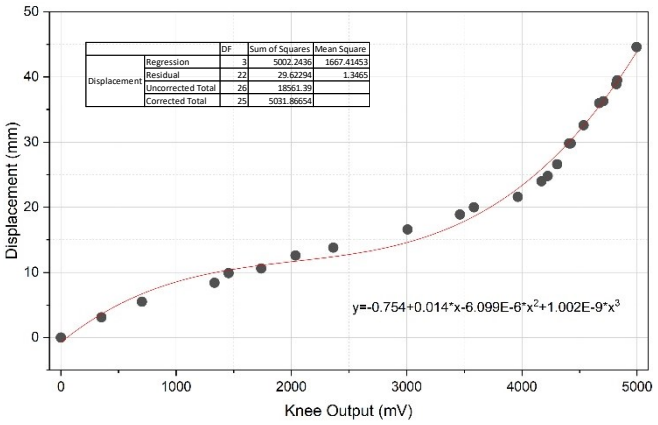
The simulation allowed determine the Vertical Force values required to produce the torque value for the corresponding angle in [6] based in the geometry of the 3F24P prosthesis and executing a static simulation with the corresponding constraints.





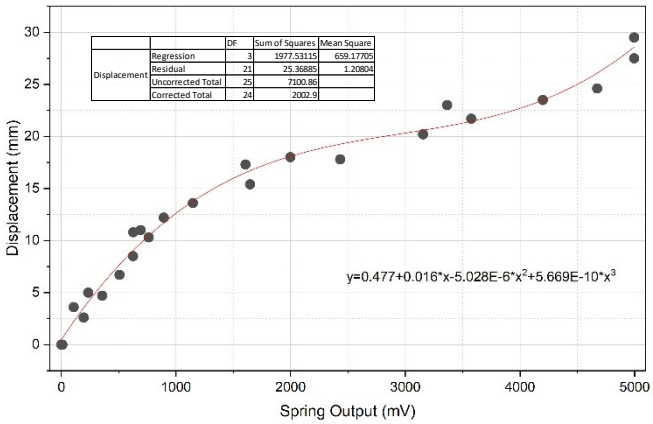


Figure 6. Vertical Force (black dots) and Torque on the Knee Joint (red dots) vs angular position of the knee joint.

To evaluate the knee joint's kinematic response, a sliding potentiometer was attached to the external case of the elastic system. A flexion-extension cycle was executed to map the relationship between the potentiometer's output and the actual knee angle relative to gravity, which was independently verified using an MPU9250/6500 IMU sensor communicating with an Arduino NANO (4.88 mV/Step) for data acquisition and command signaling.

	Uncorrected Total	25	7100.86	
	Corrected Total	24	2002.9	

Figure 8. Nonlinear fit for the spring potentiometer.

Because the components exhibited non-linear electrical responses, a polynomial curve fit was applied to translate the analog output values (in mV) into precise physical displacements. The R-squared value for the knee output fit was 0.994, while the spring output fit yielded an R-squared of 0.987. This non-linear behavior suggests that future iterations may benefit from using alternative position sensors. To specifically isolate and test the SEA output, the knee joint was mechanically blocked with a rigid bar. This constraint allowed the elastic component's deformation to be measured directly via the sliding potentiometer attached to the piston, while control pulses were sent to the stepper drive (configured at 800 steps/rev). The resulting spring deformation—caused by the piston's displacement driven by the nut and lead screw—was captured via the Arduino NANO, with analog voltage signals converted into discrete digital values for analysis.

III. PRELIMINARY RESULTS

During the dynamic flexion-extension cycle test, the output values from the knee joint sliding potentiometer were recorded by the microcontroller.

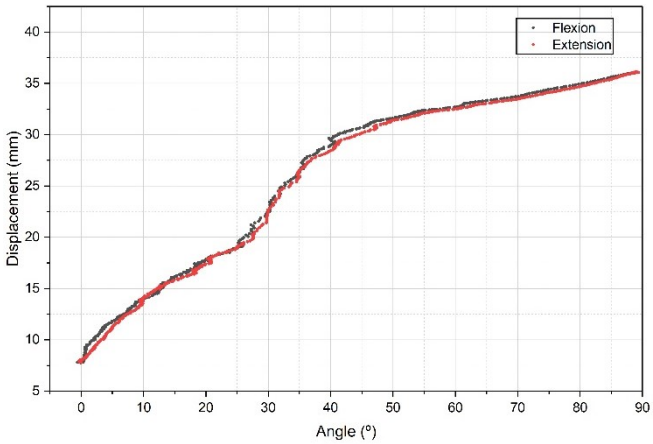

Figure 9. Potentiometer output during the flexion (black dots) and extension (red dots) cycle.

A distinct difference in the displacement trajectory was observed between the flexion and extension phases, strongly indicating the presence of mechanical backlash or other non-ideal mechanical behaviors within the physical assembly.

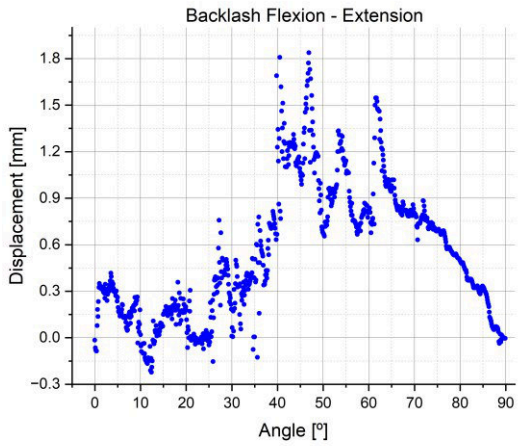

Figure 10. Backlash distribution for a cycle Flexion – Extension.

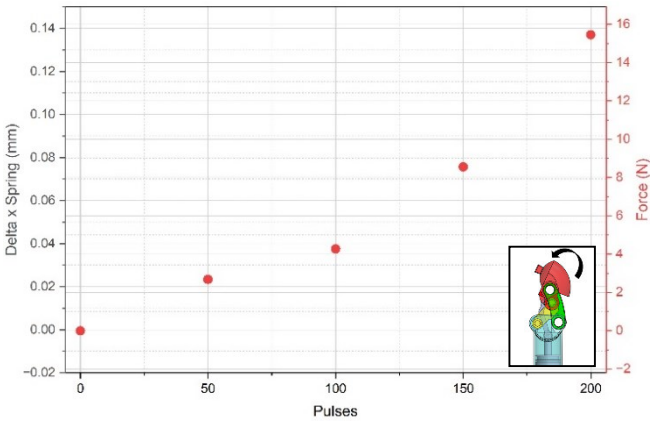

Figure 11. Output of the SEA´s spring test during the flexion phase.

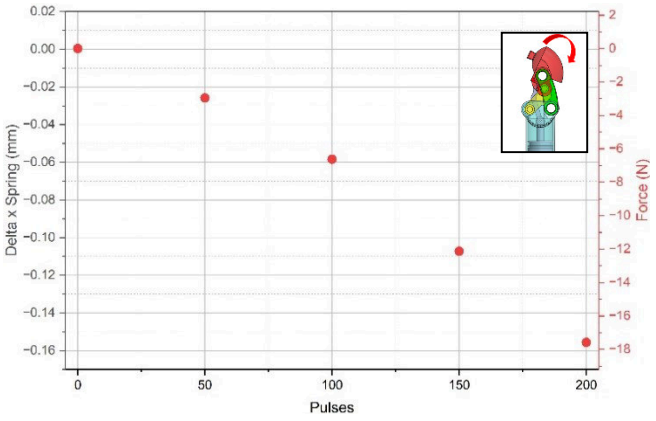

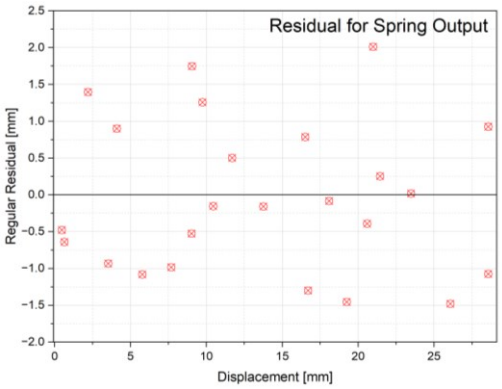

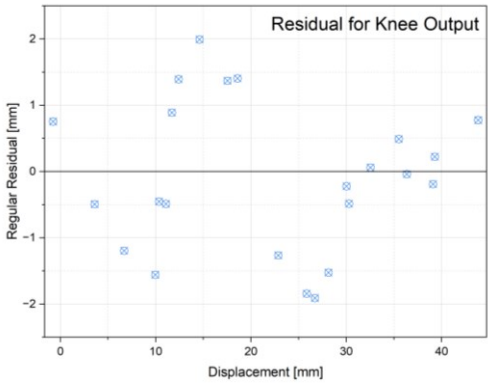

Figure 12. Output of the SEA´s spring test during the extension phase.

For the isolated SEA flexion test, the four-bar mechanism was blocked at a fixed angle of 30 degrees. Under these conditions, the registered spring deformation was 0.136 mm. Conversely, during the extension phase test—conducted under identical mechanical constraints with the knee fixed at 30 degrees—the elastic element exhibited a deformation of 0.155 mm in the opposite direction.

Figure 13. (a) Residual values in the nonlinear fit for Spring Output. (b) Residual in the nonlinear fit for Knee Output.

The residual analysis made for the Spring Output (red) nonlinear fit were +2.01 mm and -1.47 mm for maximum values, and the residual values for the Knee Output (blue) nonlinear fit were +1.99 mm and -1.91 mm in the extremes values.

IV. DISCUSSION

The continuous development of robotic prosthetics, particularly those integrating Series Elastic Actuators, represents a dynamic and critical field of research. This work is fundamentally driven by the objective of engineering solutions that not only restore mobility but tangibly improve the user's quality of life. Prior research by Herr and Grabowski on bionic ankle-foot prostheses has convincingly demonstrated how active devices can normalize the walking gait of amputees, underscoring the vital interplay between prosthetic mechanics and human biomechanics.

SEAs, pioneered by Pratt and Williamson, have proven to be exceptionally effective in applications requiring safe force thresholds and precise impedance control. By measuring force indirectly through spring deflection, SEAs successfully convert demanding force-control paradigms into highly manageable position-control algorithms. This foundational principle is critical for the deployment of sophisticated human-robot interaction controllers. Furthermore, comprehensive reviews, such as those by Sun, emphasize that optimizing structure, actuation, and control is essential for the next generation of responsive robotic knees. The integration of foundational biomechanical datasets, such as the CGA Normative Gait Database, remains an indispensable tool for

validating and calibrating dynamic models in these simulations. Combining robust theoretical frameworks with emerging rapid-prototyping technologies like 3D printing accelerates the advancement of customized robotic prosthetics. Moving forward, the integration of high-resolution linear encoders is identified as a critical next step to mitigate current non-linearities, improve measurement accuracy, and enhance the overall system response.

V. Conclusions

This research details significant advancements in the electromechanical design and kinematic evaluation of a robotic knee prosthesis powered by a series elastic actuator. The preliminary tests successfully demonstrate the feasibility and potential of integrating SEAs to enhance lower limb prosthetics. However, the experimental results also highlight the strict necessity of utilizing high-precision components to ensure absolute measurement accuracy and minimize mechanical backlash. Future work will focus on refining the mechanical design by replacing 3D-printed prototypes with machined metallic parts and integrating precise linear encoders. Ultimately, these iterative improvements aim to deliver a fully integrated lower limb prosthesis that seamlessly meets user demands, drives innovation in robotic rehabilitation, and profoundly enhances the quality of life for individuals with lower limb disabilities. Furthermore, integrating the SEA into the polycentric knee mechanism will provide proportional feedback signals to accurately monitor the joint state of the artificial limb. In this regard, future developments aim to implement user-interaction strategies that enhance the amputee's proprioceptive perception and functional embodiment of the prosthesis.

***Abstract*—Sensory impairments after stroke can negatively affect upper limb function and daily life activities. However, sensory-oriented rehabilitation strategies are still less explored than interventions focused on motor training. This study presents a robotic handlebar integrated with a serious game capable of delivering multimodal sensory stimuli during gameplay, including visual effects, vibrotactile stimulation, and resistive haptic torque. Six healthy volunteers performed four game conditions: baseline, visual rain, visual rain combined with vibrotactile stimulation, and visual wind combined with resistive torque. Task performance was evaluated using the number of collected coins, while kinematic behavior was assessed through lateral velocity, acceleration, jerk and displacements. The coin collection rate remained higher than 92% accross all conditions, with a small tendency of increase after the first condition, suggesting a practice effect rather than a specific effect of the applied stimuli. On the other hand, kinematic outcomes indicated that the experimental conditions may modulate handlebar control behavior. The visual wind combined with resistive torque produced the clearest increase in movement intensity, suggesting a higher control demand. In contrast, vibrotactile stimulation did not show a significant additional effect beyond visual rain, although it presented a descriptive tendency toward lower trajectory deviation. These preliminary results support the feasibility of the proposed platform for investigating how multimodal sensory stimuli affect user interaction and handlebar control during game-based bimanual rehabilitation tasks.**

***Index Terms*—robotic rehabilitation, sensory feedback stimuli, serious game.**

I. Introduction

Stroke is recognized as the leading cause of adult disability and the second leading cause of death globally [1]–[3], with a global cost exceeding US$891 billion. Moreover, between 1990 and 2019, the global burden of incident strokes and stroke-related deaths increased substantially, by approximately 70% and 43%, respectively. This burden is disproportionately concentrated in low-middle income countries, which account for 86% of stroke-related deaths and 89% of disability-adjusted life years related to stroke [4].

Only a small proportion of individuals affected by stroke recover their ability to resume daily life without appropriate treatment. The extent of motor impairment depends on several factors, including stroke severity and location, and the effectiveness of early medical care [5]. In addition to motor deficits, up to 85% of stroke survivors experience upper limb sensory impairments, including reduced tactile, temperature, pain, and proprioceptive perception. These sensory deficits can further compromise motor function and negatively affect functional recovery [6], [7].

In recent decades, substantial efforts have been directed toward supporting the recovery of individuals with sensorimotor impairments. In this context, serious games have been increasingly applied in different fields with the purpose of improving users' abilities in real world contexts [8]. Their various applications have the ultimate goal of allowing users to achieve a specific objective in an entertaining and engaging manner through the experience of playing the game [9]. In rehabilitation, this approach has proven effective and has provided motivational benefits during therapy sessions, being widely combined with robotic devices to support goal-oriented tasks during limb movements [10], [11].

Rehabilitation technologies, particularly robotic devices, have emerged as promising tools to assist upper-limb therapy [5]. These systems can provide repetitive, intensive, and task-oriented training over prolonged periods, which may contribute to partial or complete functional recovery. Many robotic rehabilitation approaches have primarily focused on specific aspects of motor recovery, including shoulder rehabilitation [12], hand training and assessment to improve dexterity or grip force

[13]–[15], or therapeutic strategies such as Mirror Therapy (MT) and Bilateral Arm Training (BAT) [16], [17]. However, sensory rehabilitation is often insufficiently addressed. Current interventions for recovering upper limb sensory impairments are mainly based on electrical stimulation techniques, including noninvasive wearable devices with embedded electrodes [13], [18] and Functional Electrical Stimulation (FES) systems combined with task-specific training [19], [20].

This gap is clinically relevant, since upper limb sensory impairments have a substantial negative impact on activities of daily living in stroke survivors. Nevertheless, specific and effective interventions for upper limb sensory recovery remain limited, and this aspect of rehabilitation is still frequently overlooked in clinical practice [21]–[23].

Therefore, we propose a robotic device embedded with a system capable of providing different types of sensory feedback, including visual and haptic stimuli, integrated into a more immersive serious game. The haptic feedback can be delivered through force fields, which may be assistive or resistive, as well as through vibrotactile stimulation. These haptic stimuli can be applied either independently or in combination with visual feedback on the game screen, allowing the investigation of how different sensory conditions affect user interaction, movement control, and task performance. To evaluate this approach, we conducted an initial test with six healthy adult volunteers using a bimanual robotic handlebar [24] to control a coin-collection game, with multimodal stimuli directly synchronized with game events.

II. Materials and Methods

A. The Robotic Handlebar

The experimental procedure was conducted using an instrumented robotic handlebar that was originally designed to control an on-screen cursor toward predefined targets. In the present study, the system was expanded to control a computer game displayed on a screen positioned in front of the subject. The device consists of a one-degree-of-freedom system developed for bimanual rehabilitation training with a game-based interface and bidirectional communication with the computer. Its mechanical behavior is based on the dynamics of a bicycle handlebar, modeled as a rigid body rotating around a fixed steering axis. Six load cells are integrated into the rigid link and symmetrically distributed around the device's center, two of them are embedded inside the handles to measure grip forces, while the remaining four are used to estimate interaction torques. The rotational axis is coupled to a direct current (DC) motor equipped with an encoder, allowing continuous monitoring of angular position. System control is performed through an H-bridge and a microcontroller, which also manages the communication interface and data exchange between the handlebar and the game running on the PC. This complete experimental setup can be seen in Fig. 1.

In the current version of the device, not only the handlebar can control movements on the screen, but it can also receive commands from the computer so that the game can apply torques through the motor to provide haptic feedback in the form of either resistance or assistance to the user's movement. The motor uses impedance control to ensure a safe interaction between user and robot [25]. The impedance controller parameters are tuned to create a spring-like haptic effect.

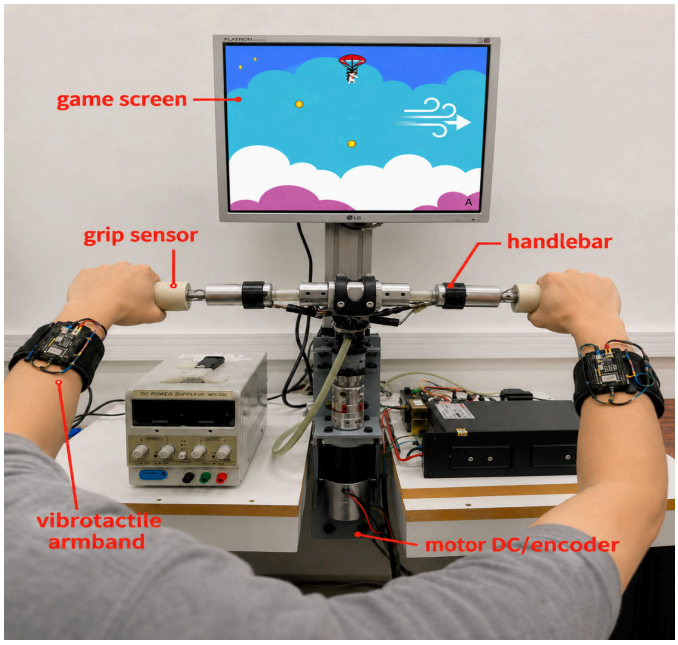

Fig. 1. Experimental setup showing the robotic handlebar, vibrotactile armbands, game screen, and main system components.

In impedance control, the robot is controlled so that the relationship between force and motion is governed by predefined mechanical parameters, such as inertia, damping, and stiffness. In the present system, this relationship can be expressed in terms of the handlebar rotational motion as

$$\tau_h = I_h(\ddot{\theta}_d - \ddot{\theta}_h) + B_h(\dot{\theta}_d - \dot{\theta}_h) + K_h(\theta_d - \theta_h), \quad (1)$$

where I_h, B_h, and K_h are the virtual inertia, damping, and stiffness terms, respectively, and θ_d is the desired angular position. In the present implementation, the desired angular position was kept as a constant during each disturbance, and no virtual inertial term was explicitly rendered [26]. Therefore, considering $\dot{\theta}_d = 0$, $\ddot{\theta}_d = 0$, the motor behavior was modeled as a rotational first order impedance controller (spring-damper behavior), in which the torque applied by the motor is given by

$$\tau_h = K_h(\theta_d - \theta_h) - B_h\dot{\theta}_h \quad (2)$$

The stiffness term K_h defines a virtual torsional spring, indicating that the restoring torque increases proportionally with the angular displacement from the desired position. The derivative term provides damping B_h, opposing motion and improving stability during interaction.

Fig. 2 shows a simulated response of the system when τ_h acts to maintain the handlebar at the setpoint defined by the game dynamics, which are described in the following section.

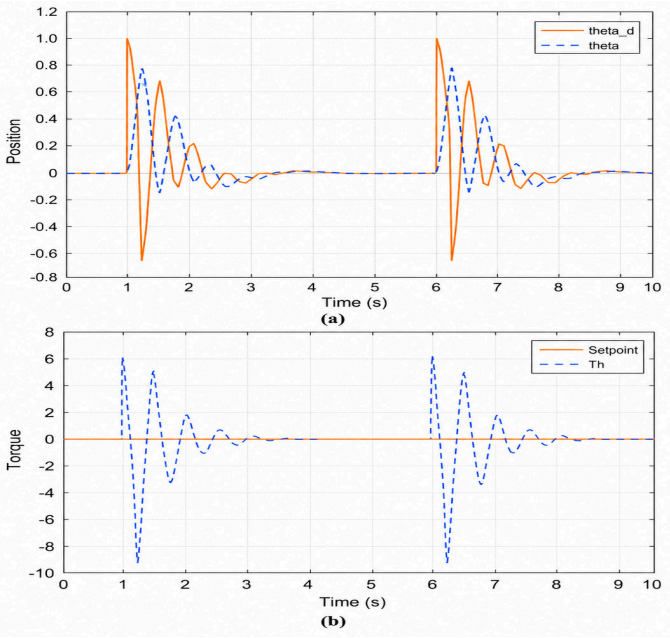

Fig. 2. Simulated response of the robotic handlebar under haptic torque control. The haptic torque τ_h drives the handlebar position toward the setpoint defined by the game dynamics. a) Position response and, b) Torque response.

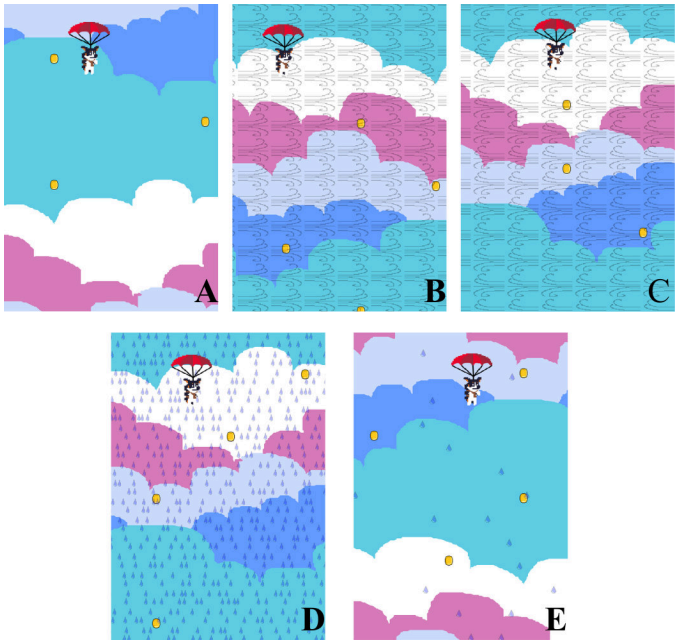

Fig. 3. The game task including the four game conditions. a) Without any visual feedback. b) With wind feedback to the left. c) With wind feedback to the right. d) With a rain intensity of 0.6 and e) With a rain intensity of 0.1.

B. The Wearable Vibrotactile Armband

To deliver the vibrotactile stimuli, two wearable armbands were developed using elastic bands coupled to embedded electronic circuits controlled by ESP32 microcontrollers, with each armband connected to two vibration motors. One armband was placed on each forearm. A third ESP32 board was connected to the computer running the game and acted as the host device, while the two armband circuits operated as feedback receiver boards. This configuration allowed the game to send commands wirelessly to both armbands and trigger the vibrotactile stimuli according to the visual events presented during gameplay.

The choice of ESP32 microcontrollers aimed to reduce the communication latency between the game and the vibrotactile actuation, thereby improving the responsiveness of the stimulation and the real time user experience [27]. Accordingly, the ESP-NOW communication protocol was selected for inter-board communication due to its low-latency performance [28].

Regarding the control system, the receiver boards were programmed to operate using predefined vibration pulses corresponding to an update rate of 5 Hz. This value was empirically defined to ensure user safety and to allow the stimulus to be interrupted in the event of communication loss or game system failure. The pulsed strategy was also adopted to reduce the perception of possible latency fluctuations during gameplay, since the pulse interval was longer than the frame-to-frame variations observed in preliminary tests.

Commands were sent from the computer to the host ESP32 board through serial communication. The host board then transmitted the vibration parameters to the receiver boards embedded in the armbands using a reduced data packet containing the vibration frequency and duty cycle. After receiving these parameters, each receiver board generated the corresponding pulse-width modulation (PWM) signal and triggered the vibration motors. This architecture allowed the game to control the vibrotactile stimulation in real time according to the rain events presented on the screen.

C. The Serious Game

The serious game adopted to guide the participants' movements was based on the platform previously presented in [29]. However, several adaptations were introduced to align the game mechanics with the objectives of the present experimental protocol. The game was configured to operate at 60 frames per second, providing smooth visual feedback during task execution, while experimental variables, including position, force data, and game events, were recorded at approximately 30 Hz.

During gameplay, the participant controls a character that moves downward on the screen while attempting to collect coins distributed along the path (Fig. 3). The horizontal position of the character is controlled through the encoder signal embedded with handlebar's DC motor, and the main task objective is to collect as many coins as possible during each trial. Each repetition of a given condition consisted of a 60-second trial in which 50 coins were available for collection. A set of five coin paths was generated using a randomization algorithm and then assigned across all game conditions. These paths were presented in the same order for each condition, ensuring that participants experienced equivalent trajectory sequences across the experimental phases.

The game presents different conditions based on visual or haptic feedback. These conditions can be implemented individually or together during gameplay. These feedback can be divided into visual stimuli, which appear as wind or rain on the game screen (Fig. 3, and physical stimuli, which are presented as haptic feedback. The haptic feedback can be applied in the form of torque, pushing the user's arms to each side, or in the form of vibrotactile cues. Usually, the haptic torques are applied together with the wind on the screen, in order to create a physical wind effect, while the haptic vibrations are applied together with the rain, simulating the effect caused by rain falling on an umbrella.

1) The Wind-Torque Effect: The wind-torque effect is applied in specific regions while the character descends and collects coins. The visual wind effect is introduced through an animation on the game screen (Fig. 3(b) and (c)), in which an unexpected gust appears and pushes the character laterally. Simultaneously, a corresponding physical torque can be applied by the robotic handlebar. Thus, when the wind appears in the game, it not only displaces the on-screen character but also sends a command to activate the motor, which pushes the user's arms in the same direction. This physical wind effect can act either as an assistive or resistive torque. When the wind direction is aligned with the target coin, the effect is considered assistive, otherwise, it is classified as resistive.

The horizontal position of the character is updated at each frame according to

$$x_{k+1} = x_k + \frac{E_k}{5} + v_w, \tag{3}$$

where x_k is the horizontal screen position at each frame k, E_k is the encoder value, and v_w is the wind-induced displacement in pixels per frame. When the character is inside the wind area $v_w = 5m_w$, being 5 the constant of wind magnitude, when bigger, stronger wind and m_w defines the direction of the wind ($m_w > 0$, push to the right and, $m_w < 0$, push to the left). When the character is outside the wind region $v_w = 0$.

For the haptic stimulus, the encoder position is converted to angular position as

$$\theta_h = \frac{E_k}{1000}\pi. \tag{4}$$

So, to define whether the haptic torque is assistive or resistive, let x_k be the horizontal position of the character on the screen and x_{c+1} the horizontal position of the next coin. The screen-based positional error is defined as

$$e_x = x_{c+1} - x_k, \tag{5}$$

where $e_x > 0$ indicates a required rightward movement and $e_x < 0$ indicates a required leftward movement. The assistive haptic torque is then applied in the same direction to the required movement, following the control law defined by (1), such that

$$\tau_h = \begin{cases} +|\tau_h|, & \text{if } e_x > 0 \\ -|\tau_h|, & \text{if } e_x < 0 \\ 0, & \text{if } e_x = 0 \end{cases}. \tag{6}$$

In the resistive condition, the haptic torque acts in the opposite direction to the required movement:

$$\text{sign}(\tau_h) = -\text{sign}(e_x). \tag{7}$$

In this context, rightward displacements on the game screen correspond to clockwise rotation of the handlebar described by positive τ_h in (6), whereas leftward displacements correspond to counterclockwise rotation and negative τ_h. Since the maximum actuator torque is 2.2 Nm, the resistive torque stimulus was limited to 70% of this value through the PWM command to avoid overloading the DC motor.

2) The Rain-Vibrotactile Effect: The rain stimulus was presented in two regions at different vertical positions along the character's descending trajectory. When the character interacted with a rain region, the corresponding vibrotactile stimulus was triggered. This interaction was quantified using a collision-based evaluation between the avatar and the raindrops, allowing the vibrotactile response to vary according to the avatar displacement during the game loop.

Two parameters defined each rain block: fill and sensitivity. The fill parameter was determined by rain intensity and speed. Rain intensity ranged from 0 to 1 and directly affected droplet distribution, whereas speed defined the number of rain layers generated at each game update. The combination of these parameters allowed different configurations of the same visual stimulus, producing variations in the number of droplets colliding with the avatar (Fig. 3(d) and (e)).

Because droplet collisions depend on both rain speed and intensity, modeling the relationship between raindrop interaction and vibration intensity would require a three-dimensional mapping. However, rain speed was kept constant at the default value of 5, since its manipulation was outside the scope of this study. This reduced the mapping to a two-dimensional problem, allowing a sigmoid curve to be fitted to the maximum number of droplets obtained across different rain intensities (Fig. 4). Thus, for each rain intensity value, the expected maximum number of droplet collisions could be estimated and used to define the threshold for the maximum vibration response.

To create different levels of association between the visual rain effect and the vibrotactile response, the sensitivity parameter was used to define the minimum level of interaction required to reach the maximum vibration intensity. In practice, sensitivity determined the minimum number of droplet collisions needed to trigger the highest vibrotactile response. Therefore, the sensitivity value (S), ranging from 0 to 1, was incorporated into the sigmoid approximation as

$$D_5 = \frac{268.43}{1 + e^{-5.21\cdot(S-0.81)}} - 3.98, \tag{8}$$

where D_5 represents the expected maximum number of droplets for a rain speed equal to 5. Both vibration intensity

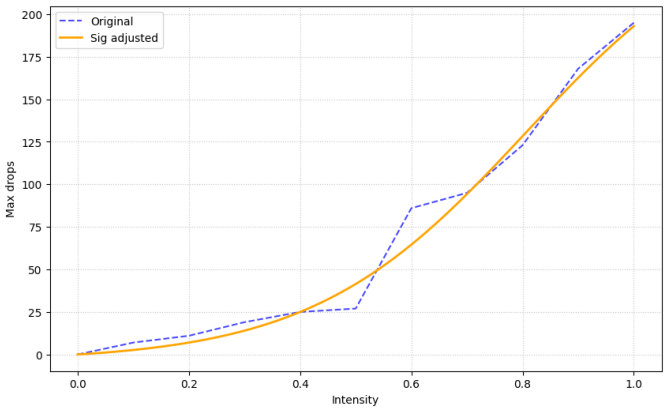

Fig. 4. Sigmoid fit on the curve of maximum droplets per intensity. The curve is rendered two-dimensional by holding the rain speed constant at 5, which establishes a fixed fall velocity of 5 pixels per update for the rain layers, in addition to a predefined minimum spacing between rain lines.

and frequency were determined from the vibration rate, which was calculated as the ratio between the number of droplets colliding with the avatar in the current frame and the previously defined value of D_5.

The vibration intensity was defined by multiplying the vibration rate by 255, corresponding to the maximum duty cycle accepted by the PWM function of the receiver board. For the vibration frequency, the dynamic response of the vibration motor was also considered, since low duty-cycle values combined with high frequencies may not provide sufficient activation to overcome motor inertia and generate a perceivable stimulus. Therefore, the frequency was adjusted according to the vibration rate using the following equation

$$V_f = 1 + (89 \cdot V_r) + (110 \cdot V_r^2), \tag{9}$$

where V_f is the vibration frequency and V_r is the vibration rate. This formulation makes the vibration frequency dependent on the vibration rate while limiting its maximum value to 200 Hz, ensuring an appropriate relationship between stimulus intensity and frequency.

D. Experimental Protocol

All experimental tests were performed at the Biomechatronics Laboratory of the Escola Politécnica, University of São Paulo. The study protocol was approved by the Ethics Committee of the University Hospital of the University of São Paulo (CAAE: 90632625.7.0000.0076), and written informed consent was obtained from all participants prior to experimental session.

The experimental protocol included six healthy adults volunteers (1 woman) with ages ranging from 20 to 41 years (mean: 27.00, SD: $\pm$ 7.13). All participants were naive to the experimental conditions, having no prior participation in any experimental procedure involving the handlebar or any recent musculoskeletal injuries to the upper limbs and trunk, as well as any cognitive-motor impairments.

Participants were equipped with vibrotactile armbands in both arms (Fig. 1) and performed the entire task while standing in front of the robotic handlebar, with their feet kept stationary. They were instructed to hold the handlebar with both hands and perform rotational movements of up to 45° to each side. Before the session, participants received a brief explanation about the game objectives and were informed that they might need to adapt to different game situations. However, they were not informed about the dynamics of the stimuli.

The first exposure to the game occurred during the first trial, as no prior familiarization or adaptation phase was applied. All volunteers performed the same four game conditions, which differed according to the type of stimulus provided. Each condition consisted of five trials and was performed in the same randomized coin path order by all participants. The first condition, considered the baseline, did not provide any visual or haptic sensory stimulus to the user, as shown in Fig. 3(a). The second condition introduced the visual rain stimulus (Fig. 3(d)), while the subsequent condition included vibrotactile stimulation combined with the appearance of rain on the game screen. The fourth and final one, implemented the visual wind on the game screen, combined with resistive haptic torque applied by the robotic handlebar actuator. The experimental protocol lasted approximately 20 minutes in total, consisting of 20 one-minute trials performed continuously, without rest intervals between trials or condition changes.

E. Data Analysis

The Friedman test was used to evaluate overall differences across the four experimental conditions. When a significant effect was observed, post-hoc planned paired Wilcoxon signed-rank tests with Holm correction were performed for specific condition contrasts. These choices are justified by the limited participant cohort and the non-parametric nature observed in the data.

Trajectory accuracy was quantified using the straight-line RMS error between consecutive coins. For each pair of consecutive coins, the ideal trajectory was defined as the straight-line segment connecting both positions. The actual player trajectory between these events was compared with this segment by computing, for each sample, the shortest Euclidean distance to the corresponding line segment. The RMS of these distances was then calculated for each trial and used as the trajectory error metric.

For all tests performed, statistical significance was set at 95% ($p = 0.05$). The analysis were performed using Python 3.13.0 and its specific statistical libraries, such as pandas, scipy.stats, statsmodel, and numpy.

III. Results

The coin collection rate differed across sequences ($\chi^2(3) = 14.60$, $p = 0.0022$). The percentage of available coins collected showed high values for all conditions, from $92.89 \pm 5.22\%$ in the baseline condition (Condition 1) to $97.93 \pm 1.91\%$ during visual rain (Condition 2), $98.88 \pm 1.30\%$ during visual rain combined with vibrotactile stimulation (Condition 3), and

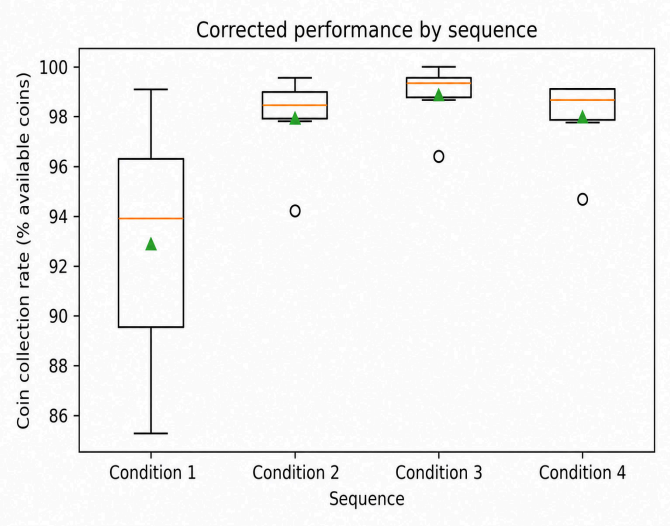

Fig. 5. Collected coin percentage across conditions

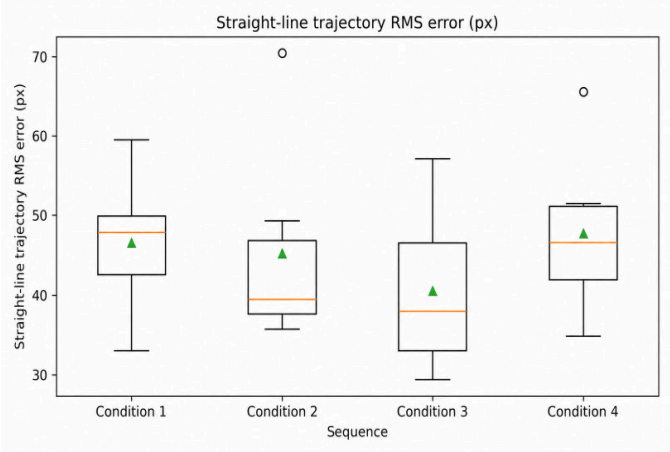

Fig. 6. Straight-line trajectory RMS error by condition.

$98.00 \pm 1.71\%$ during visual wind combined with resistive torque (Condition 4). Planned Wilcoxon comparisons suggested higher performance in the later conditions, Condition 3, ($\Delta = 0.95$, $p = 0.0313$, and Condition 4, ($\Delta = 5.10$, $p = 0.0313$. However, none of these planned comparisons remained significant after Holm correction, $p_{\text{Holm}} > 0.05$.

Significant Friedman effects were observed in device controlling behavior for mean absolute lateral velocity ($\chi^2(3) = 11.40$, $p = 0.0097$), acceleration RMS ($\chi^2(3) = 10.20$, $p = 0.0169$), jerk RMS ($\chi^2(3) = 11.00$, $p = 0.0117$), and displacement recorded by the encoder activity ($\chi^2(3) = 12.20$, $p = 0.0067$).

Relative to baseline, the visual wind combined with resistive torque, Condition 4, increased mean absolute lateral velocity ($\Delta = 29.60$ px/s, $p = 0.0313$), and its derivative terms, acceleration RMS ($\Delta = 227.36$ px/s^2, $p = 0.0313$), jerk RMS ($\Delta = 9457.99$ px/s^3, $p = 0.0313$), and encoder-derived lateral displacement ($\Delta = 0.042$ cm/frame, $p = 0.0313$).

In contrast, the additional effect of vibrotactile stimulation beyond visual rain was small for the full-trial outcomes. Compared with Condition 2, Condition 3 showed only minor changes in mean absolute lateral velocity ($\Delta = 2.22$ px/s, $p = 0.5625$), acceleration RMS ($\Delta = 13.73$ px/s^2, $p = 0.8438$), jerk RMS ($\Delta = 668.05$ px/s^3, $p = 0.8438$), and encoder-derived lateral displacement ($\Delta = -0.001$ cm/frame, $p = 0.8438$).

Since the stimuli were applied only at specific moments during each trial, it was performed an event-based analysis comparing periods in which the stimulus was active with periods in which it was inactive within the same trial. The difference between active and inactive changes in lateral velocity differed significantly across event conditions ($\chi^2(2) = 10.33$, $p = 0.0057$). The increase in lateral velocity during active events was 30.13 ± 11.62 px/s in Condition 2, 35.77 ± 18.11 px/s in Condition 3, and 69.12 ± 6.98 px/s in Condition 4. Paired comparisons showed that Condition 4 presented a higher active versus inactive velocity change than Condition 3 ($\Delta = 33.34$ px/s, $p = 0.0313$) and Condition 2 ($\Delta = 38.99$ px/s, $p = 0.0313$). However, these comparisons did not remain significant after Holm correction ($p_{\text{Holm}} = 0.0938$). Condition 1 was not included in the event-based analysis because it did not contain active visual or haptic events.

The event-related acceleration RMS, jerk RMS, and direction-change deltas did not show significant Friedman effects. No significant effect was found for acceleration RMS ($\chi^2(2) = 4.33$, $p = 0.1146$), jerk RMS ($\chi^2(2) = 4.33$, $p = 0.1146$), or direction changes ($\chi^2(2) = 3.00$, $p = 0.2231$). Nevertheless, the descriptive pattern suggested stronger event-related changes in Condition 4 for acceleration RMS and direction changes. The active and inactive relation in acceleration RMS was 203.15 ± 50.81 px/s^2 in Condition 2, 242.69 ± 66.71 px/s^2 in Condition 3, and 335.80 ± 70.56 px/s^2 in Condition 4. Planned Wilcoxon comparisons suggested higher acceleration changes in Condition 4 compared with Condition 3 ($\Delta = 93.11$ px/s^2, $p = 0.0625$, $p_{\text{Holm}} = 0.1875$) and Condition 2 ($\Delta = 132.65$ px/s^2, $p = 0.0625$, $p_{\text{Holm}} = 0.1875$), although these comparisons were not significant.

Similarly, active versus inactive direction changes were 0.25 ± 1.43 reversals/min in Condition 2, 0.77 ± 1.22 reversals/min in Condition 3, and 3.39 ± 2.26 reversals/min in Condition 4. Planned Wilcoxon comparisons indicated higher direction-change deltas in Condition 4 compared with Condition 3 ($\Delta = 2.62$ reversals/min, $p = 0.1563$, $p_{\text{Holm}} = 0.3125$) and Condition 2 ($\Delta = 3.14$ reversals/min, $p = 0.0938$, $p_{\text{Holm}} = 0.2812$). However, these effects did not remain statistically significant.

The straight-line trajectory RMS error variation is shown in Fig. 6 and did not differ statistically across sequences ($\chi^2(3) = 4.20$, $p = 0.2407$). The RMS error was 46.61 ± 8.96 px in the baseline, Condition 1, 45.25 ± 13.23 px during Condition 2, 40.54 ± 10.72 px in Condition 3, and 47.78 ± 10.62 px during Condition 4. The largest descriptive difference was observed between Condition 4 and Condition 3 ($\Delta = 7.24$ px, $p = 0.0313$, $p_{\text{Holm}} = 0.0938$).

IV. Discussion

The score analysis suggests ceiling effect across all experimental phases, as participants consistently collected over 92% of available coins regardless of condition (Fig. 5). Because small percentage shifts near ceiling level lack practical significance and failed to survive Holm correction, coin collection rates should not be interpreted as evidence of performance enhancement. Instead, the game task served primarily as an engaging tool to ensure active user participation, allowing us to evaluate the technical feasibility of synchronized multimodal feedback and analyze the underlying kinematic patterns during handlebar control.

Since this was a preliminary evaluation of the device and its game-based sensory stimuli, the interpretation of the results is limited by the small number of participants, the fixed order of conditions, and the inclusion of only healthy young adults. Future studies should use larger and counterbalanced samples and include participants with stroke or other motor impairments to better isolate the effects of each stimulus and determine whether the observed kinematic responses are relevant to rehabilitation.

Regarding the kinematic behavior during robotic handlebar control, the results indicate that the experimental conditions modulated movement intensity and device control patterns. The clearest effect was observed in the visual wind combined with resistive torque (Condition 4), which increased lateral velocity, acceleration, jerk, and encoder-derived displacement compared with the baseline condition. These findings suggest that resistive torque combined with the wind on the game screen imposed a higher control demand on the user, leading to more intense and variable handlebar movements during gameplay. This interpretation was also supported by the event-based analysis. When the stimulus events were analyzed within each trial, Condition 4 produced the largest increase in lateral movement velocity during active periods.

In contrast, vibrotactile stimulation did not show a significant additional effect when compared with the visual rain condition alone. This suggests that the visual stimulus may have been more relevant to task behavior, or that the effect of vibration was partially masked by the simultaneous visual rain stimulus. Therefore, future experiments should also include an isolated vibrotactile condition to better identify the specific contribution of vibrotactile stimulation to user performance and handlebar control.

The trajectory error analysis suggests that the sensory condition may modulate the straight line trajectory control, since the trajectory RMS error did not progressively decrease across trials, contrary to what would be expected if participants showed a clear trajectory-based adaptation effect. Although the differences across conditions were not statistically significant, a descriptive trend was observed in Condition 3, with vibrotactile stimulation, which presented the lowest trajectory deviation. This may indicate that this stimulation helped stabilize the movement trajectory, although this interpretation should be confirmed in future studies with a larger sample size.

Although most planned comparisons did not remain significant after Holm correction, the descriptive trends observed in this small cohort provide important preliminary information. These trends suggest the different effects that might be caused by sensory stimuli, helping to guide the use of the device and the design of future experimental protocols. Overall, the kinematic variations observed across our game conditions highlight the system's capacity to concurrently modulate motor demand and deliver sensory feedback, providing a more comprehensive sensorimotor challenge than standard setups that rely only on motor recovery or sensory stimulation.

While this pilot study demonstrates the feasibility of the multimodal feedback system, the fixed-order condition design followed by all participants limits our ability to draw causal conclusions. Because of this fixed order, the condition-associated differences observed may partially reflect practice effects, fatigue, or general adaptation to the game dynamics, rather than the isolated effects of the sensory stimuli alone. Furthermore, because later conditions added multiple sensory elements simultaneously, specific feedback mechanisms, such as isolating vibration from visual rain or torque from visual wind, cannot be independently evaluated in this work. Future research will employ a design with isolated stimulus conditions to analyze the impacts of each sensory modality.

From a clinical perspective, integrating multimodal sensory feedback into bimanual robotic therapy addresses a relevant gap in post-stroke rehabilitation, where sensory deficits are often under-treated [21]. To validate this system clinically, future studies will evaluate stroke patients across varying degrees of sensory and motor impairment. These upcoming trials will incorporate randomized and counterbalanced protocols with isolated stimulus conditions, adaptive force feedback tailored to individual patient capability, standard clinical outcome measures, such as the Fugl-Meyer Assessment (for both motor and sensory subscales), and kinematics-derived smoothness metrics to quantify therapeutic efficacy and functional recovery.

V. Conclusion

Even as an initial proof of concept, the present results demonstrated the technical feasibility of synchronizing bimanual robotic control of a serious game with multimodal visual, haptic, and vibrotactile feedback. The preliminary results support the feasibility of the proposed system for investigating how different sensory conditions affect task performance and handlebar control. The results also allowed us to identify kinematic patterns that may be influenced by the different types of sensory stimuli, although no causal effect of the different stimuli can be draw directly from the current protocol. Furthermore, the exposure to each stimulus appeared to modify the way participants controlled the handlebar, making the task more demanding or easier to execute depending on the condition. In particular, resistive torque combined with the visual wind effect tended to require more intense movements and greater control adjustments, whereas visual rain combined with

vibrotactile stimulation tended to produce straighter movement trajectories. The limited cohort of healthy volunteers restricts the generalizability of these findings, however future work will focus on expanding the sample size, counterbalancing conditions, and conducting clinical validation trials with post-stroke individuals to assess the therapeutic impact of multimodal sensory feedback on sensorimotor recovery.

***Abstract*— Jumping performance is a critical indicator of motor development and neuromuscular function. Individuals with Down Syndrome (DS) often exhibit motor deficits, such as hypotonia and reduced muscle strength, which impact their ability to perform complex movements like the counter movement jump (CMJ). Although motion capture systems offer quantitative insights, their high cost and complexity often limit their clinical use. The objective of this study is to evaluate the intra-examiner and inter-examiner reliability of a low-cost, 2D video-based method using Kinovea® software to quantify CMJ height in individuals with DS. Thirty-two individuals with DS (mean age 21.71 ± 7.14 years) participated in this study. The protocol involved standardized instructions, a warm-up phase, and the performance of 10 consecutive CMJ cycles. An anatomical marker was placed on the greater trochanter, and movements were recorded and analyzed using Kinovea® (version 2025.2). Reliability was assessed using the intraclass correlation coefficient (ICC), standard error of measurement (SEM), minimum detectable change (MDC), and Bland-Altman plots, evaluating test-retest, intra-examiner, and inter-examiner agreements, Additionally, the Standard Error of Measurement (SEM), and the Minimum Detectable Change (MDC), obtained through, were calculated to verify the precision and sensitivity of the measurements. The analysis revealed high agreement, with mean differences between measurements approaching zero ($\boldsymbol{p > 0.05}$). Furthermore, the method proved robust, being applicable even among participants with varying cognitive levels, as identified by the Mini-Mental State Examination. This 2D video-based assessment protocol demonstrates excellent intra-examiner and inter-examiner reliability. Therefore, low-cost method can be a viable alternative for clinical and research settings to quantify jumping height in individuals with Down Syndrome, providing a methodology for data collection and analysis for this population.**

Keywords — Down Syndrome, Kinematics, Kinovea, Reliability, Vertical Jump.

I. INTRODUCTION

Jumping is one of the fundamental movements performed by humans after they learn to walk and run [1]. The vertical jump is often used as a performance test, as it is influenced by multiple factors, including maximal strength and neuromuscular coordination of the upper and lower body segments [2]. Throughout life, humans undergo progressive changes in motor development, characterized by continuous adaptations in motor behavior across the entire life cycle [3].

Among the stages of this process, the development fundamental motor skills is particularly significant as it plays a decisive role in because they bring about decisive changes in an individual's subsequent motor development. In early childhood, typically developing children motor skills. Children go through stages in which they initially attempt to perform basic movement patterns at around 3 years of age, acquire higher coordination and control between 4 and 5 years of age, and achieve efficiency by execution and movement coordination between the ages of 6 and 7 [4]. These skills — such as running, jumping, and catching — allow for extensive exploration of the environment [4]. This development is influenced by genetic, environmental, and learning factors, as well as the degree of motor experience exposure, which results in individual variations in the rate of motor skill acquisition among children [5]. However, achieving a mature level of motor skill proficiency requires appropriate stimulation and instruction [6], Furthermore, a lack of mastery of a locomotor skill acts as a barrier to the subsequent development of more advanced and complex skills [7].

From a genetic perspective, Down Syndrome (DS) is the most common chromosomal condition and is associated with motor development impairments [3]. The phenotype of DS includes manifestations that affect multiple systems, including the musculoskeletal, neurological, and cardiovascular systems [8].

The most frequent impairments include hypotonia, ligamentous laxity, decreased muscle strength, insufficient muscle co-contraction, postural control deficits, short stature, and cognitive delay [9]. In this context, jumping stands out as a versatile, functional, and essential locomotor skill and is considered one of the first motor skills that children are expected to master [10]. The vertical jump can be used to assess the stage of motor development, because it involves the vertical projection of the body into the air through propulsion from one or both feet, followed by a bipedal landing [3].

As such, it provides valuable information on human locomotion control [11]. Jump is a skill commonly present in games, play, and daily activities [12]. Moreover, jump height has been widely measured by professionals in sports performance and rehabilitation as a practical alternative to the

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) – Finance Code 001.

direct assessment of maximal lower-limb strength and power [13].

Although individuals with Down Syndrome exhibit poorer jumping skills than typically developing individuals, this deficit can be observed from childhood onward and persists into adulthood [9]. Various technologies can be used to quantitatively assess jumping performance, including inertial measurement units (IMUs) and three-dimensional motion capture systems [10]. However, the use of these devices presents barriers in clinical practice, mainly due to their medium-to-high cost, complexity of use, and limited usability [10]. In addition, their application often requires specialized knowledge to process and analyze raw data. In recent years, video analysis software has been developed to facilitate the use of low-cost quantitative assessment methods [11].

In this context, Kinovea® (version 2025.2) is a free motion analysis software designed for kinematic studies, with a primary focus is on capturing, observing, annotating, and measuring motion variables [12]. Therefore, the purpose of this study was to evaluate the intra-examiner and inter-examiner reliability of a low-cost method for quantifying counter-movement vertical jump (CMJ) height in individuals with Down Syndrome through the analysis of linear measurements using Kinovea® software.

II. METHOD

This study was approved by the Research Ethics Committee of the Faculty of Health Sciences and Technologies (FCTS) under approval number 6.046.308, on May 8, 2023. All procedures were conducted in accordance with the applicable ethical guidelines for research involving human participants and Resolution CNS 466/12.

For the kinematic analysis of spatiotemporal variables during the counter-movement jump (CMJ), the free motion analysis software Kinovea® (version 2025.2) was used [12]. Widely validated in the literature for clinical motor and biomechanical assessment, this two-dimensional (2D) video analysis tool enables the semi-automated tracking of anatomical landmarks and the measurement of kinematic parameters [12].

As mentioned throughout the text, in tables III, IV, and V present N as the number of evaluated jumps for jump height, and as the number of evaluated participants for maximum and mean height. Tables IV and V also report the Intraclass Correlation Coefficient (ICC), Standard Error of Measurement (SEM), and Minimum Detectable Change (MDC).

To classify cognitive status, the Mini-Mental State Examination (MMSE) instrument was used to screen for cognitive impairment, detect cognitive decline, and monitor the progression of diseases. It assesses eleven domains, such as memory (immediate and recall), temporal and spatial orientation, calculation, naming, repetition, following commands, reading, sentence construction, and drawing [13].

The data collection and analysis methodology was developed by the institutionalized extension project “Group in Physical Therapy for Neurological Disorders” (GEFIN) at the Faculty of Health Sciences and Technologies (FCTS) campus, on the University of Brasília (UnB), in partnership with Center for Innovation and Technological Assessment in Health (NIATS) at the Faculty of Electrical Engineering (FEE) of the Federal University of Uberlândia (UFU). Video recordings were imported into the software, in which spatial calibration and frame-by-frame analysis were performed to extract quantitative data.

A. Participant Selection Criteria

To ensure sample homogeneity and participant of the specific eligibility criteria were applied during the recruitment phase.

1) *Inclusion criteria*

- Individuals with a clinical diagnosis of Down Syndrome (DS);
- Aged between 10 and 36 years;
- Ability to understand and follow simple or adapted instructions.

2) *Exclusion criteria*

- Diagnosed atlantoaxial instability (confirmed by clinical examination or imaging);
- Presence of cardiovascular, respiratory, or metabolic conditions that contraindicate moderate-intensity physical activity (as determined by a medical evaluation);
- Presence of recent musculoskeletal injuries (within the previous 6 months) affecting the lower extremities;
- Use of devices that directly interfere with jump execution (e.g., rigid restraints).
- Low-resolution videos in which it was not possible to follow the protocol.

B. General Produces

The overall experimental workflow and chronological stages of the study are schematically represented in Fig. 1 to provide a clear, visual overview of the systems and procedures. Initially, participants and their legal guardians signed the Informed Consent Form (ICF) (Step 1). Subsequently, baseline anthropometric measurements and the Mini-Mental State Examination (MMSE) were completed to characterize the participants' profiles (Step 2). The experimental setup then began with orthostatic positioning and system calibration (Step 3), followed by the precise placement of reflective anatomical markers (Step 4).

To ensure a proper understanding of the motor task, the examiner performed a physical demonstrated jump (Step 5), after which participants performed three practice trials for familiarization (Step 6). During these trials, technical corrections and verbal feedback were provided during these trials to ensure correct execution (Step 7). Finally, participants performed the experimental protocol, consisting of 10 consecutive countermovement jumps (CMJ) (Step 8).

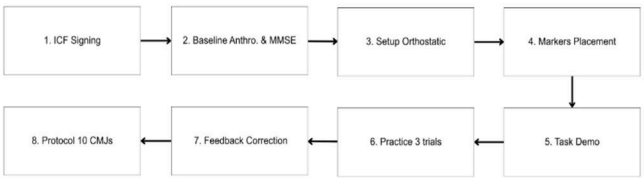

Fig. 1. Flowchart of the experimental procedures and chronological stages of the study, from initial screening to the countermovement jump (CMJ) protocol.

The marker should be positioned over the greater trochanter of the femur, on the side corresponding to the imaging plane, as shown in Fig. 2. To ensure proper placement, with the participant standing, the evaluator should palpate the lateral region of the hip while the participant is standing until the bony prominence of the greater trochanter is identified. Thereafter, the participant should be instructed to perform active internal and external hip rotation movements, following a demonstration by the evaluator, to confirm the correct identification of the structure.

The most prominent point of the greater trochanter identified during the rotational movements should be used as the anatomical reference. Once this point has been pinpointed, the hip should be returned to a neutral position, with no internal or external rotation, and the marker should then be attached to the verified anatomical landmark.

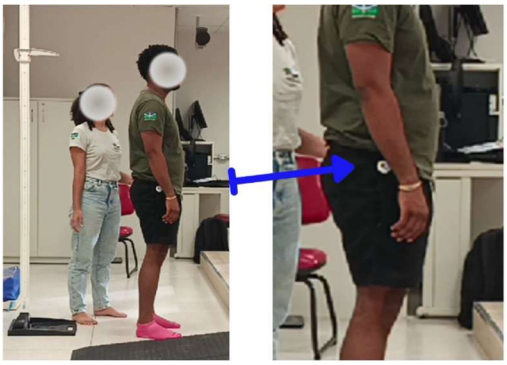

Fig. 2. Marker positioning

C. *Camera Positioning*

The camera or mobile device used for recording must be positioned horizontally, aligned with the participant's sagittal plane. The equipment must be mounted on a stable stand (e.g., a tripod), placed to the side of the participant, at approximately 3 to 5 meters. The camera height should be adjusted to approximately hip level, allowing a full-body view throughout the entire movement. The framing should ensure that the push-off, flight, and landing phases are fully captured, without the participant leaving the field of view at any point during the task.

D. *Participant orientation*

Table I below presents the stages and procedures established to ensure the proper execution of the vertical jump by the participants.

TABLE I. TRAINING AND FAMILIARIZATION PROCEDURES FOR PERFORMING THE COUNTER-MOVEMENT VERTICAL JUMP (CMJ).

Stage	Procedure
Verbal instruction	Participants received standardized instructions regarding the purpose of the test and were instructed to perform a maximum vertical jump using the countermovement jump (CMJ) technique.
Starting position	The participants stood upright, with their feet hip-width apart and their gaze directed straight ahead.
Positioning of the upper limbs	To prevent arm swing from affecting jump performance, participants were instructed to keep their arms extended at their sides or crossed over their chests, with their hands resting on their shoulders, throughout the entire exercise.
Visual demonstration	The evaluator performed a complete demonstration of the movement, including the starting position, the squat phase, and the execution of the jump.
CMJ Execution	Participants were instructed to perform a continuous movement consisting of a rapid flexion of the lower limbs followed immediately by a maximum vertical jump.
Security	Throughout the procedure, the evaluators remained close to the participants to provide support and ensure their safety while they performed the task.
Habituation	Before the official data collection, participants underwent practice sessions to ensure they understood the instructions and could perform the movement correctly.
Feedback	When necessary, guidance was provided regarding the starting position, the positioning of the upper limbs, and the continuous execution of the movement.
Start of collection	The official data collection began only after the participant demonstrated an understanding of the task and the ability to perform the movement correctly.

Measures

Video analysis and the determination of peak height during the countermovement jump (CMJ) were performed by a previously trained evaluator. To assess intra-examiner reliability, the same videos were analyzed twice by the same evaluator, with a 21-day interval between assessments. The same time points were used in both analyses to ensure consistency between measurements. Here, is reported that the sample size (N) was reduced from 42 to 32 analyzed videos in accordance with the exclusion criteria, especially because of the low-resolution videos in which it was not possible to follow the protocol.

Based on the variables presented in Table II, peak height, maximum jump height, and mean jump height were calculated as derived measures. The position of the greater trochanter over time was tracked using the anatomical marker placed directly over it.

TABLE II. Variables Analyzed

Variable	Description
Jump height (cm)	Vertical displacement of the trochanter, calculated as the difference between the maximum height and the initial position.
Maximum height of the greater trochanter (cm)	The highest vertical position reached by the trochanter during the jump.
Average jump height (cm)	The average of the heights recorded for the jumps performed.

III. Analysis Methodology

1) Calibration based on the Individual's height

To calibrate the software, the height (in centimeters) of the person being assessed is used. Following these procedures, as shown in Figure 3, the flowchart illustrates the process.

- Application of the Line Function: The program's line tool (step 3) should be positioned vertically, extending from the base of the feet to the top of the head (step 4);
- Postural Condition: The subject must be filmed in an orthostatic position (standing upright) for 3 seconds immediately before the start of the jump;
- Coordinate Reference: Ensure that the calibration line is perfectly aligned with the system's vertical axis (Y-axis).

2) Setting Up Tracking in Kinovea ("Track Path")

- This step involves using the "Track Path" tool on the marker to configure the software's tracking parameters (step 5);
- Anatomical Point Selection: The tool must be positioned exactly over the anatomical point of interest (marker);
- Tracking Window Dyna Tracking Window Dynamics: When tracking begins, Kinovea will display two bounding boxes around the point: The inner rectangle (Object Window) defines the texture and exact area of the marker that the software should recognize, and the outer rectangle (search window) defines the scan area where the software will search for the marker in the next frame. Adjusting its size is crucial for fast movements such as jumping, to prevent loss of tracking (step 6);

3) Frame-by-frame tracking of the anatomical landmark and corrections as needed until the end of the jump and return to the upright position (step 7);

4) Determination of the initial position and the maximum height of the trochanter in linear kinematics tools (step 8) to vertical positions for identifying peaks and basal values (step 9).

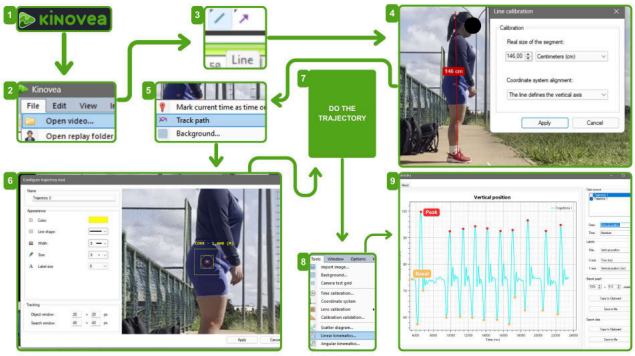

Fig. 3. Workflow for calibration, trajectory tracking, and kinematic analysis of the countermovement jump using Kinovea software.

IV. Statistical Analysis

First, a descriptive analysis of the participants was performed based on clinical and anthropometric variables. Furthermore, the distribution of the variables derived from Kinovea ® during the countermovement jump (CMJ) trials was assessed, and all variables were found to be normally distributed. Subsequently, test-retest and inter-rater reliability analyses were performed.

A descriptive analysis of the participants was initially performed based on clinical and anthropometric variables. Following this, the distribution of the variables derived from Kinovea® during countermovement jump (CMJ) tests was evaluated, and all variables were found to be normally distributed, as shown in Table III. Then, the inter-examiner and intra-examiner reliability for the variables height, maximum height, and average height of the 32 participants was assessed using the intraclass correlation coefficient (ICC) and Bland-Altman plots [14]. Additionally, the Standard Error of Measurement (SEM), and the Minimum Detectable Change (MDC), obtained through, were calculated to verify the precision and sensitivity of the measurements.

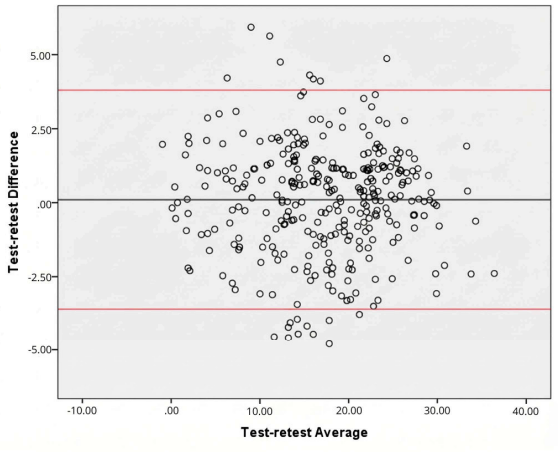
All statistical analyses adopted a significance level of $\alpha = 0.05$ and were performed using SPSS Statistics software (Statistical Package for the Social Sciences).

V. Results

This paper analyzed 314 jumps performed by 32 participants with Down syndrome. The participants had a mean age of 21.71 (±7.14) years, mean body mass of 54.88 (±13.04) kg, and a mean height of 148.52 (±10.93) cm. Regarding cognitive performance, the mean MMSE score of 28.72 (±7.16). Notably, five participants (15,63%) scored below 20 points, indicating cognitive impairment according to the cutoff adopted in this study. The Confidence Intervals (CI) and descriptive analysis of the height of the 10 consecutive jumps, including the mean and maximum height, is shown in Table III.

TABLE III. Descriptive analysis of countermovement jump heights obtained during the evaluation of 32 participants with Down syndrome

Variable	N	Mean	Standard deviation	CI (95%) Lower - Upper
Height (cm)	314	17.68	7.7	2.7 - 32.67
Maximum height (cm)	32	21.20	8.4	4.7 - 37.70
Mean height (cm)	32	17.66	7.6	2.7 - 32.60



The reliability analysis demonstrated excellent consistency and reproducibility for all jump variables evaluated (height, maximum height, and mean height).

In the intra-examiner evaluation, as shown in Table IV, high ICC values were observed for jump height (0.977; SEM = 1.16; MDC = 3.22), maximum jump height (0.976; SEM = 1.30; MDC = 3.62), and mean jump height (0.982; SEM = 1.02; MDC = 2.83), with Bland-Altman plots confirming good agreement.

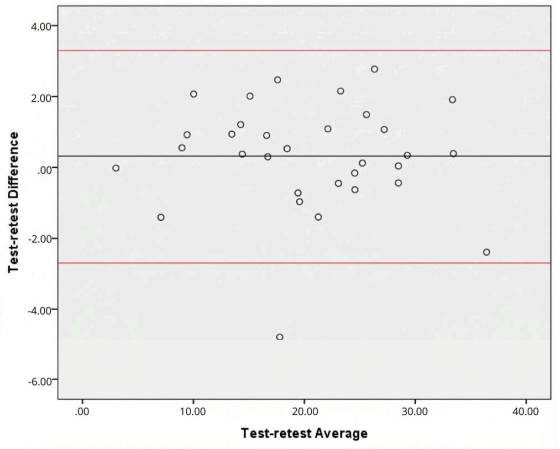


TABLE IV. Descriptive analysis of countermovement jump heights obtained during the evaluation of 32 participants with Down syndrome

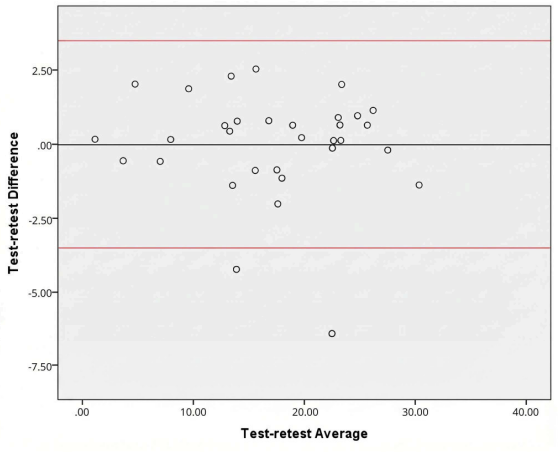
Variable	N	ICC	SEM	MDC



Height (cm)	314	0.977	1.16	3.22
Maximum height (cm)	32	0.976	1.30	3.62
Mean height (cm)	32	0.982	1.02	2.83

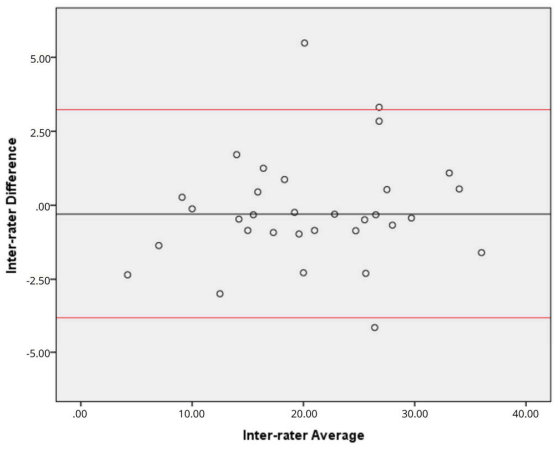
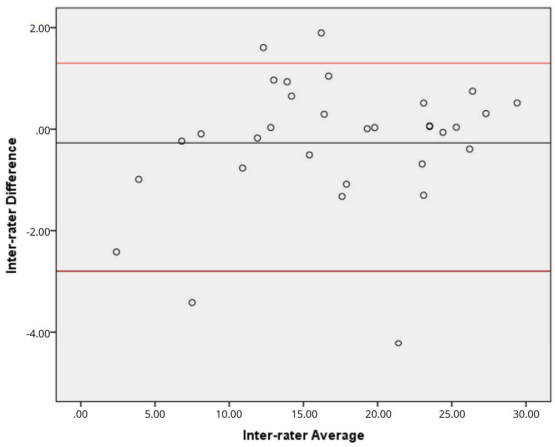
Fig. 4. Bland-Altman scatter plots regarding the intra-examiner reliability analysis of countermovement jump variables in participants with Down syndrome. Legend: (A) Graph regarding the dispersion of the height of the 314 jumps performed; (B) Graph regarding the maximum height of the jumps of the 32 participants; and (C) Graph regarding the mean height of the jumps of the 32 participants. The center lines indicate the mean difference, and the horizontal lines represent the 95% limits of agreement.



Likewise, the inter-examiner analysis, as shown in Table V, revealed high agreement between evaluators, with ICC coefficients of 0.971 for jump height (SEM = 1.30; MDC = 3.61), 0.976 for maximum jump height (SEM = 1.30; MDC = 3.61), and 0.992 for mean jump height (SEM = 0.68; MDC = 1.89), with the Bland-Altman plots in Figure 5 confirming agreement with mean differences close to zero. These findings indicate that the proposed method provides reliable and reproducible measurements for jump analysis in individuals with Down syndrome.

TABLE V. Inter-examiner reliability analysis of countermovement jump height data obtained during the evaluation of 32 participants with Down syndrome



Variable	N	ICC	SEM	MDC
Height (cm)	314	0.971	1.3	3.61
Maximum height (cm)	32	0.976	1.3	3.61
Mean height (cm)	32	0.992	0.68	1.89

VI. Discussion

The present study included individuals with DS with varying cognitive profiles. Despite the cognitive alterations observed in the sample, all participants successfully performed the jumps following prior instruction and training. These findings support the clinical applicability of the protocols. In addition to the countermovement jump, the participants' cognitive impairment was assessed using MMSE. In this case, of the total number of participants (n = 32), approximately (15.63% (n = 5) had cognitive impairment, based on the cutoff score from the article "Suggestions for the Use of the Mini-Mental State Examination in Brazil" [13].

The findings indicate that quantitative assessment of the CMJ with adequate inter-examiner and intra-examiner agreement is feasible even in individuals with cognitive impairment, provided that appropriate adaptations and visual and auditory cues are implemented, as described in Table I. It should be emphasized that the differences present in this population are significant and must be taken into account, given that children with Down Syndrome exhibit unique sensory characteristics when compared to their peers of the same mental age, whether those peers have autism spectrum disorder, typical development (TD), or a developmental disorder [15].

This characteristic may pose additional challenges in clinical and laboratory settings, particularly when using robust and high-cost motion capture systems. Such systems often require multiple reflective markers attached to the skin, specialized knowledge for system operation and data analysis, and are generally restricted to laboratory environments [10].

Another important aspect regarding clinical applicability is the type of jump analyzed. In the present study, the countermovement jump was selected. When performing this jump, not only is the flight phase considered, but there is also a preparation phase, during which the individual is instructed to perform a squat, followed immediately by the flight phase and takeoff [16]. The choice of the CMJ for clinical assessment should also be considered in relation to the musculoskeletal characteristics of this jump to the osteomyoarticular changes observed in people with Down Syndrome, including muscle hypotonia and joint hypermobility. Thus, the assessment of this type of jump goes beyond the analysis of an isolated movement. Rather, it requires prior mastery of the squat and motor coordination.

In this regard, Yorozu et al. [17] expand the classic concept of fundamental motor skills, which includes squatting and jumping — to foundational skills, which are goal-oriented movement patterns that directly and indirectly impact an individual's ability to be physically active. The development of these skills may enhance participation in different forms of physical activity, sports, and leisure throughout life, thereby contributing to health and social participation [9].

The experimental methodology adopted in this study focused on jump height, particularly maximum jump height, as these kinematic variables are commonly used to characterize CMJ performance [18], [19], [20], [21]. Given the demonstrated intra-examiner and inter-examiner agreement for maximum jump height, the measurements obtained using Kinovea, together with the anthropometric data obtained, allow for the calculation of other variables such as vertical velocity, acceleration, and time, making it mathematically possible to derive essential parameters using widely recognized equations [22]. Among these parameter, power and maximum concentric power stand out, as they provide a robust overview of the lower-limb explosive force-generation capacity in this population [22].

Overall, the findings of the present study indicate that a video-based assessment protocol using Kinovea® for CMJ analysis can provide objective and reliable measurements of jump height. These results are consistent with previous findings regarding the use of Kinovea software for motion analysis [22].

The main characteristics of the population with Down Syndrome who participated in the study include manifestations affecting the musculoskeletal, neurological, and cardiovascular systems [8], as previously reported. These manifestations include hypotonia, ligamentous laxity, decreased muscle strength, insufficient co-contraction of the [9] muscles, deficits in postural control, short stature, and cognitive impairment [23], all of which directly and indirectly affect jumping performance.

Therefore, the data from this study demonstrated that a video-based assessment protocol for countermovement jump analysis can provide objective and reliable measures of jump height. These results are consistent with previous findings regarding the use of Kinovea software for motion analysis. [22], [24], [25].

VII. Limitations

The main challenges of the study are related to video analysis. In scenarios with low video resolution and no fixed markers, tracking and tracing the movement trajectory of the anatomical point — although semi-automatic — requires a more thorough frame-by-frame correction process. Inter-individual variability was also observed in jumping performance, with differences in the number of subjects who

were able to complete the required 10 repetitions. While the proposed method showed high reliability, a limitation of this study was the absence of direct validation against the gold standard (i.e., force platform).

Consequently, there is a significant increase in the operational time required for data analysis and processing; given that there are 10 jump cycles, the analysis time ranges from 5 to 7 minutes under ideal conditions to up 1 hour until for rigorous analysis.

During the analysis, it was noted that the trochanter's location corresponds to roughly half of the subject's height, which helps locate the structure if the marker is missing. Moreover, despite careful evaluation, the final graph for a few videos was generated inverted, suggesting a possible program bug that requires correction. Therefore, if the graph is inverted, all lines must be cleared and the calibration repeated to ensure it is plotted correctly.

For future studies, the use of well-positioned anatomical markers with high visual contrast is strongly recommended. This approach may reduce the need for manual frame-by-frame corrections, optimize processing time, and improve the accuracy of the extracted variables.

VIII. Conclusion

Based on the findings of the present study, the assessment of countermovement jump height using two-dimensional (2D) video recording and Kinovea® demonstrated good intra- and inter-examiner reliability. Therefore, this low-cost assessment protocol may represent a feasible and accessible approach for evaluating countermovement jump performance in individuals with Down syndrome in both clinical and research settings.

***Abstract*— This study presents and applies spectral analysis of vertical ground reaction force (GRF_z) during impulse and landing phase from long, short and no countermovement (CM) with lower limb muscle stretch-shortening cycle (SSC). Spectral analysis of GRF_z presents as a complementary tool to the time domain, with the ability to detect hidden predictors of force production at different CM and lower limb muscle SSC using the subject body weight and FFT digital signal processing thus expanding previous studies on standing, walking and running spectral analysis while providing key data to MVJ optimization.**

Keywords—ground reaction force, FFT, maximum vertical jump, lower limb, muscle SSC

I. Introduction

Muscle stretch-shortening cycle (SSC) is a mechanism of muscle action, with muscle stretching immediately preceding muscle contraction, for efficient submaximal and powerful maximal activities [1]. Despite muscle SSC is determinant at lower limb on gait and running, its higher expression and assessment is performed at maximum vertical jump (MVJ) on countermovement jump (CMJ) with long countermovement (CM) and SSC, drop jump (DJ) with short CM and SSC, and squat jump (SJ) with no CM and SSC [2]. According to well defined objective of MVJ whole-body (WB) center of mass (COM) height (ht) during flight phase and standardized nature of different MVJ protocol, higher attention has been focused on the relation of the impulse from vertical ground reaction force (GRF_z) with MVJ WB ht to assess different long, short and no CM contribution to MVJ performance. Thus, the area below the force-time profile of GRF_z during the impulse phase has been assessed as a determinant of each MVJ and CM performance [3]. Nevertheless, GRF_z time profiles present, during impulse phases at each MVJ type, different shapes determining the area below the force-time profile and thus influencing different MVJ type performance. Time domain analysis has been performed based on impulse, power and work predictors with differences between predicted and achieved performances and an open issue on explainable differences on each MVJ type [4]. Thus, based on the complementarity of the frequency analysis of the human body vibration [5] we applied fast Fourier transformations (FFT) to GRF_z time profiles for spectral analysis and GRF_z shape comparison on impulse and landing phases searching for hints and relationships with different MVJ and CM performances, by analogy to gait and running frequency analysis [6 - 8].

II. Materials and Methods

A. Trial tests

A total of fifty-four trials were performed by a sample of six sports students with no injury or specific training, ages 21.5 ± 1.4 years old, 76.7 ± 9.3 kg mass and 1.79 ± 0.06 m height executing three repetitions of CMJ, DJ and SJ maximum vertical jumps (MVJ). The study was approved CAE200903 by the ISMAI scientific committee 01/03/2009, the subjects signed written informed consent agreement, and the ethical standards were followed on human experimentation according to the Helsinki Declaration of 1975, as revised in 2000 and 2008. After warm-up, subjects were instructed on MVJ protocol, with CMJ starting from orthostatic standing position initiating downward movement with long countermovement (CM) to 90º knee flexion and reverse to upward movement, DJ depth jump from 40 cm height step downward and short CM reverse to upward movement, with SJ initiating from squat with 90º knee flexion without CM. The subjects were given initial period for protocol familiarization, the tests were performed by each subject starting with CMJ, SJ and DJ repetitions by this order, with 2 to 3 minutes rest between trials and failed trials were rejected.

B. Signal acquisition

During trial tests ground reaction forces (GRF) were acquired with force platform AMTI BP2416-6-4000CE (Advanced Mechanical Technology Inc., USA) at 1000 Hz with coupled amplifier Mini Amp MSA-6. The force platform was previously calibrated, and the amplifier gain was adjusted to prevent saturation of vertical force component during MVJ trials. Time profiles of GRF were segmented based on vertical component (GRF_z) at the start of the impulse phase on CMJ ($GRF_z < Fg$), DJ ($GRF_z > 0$), and SJ ($GRF_z > Fg$), flight phase ($GRF_z = 0$) and landing phase ($GRF_z > 0$) at CMJ, DJ and SJ. For each CMJ, DJ and SJ trial, whole-body (WB) center of mass (COM) MVJ height (ht) was computed from flight time (t).

C. Signal processing

Fast Fourier transform (FFT) was computed for the vertical ground reaction force component (GRF_z) during impulse and landing phases at CMJ, DJ and SJ, using MATLAB R2010b (The MathWorks Inc., Natick, MA, USA), according to (1) and (2). Fourier coefficients for decomposition of GRF_z were obtained using (1) and GRF_z reconstruction below a defined harmonic performed using (2),

$$\begin{aligned} A_0 &= \frac{1}{T}\int_0^T GRF_z(t)\,dt \\ A_k &= \frac{2}{T}\int_0^T GRF_z(t)\cos(k\omega t)\,dt \\ B_k &= \frac{2}{T}\int_0^T GRF_z(t)\sin(k\omega t)\,dt \end{aligned} \quad (1)$$

$$\begin{aligned} C_0 = A_0 \quad C_k = \sqrt{A_k^2 + B_k^2} \quad \varphi_k = \tan^{-1}\left[-\frac{B_k}{A_k}\right] \\ GRF_z(t) = A_0 + \sum_{k=1}^{n_k}[A_k\cos(k\omega t) + B_k\sin(k\omega t)] \\ GRF_z(t) = C_0 + \sum_{k=1}^{n_k} C_k\cos(k\omega t + \varphi_k) \end{aligned} \quad (2)$$

with $\omega = 2\pi/T$ the fundamental frequency, and $k = 1, \ldots, n_k$ the order of the harmonic. Fourier coefficients from GRF_z were analyzed according to the frequency of the harmonic with higher amplitude and 90th percentile of the Fourier series for each MVJ type. The convergence of the Fourier series was assessed according to the normalization of the partial sum expressed by (3)

$$SC(n_k) = \sum_{k=0}^{n_k} C_k / \sum_{k=0}^{n_k^{\max}} C_k \quad (3)$$

D. Statistical analysis

Selected parameters were independently and paired compared on CMJ, DJ and SJ for each subject, using parametric T-Test with Statistical Package for Social Sciences IBM SPSS 29.0.0.0 (IBM, 2022).

III. Results

Flight time t and MVJ height ht presented on independent comparisons, higher values at CMJ than SJ ($p \geq 0.05$), both higher than DJ ($p < 0.05$), Tab. 1.

TABLE I. Mean and Standard Deviation of the Flight Time and Whole-Body Center of Mass Maximum Vertical Jump Height.

Mean ± Std	Flight phase		
	CMJ	DJ	SJ
***t* (s)**	0.550 ± 0.036	0.479 ± 0.024	0.524 ± 0.042
***ht* (s)**	0.372 ± 0.049	0.282 ± 0.027	0.338 ± 0.051

Based on paired comparisons at Tab. 2 and 3, the flight time t and MVJ height ht presented similar higher means at CMJ in relation to SJ and both higher than DJ, all with $p < 0.05$ pointing to the paired comparison higher sensitivity for detection of statistically significant differences.

TABLE II. Mean, Standard Deviation and Significance of the Flight Time Paired Diferences of Maximum Vertical Jumps.

***t* (s)**	Flight time		
	***μ* (s)**	***σ* (s)**	***α***
CMJ - SJ	0.026	0.012	$< 10^{-3}$
CMJ - DJ	0.071	0.034	$< 10^{-3}$
SJ - DJ	0.045	0.041	0.006

TABLE III. Mean, Standard Deviation and Significance of the Flight Height Paired Diferences of Maximum Vertical Jumps.

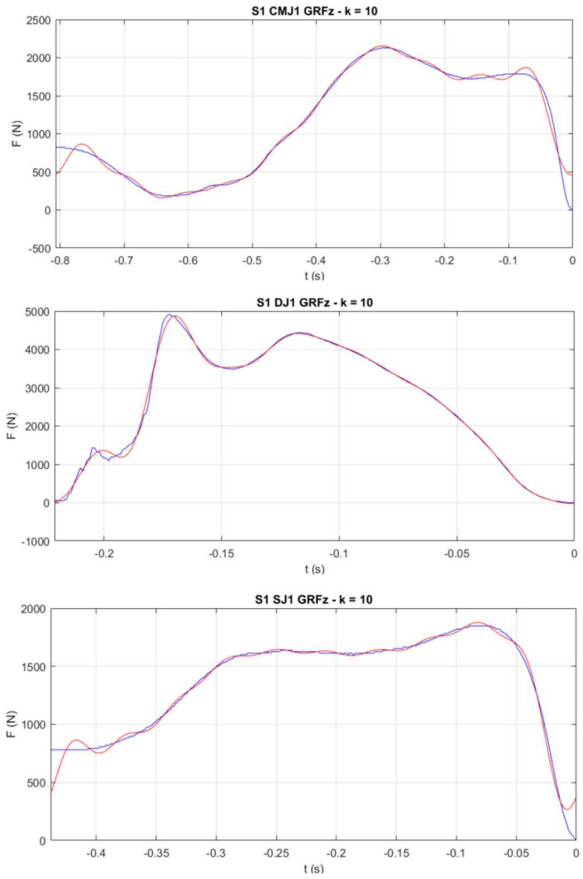

Fig. 1. Example of the vertical ground reaction force (GRF_z) (blue) and GRF_z reconstructed FFT (red) below $k = 10$ during impulse phase of CMJ, DJ, and SJ performed trials.

Fig. 2 presents corresponding time profile of the vertical ground reaction forces GRF_z and reconstructed FFT below $k = 20$ during landing phase at CMJ, DJ, and SJ performed trials.

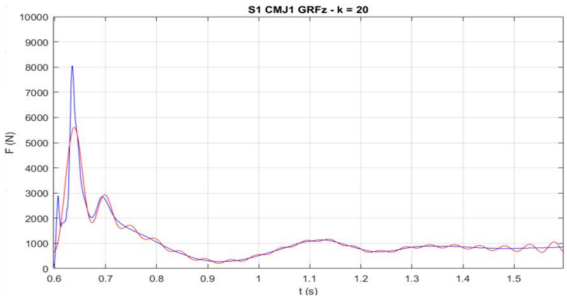

Fig. 2. Example of the vertical ground reaction force (GRF_z) (blue) and GRF_z reconstructed FFT (red) below $k = 20$ during landing phases of CMJ, DJ, and SJ performed trials.

A. *Impulse phase*

The maximum value $Max|FFT|$ resulting from Fourier decomposition (FFT) of GRF_z during impulse phase, Tab. 4, presents higher values in DJ relative to CMJ both higher than SJ ($p < 0.05$) with these maximum values being registered at higher frequencies $f(Max|FFT|)$ for DJ relative to SJ, both higher than CMJ ($p < 0.05$). Therefore, 90th percentile of FFT decomposition of GRF_z $f(p90|FFT|)$ occurs at lower frequencies for DJ relative to SJ and CMJ ($p < 0.05$) without statistically significant differences between SJ and CMJ ($p \geq 0.05$). The cumulative result of FFT decomposition of GRF_z up to the 25th harmonic $S|FFT|f25$ has higher values in DJ relative to CMJ, both higher than SJ ($p < 0.05$). The root mean squared deviation (RMSD) between the reconstructed signal up to the 25th harmonic and the GRF_z signal $RMSDf25$ presents lower values for DJ relative to SJ, both lower than CMJ ($p < 0.05$). The difference between the mean value, corresponding to the first harmonic of FFT decomposition and the original GRF_z signal $RMSDf0$ presents higher values in DJ relative to CMJ, both higher than SJ ($p < 0.05$). Therefore, when normalized to the mean value, the relative deviation between the 25th harmonic reconstruction and the GRF_z signal presents higher values in SJ relative to CMJ, both higher than DJ ($p < 0.05$).

Fig. 3 presents illustrative time profiles of the vertical ground reaction forces GRF_z and reconstructed FFT below the frequency $f(Max|FFT|)$ of the first harmonic $k = 1$ during the impulse phases of CMJ, DJ, and SJ performed trials.

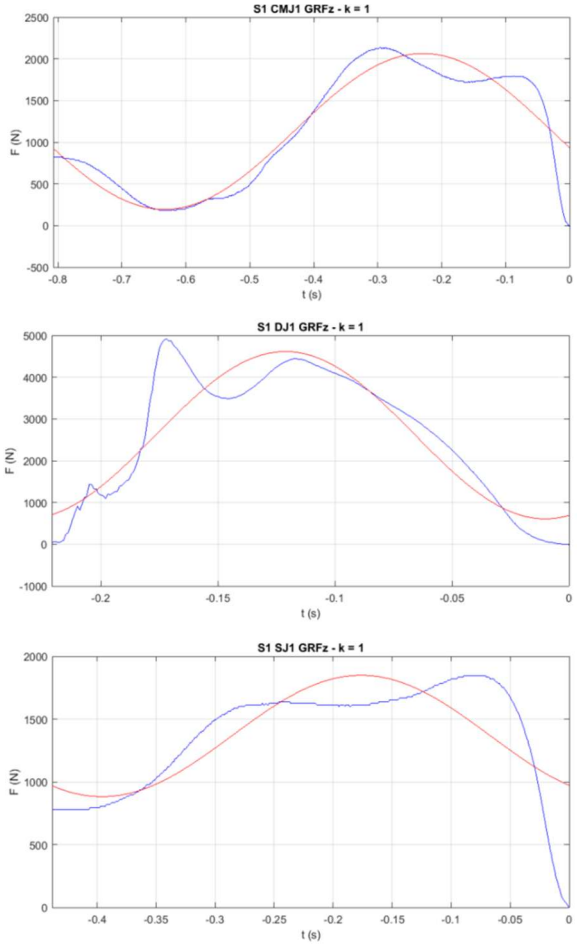

Fig. 3. Example of vertical ground reaction force (GRF_z) (blue) and GRF_z reconstructed FFT (red) below $k = 1$ during impulse phase of CMJ, DJ, and SJ performed trials.

TABLE IV. MEAN AND STANDARD DEVIATION OF THE MAXIMUM FFT, FREQUENCY OF THE MAXIMUM FFT, 90TH PERCENTILE, 25TH HARMONIC, RMSD OF 25TH HARMONIC, MEAN AND % AT CMJ, DJ, SJ IMPULSE PHASE.

Mean ± Std	Impulse phase		
	CMJ	DJ	SJ
$Max\|FFT\|$ (N)	825.22 ± 146.97	1927.88 ± 106.49	533.86 ± 74.06
$f(Max\|FFT\|)$ (Hz)	1.27 ± 0.18	4.93 ± 0.48	2.49 ± 0.40
$f(p90\|FFT\|)$ (Hz)	144.79 ± 13.9	35.05 ± 18.44	148.96 ± 7.74
$S\|FFT\|f25$	0.79 ± 0.02	0.97 ± 0.01	0.84 ± 0.01
$RMSDf25$ (N)	35.68 ± 3.68	23.00 ± 14.66	32.30 ± 3.10
$RMSDf0$ (N)	615.48 ± 103.83	1503.67 ± 109.82	448.94 ± 58.74
$RMSDf25$ %	5.94 ± 1.21	1.49 ± 0.90	7.29 ± 1.06

Paired comparison at Tab. 5 of the $Max|FFT|$ from FFT decomposition of GRF_z during impulse phase, with higher values at DJ than CMJ both higher than SJ, are in agreement with the corresponding metrics on time domain, and higher intensities of GRF_z values during DJ in relation to CMJ and SJ. Additionally, the results from the paired comparison of the harmonics frequency $f(Max|FFT|)$ on Tab. 6 for which the $Max|FFT|$ of GRF_z are registered, with higher values at DJ than SJ both higher than CMJ are in line with the short, long and no CM at DJ, CMJ and SJ, and the corresponding period of the impulse phases relation with the frequency of the fundamental harmonic at each MVJ type.

TABLE V. MEAN, STANDARD DEVIATION AND SIGNIFICANCE OF THE GRFz $Max|FFT|$ PAIRED DIFERENCES AT CMJ, DJ, SJ IMPULSE PHASES.

$Max\|FFT\|$ (N)	Maximum GRFz FFT		
	μ(s)	σ(s)	p
CMJ - SJ	292.1	151.6	$< 10^{-3}$
CMJ - DJ	-1102.7	193.2	$< 10^{-3}$
SJ - DJ	-1394.8	102.9	$< 10^{-3}$

TABLE VI. MEAN, STANDARD DEVIATION AND SIGNIFICANCE OF THE $f(Max|FFT|)$ PAIRED DIFERENCES AT CMJ, DJ, SJ IMPULSE PHASES.

$f(Max\|FFT\|)$ (Hz)	Frequency of maximum GRFz FFT		
	μ(Hz)	σ(Hz)	p
CMJ - SJ	-1.26	0.25	$< 10^{-3}$
CMJ - DJ	-3.66	0.53	$< 10^{-3}$
SJ - DJ	-2.39	0.69	$< 10^{-3}$

The results from the paired comparisons for the 90th percentile of the FFT decomposition GRF_z $f(p90|FFT|)$ on Tab. 7 corresponds to the concentration at lower frequencies for the larger signal component at DJ in relation to CMJ an SJ.

TABLE VII. MEAN, STANDARD DEVIATION AND SIGNIFICANCE OF THE $f(p90|FFT|)$ PAIRED DIFERENCES AT CMJ, DJ, SJ IMPULSE PHASES.

$f(p90\|FFT\|)$ (Hz)	Frequency of 9th percentile GRFz FFT		
	μ(Hz)	σ(Hz)	p
CMJ - SJ	-4.6	14.2	0.179
CMJ - DJ	107.7	27.3	$< 10^{-3}$
SJ - DJ	114.4	21.2	$< 10^{-3}$

Thus, DJ presents for the paired comparisons of the 25th harmonic $S|FFT|f25$ higher values in DJ than CMJ, both higher than SJ, supporting the larger concentration of GRF_z at lower frequencies on short CM than at long CM and no CM. Tab. 8. For this reason, the RMSD between the reconstructed signal up to the 25th harmonic and the GRF_z signal $RMSDf25$ presented for the paired comparison on Tab. 9 lower values on DJ in relation to SJ, and higher values on CMJ.

TABLE VIII. MEAN, STANDARD DEVIATION AND SIGNIFICANCE OF THE $S|FFT|f25$ PAIRED DIFERENCES AT CMJ, DJ, SJ IMPULSE PHASES.

$S\|FFT\|f25$	Accumulated GRFz FFT up to the 25th harmonic		
	μ (Hz)	σ (Hz)	p
CMJ - SJ	-0.048	0.018	$< 10^{-3}$
CMJ - DJ	-0.176	0.029	$< 10^{-3}$
SJ - DJ	-0.128	0.017	$< 10^{-3}$

TABLE IX. MEAN, STANDARD DEVIATION AND SIGNIFICANCE OF THE $RMSDf25$ PAIRED DIFERENCES AT CMJ, DJ, SJ IMPULSE PHASES.

$RMSDf25$ (N)	Root mean square error of GRFz FFT up to $k = 25$		
	μ	σ	p
CMJ - SJ	3.59	2.32	$< 10^{-3}$
CMJ - DJ	12.68	14.06	0.013
SJ - DJ	9.10	13.15	0.036

Regarding the paired comparisons of the differences between the mean values, corresponding to the first harmonic of FFT decomposition and the original GRF_z signal $RMSDf0$ on Tab 10, DJ presented higher values than CMJ and both higher than SJ, in line with the maximum values $Max|FFT|$ resulting from Fourier decomposition (FFT) of GRF_z. Thus, the relative deviation $RMSDf25\,\%$ between the 25th harmonic reconstruction and the GRF_z signal normalized to $RMSDf0$ presented on paired comparisons at Tab. 11, higher value on SJ than CMJ, both higher than DJ.

TABLE X. MEAN, STANDARD DEVIATION AND SIGNIFICANCE OF THE $RMSDf0$ PAIRED DIFERENCES AT CMJ, DJ, SJ IMPULSE PHASES.

$RMSDf0$ (N)	Root mean square error of GRFz FFT for $k = 0$		
	μ	σ	p
CMJ - SJ	164.1	120.9	0.002
CMJ - DJ	-888.2	115.7	$< 10^{-3}$
SJ - DJ	-1052.3	80.7	$< 10^{-3}$

TABLE XI. MEAN, STANDARD DEVIATION AND SIGNIFICANCE OF THE $RMSDf25\,\%$ PAIRED DIFERENCES AT CMJ, DJ, SJ IMPULSE PHASES.

$RMSDf25\,\%$	Root mean square error of GRFz FFT up to $k = 25$		
	μ	σ	p
CMJ - SJ	-0.013	0.017	0.030
CMJ - DJ	0.044	0.017	$< 10^{-3}$
SJ - DJ	0.057	0.011	$< 10^{-3}$

Fig. 4 present illustrative examples of the vertical ground reaction forces GRF_z FFT and relative accumulated FFT during the impulse phases of CMJ, DJ, and SJ performed trials with Fig. 5 corresponding landing phase on CMJ trial.

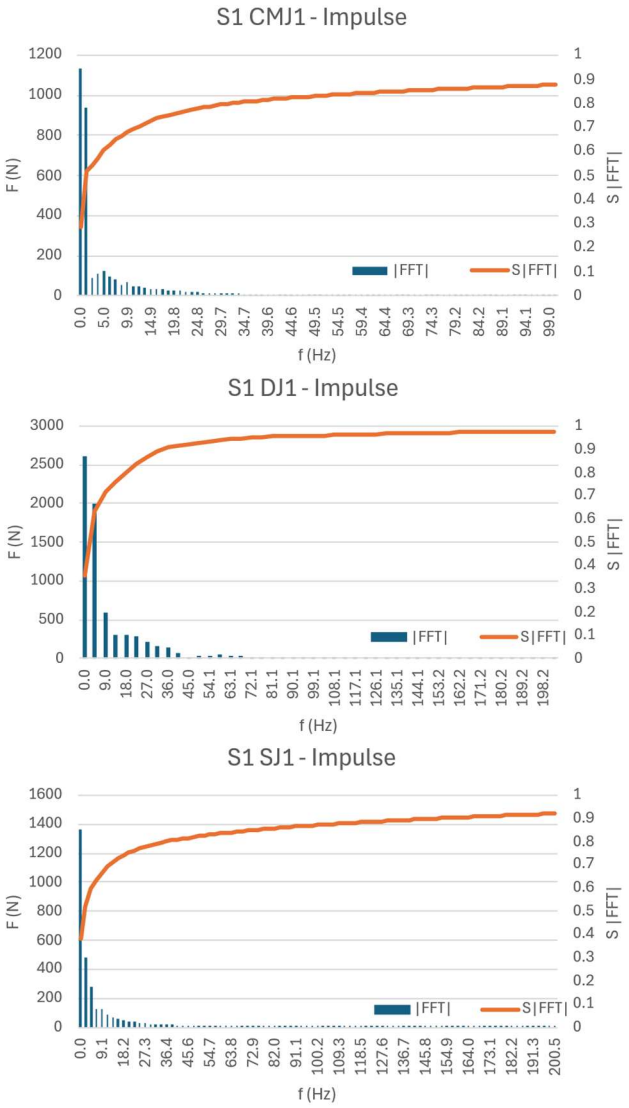

Fig. 4. Example of vertical ground reaction force (GRF_z) FFT and relative accumulated FFT during impulse phases of CMJ, DJ, SJ performed trials.

B. *Landing phase*

For the landing phases, the maximum value $Max|FFT|$ resulting from Fourier decomposition (FFT) of GRF_z presents higher values for CMJ relative to SJ, both higher than DJ ($p \geq 0.05$), Tab. 12, with the maximum values registered at similar frequencies $f(Max|FFT|)$, slightly higher for DJ relative to SJ, both higher than CMJ ($p \geq 0.05$). The 90th percentile of FFT decomposition of GRF_z $f(p90|FFT|)$ occurs at lower frequencies for DJ relative to CMJ, both lower than SJ ($p \geq 0.05$). The cumulative result of FFT decomposition of GRF_z up to the 25th harmonic $S|FFT|f25$ has higher values in DJ relative to CMJ and SJ ($p \geq 0.05$). The RMSD between the reconstructed signal up to the 25th harmonic and the GRF_z signal $RMSDf25$ presents lower values for DJ relative to SJ and CMJ ($p \geq 0.05$). The difference between the mean value corresponding to the first harmonic of FFT decomposition and the original GRF_z signal $RMSDf0$ presents higher values in CMJ relative to SJ, both higher than DJ ($p \geq 0.05$). Therefore, when normalized to the mean value, the relative deviation between the 25th harmonic reconstruction and the GRF_z signal $RMSDf25\,\%$ presents higher values in SJ and CMJ relative to DJ ($p \geq 0.05$).

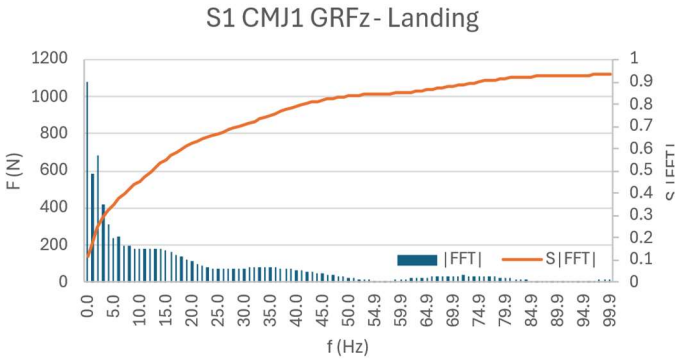

Fig. 5. Example of vertical ground reaction force (GRF_z) FFT and relative accumulated FFT during landing phase of CMJ performed trial.

TABLE XII. MEAN AND STANDARD DEVIATION OF THE MAXIMUM FFT, FREQUENCY OF THE MAXIMUM FFT, 90TH PERCENTILE, 25TH HARMONIC, RMSD OF 25TH HARMONIC, MEAN AND % AT CMJ, DJ, SJ LANDING PHASE.

Mean ± Std	**Landing phase**		
	CMJ	**DJ**	**SJ**
$Max\|FFT\|$ (N)	579.04 ± 171.74	487.36 ± 99.14	507.57 ± 69.97
$f(Max\|FFT\|)$ (Hz)	1.56 ± 0.53	1.67 ± 0.71	1.60 ± 0.52
$f(p90\|FFT\|)$ (Hz)	67.93 ± 10.35	60.16 ± 20.59	75.63 ± 15.37
$S\|FFT\|f25$	0.73 ± 0.07	0.77 ± 0.06	0.72 ± 0.07
$RMSDf25$ (N)	179.70 ± 93.62	125.70 ± 45.08	179.62 ± 108.44
$RMSDf0$ (N)	782.36 ± 164.98	738.83 ± 129.20	754.65 ± 182.44
$RMSDf25$ %	21.73 ± 9.08	17.30 ± 6.45	22.39 ± 10.16

The paired comparisons of the FFT parameters from GRF_z during the landing phases on Tab. 13 - 19 confirm the general trend detected with the independent comparisons on Tab. 12 for the absence of statistically significant differences among MVJ types. Nevertheless, the paired comparisons presented higher sensitivity for detection of statistically significant differences at $p < 0.05$ in association with maximum vertical jump height ht.

Thus, based on paired comparison of the FFT parameters from GRF_z during the landing phases, statistically significant differences were exclusively detected for the $Max|FFT|$ on Tab. 13 with higher value on CMJ than DJ in association with higher ht, the $f(p90|FFT|)$ on Tab. 15 with lower value at DJ than SJ and the $S|FFT|f25$ on Tab. 16 with higher value at DJ than CMJ due to higher FFT convergence associated with GRF_z time profile.

C. Correlations with MVJ height

Selected metrics from FFT decomposition of GRF_z presented during the impulse phases higher correlations, Tab. 20, between the vertical jump height ht with negative associations to $Max|FFT|$, $f(Max|FFT|)$, $S|FFT|f25$, $RMSDf0$ whereas positive associations were detected with $(p90|FFT|)$, $RMSDf25$, and $RMSDf25\,\%$ due to the clustering at DJ with lower ht, higher $Max|FFT|$, $f(Max|FFT|)$, $S|FFT|f25$ and lower $f(p90|FFT|)$, $RMSDf25$, $RMSDf0$, $RMSDf25\,\%$ and the opposite at CMJ and SJ. As regards to the landing phases, the dominant associations correspond to the positive correlations of ht with $Max|FFT|$, $f(p90|FFT|)$, $RMSDf25$, $RMSDf0$ and $RMSDf25\,\%$, negative correlation with $S|FFT|f25$, very low correlation with $f(Max|FFT|)$ and mixed variable association at different MVJ type.

TABLE XX. CORRELATRIONS OF THE MAXIMUM VERTICAL HEIGHT WITH MAXIMUM FFT, FREQUENCY OF THE MAXIMUM FFT, 90TH PERCENTILE, 25TH HARMONIC, RMSD OF 25TH HARMONIC, MEAN AND % AT CMJ, DJ, SJ IMPULSE AND LANDING PHASES

Variable	Correlations r with ht (m)			
	Impulse r, p		Landing r, p	
$Max\|FFT\|$ (N)	-0.528*	0.004	0.629*	$< 10^{-3}$
$f(Max\|FFT\|)$ (Hz)	-0.681*	$< 10^{-3}$	0.180	0.359
$f(p90\|FFT\|)$ (Hz)	0.581*	0.001	0.383*	0.044
$S\|FFT\|f25$	-0.654*	$< 10^{-3}$	-0.638*	$< 10^{-3}$
$RMSDf25$ (N)	0.548*	0.003	0.637*	$< 10^{-3}$
$RMSDf0$ (N)	-0.519*	0.005	0.554*	0.002
$RMSDf25\,\%$	0.556*	0.002	0.528*	0.004

IV. DISCUSSION

Whereas the selected metric of GRF_z FFT presented clear distinction at long, short and no CM on different MVJ impulse phases ($p < 0.05$), the corresponding metrics on landing did not present dominant statistically significant differences between CMJ, DJ and SJ ($p \geq 0.05$) pointing to clear differences of the GRF_z distribution in terms of FFT content during impulse phase at different CM, and similar GRF_z distributions assessed through FFT content during the landing phases, regardless of different CM and MVJ type.

A. Impulse phase

Thus, whereas the higher maximum value of $Max|FFT|$ at DJ in relation to CMJ and SJ is associated with the highest level of peak GRF_z during the impulse phase at DJ regarding CMJ and SJ, the fact that these maximum values are achieved at higher frequencies $f(Max|FFT|)$ for DJ relative to SJ, both higher than CMJ can be associated with the shortest duration of the impulse phase at DJ in relation to SJ, and both lower than CMJ.

The fact that the 90th percentile of FFT decomposition of GRF_z $f(p90|FFT|)$ occurs at lower frequencies for DJ in relation to SJ and CMJ points to the concentration at a lower number of harmonics for the same level of percentage, 90% of the signal content on DJ relatively to SJ and CMJ, and this being corroborated with the highest level of cumulative result from the FFT decomposition of GRF_z up to the 25th harmonic $S|FFT|f25$ at DJ in relation to CMJ, both higher than SJ.

This can be additionally confirmed by the lowest values at DJ in relation to SJ and CMJ of the root mean squared deviation (RMSD) between the reconstructed signal up to the 25th harmonic and the GRF_z sinal $RMSDf25$, pointing to the higher proximity of the reconstructed GRF_z with the initial 25 harmonics to the original GRF_z signal at DJ than SJ and CMJ, with higher concentration of the signal energy at lowest harmonics, intermediate dispersion at the signal content on SJ and the highest dispersion on CMJ.

Regarding the highest difference between the first harmonic $RMSDf0$ of FFT decomposition and the original GRF_z signal at DJ in relation to CMJ, both higher than SJ, this fact can be associated to a larger magnitude, with higher peak values of GRF_z signal in relation to its mean value at DJ, the next higher levels of GRF_z peak values at CMJ and the lowest peak values at SJ.

For this reason, despite the highest $RMSDf25$ at CMJ in relation to SJ and DJ, the normalization to $RMSDf0$ conduced to the relative deviation between the 25th harmonic reconstruction and the GRF_z signal $RMSDf25\%$ with higher value at SJ in relation to CMJ, both higher than DJ.

B. Landing phase

Despite the differences in the mean values and variabilities assessed through the standard deviations of the various selected metrics at FFT domain, the dominant absence of statistically significant differences ($p \geq 0.05$) of these metrics during the landing phases between CMJ, DJ and SJ clearly point that there were detected no shape distinction of GRF_z assessed through FFT domain during the landing, regardless of the CM type and MVJ flight height.

C. Correlations with MVJ height

Additionally, the groups of selected metrics for GRF_z FFT domain correlation to MVJ height presented clear distinction between the impulse and the landing phases. Thus, whereas the correlations at the impulse phases led to clear distinction among different MVJ with clear clustering for CMJ, DJ and SJ, the corresponding correlations at the landing phases conduced to indistinguishable clusters for CMJ, DJ, and SJ pointing to the selected FFT parameters as good predictors of ht both on impulse and the landing phases, with the ability for discrimination between MVJ type restricted to the impulse phase, preserving at the landing phases the association with ht performance independently of the MVJ and CM type.

V. CONCLUSION

According to the achieved results, spectral analysis of GRF_z presents as a complementary tool to the time domain analysis, focusing on the shape of GRF_z in terms of its FFT harmonics distribution and amplitudes. Thus, whereas FFT selected metrics led to clear distinction at the frequency domain of GRF_z during impulse phase of MVJ long, short and no CM, invariant remarkable behavior was detected for these FFT metrics during landing phase of different long, short and no CM from various MVJ, while preserving the ability for prediction of the explosive performance assessed through maximum vertical jump height.

The FFT allowed for the comparison of time-series spectra that would otherwise not be directly comparable due to differing curve shapes, such as those observed during the impulsion phases of the various maximum vertical jumps, and

especially during landing phases, where temporal profiles are incomparable on a point-by-point basis.

Based on this study involving the spectral analysis of the maximum vertical jumps, it is possible to optimize each subject's individual performance for each type of maximum vertical jump, using the detected frequencies in relation to the body segments' natural vibration frequencies estimated in previous studies.

Specifically, the performed spectral analysis also allows for the objective differentiation—based on detected frequencies associated with vertical force curve shapes during the impulsion phases—of tendencies toward a long countermovement in the CMJ, clearly distinguishing it from short countermovement executions and the non-countermovement actions seen in the DJ and SJ.

To the best of our knowledge, this is a pioneering study applying spectral analysis to various vertical counter-movements, expanding and deepening the knowledge gained from previous studies regarding body segment spectral behaviour during standing, walking, and running.

***Abstract*—Three-dimensional understanding of biological structures is one of the central challenges in biomedical education: students are routinely introduced to molecular, microbiological, and cellular concepts that cannot be directly observed, and conventional two-dimensional illustrations often struggle to convey their spatial organization.**

Additive manufacturing offers a promising way to address this gap, producing tangible models that students can manipulate and explore from multiple angles, with the added potential to make biological structures accessible through touch. This paper proposes a digital-to-physical workflow for producing this kind of biomedical educational model — from biological data acquisition through digital preparation, slicing, fabrication, and assembly — and illustrates it with a first proof of concept: an open-source DNA double-helix model, adapted and manufactured using fused deposition modeling (FDM). Masked stereolithography (MSLA), planned for future higher-resolution models, was not yet available during this stage, so the comparison between the two technologies discussed here draws on the literature rather than on our own measurements.

The resulting prototype shows that the workflow can be carried out end to end, from a digital reference file to an assembled, handheld object, and surfaces practical manufacturing considerations that will guide the next iterations. This is presented as a workflow proposal illustrated by a single case rather than a fully validated methodology: learning outcomes, accessibility benefits, durability, and a direct FDM-versus-MSLA comparison are left for future work.

***Index Terms*—additive manufacturing, biomedical education, fdm, msla, three-dimensional models, tactile learning, inclusive education**

I. Introduction

Biomedical engineering integrates concepts from biology, chemistry, physics, medicine, and engineering to develop technologies that improve healthcare. Because of its interdisciplinary nature, students must understand biological structures ranging from organs to molecular assemblies. Many of these structures exhibit complex three-dimensional geometries that are difficult to interpret when presented only through conventional two-dimensional educational resources.

Traditional teaching materials rely heavily on textbook illustrations, microscopy images, slides, and computer-generated renderings. Although these resources provide valuable information, they require students to mentally reconstruct three-dimensional geometries from flat representations, increasing the cognitive effort required to understand spatial organization. This limitation becomes particularly evident when studying structures such as DNA molecules, proteins, viruses, and cellular organelles, whose biological function is closely associated with their three-dimensional arrangement [1], [2].

Scientific education also presents accessibility challenges, as most biological concepts are communicated through visual resources. For students with visual impairments, tactile graphics and verbal explanations are often insufficient to represent complex spatial geometries. Three-dimensional printed models have been reported to overcome part of this limitation by allowing the exploration of shape, symmetry, and structural organization through touch [3]; the present work adopts this as a design motivation rather than as a claim evaluated in this study.

Recent advances in additive manufacturing have enabled educational institutions to produce customized teaching resources at relatively low cost. Compared with commercial educational kits, 3D printing provides greater flexibility by allowing educators to adapt dimensions, geometry, and modularity according to specific pedagogical objectives. Previous studies have reported improvements in spatial reasoning, classroom engagement, and active learning through the use of three-dimensional printed educational models [4].

Despite these advances, most reported applications focus on macroscopic structures such as bones, organs, and anatomical models. Comparatively fewer studies investigate molecular and microbiological educational models, whose development requires a structured workflow involving scientific validation, digital modeling, mesh preparation, and additive manufacturing before physical fabrication can be achieved [4].

This work proposes a reproducible workflow for developing biomedical educational models using additive manufacturing and illustrates it through a single case study. Rather than evaluating multiple printed artifacts, the paper documents one complete digital-to-physical process, including biological

data acquisition, digital preparation, slicing, fabrication, and technical assembly. As a proof of concept, an open-source DNA double-helix model was adapted and manufactured using fused deposition modeling (FDM). Since the laboratory resin-printing infrastructure was still being implemented during the experimental phase, FDM was used to exercise the workflow ahead of a future migration to masked stereolithography (MSLA).

The main contributions of this work are:

1) a proposed, reproducible workflow for transforming biological information into physical educational models through additive manufacturing;
2) a single proof-of-concept demonstration of this workflow, using a DNA double-helix prototype manufactured by FDM;
3) a manufacturing strategy that uses FDM to exercise the workflow end to end while identifying MSLA as the intended technology for future higher-resolution production;
4) a discussion of accessibility and tactile-learning considerations as design objectives to guide future iterations of biomedical educational models, rather than as outcomes evaluated in this work.

II. Related Work

A. Additive Manufacturing in Biomedical Education

The incorporation of additive manufacturing into education has expanded considerably over the last decade due to reductions in equipment cost, improvements in printing quality, and the growing availability of open-source digital models. Desktop 3D printers have become valuable educational tools by enabling students to transform theoretical concepts into tangible objects while integrating digital modeling, manufacturing, and engineering principles [4].

Within biomedical education, additive manufacturing has been widely adopted to produce anatomical replicas for teaching, surgical planning, and simulation. Physical models are reported to improve students' spatial understanding by allowing direct manipulation of structures that would otherwise be observed only through images or computer renderings. However, successful implementation depends on a well-defined workflow involving digital modeling, mesh preparation, slicing, and manufacturing, aspects that are often only briefly addressed in the literature [4].

B. Molecular Educational Models and Accessibility

Compared with anatomical applications, relatively few studies investigate additive manufacturing for molecular and microbiological education. Models representing DNA, proteins, viruses, and other microscopic biological structures require additional processing to convert scientific data into printable geometries while preserving their educational relevance.

Three-dimensional printed models have also been reported to contribute to inclusive education by transforming visual scientific information into tactile educational resources [3]. Recent studies have demonstrated the feasibility of integrating computational modeling and additive manufacturing into molecular biology education, reinforcing the potential of customizable three-dimensional educational resources in higher education [5].

Motivated by these advances, the present work proposes a standardized workflow that integrates scientific validation, digital modeling, additive manufacturing, and educational evaluation into a single reproducible methodology intended to support the future development of biomedical educational models.

III. Methodology

This research proposes a reproducible workflow for developing biomedical educational models through additive manufacturing. Rather than focusing on a single printed object as an end in itself, the methodology standardizes the digital-to-physical process so it can, in principle, be applied to different biological structures with minimal adaptation; this generality is a design intention and has so far been exercised on a single structure (Section V).

The workflow consists of six sequential stages:

1) Selection of the biological structure;
2) Scientific validation and data acquisition;
3) Digital modeling and mesh preparation;
4) Additive manufacturing;
5) Post-processing;
6) Technical and educational evaluation.

Table I summarizes the primary objective of each stage.

A. Biological Structure Selection

Candidate structures are selected according to three criteria:

- relevance to biomedical engineering education;
- three-dimensional complexity;
- feasibility of additive manufacturing.

This methodology is intended for structures such as DNA, proteins, viruses, bacteriophages, cellular organelles, and molecular assemblies.

B. Scientific Validation and Digital Preparation

Biological information is obtained from peer-reviewed literature and specialized databases. For molecular structures, three-dimensional data may be acquired from the Protein Data Bank (PDB) [5] and inspected using molecular visualization software such as UCSF ChimeraX [6]. For the DNA model reported in this paper, scientific accuracy was reviewed by Prof. Raphael Cardoso Mota Pereira, who also advised on the fabrication adjustments described in Section V-A that ultimately resolved the model's printing issues.

The models are then prepared for manufacturing through mesh repair, scaling, wall-thickness adjustment, removal of geometric artifacts, reinforcement of fragile regions, and export to STL format for slicing and printing.

C. Manufacturing Strategy

The proposed methodology combines two complementary additive manufacturing technologies.

The workflow was exercised using fused deposition modeling (FDM), since the laboratory MSLA infrastructure was still under acquisition during the experimental phase. FDM allowed the digital preparation, slicing configuration, fabrication, assembly, and handling stages to be carried out end to end without delaying the project.

Future production is planned to employ masked stereolithography (MSLA), whose higher resolution is better suited to educational models with fine biological detail, such as viruses, proteins, and molecular complexes. FDM was used to exercise the workflow in the meantime; no direct experimental comparison between the two technologies was performed in this work.

D. Post-processing and Evaluation

After fabrication, prototypes undergo support removal, cleaning, assembly when necessary, and visual inspection. The validation process considers:

- dimensional consistency;
- structural stability;
- manufacturing quality;
- ease of handling;
- educational interpretation;
- potential for tactile accessibility.

In the present work, this evaluation was carried out qualitatively (visual and manual inspection); it did not include quantitative metrology, mechanical testing, or assessment by students, instructors, or visually impaired users. The evaluation results are intended to be incorporated into subsequent design iterations.

TABLE I
WORKFLOW ADOPTED FOR BIOMEDICAL EDUCATIONAL MODEL DEVELOPMENT

Stage	**Objective**
Selection	Choice of a biologically relevant structure.
Scientific validation	Collection and verification of biological data.
Digital preparation	Mesh optimization and STL generation.
Manufacturing	Prototype fabrication using additive manufacturing.
Post-processing	Cleaning, assembly and inspection.
Evaluation	Technical and educational validation.

IV. MATERIALS, INFRASTRUCTURE, AND SCALABILITY

The proposed workflow was developed and exercised at FabLab Inatel, which provides the computational and manufacturing resources required for rapid prototyping. The laboratory supports digital modeling, mesh preparation, slicing, fabrication, prototype assembly, and iterative evaluation.

Fig. 1 presents the laboratory used during the experimental activities.

Fig. 1. FabLab Inatel, where the digital modeling, fabrication, and evaluation stages of the proposed workflow were carried out.

A. Manufacturing Technologies

The methodology intentionally combines FDM and MSLA technologies. FDM provides a fast, economical, and accessible platform for iterative development, while the literature reports MSLA as offering higher dimensional accuracy and finer surface quality, better suited to structures with intricate biological detail [4], [7]. Fig. 2 illustrates the general differences between both technologies, as reported in the cited source. This project uses FDM to exercise and document the workflow first, with MSLA reserved for future high-resolution production; the comparison itself has not been tested experimentally by the authors.

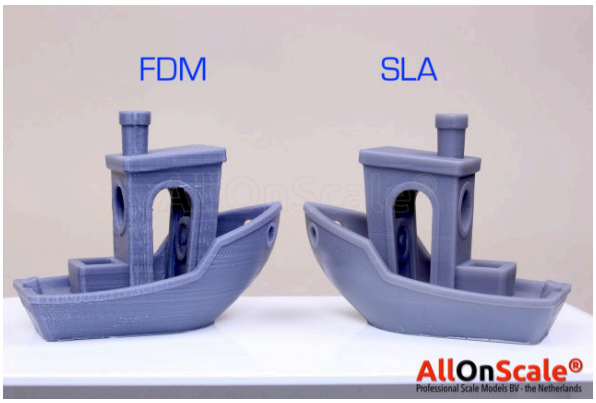

Fig. 2. General comparison between FDM and stereolithography-based resin printing technologies, as reported in the literature. Adapted from AllOnScale [7].

B. Available and Selected Equipment

FabLab Inatel provides three FDM printers, used across the different components of this project: a Creality K1 Max (build volume 300 × 300 × 300 mm), a Bambu Lab H2C (single-nozzle build volume ≈325 × 320 × 320 mm), and an UltiMaker 2+ Connect (build volume 223 × 220 × 205 mm). All three ship with a 0.4 mm nozzle as standard and support PLA, among other materials.

Future high-resolution production is planned to employ an Anycubic Photon Mono M7 Pro MSLA printer, already acquired by the research group. The equipment was not yet available during fabrication of the proof-of-concept prototype

(Section V-B); its incorporation represents the next stage of the proposed workflow. Fig. 3 shows the selected MSLA printer.

Fig. 3. Anycubic Photon Mono M7 Pro selected for future MSLA production of biomedical educational models.

C. Scalability

Once a digital model is prepared, it can in principle be reproduced and adapted without repeating the modeling process, supporting the gradual creation of an institutional repository of biomedical educational models. This is a design goal the current single-model proof of concept does not yet demonstrate, but is built to support.

V. Proof of Concept: DNA Double-Helix Model

To exercise the proposed workflow, a DNA double-helix model was selected as the first educational prototype. DNA is one of the central topics in biomedical engineering curricula, being addressed in molecular biology, genetics, biochemistry, biotechnology, and bioinformatics courses. Despite its importance, the molecule is commonly presented through two-dimensional textbook illustrations that often fail to convey its spatial organization and the relationships among its structural components.

The DNA model was chosen not because it represents the most complex biological structure, but because it provides an appropriate balance between educational relevance and manufacturing feasibility. The characteristic double helix incorporates repeated geometries, symmetry, continuous curvature, and modular organization, allowing the manufacturing workflow to be exercised before extending the methodology to more intricate biological structures such as proteins, viruses, and molecular complexes.

This proof of concept was intended to exercise the proposed methodology on a single case, rather than to demonstrate the maximum manufacturing capabilities of the selected technology or to statistically validate the workflow. The objective was to carry out every stage of the workflow at least once, from digital preparation to physical inspection, while establishing a reference process that can be reproduced and measured more rigorously in future prototypes.

A. Digital Model Preparation

The prototype was based on an open-source DNA double-helix model made available by the MakerWorld user WMZ [8]. The model's MakerWorld page confirms a Standard Digital File License: sharing, sub-licensing, selling, renting, hosting, transferring, or otherwise distributing the digital or 3D-printed object or any derivative work is prohibited, as is any use involving fees or payment; the specific file version was not separately recorded. Rather than being directly printed, the original model was adopted as a geometric reference and underwent a preparation stage consistent with the workflow proposed in this research.

Before fabrication, the geometry was inspected to verify mesh integrity, identify possible inconsistencies, and define the most suitable printing orientation. Digital preparation produced two related files: the assembled double-helix backbone (`Base.stl`), with a final size of 140.0 $\times$ 140.0 $\times$ 246.1 mm (17,158 triangles), and a combined file of modular components — nitrogenous bases and phosphate groups, printed separately for future assembly — scaled to 170% of the original open-source geometry (`Todos_DNA_170%.stl`), with a final size of 130.9 $\times$ 93.4 $\times$ 43.0 mm (9,628 triangles). Slicer inspection initially flagged 8 non-manifold edges in the combined modular-components file; redoing the scaling operation resolved these edges, and the file sliced without further errors afterward.

Because the model exists as a digital asset, modifications such as this scaling can be introduced before fabrication to improve manufacturability or structural resistance without requiring reconstruction of the entire geometry.

Fig. 4 illustrates the prepared digital model used throughout this stage.

B. Prototype Fabrication

During the experimental phase of this research, the laboratory MSLA infrastructure had not yet been fully implemented. The proof-of-concept prototype was therefore fabricated using fused deposition modeling (FDM), distributed across the FDM printers available at FabLab Inatel (Section IV-B): the double-helix backbone (`Base.stl`) was printed on the Creality K1 Max, whose 300 mm build height accommodated the piece's 246 mm height (exceeding the UltiMaker's 205 mm Z limit); the modular components (`Todos_DNA_170%.stl`) — printed individually in different colors, as visible in Fig. 6 — were fabricated using the lab's other available FDM printers. The parameters used for the backbone are summarized in Table II; Fig. 5 shows the sliced model in its printing orientation.

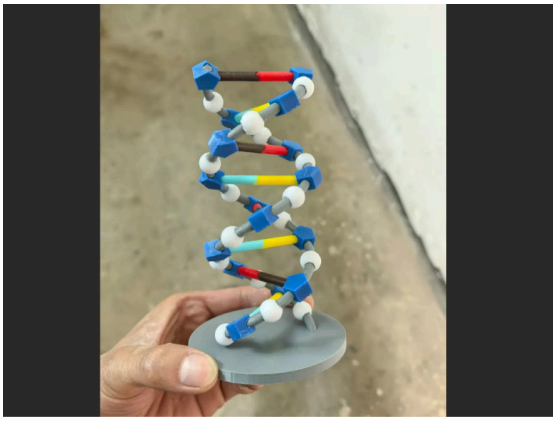

Fig. 4. Digital representation of the DNA double-helix model after preparation for additive manufacturing. Adapted from the open-source model published by WMZ [8].

TABLE II
FABRICATION PARAMETERS FOR THE DOUBLE-HELIX BACKBONE (BASE.STL)

Parameter	Value
Printer / model	Creality K1 Max (build volume 300 × 300 × 300 mm)
Nozzle diameter	0.4 mm
Filament	PLA
Layer height (initial layer)	0.2 mm (0.2 mm)
Default line width	0.42 mm
Wall (perimeter) loops	2
Top shell layers (thickness)	5 (1 mm)
Top surface density	100%
Infill density	15% (grid pattern, 45° direction)
Support strategy	None; the part was oriented specifically to be self-supporting
Print orientation	Vertical, standing on the circular base
Total print time	6h07min (6h01min model printing time)
Material mass used	90.50 g
Failed prints	0 for this piece (≈8 modular components failed separately, see below)
Material cost (FabLab service, invoiced)	R$ 184.00

For reference, the combined modular-components file (`Todos_DNA_170%.stl`) took approximately 3h50min to print and consumed about 70.44 g of PLA, at a cost of approximately R$ 80, fabricated using the lab's other available FDM printers. Of the kit's approximately 45 components, an early test batch printed at the original scale yielded 8 undersized, unusable pieces, which were discarded and reprinted at the corrected 170% scale (Section V-A) — a success rate of about 85% (45/53) for that batch; discarded material is not included in the totals above.

The printing process confirmed that a digital biological representation could be transformed into a physical educational artifact without major manufacturing difficulties, and it provided useful, qualitative information on orientation, mesh preparation, and handling that will carry over to future MSLA production. This evaluation remained qualitative (visual and manual inspection); dimensional metrology, mechanical testing, and user evaluation are left for future work.

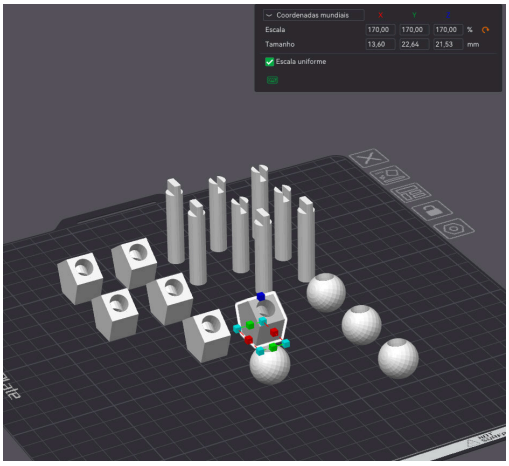

Fig. 5. Slicer preview of the double-helix backbone in its printing orientation, standing vertically on the circular base within the printer's build volume.

Fig. 6 presents the manufactured prototype obtained during this stage.

Fig. 6. DNA educational prototype manufactured using FDM. The assembled double helix demonstrates the manufacturing process end to end; individual components for a future modular educational assembly are under development. Adapted from WMZ [8].

C. Workflow Outcome

Fabrication of the prototype showed that the proposed workflow can be carried out end to end, from digital preparation to a physically assembled artifact — a demonstration on a single

case, with the workflow's applicability to other technologies or structures still to be tested.

The assembled prototype reproduces the macroscopic organization of the DNA molecule on visual inspection, and the project is evolving toward a fully modular educational kit: individual elements representing phosphate groups, deoxyribose sugars, nitrogenous bases, and carbon atoms are being designed and evaluated independently before integration into the complete model. Rather than observing a static representation, students would eventually be able to assemble the molecule themselves, exploring nucleotide composition, complementary base pairing, and the structural organization of the double helix — a design objective inspired by similar modular approaches reported for active learning in science education [9], still to be tested with real students.

Fabrication also surfaced practical, qualitative observations that will guide future prototypes: mesh optimization before slicing reduced printing failures (most visibly in the modular-components batch above), printing orientation affected dimensional quality and handling, and small geometric adjustments — including the rescaling that resolved the non-manifold edges described in Section V-A — improved handling without changing the model's scientific interpretation. These are working notes rather than measured results, but they already point to a clear next step: quantifying them in the SLA/MSLA prototypes planned for future work.

VI. Discussion

The outcome of this proof-of-concept stage indicates that additive manufacturing can be incorporated into biomedical education through a structured, documented workflow. Rather than reporting the fabrication and validation of multiple models, this work emphasizes documenting the entire digital-to-physical process on a single case, so that it can be replicated and evaluated more rigorously going forward.

FDM proved to be an adequate choice for exercising this workflow. Although the literature reports its geometric resolution as lower than that of resin-based systems [4], [7], filament deposition still allowed every stage — model preparation, slicing configuration, fabrication, assembly, and visual inspection — to be carried out at least once, reducing technical uncertainty ahead of adopting higher-resolution processes.

An important distinction underlying this work is between exercising a workflow and validating final manufacturing quality: the goal of the DNA prototype was not the highest possible geometric fidelity, but showing that the proposed steps can be carried out in sequence on a real case. Educational effectiveness, in this view, depends on digital preparation, scientific accuracy, manufacturability, and pedagogical adaptation, not on printing resolution alone.

The proposed methodology complements previous studies on additive manufacturing in education [3], [4]. While existing literature frequently focuses on anatomical replicas and medical simulation, this work extends the discussion toward molecular and microbiological educational models, whose development calls for additional attention to mesh preparation, structural simplification, modularity, and manufacturability.

Accessibility and tactile learning were treated as design objectives throughout: decisions about geometry, dimensions, component separation, and structural reinforcement were made with tactile handling in mind, in the spirit of prior studies on three-dimensional printed educational resources for visually impaired and sighted learners alike [1], [2]. No accessibility or usability evaluation with real users was carried out in this work, so these benefits remain a design objective rather than a demonstrated outcome — a natural next step once the modular kit described in Section V-C is complete.

Finally, the workflow is meant to be scalable: once exercised, it is expected to apply to different classes of biological structures with only minor adaptations during digital preparation, supporting the gradual development of an institutional repository of biomedical educational models.

VII. Limitations

The primary limitation of this study is that the complete proof of concept was carried out on a single structure (a DNA double helix). The stereolithography (SLA/MSLA) printer planned for this project was still under acquisition during the experimental phase and therefore could not be used to manufacture the model; the comparison between FDM and SLA/MSLA presented throughout this work is accordingly based on findings reported in the literature rather than on experimental measurements performed by the authors, and should be read as such [4], [7].

The validation procedure was qualitative: the manufactured prototype was evaluated through visual inspection and verification of assembly feasibility, without dimensional metrology, mechanical characterization, long-term durability testing, or educational assessment involving students, instructors, or visually impaired users. Claims regarding educational usability and accessibility in this paper should accordingly be read as design objectives motivating the work, not as demonstrated outcomes.

Table II reports a reasonably complete fabrication record for the backbone, reconstructed after the fact from the project's build history rather than logged systematically during printing. Notably, it does not include a measured dimensional error between the printed object and the digital file, which would require a follow-up caliper or scanner comparison.

Finally, only one biological structure was investigated. Although the proposed methodology is intended to extend to different educational structures, additional studies are necessary to evaluate its applicability to more complex geometries, other manufacturing technologies, and other areas of health education.

VIII. Future Work

Future work includes manufacturing the same DNA model using MSLA technology in order to experimentally compare dimensional accuracy, surface quality, feature reproduction,

production time, material consumption, and manufacturing cost under comparable conditions.

Additional investigations should include quantitative metrological analyses using precision measuring instruments, mechanical resistance tests, dimensional deviation mapping, and print success/failure rate tracking, together with a documented review of scientific accuracy against a defined checklist. Such analyses would strengthen the validation of the proposed workflow and provide objective criteria for selecting the most appropriate manufacturing technology for a given educational application.

A further direction, likely in the form of an anonymous questionnaire, is a structured educational evaluation involving students, instructors, and visually impaired users, to assess the learning gains, usability, and accessibility benefits that are, at this stage, design objectives rather than measured outcomes. The methodology may also be expanded to different biological structures and, eventually, to anatomical models such as organs and skeletal structures, enabling the creation of larger educational collections.

IX. Conclusion

This work presented a digital-to-physical workflow for producing biomedical educational models through additive manufacturing, illustrated by a first proof of concept: a DNA double-helix model, designed, fabricated, and assembled using the FDM printers available at FabLab Inatel. The process succeeded end to end and surfaced practical manufacturing considerations — around orientation, mesh preparation, and handling — that will directly inform the next iterations of the workflow, including the modular educational kit already under development (Section V-C).

The literature suggests FDM and SLA/MSLA are complementary: FDM for lower cost and simpler operation, resin-based processes for higher dimensional precision and surface quality [4], [7]. This work did not test that comparison experimentally, and reports it on the strength of the cited literature alone.

Learning gains, tactile-accessibility benefits, long-term durability, and a direct FDM-versus-MSLA comparison are left for future work, once the modular kit, the planned resin prototypes, and a structured evaluation with students, instructors, and visually impaired users are in place. What this paper does establish is a documented, reproducible starting point — a workflow, and a first working proof of it — for the biomedical educational models the group plans to build next.

***Abstract*—Despite the growth of the healthcare technology sector in Brazil, there is still a lack of systematic information regarding the professional profile and competencies required for biomedical engineers. Building upon studies conducted in 2022 and 2024, this work aimed to analyze the profile of employment opportunities and the most frequently required skills for biomedical engineers in Brazil based on job advertisements. A total of 115 job postings were collected from the Indeed platform in April 2026 using a web crawler. After screening by three independent reviewers, 61 positions were classified according to professional specialization based on the 2017 Undergraduate Biomedical Engineering Program at the Federal University of ABC (UFABC), and their descriptions were analyzed. The results showed that most opportunities were concentrated in the General (39.3%), Instrumentation (26.2%), and Clinical Engineering (19.7%) areas, predominantly located in the Southeast region of Brazil (64.4%) and requiring on-site work (73.8%). The most frequently hard skills mentioned in job advertisements were quality control (33 job postings) and knowledge of regulatory standards (27 job postings). Communication and teamwork were the most frequently mentioned soft skills. The findings provide a descriptive overview of job advertisements for biomedical engineers, indicating a consolidation of the profession compared with analyses performed in previous years (2022 and 2024).**

***Index Terms*—Biomedical Engineering; Job Market; Hard Skills; Soft Skills.**

I. Introduction

One of the primary objectives of engineering education is to prepare professionals capable of succeeding in the labor market or pursuing entrepreneurial careers independently. Achieving this objective requires continuous monitoring of the competencies demanded by industry, enabling educational institutions to align pedagogical activities with curricular content and better prepare graduates to meet social and professional needs.

Recent studies have consistently demonstrated the increasing importance of soft skills in the engineering labor market across North America, regardless of engineering discipline or research methodology. Hirudayaraj et al. [3], in a meta-analysis, identified teamwork, proactivity, and communication across hierarchical levels and multidisciplinary teams as increasingly important competencies during recruitment processes. Similar conclusions were reported by Beagon and Bowe [4] for engineering education in general and by Akinci-Ceylan and Ahn [5] specifically for the aerospace engineering industry. Likewise, Fleming et al. [1], through an analysis of engineering job advertisements, reached the same conclusions, reinforcing the consensus that collaboration and interdisciplinary communication are essential competencies, regardless of whether evidence comes from employer interviews, graduate follow-up studies, or job advertisement analyses.

The Brazilian National Curriculum Guidelines for Engineering Undergraduate Programs [6] state that the profile of an engineer extends beyond technical expertise. The guidelines emphasize the integration of technical and social competencies throughout the educational process, supported by active learning methodologies, practical activities, interdisciplinary projects, and supervised internships. These experiences expose students to real-world situations that require both technical knowledge (hard skills) and interpersonal and managerial abilities (soft skills).

Specifically for Biomedical Engineering, despite the strategic importance of healthcare technologies, there remains a shortage of systematic information regarding the professional profile, scope of practice, and labor market demand in Brazil. This knowledge gap makes it difficult to align undergraduate curricula with the actual needs of the healthcare technology sector.

Therefore, this study extends previous investigations on Biomedical Engineering employment opportunities in Brazil [7], [8]. The objectives were to classify biomedical engineering job opportunities into different professional areas according to the 2017 Undergraduate Biomedical Engineering Program at the Federal University of ABC (UFABC) [9] and to identify the technical and interpersonal skills most frequently requested by employers based on job descriptions.

II. Materials and Methods

Job postings were collected using a web crawler developed in Python 3.12 with the Selenium library. The crawler extracted job advertisements using the search terms “Biomedical

Engineering" and "Biomedical Engineer" (in Portuguese) from the Indeed platform, which was selected because it provides a publicly accessible and free database of employment opportunities. Data collection was performed in a single batch during April 2026 and restricted to positions located in Brazil. The crawler automatically navigated through all available result pages for each search term and extracted the job title, full job description, and location. No additional filters were applied, and no specific sorting criteria were selected. Duplicate postings were automatically removed by comparing their unique identification numbers.

Three independent reviewers screened the collected advertisements to determine their relevance to Biomedical Engineering. The level of agreement among the reviewers was approximately 96.5%, and disagreements were resolved by consensus. Technical-level positions and advertisements unrelated to Biomedical Engineering, such as positions specifically intended for Nursing or Biomedical Sciences professionals, were excluded.

To evaluate overlap with other engineering and computing professions, additional job postings were collected using the keywords Electrical Engineering, Mechanical Engineering, Chemical Engineering, Mechatronics Engineering, Materials Engineering, Production Engineering, Engineering Management, Data Science, and Computer Science.

The reviewers subsequently classified all relevant Biomedical Engineering positions into six professional areas: Clinical Engineering, Instrumentation, Biomaterials, Computing, Biomechanics, and General. These categories were based on the 2017 Undergraduate Biomedical Engineering Program [9] at UFABC. The additional General category was introduced to include positions suitable for biomedical engineering graduates but involving professional activities shared with other engineering disciplines.

The analysis of job descriptions was organized into four categories:

- General characteristics (salary, geographic region, and work modality);
- Hard skills common to engineering professions (English proficiency, programming, CAD/CAE, risk management, validation, and quality control);
- Biomedical Engineering-specific hard skills (regulatory affairs, maintenance, and management of medical equipment);
- Soft skills (communication, time management, proactivity, and teamwork).

All evaluations were independently performed by the three reviewers based exclusively on the information provided in the job advertisements.

III. Results

The initial search on the Indeed platform returned 115 job postings using the keywords Biomedical Engineering and Biomedical Engineer. After screening by the reviewers, 61 positions were classified as relevant to undergraduate Biomedical Engineering education. The primary reason for exclusion of 54 was that the position required only a technical qualification rather than a bachelor's degree (84.5%). The remaining 17.2% correspond to positions in other fields (Biomedicine, Nutrition, and Veterinary Medicine) or to roles with requirements incompatible with biomedical engineering, such as software support functions or specialization in NR-13 (pressure vessels and boilers). The distribution of the selected positions according to professional area is presented in Figure 1. Most positions were classified in the General category (39.3%), whereas the Biomedical Engineering-specific areas with the largest number of opportunities were Instrumentation (26.2%), Clinical Engineering (19.7%), and Biomaterials (8.2%). No job posting was classified into two categories.

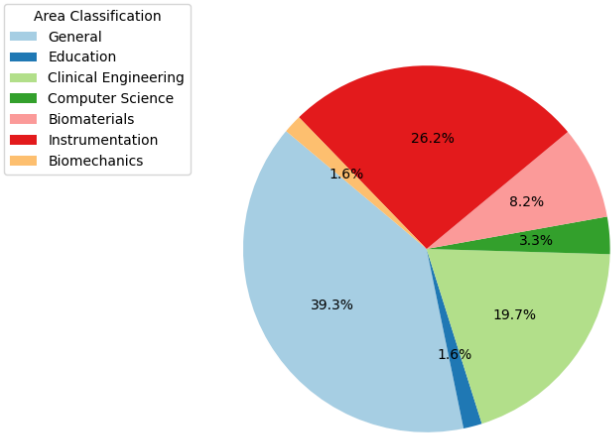

Fig. 1. Distribution of the selected job postings according to professional area.

The analysis of overlap between Biomedical Engineering positions and other professional fields identified five overlapping positions with Electrical Engineering, two with Chemical Engineering, five with Mechatronics Engineering, three with Materials Engineering, two with Production Engineering, one with Engineering Management, and one with Mechanical Engineering. No overlap was observed with Data Science or Computer Science positions.

The analysis of the general characteristics of the job postings showed that 86.9% required a completed undergraduate degree, whereas the remaining 13.1% corresponded to internship positions or required applicants to be currently enrolled in an undergraduate program.

In terms of educational requirements, of the 54 positions analyzed (internships excluded), 83.3% required a bachelor's degree with no mention of postgraduate or specialization qualifications, 13% listed postgraduate or specialization qualifications as desirable, 1.9% required a postgraduate degree, and 1.9% were open to candidates currently enrolled in an undergraduate program. Regarding seniority, the analysis was restricted to permanent positions and to explicit mentions of work experience in job descriptions. Among the same 54 positions, 11.1% required up to 2 years of experience, 11.1%

required 3 to 5 years, 5.6% required 5 to 7 years, and 1.9% required more than 7 years. The remaining 70.4% did not specify any experience requirement.

Most job postings (80.3%) did not disclose salary information. Among the positions requiring a completed undergraduate degree that reported salary, compensation ranged from R$3,000 to R$ 10,000, with an average monthly salary of R$6,400. Regarding geographic distribution, companies located in the Southeast region accounted for 67.2% of the job postings, followed by the Central-West (14.8%), South (9.8%), Northeast (3.3%), and North (1.6%) regions. Two postings did not provide location information (3.3%).

Concerning work modality, 73.8% of the positions (45 postings) required on-site work. Only three positions (4.9%) offered hybrid work arrangements, one position (1.6%) was fully remote, and in twelve postings (19.7%) the work modality was not specified. Furthermore, 21.3% of the advertisements explicitly mentioned business travel or field visits, all of which were associated with the Instrumentation or General professional areas.

Figure 2 summarizes the occurrence of hard skills commonly required across different engineering disciplines. Nearly half of the job postings (28) required English proficiency, and four of these also required Spanish proficiency. Only three advertisements explicitly mentioned programming skills. More than half of the positions (33 postings) required knowledge related to quality control or equivalent terms.

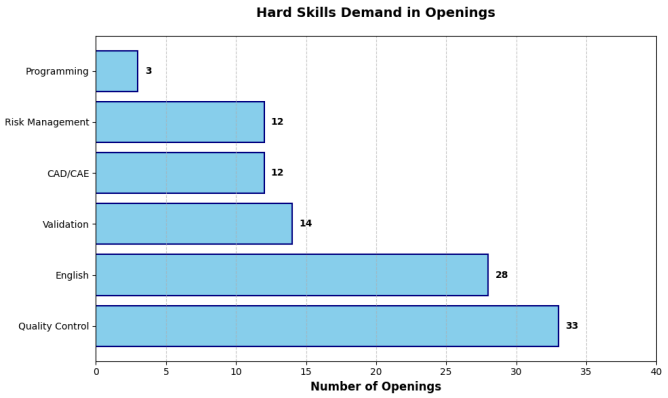

Fig. 2. Frequency of hard skills common to engineering disciplines mentioned in the job descriptions.

The Biomedical Engineering-specific hard skills are presented in Figure 3. Nearly half of the job postings (27) explicitly required knowledge of healthcare regulations and standards. Among these, the Brazilian Health Regulatory Agency (ANVISA) was the most frequently cited regulation (15 mentions), followed by ISO 13485 (12 mentions). Skills related to medical equipment were also commonly requested: 22 postings mentioned equipment maintenance, 12 referred to equipment management, and 10 required knowledge of medical imaging techniques.

Figure 4 presents the five most frequently requested soft skills. Communication, teamwork, proactivity and autonomy, organization/time management, and problem-solving/analytical thinking were the competencies most commonly mentioned by employers.

Fig. 3. Frequency of Biomedical Engineering-specific hard skills mentioned in the job descriptions.

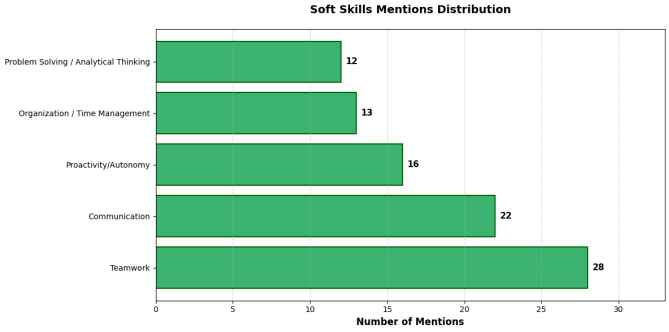

Fig. 4. Five most frequently requested soft skills in the analyzed job postings.

IV. Discussion

A total of 61 job postings identified during the first semester of 2026 were considered relevant to a Bachelor's degree in Biomedical Engineering. This result is consistent with the study conducted using the same methodology in 2024 (67 job postings) [7] and represents a substantial increase compared with the results obtained in 2022 (14 job postings) [8]. Although the linear trend test was not significant ($p > 0.05$), likely due to the small number of time points (n=3), the chi-square test indicated significant year-to-year differences ($p < 0.05$), mainly due to the post-pandemic outlier in 2022 [8]. The similarity between the 2024 and 2026 results may point to a continued consolidation of the Biomedical Engineering profession in the Brazilian labor market. However, future studies incorporating data from additional years are needed to support more robust trend estimations.

A. Professional Areas

The classification of job postings into the areas of Biomaterials, Biomechanics, Computing, Clinical Engineering, Instrumentation, Education, and General (Figure 1) identified employment opportunities in all professional categories. Overall,

39.3% of the positions were classified as General, consisting primarily of activities related to quality assurance, regulatory compliance, certification, sales, and commercialization, which require competencies developed during the common core of engineering programs. Instrumentation represented the second largest professional area (26.2%), mainly involving maintenance, repair, and calibration of medical equipment. Clinical Engineering ranked third (19.7%), including positions focused on equipment management, maintenance supervision, and hospital engineering services. Biomaterials accounted for 8.2% of the positions and primarily involved research, development, and validation of materials for medical devices. The limited number of positions classified in Computing (3.3%), Biomechanics (1.6%), and Education (1.6%) prevented the identification of representative employment profiles for these areas. Considering the significant presence of medical device manufacturers and healthcare technology companies in Brazil, the predominance of employment opportunities in General, Instrumentation, and Clinical Engineering suggests that the labor market recognizes biomedical engineers as professionals qualified to ensure regulatory compliance and support the maintenance and management of healthcare technologies [10].

The analysis of overlap with other engineering professions showed only limited overlap between Biomedical Engineering positions and those identified for other engineering disciplines, suggesting that employers recognize the unique competencies associated with Biomedical Engineering.

Compared with the 2024 results [7], the three most prominent professional areas remained unchanged—Instrumentation, Clinical Engineering, and General—although the proportion of General positions increased, moving from third place in the previous study to first place in the present analysis. The persistence of these three leading professional areas reinforces the perception that Biomedical Engineers are recognized as qualified professionals capable of contributing to multiple stages of the medical device commercialization process. It should be noted that the present study represents a temporal snapshot of the labor market. Consequently, the results may be influenced by temporary hiring demands, such as the establishment or expansion of departments within companies operating in Biomedical Engineering-related sectors or by seasonal bias. Furthermore, the analysis was restricted to a single recruitment platform, which may have influenced the observed employment profile.

B. General Characteristics

The results concerning educational qualifications and seniority indicate that the market remains receptive to candidates holding only a bachelor's degree, given that fewer than 15% of the positions listed postgraduate or specialization qualifications as mandatory or desirable. Additionally, the fact that 70.4% of the job postings did not specify experience requirements suggests that this information is not a priority in the advertisements, which may reflect positive prospects for newly graduated professionals.

The analysis of the job postings revealed an average reported salary of R$ 6,400, which is below the legally established minimum salary for engineers in Brazil, currently equivalent to six minimum wages for a six-hour workday, as established by Federal Law No. 4,950-A/1966 [11]. However, because only approximately 20% of the job postings disclosed salary information and most of them did not specify the corresponding workload, additional data are required to draw reliable conclusions regarding the average salary of Biomedical Engineers in Brazil. Furthermore, some job advertisements simultaneously targeted professionals with technical and undergraduate qualifications, broadening the salary range to accommodate both profiles and consequently affecting the estimated average.

The geographic distribution of the analyzed job postings showed a strong concentration in the Southeast region, which accounted for 67.2% of the 61 postings. This concentration is consistent with the fact that approximately 48% of the healthcare equipment currently in operation in Brazil is located in the Southeast region [12]. However, given the sample limitations (single platform, single month), these findings should not be interpreted as a complete representation of regional job availability for Biomedical Engineers in Brazil.

Most positions (73.8%) required on-site work, reflecting the professional activities typically performed by Biomedical Engineers in hospitals, healthcare institutions, manufacturing companies, and maintenance services. Additionally, 21.3% of the job advertisements explicitly mentioned business travel or field visits, all of which were associated with the Instrumentation or General professional areas, where professionals commonly provide technical support, installation, maintenance, and commercial assistance for medical devices.

C. Skills

The analysis of hard skills common to engineering disciplines (Figure 2) showed that more than half of the job postings (33 positions) explicitly mentioned quality control or equivalent terms. This observation aligns with the Brazilian National Curriculum Guidelines for Engineering Undergraduate Programs [6], which prescribe implementation, supervision, and control of engineering solutions as core competencies expected from engineering graduates. However, this alignment does not necessarily indicate that the guidelines are being effectively implemented in curricula or that the frequency of mentions reflects actual employer priorities, it only shows consistency between advertised requirements and policy expectations. Among the analyzed positions, references to quality control were particularly frequent in the General (14 postings) and Biomaterials (5 postings) categories, reflecting the regulatory and product development activities that characterize these areas.

The analysis of Biomedical Engineering-specific hard skills (Figure 3) suggests an important role for quality assurance and regulatory compliance within the profession. Nearly half of the analyzed job postings (27 positions) mentioned knowledge of healthcare regulations and standards. Skills related to medical

equipment also appeared frequently, with 22 postings mentioning equipment maintenance and 12 referring to equipment management, which may be associated with the Biomedical Engineer's responsibility for ensuring the safe operation, maintenance, and lifecycle management of healthcare technologies.

The analysis of soft skills (Figure 4) corroborates findings reported in previous studies [3]–[5]. Communication and teamwork were the two most frequently mentioned competencies in the analyzed job postings, followed by proactivity and autonomy, organization and time management, and problem-solving and analytical thinking. Given the inherently multidisciplinary nature of Biomedical Engineering, professionals routinely interact with physicians, nurses, technicians, engineers from other disciplines, regulatory specialists, and commercial teams. Therefore, it is expected that effective communication and collaborative teamwork are desirable for professional practice. These competencies are also explicitly recognized by the Brazilian National Curriculum Guidelines for Engineering Undergraduate Programs, which identify effective communication, teamwork, and autonomous learning as fundamental outcomes of engineering education.

However, it is important to note that the frequency of skill mentions in job advertisements does not necessarily equate to their importance in actual hiring decisions or professional practice. Advertised requirements may reflect ideal candidate profiles, marketing strategies, or template descriptions rather than the competencies most critical for job performance.

V. Conclusion

The findings of this study, together with comparisons with similar investigations conducted in 2022 and 2024, provide an updated perspective on the content of job advertisements for Biomedical Engineering on the Indeed platform. The results indicate that the analyzed postings primarily describe opportunities in positions related to the commercialization, maintenance, management, and regulatory compliance of medical devices. However, these findings should not be generalized to the entire Brazilian labor market without further validation using multiple data sources.

Most of the job opportunities analyzed are in positions related to the commercialization, maintenance, management, and regulatory compliance of medical devices. Among the technical competencies, quality control, knowledge of healthcare regulations, and medical equipment maintenance were the most frequently mentioned hard skills in the analyzed job postings. Regarding interpersonal competencies, communication and teamwork were also the most frequently mentioned soft skills. However, these findings reflect what employers choose to include in job advertisements, not necessarily a direct measure of the actual importance or prioritization of these skills in hiring decisions.

The lack of standardization among job advertisements, together with the frequent omission of information regarding working hours and salary, represented the main limitations encountered during the characterization of the analyzed job market.

Overall, the present results indicate a continued consolidation of Biomedical Engineering as suggested by the analyzed job postings. From a policy perspective, these findings may reinforce the importance of aligning undergraduate curricula with the competencies frequently mentioned in job advertisements. However, further researchers are required to correlate curricular content with graduate employment outcomes for curriculum development and educational planning.

***Abstract*— Objective: This study aimed to evaluate the prevalence of unmarked retracted publications across two major research-sharing platforms. Design: In this cross-sectional study, the Retraction Watch database on retractions was searched for papers fulfilling the following criteria: From Brazil, in all areas of health science, published between 2010 and 2020, and retracted for unreliability-related reasons (data fabrication, fraud, and data/methods/analysis problems). Expressions of Concern (EoCs) were also included. Once selected, these articles were searched on two research-sharing platforms: Research Gate and Academia.edu. Searches were conducted between Nov/24 and Jan/25, and papers were considered available when the manuscript could be found with no indication that a retraction/EoC had occurred and no retracted/EoC version could be found in the respective platform. Identified "abstracts only" within the conditions were also recorded, and, in addition, a standard Google Search was conducted, looking for papers/abstracts available in other platforms. All searches were performed by two researchers and independently double-checked by a third one. In cases of doubt, researchers convened to meet a consensus. The following information was collected: date of publication, date of retraction, title and (Google Scholar) citations received. Results: A total of 66 retractions could be selected. Out of these, 22 (1/3) were available unmarked at the platforms (13 Academia, 5 Research Gate, 4 in both). Additionally, 07 other unmarked abstracts were found (04 Research Gate, 03 in other repositories). The total post-year of retraction citations for the full papers was 730 (average 33.2), and for the abstracts, 166 (average 23.7). Conclusions: This study provides empirical evidence for the high persistence of unmarked retracted publications in academic social networks, thus highlighting potential noteworthy gaps in retraction-signaling practices on academic social networks.**

***Keywords*— Retraction, scientific publications, citation, research ethics**

I. INTRODUCTION

The retraction of scientific articles is a process in which a previously published article is invalidated due to serious problems that compromise its integrity, namely fraud, plagiarism, or significant methodological errors [1, 2]. These retractions serve as a crucial mechanism for maintaining research integrity within the scholarly ecosystem [3]. However, the efficacy and quality of retraction notifications across academic platforms remain unsatisfactory [3,4], potentially compromising the self-correcting nature of science [5].

The use of such papers can have consequences such as loss of scientific credibility, decline of science respect for ethical precepts, and the negative impacts of projects based on erroneous information. Thus, the fact that articles remain in databases without a clear indication of their invalidation is a cause for concern in the scientific community [6-8], which is investing in measures to deal with this problem.

Despite the rising interest in the problem, there are still significant gaps in understanding its causes. So, the extent of the presence of articles without proper retraction signposting in Internet databases is not fully understood, and neither are the reasons for their continued citation [3,4].

Therefore, the aim of this study was to identify retracted articles available on internet databases and to verify their citation rates, with the aim of contributing to an understanding of the impact of this problem and the development of more effective policies for controlling and signaling retractions.

II. METHODS

A. Data

In this descriptive study, the Retraction Watch (RW) database on retractions was searched for papers fulfilling the following criteria: from Brazil, in all areas of health science, published between 2010 and 2020, and retracted for unreliability-related reasons. Nationality was defined according to the first author's affiliation. Unreliability was defined by alleged retraction reasons related to data fabrication, fraud, and problems with data/methods/analysis.

Expressions of Concern (EoCs) were also included in the search. These are warnings, usually implemented when a paper is under investigation for retraction but no decision

has yet been found. They indicate serious concerns on the validity of a paper and thus should also impede paper citation. When a paper received a retraction after an EoC only the retraction was considered for analysis.

B. Search criteria

Once selected, the RW-identified retractions were searched on two research-sharing platforms. The first, Research Gate, has about 20 million members from 190 countries and presents itself as "the Facebook of scientists". The second, Academia.edu, claims to have more than 280 million users [9.10]. These are the two most prominent research-sharing platforms used by researchers.

Searches were conducted in Nov/24 and repeated in Jan/25, and papers were considered available when the manuscript could be found with no indication that a retraction/EoC had occurred and no retracted/EoC version could be found in the respective platform. Searching was perfomed with the standard search engines of the platforms, by looking for the article title, and, also, for the title in conjunction with the keywords "retraction", "retracted", "withdrawn" and "expression of concern" (in order to make sure that a retracted version was not available). In addition, once identified, a double-check was perfomed, so as to guarantee that the available version was the same one registered as "retracted" by the RW database (same venue and publication dates).

Identified "abstracts only" within the conditions above were also recorded, and, in addition, a standard Google Search was conducted, looking for these papers/abstracts in other platforms.

C. Information collection

All searches were performed by two researchers and independently double-checked by a third one. In cases of doubt or disagreement, researchers convened to meet consensus. The following variables were collected for the study: date of article publication, date of retraction, title, and (Google Scholar) citations received. Citations were divided as *post* and *pre-retraction*, where post-retraction citations were defined as those received from the calendar year following retraction onward. From these data, the percentage of post-retraction citations was calculated as: post-retraction citations / (pre-retraction + post-retraction citations).

III. RESULTS

A total of sixty-six (66) retractions could be selected from the Retraction Watch database accordingto the described criteria. Out of these, 22 (1/3) were available unmarked at the platforms (13 Academia, 5 Research Gate, 4 in both). Additionally to these 22 papers, 07 other unmarkedabstracts were found (04 Research Gate, 03 in other repositories).

Figure 1 shows the pre-post retraction rates of the analyzed papers. Total post-year of retractioncitations for the full papers were 730 (average 33.2), and for the abstracts were 166 (average 23.7). Table 1 provides a quantitative summary of the availability and citation data for the 22 full-text articles found unmarked on the platforms, complementing the individual-level visualization presented in Figure 1. Across these articles, citations accumulated both before and after the year of retraction, with the post-retraction period accounting for a substantial proportion of total citations in several cases. The seven abstracts identified without retraction labeling are reported separately, given that their availability was partial and their citation counts represent a distinct subset of the overall findings

Table 1. Summary of availability and citation data for retracted articles found unmarked on academic sharing platforms (2010–2020).

Characteristic	Full papers (n = 22)	Abstracts only (n = 7)
Platform distribution		
Academia.edu only	13	—
ResearchGate only	5	4
Both platforms	4	—
Other repositories	—	3
Total citations (pre + post retraction year)		
Total	1.332	279
Median per article	60,5	39,9
Median per article (IQR)	46,5 (24-75)	23,0 (12-76)
Range	0-320	0-130
Pre-retraction year citations		
Total	602	113
Median per article	27.3	16.1
Median per article (IQR)	16.0 (6–31)	2.0 (0–36)
Range	0–134	0–39
Post-retraction year citations		
Total	730	166
Mean per article	33.2	23.7
Median per article (IQR)	17.0 (6–36)	13.0 (11–35)
Range	0–186	0–61
Proportion of citations post-retraction (%)		
Mean (%)	53.4	74.4
Median % (IQR)	51.0 (36.1–66.0)	78.8 (59.3 –93.3)
Range	11.7 –100.0	36.8 –100.0

IQR: interquartile range. Citation counts retrieved from Google Scholar.

A Spearman correlation between time from publication to retraction (in days) and number of post-retraction citations indicated no statistically significant association ($\rho = -0.108$, $p = 0.631$).

IV. DISCUSSION

A retraction represents the nullification of a scientific paper, implying in its withdrawal from the valid literature. In this study, retractions were restricted to those pertaining to Brazilian first-author affiliations, a pragmatic delimitation adopted to maintain dataset homogeneity and manageability within the scope of the study. The focus on health sciences reflects the direct implications of retracted biomedical literature for clinical practice and public health policies. These choices limit the direct generalizability of findings to other national contexts or scientific disciplines (see "limitations" below).

High citation rates after the retraction of a paper are a well-known phenomenon inthe scientific literature [6,7,11-13]. Indeed, Gabehart [14] studied the persistence of citationsin retracted articles and concluded that around 30% of their citations occurred after the retraction date, demonstrating that, frequently, researchers continue to reference themwithout knowledge of their status.

An explanation for this phenomenon is that the indexing of scientific articles is many times deficient, introducing problems to the clear identification of their scientific status. Such flaws have been found even in renowned indexing databases and repositories, such as PubMed and Web of Science [3,4,6,15].

Another possibility, explored here, is that they can still be found over the Internet, without proper signposting, that is, with no indication that a retraction had happened. This was the possibility studied here, and indeed it could be observed that a large proportion of those retracted articles available in the analyzed databases had no indication whatsoever that they were not valid scientific literature anymore.

Worse yet, these retracted papers had a post-retraction citation rate of about 33 citations/paper. For comparison, Pfeifer and Mouton [17] and Wang et al. [18] reported post-retraction citation rates in of 733/82 and 954/128, respectively, values largely exceeded by the rates observed here. Although direct comparisons are limited by differences in study design, sample selection criteria, contexts and time frames, it is therefore possible that the lack of identification contributed for the dissemination and use of retracted material in other scientific reports.

The problem is even more serious if one considers that the analyzed retractions concerned health sciences, and, if left unchecked, may contribute to the incorporation of invalidated findings into literature reviews. This presents potential downstream implications for clinical guidance and evidence-based policy, a scenario that, while plausible, was not directly assessed in this study and warrants dedicated empirical investigation. Besides, time and resources will be diverted to replicate flawed research, adding to the already existing waste of resources introduced by shoddy scientific literature [16].

One could argue about who could be responsible for the persistent presence of unidentified retracted material on publicly available databases: authors or databases. Indeed, authors have a responsibility to, after a retraction, add clear indications that it has happened to impede the unwarned access to that material. However, databases also have their share of responsibility.Although a formal comparative analysis of their retraction-signaling policies falls outside of the scope of this study, ResearchGate and Academia.edu do not differ much in their governance models and content policies. Both operate as researcher-driven platforms, with some automated content controls and limited editorial vetting; and both would do well striving to develop guidelines and procedures to stop inappropriate dissemination of information.

Limitations: First, as mentioned, the sample is restricted to articles with Brazilian first-author affiliations in health sciences, limiting generalizability to other national or disciplinary contexts. Second, only two platforms were examined; the extent of the problem across other academic repositories, preprint servers, or institutional repositories remains unknown. Third, whether specific retraction reasons (such as data fabrication, fraud, or methodological problems) are associated with greater persistence on sharing platforms or with higher post-retraction citation rates remains an open question. The present dataset, while not powered for such subgroup analyses, may serve as a basis for future investigations examining retraction reason as a potential moderating variable in the persistence of invalidated content. Finally, citation counts were retrieved from Google Scholar, which may differ from other citation databases in coverage and update frequency.

V. CONCLUSION

In summary, this study provides empirical evidence for the high persistence of unmarked retracted publications in academic social networks, highlighting potential noteworthy gaps in retraction-signaling practices on academic social networks. The discussion of this topic addresses basic issues related to academic integrity and the reliability of scientific information. By understanding the factors that contribute to the dissemination of retracted articles and identifying solutions to reduce this problem, it could be possible to promote advances in the way scientific production is managed and disseminated.

Therefore, the availability of these unmarked versions may represent an additional route for the persistence and circulation of retreated content. These findings suggest that current practices for signaling retraction events on academic social networks may be insufficient to prevent continued access to invalidated literature. Potential responses could

include: (a) development of automatic notification mechanisms linking retraction databases (e.g., Retraction Watch, CrossRef) to content-sharing platforms; (b) establishment of clear editorial responsibilities for platform operators regarding content uploaded by registered users; and (c) enhanced guidance for authors regarding the obligation to update or remove uploaded manuscripts following retraction. These observations, while based on a bounded and exploratory sample, may inform future policy discussions on interoperability standards for retraction data.

***Resumo*—O presente trabalho relata a experiência de aplicação de metodologias ativas na disciplina de Biomecânica para Engenharia Biomédica da Universidade Federal do Rio Grande do Norte (UFRN), com o objetivo de promover o protagonismo estudantil, a interdisciplinaridade e a integração entre teoria e prática. Foram desenvolvidas duas atividades principais: um projeto contínuo de análise biomecânica do movimento humano, estruturado em três etapas ao longo do semestre, e uma aula invertida baseada na produção de um vídeo educativo em formato de cordel. A experiência possibilitou aos estudantes aplicar conhecimentos de diferentes áreas, desenvolver competências técnicas e transversais, como trabalho em equipe, organização, comunicação, resolução de problemas e tomada de decisão, além de favorecer a aprendizagem significativa por meio de feedback contínuo. Os resultados sugerem uma associação entre a implementação das metodologias ativas e a melhoria dos indicadores de percepção discente.**

***Resumo*—This paper reports on the experience of applying active learning methodologies in the Biomechanics for Biomedical Engineering course at the Federal University of Rio Grande do Norte (UFRN), aiming to foster student agency, interdisciplinarity, and the integration of theory and practice. Two main activities were conducted: an ongoing project involving the biomechanical analysis of human movement—structured in three stages throughout the semester—and a flipped classroom activity based on the production of an educational video in the style of cordel (traditional Northeastern Brazilian folk poetry). The experience enabled students to apply knowledge from various fields and develop both technical and transversal skills—such as teamwork, organization, communication, problem-solving, and decision-making—while also promoting meaningful learning through continuous feedback. The results suggest a link between the implementation of active learning methodologies and improvements in indicators of student perception.**

***Index Terms*—Educação, Engenharia Biomédica, Aprendizagem, Biomecânica**

I. Introdução

Os modelos tradicionais de ensino em engenharia, durante muitos anos, consolidaram práticas pedagógicas centradas na transmissão unilateral do conhecimento, seja por meio de aulas expositivas, seja por atividades experimentais predominantemente demonstrativas. Nesses modelos, o professor costuma ocupar a posição central do processo educativo, enquanto o estudante permanece em uma postura mais passiva. De acordo com Geurts et al. [1], ambientes educacionais que não valorizam a participação discente tendem a limitar o potencial transformador da educação e o desenvolvimento da autonomia, da autoconfiança e do pensamento crítico. Metodologias excessivamente centradas no professor também podem contribuir para a desmotivação discente, resultando em menor participação em sala, baixo rendimento acadêmico e menor retenção do conhecimento [2]. Tais habilidades e competências são, atualmente, objetivos centrais dos novos currículos de engenharia [3].

Nesse cenário, promover o protagonismo estudantil ocupa posição central nos debates pedagógicos contemporâneos, sendo compreendido como a capacidade do estudante de tomar decisões, participar ativamente da construção do conhecimento e assumir a responsabilidade pelo próprio percurso formativo [4]. Como consequência, a ausência de protagonismo compromete tanto o desempenho acadêmico quanto a formação profissional e cidadã, reforçada muitas vezes pela insegurança e pelo medo de errar Gonçalves et al. [5].

Para superar essa realidade, torna-se necessária a implementação de estratégias pedagógicas capazes de transformar o aluno em agente central da construção do conhecimento, como o uso de espaços não formais de ensino, metodologias ativas e aulas expositivas dialogadas. Entre as metodologias ativas, pode-se destacar estratégias como a Aprendizagem Baseada em Projetos (PBL ou ABP), a resolução de problemas, as atividades colaborativas, e aulas invertidas que favorecem o desenvolvimento da responsabilidade, da autorregulação, do pensamento crítico e da autonomia intelectual. Essas abordagens apresentam grande potencial na área de exatas, uma vez

que exigem interação, tomada de decisão, gestão organizacional, autogestão e resolução conjunta de problemas [6].

Contudo, a implementação dessas metodologias exige mudanças estruturais, demandando mediação docente e estratégias organizacionais que orientem o planejamento e o trabalho colaborativo [6]. Soma-se a isso o desafio da fragmentação curricular, na qual a organização dos conteúdos em disciplinas isoladas dificulta a percepção das conexões entre diferentes saberes e prejudica a construção de uma visão sistêmica da futura atuação profissional [7]. Nesse contexto, práticas interdisciplinares tornam-se essenciais para integrar conceitos, aproximar a teoria de situações reais e conferir maior significado à aprendizagem [8], [9]. Nos cursos de engenharia, essa articulação é indispensável, sobretudo na Engenharia Biomédica, cuja atuação profissional exige a integração constante entre ciências exatas, biológicas e da saúde [10].

Diante da dificuldade histórica em conectar saberes com estruturas de ensino tão distintas, práticas integradoras apoiadas em metodologias ativas tornam-se essenciais. Nesse contexto, relatos de experiência tornam-se relevantes por documentarem estratégias pedagógicas aplicadas em contextos reais de ensino, permitindo compartilhar desafios, adaptações e resultados que podem subsidiar novas práticas no ensino de Engenharia Biomédica. Dessa forma, este texto apresenta um relato de experiência sobre a aplicação de duas metodologias ativas na disciplina de Biomecânica para a Engenharia Biomédica, na UFRN, realizadas no período letivo de 2026.1. A proposta concentra-se no desenvolvimento de competências e habilidades específicas, bem como na aplicação de conceitos de dinâmica.

Adicionalmente, com o intuito de complementar o relato de experiência, o trabalho apresenta um estudo comparativo descritivo fundamentado no histórico de avaliação da disciplina pelos próprios estudantes, compreendendo o período de 2018.1 a 2025.2, período esse em que ocorreu a inserção da disciplina na grade. A análise busca confrontar as avaliações docentes de semestres anteriores com os resultados coletados após a inserção estrutural das metodologias ativas, ocorrida a partir de 2023.1. Essa abordagem visa demonstrar o impacto do modelo ativo no engajamento, na motivação e na satisfação geral da turma ao longo dos anos.

II. Metodologia

No início da disciplina de Biomecânica para Engenharia Biomédica na UFRN em 2026.1 o docente apresentou o plano de curso contendo duas atividades práticas de caráter não tradicional a serem desenvolvidas ao longo do período letivo, com apresentações presenciais na sala de aula. Essa apresentação inicial permite que os estudantes saibam, previamente, quais conhecimentos serão necessários para sua apresentação final. Esse conhecimento também é reforçado durante as aulas, nas quais o professor associa o aprendizado às entregas das atividades. Há também aulas somente para discutir o desenvolvimento das atividades e esclarecer dúvidas sobre elas.

A turma apresentada neste relato é composta por 10 estudantes, que foram organizados em dois grupos, os quais atuaram de forma distinta desenvolvendo as duas atividades independentemente. Será apresentado aqui o resultado de somente um dos grupos em cada uma das atividades. Para garantir a participação de todos do grupo, além da avaliação pelo professor no conteúdo e na apresentação, cada aluno entregou um relatório de autoavaliação e de avaliação dos colegas, onde estimaram o desempenho, comprometimento, entendimento, entregas e trabalho em equipe, em cada uma das atividades.

A. Atividade 01 – Análise do movimento

A atividade 01 consistiu na análise biomecânica do movimento humano em um projeto desenvolvido em três entregas parciais ao longo do semestre. Ela iniciou como o registro em vídeo de movimentos do membro superior humano, seguido do rastreamento de pontos anatômicos via software Kinovea® e do desenvolvimento de modelagem cinemática e cinética bidimensional em linguagem Python, Matlab ou qualquer outra que o aluno tenha conhecimento para cálculos e construção de gráficos e análises biomecânicas.

1) A condução do projeto: As atividades foram desenvolvidas em três etapas ao longo do semestre, conforme apresentado na Figura 1: análise cinemática do ponto material, cinemática de corpo rígido e cinética de corpo rígido bidimensional. Todo o material de apoio foi disponibilizado aos estudantes por meio de sistema acadêmico online, contendo a descrição de cada etapa do projeto.

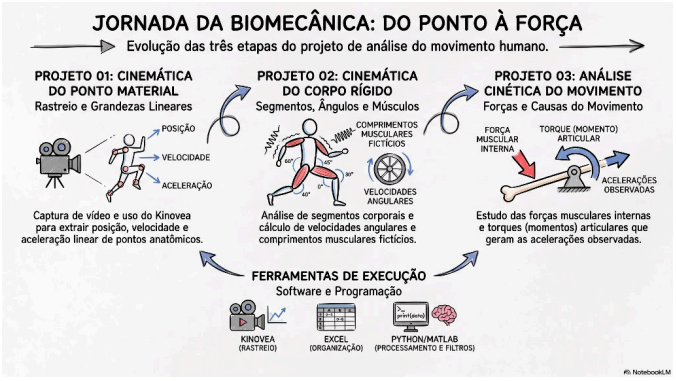

Figura 1: Divisão das atividades de acordo com as entregas. Fonte: autoria própria – Desenvolvido por IA, NotebookLM.

Após a primeira entrega do material solicitado na etapa 01, o professor realizou uma análise detalhada do relatório, destacando os pontos positivos e negativos do grupo. Também apresentou orientações para a condução das duas etapas seguintes, adequou o texto ao formato de relatório e buscou relacionar os conhecimentos trabalhados com conteúdo de outras disciplinas. Em seguida, devolveu o texto aos estudantes com correções, observações e análises de cada etapa e de cada fórmula apresentada.

A análise do segundo relatório ocorreu de forma mais pontual, durante encontros em sala de aula com cada grupo,

nos quais foram indicadas as falhas que ainda persistiam nos relatórios. Nessa etapa, não houve devolutiva escrita do documento, como ocorreu na primeira entrega.

A terceira etapa consistiu em uma apresentação expositiva realizada pelos estudantes, contemplando todo o material desenvolvido, os gráficos, as análises e a relação entre os valores determinados nos cálculos e os movimentos analisados, como flexão e extensão. Ao final, o professor avaliou o conteúdo apresentado, e questionou os alunos sobre as decisões durante o projeto.

2) O desenvolvimento do projeto: Os estudantes realizaram a filmagem do movimento das duas articulações em um único plano, com marcações anatômicas aplicadas ao participante. O vídeo foi processado no software Kinovea®, no qual foram rastreados os pontos anatômicos e exportados dados em formato CSV (comma separated values), contendo as informações de posição de cada ponto em cada instante de tempo. Com os dados obtidos, foi realizada uma análise cinemática e cinética bidimensional do membro por meio de programação em Python. O fluxo de execução estabelecido pelos discentes é apresentado na Figura 2.

Na primeira etapa, foram calculados os ângulos articulares, as velocidades e as acelerações lineares dos pontos anatômicos, a partir dos quais foram gerados gráficos animados e estáticos. Também foi realizada a comparação entre os valores da análise cinemática calculada pelos estudantes e os valores determinados pelo software Kinovea®, utilizado como referência para validação.

Na segunda etapa do projeto, foi analisada a dinâmica muscular do par agonista-antagonista bíceps e tríceps braquial e sua relação com a articulação do cotovelo. A escolha do par muscular a ser estudado foi realizada pelos alunos. Nessa etapa, foram calculadas as velocidades e acelerações angulares, além das velocidades e acelerações associadas à contração muscular. Novamente, foram gerados gráficos animados e estáticos; e relações biomecânicas do movimento foram descritas e estudadas, como velocidade de contração, movimento de flexão ou extensão entre outros, relacionando-as aos valores encontrados.

Na terceira e última etapa, foi realizada a análise das forças envolvidas no modelo criado de cálculo cinético. Foram determinados os ângulos entre cada músculo e o ponto de aplicação da força, o torque necessário para o movimento, e a força exercida por cada músculo do modelo. Mais uma vez, foram elaborados gráficos e discutiu-se a relação entre esses resultados e o movimento realizado.

3) Critérios avaliativos da atividade: A avaliação de cada relatório parcial e da apresentação final baseou-se em quatro eixos:

- Apresentação e qualidade do relatório: Clareza, organização e tipo de representação gráfica dos dados, avaliando negativamente a presença de gráficos confusos ou sem legendas, e a falta de objetividade no relatório.
- Qualidade do memorial de cálculo descritivo: Abrangência conceitual, organização lógica e modelagem físico-matemática clara das equações de movimento, garantindo que o documento seja autoexplicativo para a replicação por terceiros.
- Recursos: Adequação das ferramentas didáticas utilizadas (como animações) e profundidade das referências bibliográficas adotadas.
- Criatividade e trabalho em equipe: Complexidade do movimento escolhido, inovação na apresentação e nos conceitos apresentados.

B. Atividade 02 – Aula invertida

Os alunos deveriam apresentar uma aula criativa sobre um tema de Biomecânica, integrando uma apresentação presencial a um vídeo educativo de formato livre com até 15 minutos. Além da exibição, exigiu-se a entrega de um roteiro, de material de apoio e de questões relacionadas, que foram posteriormente compartilhados com toda a turma para estudo.

1) A condução da atividade: A proposta da atividade pode ser observada no infográfico da Figura 3, que apresenta o roteiro do desenvolvimento.

A proposta do vídeo e o material de apoio foram apresentados e discutidos com os estudantes, que selecionaram um dos temas propostos. A elaboração do vídeo teve formato livre, e pôde ser desenvolvida em forma de jornal, teatro, apresentação gravada ou qualquer outra estratégia adotada pelos alunos, que foram estimulados a serem criativos. Os alunos deveriam entregar para o professor o roteiro, o relatório, as fontes consultadas e exercícios sobre o tema. Ao longo do semestre, foram realizadas aulas destinadas ao esclarecimento de dúvidas e à orientação sobre o desenvolvimento da atividade. Ao final da apresentação, o grupo aplicou o questionário sobre o tema para o restante da turma.

2) O desenvolvimento da aula invertida: O grupo, buscando maior engajamento dos discentes e aproveitando o contexto festivo do mês de junho para valorizar a cultura nordestina, optou por estruturar o trabalho no formato de literatura de Cordel. Inspirado pela possibilidade de comunicar o conteúdo de forma acessível e popular, o grupo uniu a elaboração do cordel ao conteúdo relacionado com o crescimento do tecido ósseo. A primeira etapa do projeto consistiu na elaboração do relatório técnico, que serviu de base teórica para a adaptação dos conceitos biológicos e mecânicos à linguagem literária.

A segunda etapa consistiu no desenvolvimento da construção das rimas e da métrica tradicional do cordel. No entanto, o grupo não possuía experiência prévia com esse gênero literário nem ferramentas adequadas para a criação manual de xilogravuras. Por esse motivo, optou pela utilização de ferramentas de Inteligência Artificial generativa como suporte inicial para a estruturação dos versos e para a geração das ilustrações. Foi utilizado Google Gemini, com modelo Nano Banana, para gerar imagens e ChatGPT em conjunto com Google Gemini para composição dos versos.

A Inteligência Artificial ofereceu um ponto de partida ágil para a construção dos versos; porém, os resultados iniciais não alcançaram o padrão desejado pelo grupo, pois não apresentavam o rigor estético, cultural e literário exigido pela

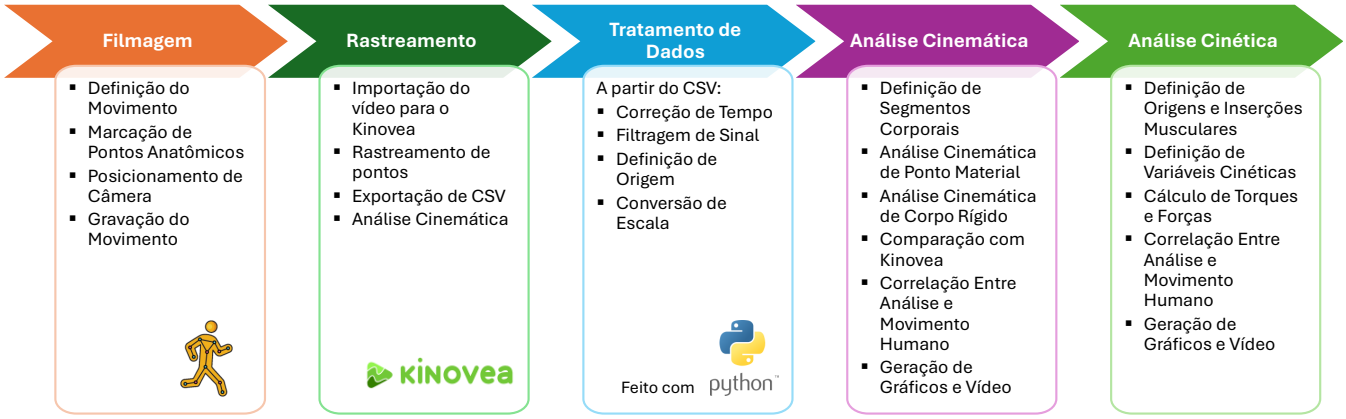

Figura 2: Fases da elaboração do projeto contínuo. Fonte: autoria própria.

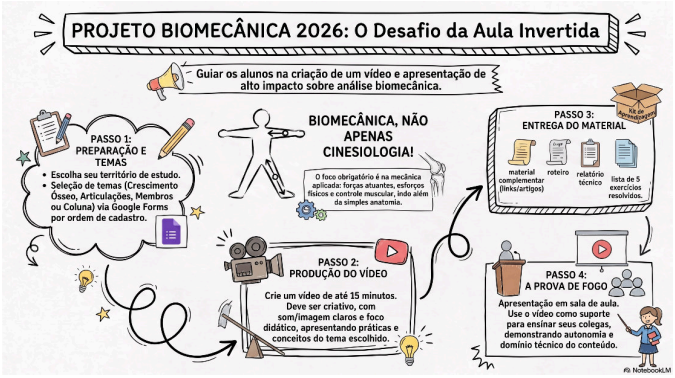

Figura 3: Roteiro da elaboração da atividade de aula invertida com vídeo. Fonte: autoria própria - Desenvolvido por IA, NotebookLM.

tradição poética. Foi necessária, portanto, uma intervenção criteriosa dos estudantes. Os versos passaram por um processo minucioso de revisão manual, no qual a equipe realizou correções de métrica, ajustes de rimas, substituições lexicais e inclusão intencional de expressões típicas nordestinas. Esse processo iterativo permitiu que a linguagem técnica sobre o comportamento mecânico dos ossos incorporasse ritmo, identidade e características próprias do cordel.

As imagens geradas inicialmente também não apresentavam a textura rústica, a identidade cultural e a expressividade próprias da xilogravura. Para compensar essa lacuna, o grupo valorizou a oralidade, elemento central dessa literatura historicamente concebida para ser cantada e declamada em voz alta diante do público. O vídeo foi narrado com sotaque típico por um discente natural do Sertão do Apodi (RN), promovendo uma imersão sonora que preservou características da apresentação dos poetas populares.

Por fim, durante a apresentação em sala, além da exibição do vídeo contendo as etapas do cordel, um dos estudantes, em referência ao legado de Luiz Gonzaga, o Rei do Baião, utilizou sua sanfona para reinterpretar o tema. Sustentando a apresentação final por voz e instrumento, o grupo articulou conceitos biomecânicos, linguagem regional e elementos da cultura popular nordestina.

3) A avaliação da atividade: Nessa atividade, realizada no meio do semestre, a avaliação foi calculada seguindo critérios específicos, descritos no documento entregue aos alunos e discutido em sala; são estes:

- Apresentação e qualidade do vídeo: Aspectos técnicos de gravação, edição, dinamismo visual e clareza de áudio.
- Qualidade do conteúdo: Profundidade conceitual com foco estrito em biomecânica aplicada, forças atuantes e torques no corpo humano, em detrimento de uma abordagem meramente anatômica ou cinesiológica tradicional.
- Recursos didáticos: Utilização de materiais de apoio inovadores para engajamento da turma, como slides, folhetos ilustrados, música, formato da apresentação entre outros.
- Relatório de produção e perguntas: Análise do material entregue, o roteiro, o relatório com o estudo realizado, a lista com os exercícios resolvidos entre outros.

Durante e após a apresentação os alunos foram questionados pelo professor da disciplina sobre os conceitos apresentados e sobre a participação de cada um.

C. Avaliação do desempenho dos estudantes

A UFRN possui sistema institucional de avaliação estudantil quanto à satisfação com as disciplinas cursadas a cada semestre. O sistema inclui avaliação da atividade docente, assim como autoavaliação do engajamento discente. Para avaliar o impacto pedagógico e a percepção discente em relação à disciplina de Biomecânica de forma longitudinal, realizou-se um estudo comparativo retrospectivo fundamentado nos relatórios do sistema de avaliação. O estudo abrangeu as quinze turmas entre 2018.1 e 2025.2, período no qual a grade curricular atual foi implementada no curso de Engenharia Biomédica. O número de estudantes por turma variou expressivamente, entre 6 e 35 alunos.

Em razão dessa variação e do baixo número de turmas analisadas, a taxa de aprovação pode não representar uma métrica robusta. Por esse motivo, o delineamento metodológico

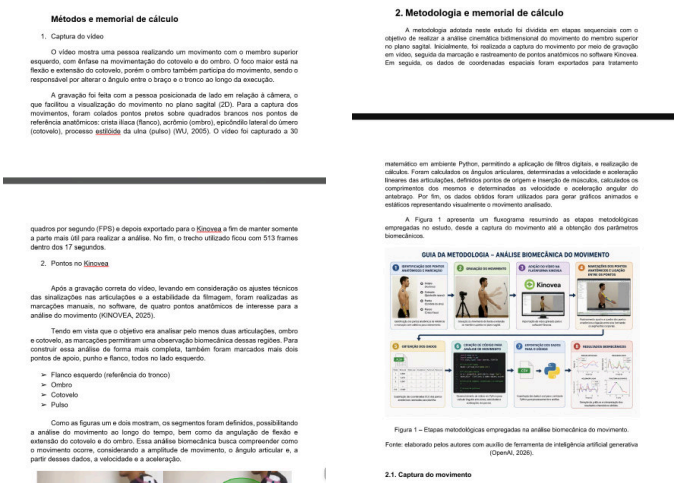
concentrou-se na evolução dos indicadores quantitativos de autoavaliação dos estudantes e de avaliação docente, combinados à análise qualitativa do conteúdo de comentários e críticas registradas nos relatórios institucionais. Dessa forma realizou-se uma análise do grau de satisfação e do engajamento dos alunos com a disciplina. Essa abordagem permitiu contrastar o período conduzido sob o modelo expositivo tradicional com a fase de implementação contínua das metodologias ativas iniciada em 2023.1.

III. Resultados e Discussão

Desde a apresentação das atividades e da divisão da turma em grupos os discentes precisaram definir objetivos, levantar requisitos, pesquisar, organizar cronogramas e tomar decisões técnicas, permitindo a aplicação integrada de conceitos abordados em diferentes componentes curriculares anteriormente cursados. Inicialmente, os estudantes passaram por um processo gradual de reconhecimento das habilidades e afinidades de cada membro do grupo, o que permitiu a divisão em sub equipes focadas em programação e elaboração de relatório. Todos os grupos evoluiram durante o decorrer do semestre e as interações entre os membros foram cruciais para um desenvolvimento ótimo das atividades.

A. Atividade 01 – Análise do movimento

Projetos acadêmicos em grupo são normalmente desenvolvidos no final do semestre, a experiência acadêmica de projeto continuado, sendo elaborado durante o semestre com conhecimentos cumulativos foi de maior complexidade organizacional para os alunos.



Durante a primeira etapa surgiram dificuldades relacionadas à falta de entendimento do problema, à falta de compreensão na comunicação entre os membros e à fragmentação das atividades, especialmente no desenvolvimento dos códigos e na escrita do relatório. A partir do primeiro *feedback* recebido do professor, de forma oral e escrita, os alunos reorganizaram o desenvolvimento e rearranjaram a estratégia de gerenciamento do projeto. Os estudantes adotaram, por conta própria, uma estratégia de gestão mais organizada e baseada em Kanban. Passaram então a realizar a definição de tarefas em tópicos, fazer o acompanhamento de pendências e realização de reuniões periódicas para alinhamento. Dessa forma, a avaliação contínua permitiu constante reiteração e adaptação do desenvolvimento do projeto.

Os resultados da experiência de aprender com base em projetos incluíram melhorias significativas na comunicação, na organização e na integração do trabalho em equipe. Os alunos relataram que a adoção de uma estrutura mais clara de divisão de tarefas possibilitou maior autonomia e melhor aproveitamento do tempo disponível. Como consequência, houve maior colaboração entre os responsáveis pela programação e pela escrita do relatório. Isso resultou em um relatório que a cada etapa ficou mais coeso, conciso e mais consistente quando comparado ao relatório inicial, além de códigos mais bem integrados com maior clareza sobre sua estruturação e capacidade de gerar os resultados apresentados no relatório. Toda a experiência proporcionou aos discentes a oportunidade de assumir o papel de executor e por consequência, sair do papel de ouvinte na turma.

Além disso, a experiência favoreceu não apenas a consolidação dos conhecimentos teóricos da disciplina, mas também contribuiu para o desenvolvimento de competências necessárias para a atuação de um engenheiro biomédico no mercado de trabalho, tais como: gerenciamento de projeto, organização de cronogramas, levantamento de requisitos, tomada de decisão, colaboração e resolução de problemas em grupo.

É interessante destacar que em sessões de *feedback* com os alunos foram levantadas discussões sobre que tipo de filtro se deve utilizar no sistema, butterworth ou o de Savitzky-Golay, pois os alunos durante a leitura da documentação do Kinovea® perceberam que o programa utiliza o segundo. Foi também observado pelos alunos a possibilidade de no cálculo da derivada numérica utilizar o método de Diferenças Finitas Centrais (DFC), ao contrário do método tradicional. Discussões essas que não seriam trazidas pelo professor em um modelo tradicional de ensino em uma disciplina de biomecânica.

Outro resultado importante é em relação a qualidade do material produzido. Do primeiro relatório para o último, é notória a diferença de qualidade, desde a capa até a qualidade de figuras e do texto como pode ser observado na Figura 4, que apresenta um recorte do primeiro relatório (4a) e do último relatório (4b) do grupo. Os relatórios são incrementais, dessa forma se utiliza do primeiro relatório para continuar a escrita para o segundo e para o terceiro. Porém o grupo entendeu a necessidade de mudanças em todo o texto durante o desenvolvimento.

(a) (b)

Figura 4: (a) recorte do início do capítulo de metodologia do primeiro relatório. (b) Recorte do início do capítulo de metodologia do último relatório. Fonte: autoria própria.

Fica claro que o desenvolvimento do projeto contínuo exigiu o resgate e progressão de conhecimentos adquiridos anteriormente em áreas diversas, como programação em linguagem

Python, análise de dados, anatomia, cinesiologia, e escrita científica. Somente a partir da integração destes, em conjunto com o conhecimento construído na disciplina de biomecânica, pôde-se desenvolver o projeto.

B. Atividade 02 – Aula Invertida

Essa experiência, apesar de não ser contínua durante todo o semestre, também contribuiu significativamente para o desenvolvimento de competências transversais exigidas na prática da Engenharia Biomédica. Competências essas que no ensino tradicional seria de difícil introdução em uma matéria como Biomecânica para Eng. Biomédica. O esforço de traduzir conceitos complexos de mecânica óssea para uma linguagem acessível e ritmada exigiu que os estudantes superassem a memorização passiva. Ao estruturarem as estrofes, os discentes precisaram dominar os fenômenos biomecânicos a ponto de conseguir explicá-los de forma acessível e popular. Essa transposição didática confirmou a eficácia das metodologias ativas em integrar o rigor científico à prática ativa.

Exemplos desse desafio podem ser observados na Figura 5 (5a) e (5b), as quais representam conceitos como o de remodelação óssea, uma sobre osteoblastos e osteoclastos (5a) e outra sobre a lei de Wolf (5b) traduzidos graficamente e na leitura do cordel.

(a) (b)

Figura 5: (a) Remodelagem óssea por meio de osteoblastos e osteoclastos, (b) Remodelagem óssea devido a tensões (lei de Wolf). Fonte: autoria própria, gerado com IA (Google Gemini).

Além do impacto pedagógico, uma reorganização do grupo também foi necessária. O uso da IA para realizar grande parte do trabalho se provou ineficiente da forma como pensado, o que levou a um maior estudo e dedicação por parte do grupo.

Diante dessas limitações, foi necessária uma intensa participação e intervenção dos alunos por meio do entendimento dos conceitos envolvidos na aula. A revisão manual dos versos pelos estudantes foi essencial para garantir a harmonia sonora exigida pelo gênero. Esse processo demonstrou na prática que a confecção autêntica do cordel exige um aprendizado que não se extrai apenas de regras gramaticais programáveis, mas de uma formação que provém do convívio, da tradição coletiva e de um saber transmitido ao longo de gerações.

No aspecto visual, a tentativa de simular ilustrações por IA revelou uma acentuada lacuna estética e identitária, sendo necessários refinos e mais refinos, nas descrições das imagens para uma textura mais rústica e com a força expressiva das metáforas visuais concebidas de forma orgânica pelos xilógrafos tradicionais. A Figura 06. apresenta imagens desenvolvidas para um mesmo tópico, mas gerados de forma diferentes e que foram adaptadas para a versão final. A Figura 6 apresenta imagens desenvolvidas para um mesmo tópico, mas gerados de forma diferentes e que foram adaptadas para a versão final.

(a) (b)

Figura 6: (a) e (b) Tentativas de representar a relação de carga e mudança óssea no desenho do cordel. Fonte: autoria própria, gerado com IA (Google Gemini).

Para suprir essa incapacidade tecnológica em reproduzir a "alma"do cordel, o grupo ancorou seus resultados práticos na força da oralidade. Dessa forma o grupo acabou desenvolvendo duas apresentações complementares com oralidades distintas, com conteúdo semelhante, mas com descrições diferentes. No cordel apresentado no vídeo foi adicionado um sotaque genuíno do sertão que narrou todo o desenvolvimento. Na apresentação em sala uma nova apresentação com nova oralidade, um cordel com performance movida a sanfona ao vivo, resgatou a atmosfera dos mercados públicos e praças onde os "poetas de bancada"interagem com a sociedade (Figura 7). O produto do trabalho tornou-se, assim, um híbrido que uniu a técnica das ciências exatas ao legado de uma cultura ancestral e conceitos técnicos e multidisciplinaridade em uma aula invertida com música e diversão.

C. Avaliação discente e Eficácia Pedagógica

A análise dos relatórios institucionais de avaliação da disciplina de 2018.1 a 2025.2 indica uma melhora positiva a partir de 2023.1, período em que as aulas puramente expositivas foram substituídas pelo projeto prático contínuo e pela sala de aula invertida. Conforme pode ser observado na Figura 8, os índices médios de autoavaliação e percepção docente (medidos de 0 a 10) eram de 8,6 e 7,8 respectivamente, e mudaram para 9,1 e 9,1 após a inserção da metodologia. Pode-se observar que os discentes chegaram a relatar um índice de engajamento estudantil superior a 9,5 em mais de uma ocasião.

Essa análise quantitativa deve ser seguida em trabalhos futuros de uma análise qualitativa do engajamento, da motivação e da satisfação geral dos alunos, visto que há uma grande variedade no número de alunos regulares e poucos semestres especificados, o que impossibilita uma análise estatística completa.

Ao se analisar o engajamento, por meio da participação em sala, e a motivação e a satisfação por meio dos comentários registrados nos relatórios institucionais de avaliação, essa

Figura 7: Apresentação em sala do cordel. Fonte: autoria própria.

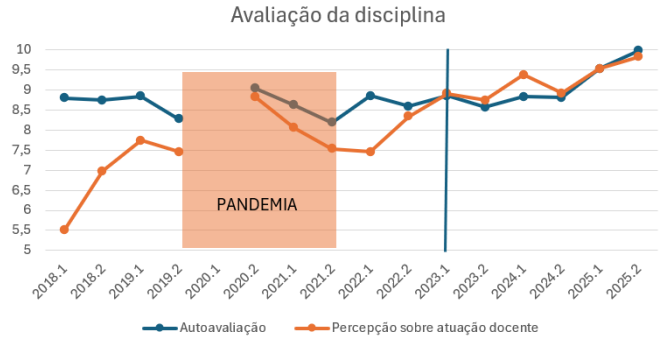


Figura 8: Gráfico de avaliação da disciplina ao longo dos anos. Fonte: autoria própria.

percepção e melhoria se amplia. Nos registros do período anterior ao modelo adotado em 2023.1, predominavam, na análise dos relatórios relatos de sobrecarga e descontentamento didático, evidenciados em apontamentos de que as atividades *"superlotam a agenda do aluno, mas pouco contribuem para a efetividade do ensino"* (2021.1) e críticas de que *"apesar de ter total conhecimento do assunto, o professor demonstrou uma didática pouco efetiva"* (2022.1).

Com as metodologias ativas, as críticas de natureza pedagógica foram superadas. Ocorreram críticas iniciais em relação a ajustes operacionais, para adaptações ao desenvolvimento do projeto. Em 2024 e 2025 as críticas foram substituídas por avaliações espontâneas de reconhecimento, culminando no registro de que a disciplina *"foi a melhor matéria do meu semestre"* (2025.1). Essa mudança no teor dos depoimentos demonstra que, apesar da impossibilidade de comprovação estatística na melhoria do ensino, a mudança de metodologia promoveu um ambiente de aprendizagem mais engajado, participativo e colaborativo.

IV. Conclusões

A experiência apresentada sugere que a utilização desses dois modelos de metodologias ativas (PBL e Aula invertida), contribuíram para aumentar o engajamento, a motivação e satisfação dos alunos durante o curso. As atividades possibilitaram a integração teoria-prática, fazendo interface com a interdisciplinaridade e aumentando o interesse e participação dos alunos.

O desenvolvimento dessas atividades exigiu a aplicação integrada de conhecimentos de diferentes disciplinas, isso gerou novos aprendizados que foram além do escopo inicial da disciplina.

A experiência contribuiu para o desenvolvimento de habilidades e competências importantes para a atuação do engenheiro biomédico, como planejamento, organização, trabalho em equipe, comunicação, pesquisa, resolução de problemas e tomada de decisão. As entregas parciais e os *feedbacks* contínuos também possibilitaram ajustes durante a execução do projeto, tornando o processo de aprendizagem mais reflexivo e colaborativo.

Este relato, em conjunto com a análise qualitativa do engajamento da motivação e satisfação dos alunos, indica que está ocorrendo uma melhora no andamento da disciplina após sua reformulação. Espera-se que esta experiência possa servir como referência para a implementação de estratégias semelhantes em disciplinas da Engenharia e contribuir para futuras discussões sobre inovação no ensino superior principalmente em disciplinas com uma alta carga técnica de física e matemática.

Nota sobre o uso de Inteligência Artificial

Durante a elaboração deste texto, ferramentas de Inteligência Artificial foram utilizadas como apoio à revisão linguística, à organização das ideias, à reestruturação de trechos e ao aprimoramento da clareza textual. O uso dessas ferramentas ocorreu de forma auxiliar, sem substituir a análise crítica, a autoria intelectual e a responsabilidade dos autores pelo conteúdo apresentado. Todas as informações, interpretações e decisões finais foram revisadas, ajustadas e validadas pelos autores, garantindo a coerência acadêmica, a adequação ao objetivo do trabalho e a preservação da originalidade do relato.

***Abstract*—The objective assessment of cognitive load in educational environments remains a methodological challenge due to high inter-individual variability. This work presents a pilot study functioning as a proof of concept to evaluate the preliminary technical feasibility of using a Brain-Computer Interface (BCI) for real-time monitoring during audiovisual instruction in a second language. An Emotiv EPOC X device and a Python-based architecture were used to record the electroencephalographic (EEG) signals of nine participants in an ecologically realistic laboratory environment. To mitigate ocular artifacts, the neurophysiological Frontal Theta / Parieto-Occipital Alpha index was implemented. The analysis using robust statistical estimators revealed significant inter-subject variability and a significant correlation (Spearman rank correlation coefficient = 0.85, p-value = 0.006) between the baseline and the task Theta/Alpha index, suggesting possible limitations of relying on static group metrics. The system integrated personalized dynamic thresholds, identifying candidate episodes of increased cognitive demand in an average of 17.75% of the instruction time. These threshold exceedances should be interpreted as preliminary evidence of individualized monitoring feasibility, not as definitive cognitive overload. The results suggest that individualized calibrations provide a methodological advantage in educational BCIs and expose the potential susceptibility of short baselines to anticipatory anxiety, emphasizing the need for behavioral ground-truth validations in future educational neurotechnology applications.**

***Index Terms*—Cognitive Load, EEG, BCI, Emotiv EPOC X, Second Language, Neuroeducation, Dynamic Threshold.**

I. Introduction

Learning novel concepts in a foreign language imposes a high extrinsic and intrinsic load on a person's working memory [1]. The difficulty in real-time monitoring of when a student reaches their cognitive limit often results in a decrease in academic performance. Traditionally, the evaluation of this effort has been performed using deferred questionnaires, such as the NASA-TLX [2]. However, advances in neurotechnology make the exploration of continuous mental state measurement viable [3].

Electroencephalographic (EEG) signals offer direct access to attentional states [12], [13]. Several studies [14], [15] have used the frontal Beta/Alpha ratio in EEG signals; however, such an approach is susceptible to contamination by muscular (electromyography-EMG) and eye (electrooculography-EOG) artifacts, especially eye blinks [4]. Current literature suggests that verbal working memory demand is more robustly reflected in the ratio between Theta (4–8 Hz) in the frontal, and Alpha (8–12 Hz) in parieto-occipital areas [5]–[7].

The main methodological contribution of this work is to present a proof of concept for the implementation and critical analysis of a neurofeedback platform developed using the Emotiv EPOC X device [8]. Unlike approaches based on static universal metrics, this study explicitly evaluates the technical advantage of individualized dynamic thresholds to monitor transient episodes of increased cognitive demand in an ecologically valid environment [9]. By proposing robust statistical estimators over traditional mean-based thresholds, it aims to better account for inter-individual variability and identify methodological boundaries regarding physiological interpretations when behavioral ground truth is absent.

II. Methodology and System Design

The system is based on a modular Front-end and Back-end architecture for the acquisition and digital processing of EEG (Fig. 1).

A. Theta/Alpha Index Processing

EEG acquisition was performed using the Emotiv EPOC X with a sampling frequency of 128 Hz. The device features 14 EEG channels positioned according to the international 10-20 system. The Band Power stream is calculated internally through Fast Fourier Transform (FFT) applying a 2 s Hanning window. To isolate cognitive effort from muscular noise, the pipeline extracts spectral power as follows:

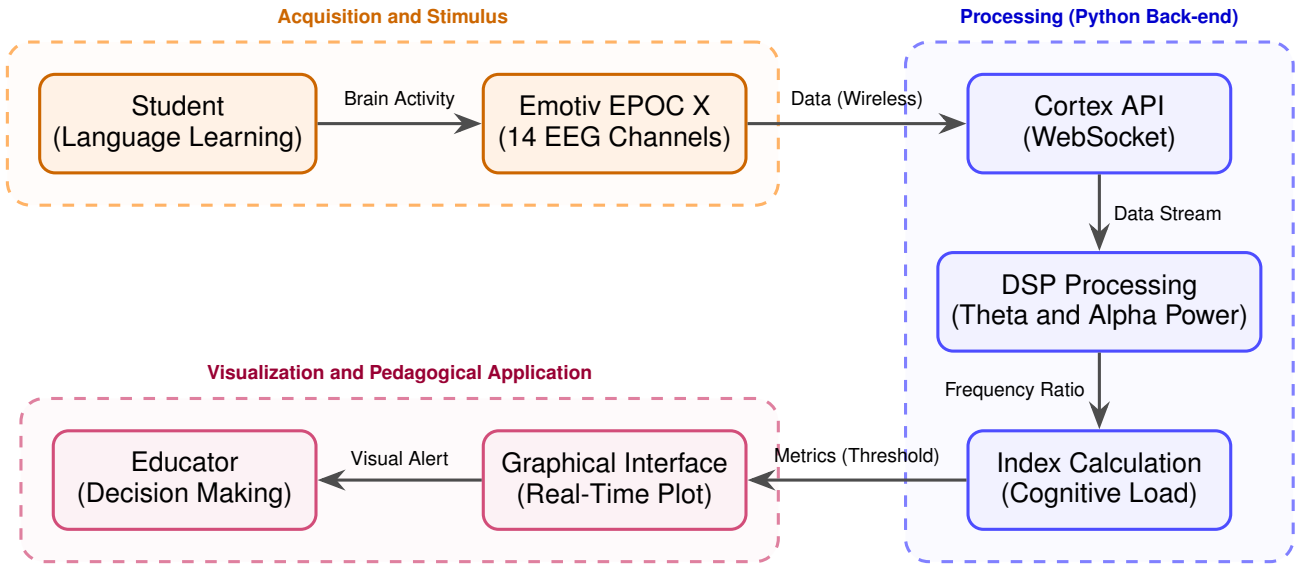

Fig. 1. Block diagram of the cognitive load assessment system architecture.

1) **Frontal Load (Theta):** The spectral band in frontal channels (AF3, F3, F4, AF4) is averaged, theoretically associated with mental effort.
2) **Posterior Processing (Alpha):** Activity in parieto-occipital channels (P7, O1, O2, P8) is averaged, linked to working memory.
3) **Threshold Calculation:** Given the non-normal distribution of the biometric data, the system established an adaptive threshold based on robust estimators (Median$+$ $1.5 \times$ MAD), where MAD represents the Median Absolute Deviation, calculated during the first 60 s of the user's baseline. The factor 1.5 was selected as a heuristic to define individualized exceedances; it is not intended as a formal statistical cutoff.

For each subject, the instantaneous Theta/Alpha ratio was smoothed with a 16-sample moving average. Values exceeding 1.5 interquartile ranges (IQR) beyond that subject's own first or third quartile were then clipped to the corresponding outlier boundary (MATLAB `filloutliers`, quartile method), prior to computing that subject's robust baseline and task statistics.

B. Participants and Ethical Considerations

This pilot study included 9 independent university students (19 to 25 years old) without diagnosed neurological disorders. The sample integrated native Spanish and Portuguese speakers with an English intermediate-advanced level (B1 or higher) as a second language, ensuring comprehension of the stimulus. Participants were informed about the nature of the test and signed an informed consent form, guaranteeing the confidentiality of their biometric data.

C. Stimulus and Experimental Environment

To induce a double cognitive load (linguistic processing and assimilation of technical concepts), the English video *"ALL OF PHYSICS explained in 14 Minutes"* was used. Prioritizing ecological validity—defined here as an experimental design aiming to better approximate the conditions of a natural learning environment outside of a sterile, soundproof booth [9]—the experiment took place in a shared classroom condition. Each session lasted 16 min: 1 min of basal calibration followed by 15 min of stimulus. During the 60-second baseline, participants remained seated with eyes open and were instructed to relax and prepare to watch the video. Fig. 2 presents the average temporal evolution of the ratio.

D. Statistical Analysis

To address the non-normal distribution typical of EEG signals, non-parametric statistical measures were implemented [11]. The Wilcoxon signed-rank test was used to compare baseline and task medians. Spearman correlation was used to assess the association between baseline and task Theta/Alpha index. Effect sizes were estimated per subject as a robust Cohen's d, defined as the standardized median difference between task and baseline Theta/Alpha values, using a pooled estimate of the median absolute deviation (MAD) from both conditions.

III. Results

The descriptive analysis of the Theta/Alpha index was performed using robust statistical estimators (Fig. 3). The Jarque-Bera test applied to the baseline medians did not follow a normal distribution ($p = 0.018$), justifying the use of the median and MAD. Extreme inter-individual variability was observed, with a basal median interquartile range (IQR) of 6.29.

The comparison of the basal median against the instruction task using the Wilcoxon signed-rank test did not reveal a significant global increase ($W = 17.0$, $p = 0.570$). An approximate retrospective power analysis based on a paired

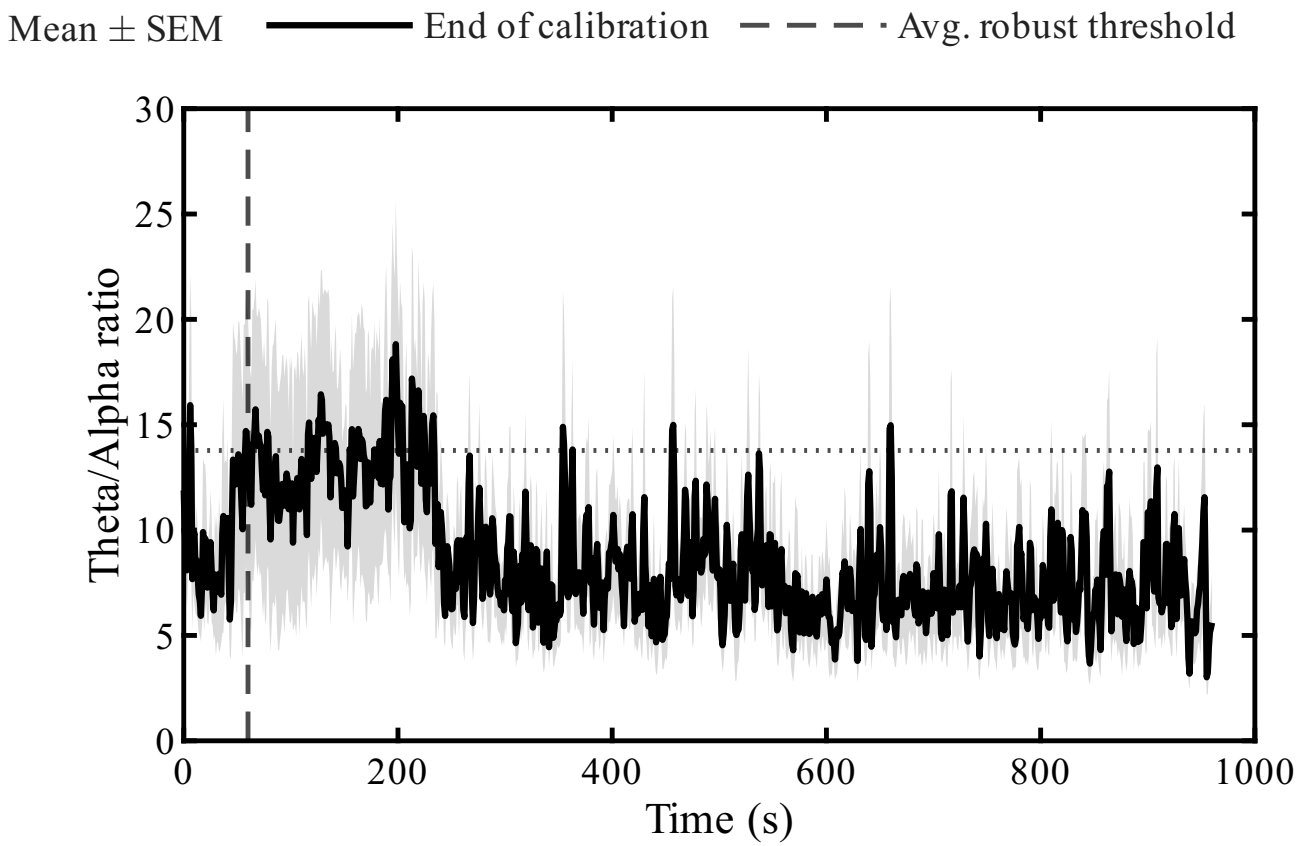

Fig. 2. Average temporal evolution of the Theta/Alpha ratio ($n = 9$). The shaded band represents ± 1 Standard Error of the Mean (SEM). The solid black vertical line indicates the end of calibration; the dashed line shows the average robust threshold.

Table I
INDIVIDUAL METRICS USING ROBUST THRESHOLDS BASED ON THE MEDIAN AND MAD.

Subject	Threshold	Median (Task)	Time > Thresh. (%)	Cohen's d
S01	2.73	1.16	9.6%	-0.95
S02	4.00	1.72	10.6%	-0.74
S03	17.54	9.52	22.1%	0.18
S04	40.77	13.06	18.8%	-1.65
S05	17.92	12.43	21.1%	0.13
S06	13.30	3.18	0.0%	-1.73
S07	8.17	2.65	0.0%	-2.07
S08	6.96	3.70	22.7%	0.11
S09	12.62	13.45	54.8%	1.33

t-test model indicates that, with $n = 9$, this study had approximately 26% power to detect a medium effect ($d = 0.5$) and 56% power to detect a large effect ($d = 0.8$) at $\alpha = 0.05$; a sample of approximately 33 participants would be required to reach 80% power for a medium effect. Although this approximation assumes normality, it provides a useful reference for interpreting the null result. The non-significant Wilcoxon result should therefore be interpreted as inconclusive rather than as evidence of no change between baseline and task. Despite the overall stability of the median, the system detected that users crossed their personalized dynamic threshold in an average of 17.75% of the instruction time (Table I).

A key statistical finding was the Spearman correlation test, demonstrating a strong positive association between the basal median and the task median ($\rho = 0.85$, $p = 0.006$), as shown in Fig. 4. This correlation supports the individual stability of the index across the transition from rest to cognitive effort, although it may alternatively indicate that the index is influenced by trait-like individual factors (e.g., baseline cortical activity, electrode impedance) rather than purely reflecting task-induced cognitive state changes.

IV. DISCUSSION

This study demonstrated the preliminary technical feasibility of using dynamic thresholds in environments with ecological validity, providing important methodological insights for computational neuroeducation.

It is important to distinguish the constructs potentially reflected in the Theta/Alpha index. Frontal theta has been associated with working memory engagement and cognitive effort, while parieto-occipital alpha is more closely linked to visual attentional allocation [5], [6]. Neither directly indexes learning outcomes, and both are also sensitive to arousal and affective state, including anxiety. Consequently, an increase in the Theta/Alpha ratio observed in this study is best interpreted as a marker of increased neural engagement or spectral vari-

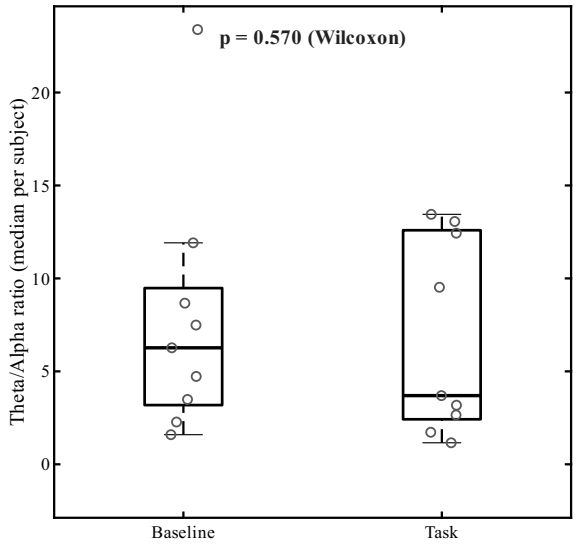

Fig. 3. Comparison of the Theta/Alpha ratio median distribution per subject in the baseline and during the task ($p = 0.570$, Wilcoxon).

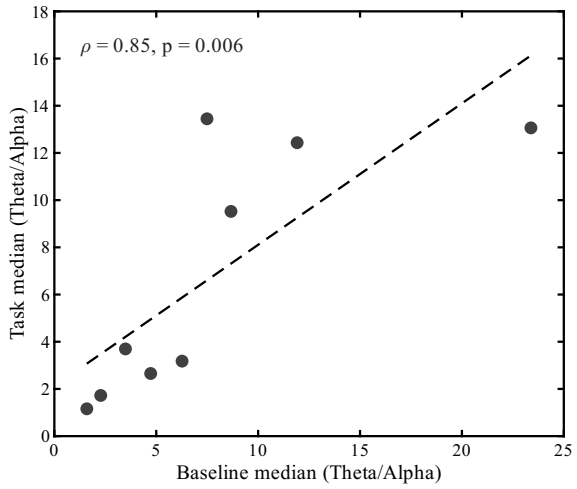

Fig. 4. Scatter plot of baseline versus task Theta/Alpha medians. The dashed line represents a linear least-squares fit for visual reference; the reported correlation is Spearman's $\rho = 0.85$, $p = 0.006$.

ation, which may reflect cognitive effort, attentional shifts, or anticipatory stress — constructs that are not distinguishable using this single index alone.

The absence of a statistically significant increase in the group's cognitive load index ($p = 0.570$, though likely underpowered as noted above) and the descriptively observed reduction of task medians compared to baselines raise the plausible hypothesis of an anticipatory anxiety effect. Anticipatory anxiety, linked to stress regulation when an individual expects an impending evaluation [10], might artificially elevate baseline activity. Upon starting the video, students may have transitioned into a more stable attentional state. While this aligns with literature suggesting pre-task EEG states can be contaminated by expectation stress, it remains a hypothesis requiring validation through subjective scales or heart rate monitoring. To minimize this effect in future protocols, strategies such as a 3-to-5 minute acclimatization period prior to baseline recording should be implemented.

The strong basal-task correlation ($\rho = 0.85$) supports the core premise of this work: marked inter-individual variability suggests caution when imposing universal "group thresholds", although this study does not directly compare individualized versus group-threshold performance. Because an individual's resting state heavily influences their operational baseline, the dynamic parameterization (Median $+ 1.5 \times$ MAD) emerges as a plausible engineering approach to capture transient variations (average 17.75% time above threshold) during complex academic stimuli. Exceeding this statistical threshold indicates spectral variation, though it does not automatically equate to cognitive overload.

It is imperative to acknowledge the limitations of this pilot study. First, the small sample size ($n = 9$) restricts statistical generalization. Second, the use of a single experimental activity limits the extrapolation of the results to other pedagogical formats. Third, reliance on Band Power values provided by the commercial API acts as a "black box", severely limiting control over fundamental preprocessing steps such as frequency filtering and advanced artifact rejection techniques like Independent Component Analysis (ICA). Finally, the absence of behavioral measures of learning or subjective questionnaires (e.g., NASA-TLX) prevents unequivocally linking EEG peaks with actual mental saturation.

Sensitivity analyses across baseline durations and test-retest reliability could not be conducted in this pilot, as each participant completed a single session with one fixed 60-second baseline; these analyses require a dedicated multi-session protocol and are identified as priority next steps (Section V).

Lessons Learned and Research Gaps

This pilot study highlights that ecological BCI protocols must account for pre-task psychological stressors, as short immediate baselines are easily corrupted by anticipatory anxiety. A critical lesson learned is that static, universal thresholds may be poorly suited to educational settings due to extreme inter-subject variability. Consequently, a significant research gap exists in standardizing dynamic, individualized baselines. Future research must bridge this gap by combining these dynamic EEG thresholds with behavioral learning metrics and raw signal processing to ensure accurate pedagogical monitoring.

V. Conclusion and Future Works

This study demonstrated the preliminary feasibility of a proof-of-concept system for individualized EEG monitoring in an ecologically valid educational environment. The robust non-parametric statistical threshold (Median$+1.5\times$MAD) provided a methodological alternative for individualized monitoring under high population variability. This preliminary evidence suggests potential advantages over static group metrics, but direct comparative validation is still required. The results suggest that ecological protocols utilizing short 60-second baselines

are susceptible to anticipatory anxiety biases, indicating that the true pedagogical utility of this marker requires deeper, multi-modal investigation.

As future work, the statistical sample must be expanded to include behavioral validations of acquired knowledge and subjective cognitive load surveys to establish a reliable ground truth. Additionally, sensitivity analyses across different baseline durations and threshold definitions will be conducted to optimize the calibration period. Regarding signal processing, a critical transition will be made to extracting raw EEG data to apply ICA algorithms, optimizing the BCI's diagnostic precision and artifact rejection capabilities for its eventual integration into intelligent tutoring systems.

***Abstract*—Tensile testing machines are used to characterize polymers, membranes and scaffolds relevant to Biomedical Engineering, but commercial equipment is expensive and often unavailable in teaching laboratories. This paper reports the design, construction and experimental testing of a low-cost horizontal tensile testing machine assembled from 3D-printed parts, an aluminum structural profile and off-the-shelf electronics. The machine uses a NEMA 23 stepper motor coupled to a TR12 trapezoidal lead screw of 8 mm lead, an S-type load cell with an HX711 24-bit amplifier, and an Arduino Mega 2560 controlled from a PyQt6 interface that records force and crosshead displacement and computes stress, strain and the elastic modulus from the specimen geometry. The mechanical and electronic architecture, the open bill of materials, the published CAD models and source code, and a costed build of approximately R$ 3,702 (2026 prices) are presented. Three specimens whose geometry was defined experimentally — a rigid PVC strip, an HDPE strip and an elastomeric ring — were tested to failure with a 40 mm free length between grips, and the recorded curves reproduce the behaviour expected for a brittle polymer, for a semi-crystalline polymer with yielding and cold drawing, and for a hyperelastic material. The computed moduli span roughly four orders of magnitude across the three materials and place them in the correct relative order, showing that stiffness, strength, deformability and toughness are distinct properties and that the same acquisition chain resolves material classes that differ widely in stiffness.**

This work was supported by the Brazilian National Council for Scientific and Technological Development (CNPq) through a research scholarship, and by the National Institute of Telecommunications (Inatel).

I. Introduction

Mechanical characterization requires instrumentation capable of relating an applied force to the resulting deformation of a specimen. Tensile testing machines produce the stress–strain curve, from which the elastic modulus, the yield strength and the tensile strength are obtained [1]. In Biomedical Engineering this is relevant for polymeric materials used in devices, implants, membranes and scaffolds for tissue engineering, whose mechanical behaviour affects clinical performance.

A. Problem and motivation

Professional tensile testing machines are expensive for two main reasons. Most commercial models are universal machines able to perform tensile, compression, bending and fatigue tests, which increases complexity; and industrial-grade frames must be stiff enough that their own deformation does not corrupt the measurement, which requires costly components. This equipment is therefore frequently out of reach for teaching institutions and small laboratories, where contact with mechanical testing is limited by availability. A low-cost machine lets students observe stress, strain, the elastic regime, yielding and rupture directly; the present work targets low-strength materials, mainly polymers.

B. Related low-cost initiatives

Several groups have published simplified prototypes. An Arduino-based uniaxial tensile tester built for under one hundred dollars has been reported for teaching mechanical properties and characterizing soft materials, including biomedical applications [2]. Educational tensile testing machine projects are also documented in Brazilian teaching material [3]–[5].

Fig. 1. Instron 3400 Series dual-column universal testing system, a currently marketed commercial machine of the type discussed in this section, with capacities from 500 N to 300 kN.
Source: Instron [10].

As the main constructive reference, this project adopted an extensively documented open-source horizontal model [6].

C. Contributions

The contributions of this work are: (1) a reproducible horizontal tensile testing machine architecture, with an open bill of materials, published CAD models [7] and published firmware and interface source code [8]; (2) a costed build under 2026 Brazilian market conditions, with the reference year and exchange rate stated explicitly; (3) tensile tests on three polymer specimens, recorded on video [9], with the resulting curves and computed quantities; and (4) an analysis of those results relating the observed behaviour of each material to the mechanical properties the stress–strain curve is meant to expose.

II. Related Work

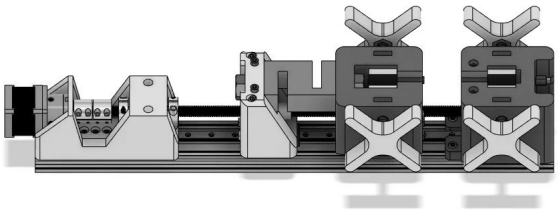
A. Commercial testing machines

Commercial tensile testing machines from manufacturers such as Instron (Fig. 1) [10], Shimadzu and EMIC are used in industrial and research laboratories because they provide verified force accuracy, repeatability and compliance with testing standards, such as ASTM D638 for plastics [11] and ASTM E8/E8M for metals [12]. Their force-measuring systems are periodically verified according to ISO 7500-1 [13], and strain is normally measured with a class-rated extensometer [14] rather than inferred from crosshead motion. In the Brazilian market, prices range from about R$ 4,300 for manual benchtop models to more than R$ 40,000 for automated universal machines [15].

B. Low-cost models studied

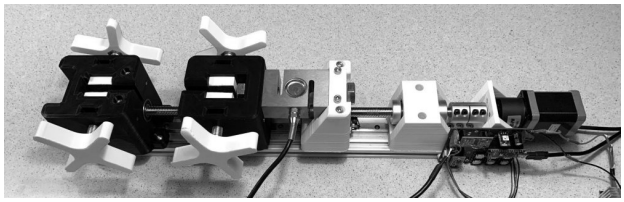
Two low-cost models were analysed during development: a vertical prototype previously available in the institution's laboratory (Fig. 2), and the open-source horizontal model of [6] (Fig. 3).

Fig. 2. Vertical testing machine model previously available in the laboratory, used as a case study.
Source: The authors (2025).



1) Previous vertical model — case study: The first model was used only as a source of design problems to avoid. Two vertical wooden pillars carried a movable upper grip connecting the specimen to the load cell, actuated by a conventional (non-stepper) motor with belt transmission, driven from an Arduino Uno through a relay. A conventional motor rotates continuously, so position and speed cannot be commanded and displacement control would depend entirely on external sensing; the wooden frame has low axial stiffness compared to metal profiles; and the vertical orientation makes alignment between the load axis and the cell harder to guarantee. These limitations motivated the move to a stepper-driven horizontal architecture.

2) Reference horizontal model — constructive basis: The second model [6] was adopted as the direct constructive basis. It shares the mechanical architecture used here: a carriage moving along a linear guide, driven by a lead screw and nut rotated by a stepper motor. In its original form it uses a NEMA 17 stepper with a planetary gearbox and a 500 kg–1 t S-type load cell, and two microcontrollers — one for machine control and an ATtiny85 dedicated to load cell acquisition. The adaptations made here are summarized in Table I: a direct-drive NEMA 23 stepper (3 N m), a TR12 trapezoidal lead screw of 8 mm lead, control centralized in a single Arduino Mega 2560 with a TB6600 driver, and a computer graphical interface written from scratch, replacing the stand-alone button-and-display operation of the original.



III. System Design

A. Mechanical design

The machine is built on a structural aluminum profile ($20 \times 60\,\mathrm{mm}$, channel 6) that acts as base and structural reference. Linear displacement is guided by a 15 mm linear guide with two carriages. One end holds the stationary grip; the opposite end holds the moving grip. Both grips are 3D-printed jaws tightened by wing screws, which allows the clamping force to be adjusted and specimens of different thicknesses to be accommodated. An S-type load cell is mounted between the moving grip and the carriage, through the moving load cell mount, so that the cell travels with the moving grip and the

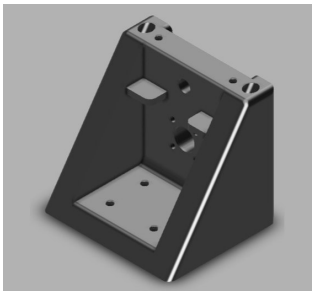
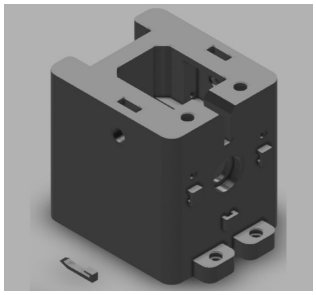
whole load path (stationary grip, specimen, moving grip, load cell, carriage) passes through it.

Actuation is provided by a stepper motor at the end of the rail, whose shaft is connected through a rigid coupling to a TR12 trapezoidal lead screw with a *lead* of 8 mm per revolution. The lead, not the thread pitch, sets the displacement per revolution in (2). The screw spans the full length of the frame and passes through the moving assembly, so that the load path stays coaxial with the rail over the whole stroke. A nut mounted on the carriage converts screw rotation into linear travel of the moving grip.

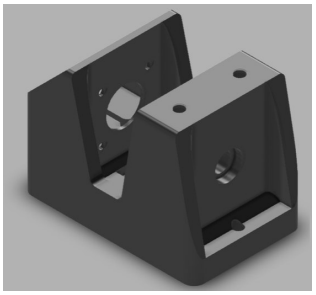


The maximum axial force the actuator can produce follows from the screw relation

$$F_{\max} \approx \frac{2\pi\,\eta\,T}{L_s}, \tag{1}$$



where T is the motor torque, L_s the screw lead and η the screw



(a) moving grip.

(b) moving load cell mount.

(c) stationary grip.

(d) stepper motor mount.

Fig. 4. Main parts designed in CAD and 3D printed. Source: The authors (2026).

efficiency. With $T = 3\,\mathrm{N\,m}$ and $L_s = 8\,\mathrm{mm}$, this gives about 707 N for a typical unlubricated trapezoidal screw ($\eta \approx 0.3$). Reducing the lead relative to the reference design increases the force available at a given torque and halves the displacement per step, at the cost of a lower maximum crosshead speed. Three protections are implemented: a software force limit, a maximum-displacement stop, and a physical emergency button.

1) 3D-printed components: A large part of the functional structure consists of parts designed in Autodesk Fusion 360 and manufactured by fused-filament 3D printing, which lowers cost and makes reproduction easier. Fig. 4 shows the main parts: the moving grip, which holds the moving end of the specimen; the moving load cell mount, which connects the cell to the carriage; the stationary grip, which holds the fixed end; and the stepper motor mount, which fixes the motor and aligns its shaft with the screw. A grip block completes the jaw assembly. All CAD models are publicly available [7].

B. Control and acquisition system

The control system has three loosely coupled layers: the graphical interface (frontend) and the orchestration logic (backend), both on the computer, and the firmware in the microcontroller, linked by a USB serial connection at 9600 bit/s. Widgets expose Qt signals and contain no hardware logic; the main window connects those signals to the controller, which is the single coupling point between frontend and backend; the controller translates them into commands for the serial bridge, which converts command enumerations into bytes. Fig. 5 shows the layers and the data flow. The repository also includes a mock firmware that emulates the hardware

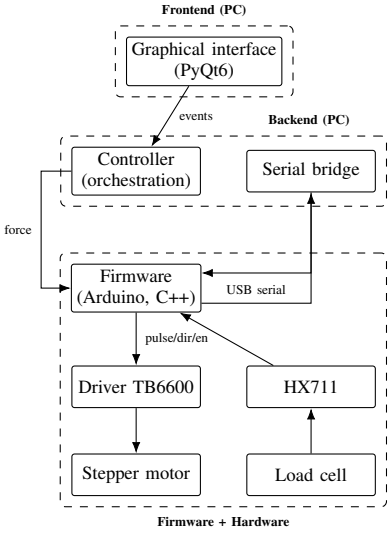


Fig. 5. Block diagram of the control and acquisition system, in three layers, with the interface decoupled from the hardware.
Source: The authors (2026).

Fig. 6. Settings tab of the control interface, showing the manual grip control, the serial connection and the entry of the specimen geometry.
Source: The authors (2026).

responses, allowing the interface to be exercised without the machine, and continuous-integration workflows [8].

1) Electrical system: An Arduino Mega 2560 generates the logic control signals, and a TB6600 driver converts them into coil current, isolating the control circuit from the power circuit. Force is measured by an S-type load cell connected to an HX711 module, a 24-bit ADC dedicated to bridge sensors. The main components are: Arduino Mega 2560; TB6600 stepper driver; NEMA 23 stepper motor with step angle of 1.8° (200 full steps per revolution), 3 N m torque, 3 A per phase, 3.9 V rated and 8 mm shaft; HX711 amplifier; S-type load cell; and a 12 V, 5 A supply.

2) Control interface: The interface was written in Python with PyQt6 [8]. It has two tabs. In the settings tab the operator jogs the grips manually, enters the specimen geometry (cross-section type and dimensions, and free length) and configures the stop conditions: maximum load, maximum displacement, or manual stop (Fig. 6).

In the test tab, force versus displacement and stress versus

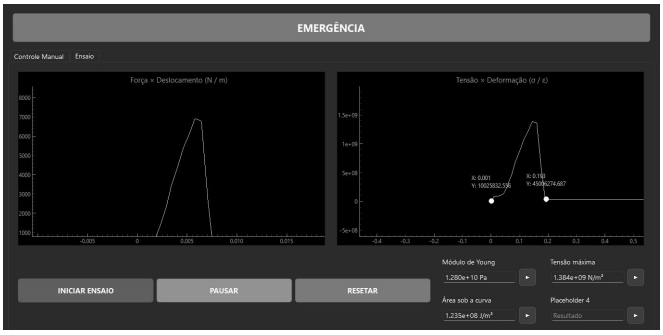

Fig. 7. Test tab of the control interface during an acquisition, with the force–displacement and stress–strain plots and the numerical indicators.
Source: The authors (2026).

strain are plotted in real time, together with numerical indicators for the elastic modulus, the maximum stress and the area under the curve, and the record can be exported. An always-visible emergency control stops the drive (Fig. 7).

3) Firmware: The firmware runs a non-blocking state machine based on `millis()` rather than `delay()`, so that command parsing, step pulse generation and load cell reading proceed concurrently. Its states are idle, up and down (manual grip adjustment), and test, in which the motor advances while the load cell is read every 50 ms and the value is streamed to the computer. Each command travels as a single byte over the serial port. The emergency button is served by a hardware interrupt on a dedicated pin, so the drive stops regardless of the current state and without depending on the main loop.

IV. Cost of the Build

Table II lists the items purchased and printed for this prototype, separated into electromechanical components and manufacturing of the 3D-printed parts. All prices are the amounts paid in the Brazilian domestic market during the first half of 2026; the reference exchange rate was R$ 5.10 per US dollar [16]. The component subtotal is R$ 1,558.32 and the total build cost is R$ 3,701.53.

Two aspects deserve comment. First, the manufacturing line exceeds the whole component subtotal. This is not a filament-material cost: the parts were produced through an outsourced printing service, so the figure includes machine time and labour. A laboratory with its own printer would replace this line by the filament mass alone. Second, the reference project reports about US$ 200 [6], and converting that figure does not reproduce the cost of building the same machine in Brazil, since import duties, freight and retail margins raise component prices and the NEMA 23 motor adopted here is more expensive than the geared NEMA 17 of the original. The build cost is below the entry price of commercial benchtop machines in the same market [15], but that is a comparison of purchase price, not of capability.

TABLE II
PROTOTYPE ITEMS AND COSTS (BRL, 2026 PRICES)

Item	Qty.	Total (R$)
Electromechanical components		
NEMA 23 stepper motor	1	229.00
15 mm linear guide kit + 2 carriages	1	261.90
Aluminum profile 20 × 60 (600 mm)	2	166.04
Arduino Mega 2560 board + cable	1	159.90
TR12 trapezoidal lead screw + nut	1	101.46
T-slot nut kit M3/M4/M5	1	65.25
Stainless Allen screw kit M3/M4/M5	1	72.48
Breadboard, 1660 points	1	48.90
Rigid coupling 8 × 12 mm	1	48.00
Ball bearings	3	43.77
Emergency button	1	34.99
Jumper cable kit	1	31.47
Step-down voltage regulator	2	33.40
Structural M5 screws (100 and 120 mm)	2	103.81
M12 nuts and bolts	2	46.57
M8 wing screw kit	1	23.99
12 V power supply	1	23.99
Kit of 10 adapters for 12 V supply	1	20.79
HX711 module	1	19.61
Stepper driver	1	23.00
Component subtotal		**1,558.32**
Manufacturing		
3D-printed parts (outsourced printing service)	–	2,143.21
Total		**3,701.53**

V. DATA REDUCTION

A. Commanded displacement resolution

The displacement commanded per microstep follows from the screw lead, the motor step count and the driver microstepping factor:

$$\Delta x = \frac{L_s}{N_{\text{steps}} \times \mu}, \tag{2}$$

where $L_s = 8\,\text{mm}$ is the lead, $N_{\text{steps}} = 200$ the full steps per revolution and μ the microstepping factor. With $\mu = 16$ the commanded increment is 2.5 µm. This is a commanded increment rather than a measured positioning accuracy, since backlash in the screw–nut pair and any lost steps are not captured by (2).

B. Stress, strain and modulus

Engineering stress is computed from the measured force F and the initial cross-sectional area A_0 [1], and engineering strain from the crosshead travel Δx and the free length L_0:

$$\sigma = \frac{F}{A_0}, \qquad \varepsilon = \frac{\Delta x}{L_0}. \tag{3}$$

Because Δx is taken at the crosshead, it also contains the elastic deflection of the frame, of the grips and of the printed parts, and any slip of the specimen in the jaws. Writing C_m for the machine compliance and δ_s for the slip, the specimen strain is

$$\varepsilon_{\text{sp}} = \frac{\Delta x - C_m F - \delta_s}{L_0} \;\leq\; \varepsilon. \tag{4}$$

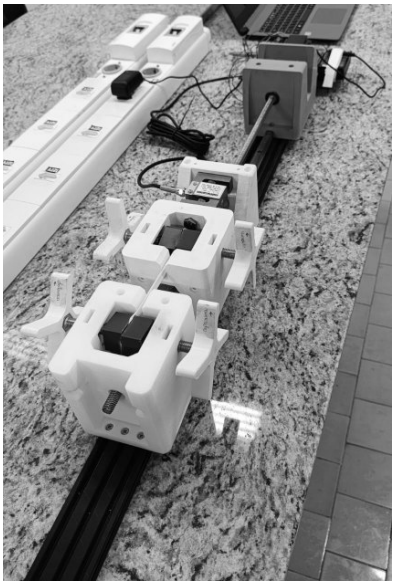

Fig. 8. Assembled prototype during a test, with an elastomeric ring mounted between the 3D-printed grips. From front to back: stationary grip, moving grip, S-type load cell, trapezoidal lead screw and NEMA 23 stepper motor on the aluminum profile.
Source: The authors (2026).

The elastic modulus is the slope of the initial linear portion of the stress–strain curve, obtained by a least-squares fit over a declared strain interval $[\varepsilon_1, \varepsilon_2]$ rather than from a single-point ratio:

$$E = \frac{\sum_i (\varepsilon_i - \bar{\varepsilon})(\sigma_i - \bar{\sigma})}{\sum_i (\varepsilon_i - \bar{\varepsilon})^2}, \qquad \varepsilon_i \in [\varepsilon_1, \varepsilon_2]. \tag{5}$$

The indicator labelled area under the curve is the trapezoidal integral $u = \int_0^{\varepsilon_f} \sigma \, d\varepsilon$, in energy per unit volume.

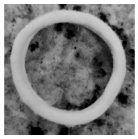
VI. EXPERIMENTAL TESTS

A. Test setup

All tests reported below were carried out on the assembled prototype shown in Fig. 8, in which the parts described in Sections III-A and III-B are integrated into a working machine. The specimen is clamped between the stationary grip, at the front, which is fixed to the aluminum profile, and the moving grip, which carries the S-type load cell and is driven along the profile by the trapezoidal lead screw and the NEMA 23 stepper motor visible at the back. The load cell therefore travels with the moving grip and remains in series in the load path throughout the test, and the whole assembly is operated from the computer through the interface of Figs. 6 and 7. Placing the specimen horizontally at bench height keeps the grips accessible during mounting and makes the deformation of the specimen directly observable throughout the test, which is a practical advantage for teaching use.

B. Specimens

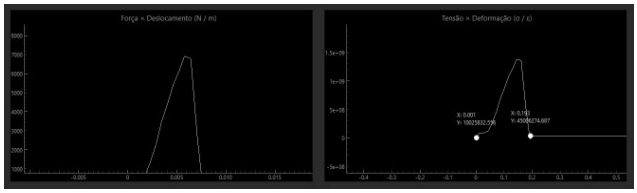
Three materials were tested: a rigid PVC strip, a high-density polyethylene (HDPE) strip and a commercial elastomeric ring (Fig. 9). The geometry and the dimensions of



(a) rigid PVC strip.

(b) HDPE strip, before testing.

(c) HDPE strip, after testing.



(d) elastomeric ring.

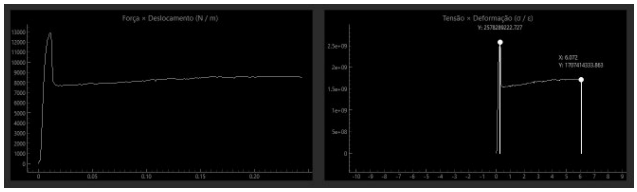
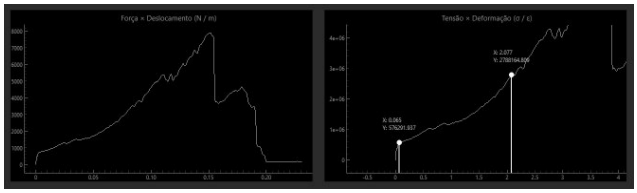
Source: The authors (2026).



the specimens were defined experimentally, from a series of preliminary tests carried out with the developed machine. Different configurations were evaluated with respect to test stability, specimen clamping, load application capability and the quality of the resulting curves. Based on these tests, dimensions of $170 \times 5 \times 1\,\mathrm{mm}$ were selected for the rectangular specimens, and 40 mm outer diameter with 5 mm width for the circular specimen, since these presented the behaviour best suited to the operating conditions of the equipment. In every test the free length between the grips was set to 40 mm, so that L_0 in (3) is the same for all specimens and the strain axes are directly comparable across materials.

C. Procedure



The specimen tests and load cell calibration were performed in triplicate. The specimens were tested under displacement control, with a constant speed applied to the crosshead, until failure or until the previously established displacement limit was reached. The load cell was calibrated using a reference mass, with the system zero set with the grips unloaded before each test. Force was sampled every 50 ms and streamed to the interface, which computed stress, strain, the elastic modulus and the area under the curve in real time from the entered geometry. The complete sequence of the three tests, including specimen mounting, grip adjustment and failure, was recorded and is available as supplementary material [9].

D. Results

Fig. 10 shows the interface output for the three tests, and Table III collects the quantities computed by the software at the end of each test.

E. Analysis

1) Rigid PVC: The PVC strip exhibited a steep and approximately linear increase in the curve, indicating predominantly elastic behavior up to failure, which occurred at a strain of 0.19. No clearly defined yield point or formation of a neck or necking was observed during the test. After reaching the maximum load, an abrupt decrease in load occurred, and the two recovered fragments exhibited a clean transverse fracture. This behavior is consistent with that of a predominantly amorphous and rigid polymer, which exhibits limited plastic deformation before failure. The absence of an extensive plastic deformation region is also consistent with the small area under the curve presented in Table III. The PVC absorbed approximately two orders of magnitude less energy per unit volume than HDPE before failure, despite exhibiting a similar calculated modulus.

This result demonstrates that the elastic modulus, associated with material stiffness, is not sufficient to characterize its ability to absorb energy up to failure. Therefore, the test clearly distinguishes stiffness from toughness. While PVC exhibited predominantly elastic behavior, with no clearly defined yield point or neck formation, and relatively abrupt failure, HDPE exhibited yielding, neck formation and propagation, and large deformation before failure. This difference demonstrates one of the main characteristics that the analysis of the stress–strain curve is intended to reveal.

2) HDPE: The HDPE strip exhibited the most characteristic curve among the three materials. Initially, there was a sharp increase in load corresponding to the elastic deformation region until the yield point was reached, identified by the peak of the curve. From this point onward, plastic deformation of the material began, accompanied by the formation of a neck or localized narrowing, characterized by a localized reduction in the strip width. After neck formation, a drop in load occurred, followed by a long, nearly constant portion of the curve that extended to a strain of 6.07, corresponding to more than six times the initial 40 mm free length. During this stage, the neck propagated along the free length while the material continued to elongate. This process, known as cold drawing, occurs with the load remaining approximately constant. The formation and propagation of the neck were also visually observed in the specimen. After the test, the drawn region extended over practically the entire free length (Fig. 9c), leaving the strip visibly thinner and longer than before the test (Fig. 9b). The long deformation region under approximately constant load explains why HDPE exhibited the largest area under the curve among the three materials, approximately two orders of magnitude greater than those of the other materials. This indicates that HDPE was able to absorb a much greater amount of energy before failure. This test was also the most demanding for the machine, as it was necessary to maintain movement over a long distance while the specimen remained under load, without loss of grip at the clamps. Thus, the test demonstrated both the characteristic behavior of a semi-crystalline polymer and the machine's ability to perform tests involving large deformations.

3) Elastomer: The elastomeric ring exhibited low stiffness and a high capacity for elongation. The curve showed a progressive increase in stiffness as the material was elongated, a behavior characteristic of elastomeric materials with a hyperelastic response. Near failure, an irregular decrease in load was observed. The calculated elastic modulus was 9.468×10^5 Pa, representing the lowest value among the three materials evaluated, approximately four orders of magnitude lower than the values obtained for HDPE and PVC. This result highlights the difference in stiffness among the materials: while HDPE and PVC exhibited behavior characteristic of rigid polymers, the elastomer showed greater ease of deformation under an applied load. This result is also important for evaluating the performance of the machine because, using the same acquisition system and changing only the specimen, it was possible to characterize materials with very large differences in stiffness. The difference between the calculated moduli was approximately 13,500-fold, and the machine correctly identified the relative order of stiffness of the materials. Thus, the test clearly demonstrates the difference between a rigid polymer and an elastomer, which is particularly relevant for the educational purpose of the equipment.

Therefore, the results presented in Table III show clear differences among the three materials. PVC and HDPE exhibited similar elastic moduli, indicating comparable stiffness; however, they showed distinct behaviors after the onset of deformation. PVC exhibited low deformation at break (0.19) and abrupt fracture, whereas HDPE exhibited large deformation (6.07), with yielding, neck formation, and stretching, resulting in the highest energy absorption. The elastomer exhibited the lowest elastic modulus, approximately four orders of magnitude lower than those of the rigid polymers, demonstrating its low stiffness and high deformation capacity. Therefore, the results demonstrate that stiffness, strength, deformability, and toughness are distinct properties, and that the elastic modulus alone is not sufficient to describe the mechanical behavior of the materials.

VII. Future Work

Although the machine is operational, the project has considerable room for improvement in its structure, hardware and software.

Gearbox coupled to the motor. Adding a gearbox to the stepper motor would convert part of the motor speed into torque, increasing the available force and reducing the rotational speed, which allows finer control of the crosshead movement.

Replacing the microcontroller. The project currently uses an Arduino Mega, which lacks some resources that would benefit the system. A more suitable microcontroller would be an ESP32, which supports multithreading and can therefore execute two software processes in parallel. This makes it possible to separate motor control from the process responsible for reading the load cell, preventing a malfunction in one from directly affecting the other.

Soldered circuit. A soldered circuit allows better organization of the hardware and removes the risk, inherent to the breadboard, of wires disconnecting accidentally.

Maximum and minimum points within the defined interval. At present the minimum point of the stress–strain plot is not computed, and the maximum point does not respect the interval defined by the user, since the maximum of the complete plot is displayed instead. Making both points respect the user-defined interval would improve the accuracy of the calculations.

Data persistence. A feature to save the data obtained during a test can be implemented, building over time a broad catalogue of records from different tests.

In addition to these improvements, the planned continuation includes calibrating the force chain over 10–100 % of the working range in ascending and descending sequences [13], reporting linearity, hysteresis, zero return and repeatability with

an uncertainty statement [17]; determining the machine compliance and the screw backlash; and comparing ASTM D638 specimens [11] from a single batch against a calibrated universal testing machine, with at least five replicates per condition.

VIII. Conclusion

This paper presented the design, construction and experimental testing of a low-cost horizontal tensile testing machine for teaching laboratories, built from 3D-printed parts, an aluminum profile and off-the-shelf electronics, with a documented architecture, published CAD models and source code, and a costed build of approximately R$ 3,700 at 2026 Brazilian prices. Three specimens, whose geometry was defined experimentally from preliminary tests with the machine itself, were tested to failure with a common 40 mm free length, and the machine reproduced brittle fracture in rigid PVC, yielding followed by neck formation and cold drawing in HDPE, and hyperelastic stiffening in an elastomeric ring, with the drawing mechanism confirmed on the specimen itself. The computed moduli span about four orders of magnitude across the three materials and place them in the correct relative order, which shows that the acquisition and data reduction chain resolves material classes as intended and that stiffness, strength, deformability and toughness are distinct properties that the stress–strain curve makes visible to the student.

Acknowledgments

The authors thank the Brazilian National Council for Scientific and Technological Development (CNPq) for the research scholarship, and the National Institute of Telecommunications (Inatel) for supporting the development of this work. ***Abstract*—The Brazilian National Common Curricular Base includes the investigation of mechanisms involved in the transmission and reception of sound and images, the classification of electromagnetic radiation, and the discussion of technologies used in medical diagnosis and treatment. In this context, ultrasound provides an opportunity to connect wave physics, sensing technologies, and biomedical applications. This paper presents the technical development of a portable and low-cost teaching apparatus based on an Arduino Uno and an HC-SR04 ultrasonic sensor, together with a pedagogical sequence for introducing pulse-echo principles to middle school students. The apparatus estimates the distance to an object from the ultrasonic time-of-flight and converts the measurement into a visual light-emitting diode (LED) display, providing a tangible representation of an otherwise invisible process. The estimated cost of the prototype was approximately 83.50 Brazillian real. The proposed sequence connects everyday echoes, animal echolocation, audible and inaudible frequencies, wave reflection, and time-of-flight measurements. A preassembled version of the apparatus was operationally implemented during a 50-minute teaching-practice session at Universidade Federal do ABC. The implementation indicated that the core demonstrations and guided discussions can be conducted within one class period, whereas student-led assembly and a quantitative distance investigation would require additional time. Rather than evaluating student learning outcomes, this work focuses on the technical development, reproducibility, operational feasibility, pedagogical organization, and limitations of the proposed teaching resource. The resulting apparatus offers an accessible means of connecting wave physics, educational robotics, and introductory biomedical engineering concepts in basic science education.**

***Index Terms*—Ultrasound education, HC-SR04, low-cost apparatus, BNCC, physics teaching, educational robotics**

I. Introduction

The Brazilian National Common Curricular Base (BNCC) includes items related to waves, communication technologies, and applications of radiation in health [1]. Brazilian initiatives have also encouraged the inclusion of educational robotics, physical computing, and computational thinking in basic education [2]. Research involving educational robotics in Brazilian public-school contexts suggests that such activities may create opportunities for interdisciplinary work involving science, mathematics, electronics, and programming, provided that the technological resources are associated with explicit educational objectives [3].

The use of experimental resources in science education nevertheless requires careful planning. Limited preparation time, lack of ready-to-use activities, maintenance difficulties, and insufficient access to equipment may restrict the use of practical activities in schools [4]. Moreover, the presence of an apparatus alone does not demonstrate educational effectiveness; the physical resource must be connected to well-defined questions, representations, and opportunities for conceptual discussion [4], [5].

Skill EF09CI05 proposes the investigation of mechanisms involved in the transmission and reception of images and sounds and skill EF09CI07 extends this discussion to technologies used in medical diagnosis and treatment, including X-ray imaging, ultrasound, nuclear magnetic resonance, radiotherapy, and optical laser surgery [1]. Although ultrasound is a mechanical wave rather than electromagnetic radiation, the progression among these competencies provides a useful curricular context (while sound propagates as a mechanical wave, distinct from electromagnetic phenomena, there are physical similarities between the two which can be made use of in teaching). Concepts previously in skill EF09CI06 such as frequency, propagation, reflection, and signal reception can be connected to the classification of infrasound, audible sound, and ultrasound. This connection can then support an introductory discussion of how reflected acoustic signals are used in medical imaging.

The literature on the use of ultrasonic sensors in educational contexts and on the teaching of ultrasound-related concepts has shown a wide range of approaches. In some studies, the focus was on scientific literacy and the contextualization of medical technologies through didactic sequences, discussions, and other educational activities [6]–[8]. Other studies employed playful approaches and gamification-based strategies to address concepts related to waves and ultrasound [9], [10]. Another line of research focused on experimentation as a teaching methodology, using ultrasonic sensors and platforms such as Arduino to investigate physical phenomena or perform

This work was supported by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), Brazil, through a master's scholarship.

data acquisition [11]–[13]. Despite the diversity of the studies identified, a significant proportion of these proposals are aimed at upper secondary or higher education students and, in some cases, involve extensive didactic sequences or greater technical complexity. This scenario suggests an opportunity for the development of simplified experimental approaches aimed at lower secondary education and compatible with the time and resources available in the classroom.

In this context, the objective of this work is to describe the development of a low-cost ultrasonic teaching apparatus and to organize a pedagogical sequence for introducing ultrasound principles in middle school science classes. The article evaluates the construction, cost, reproducibility, classroom timing, and technical limitations of the resource.

II. Theoretical Background

A. Ultrasound, Pulse-Echo and Time-of-Flight Measurement

Medical ultrasound is a diagnostic imaging technique that exploits the acoustic properties of human tissues to provide anatomical or functional information. Medical ultrasound includes multiple techniques - such as B-mode pulse-echo imaging, Doppler imaging, elastography, and tomographic methods - beyond the scope required for an introductory middle school activity. The present proposal therefore focuses on the fundamental sequence of pulse emission, propagation, reflection, echo reception, and time-of-flight estimation.

In a pulse-echo mode, a short acoustic pulse is emitted into a medium, such as the human body, and part of its energy is reflected when it encounters an object or an interface. The distance to a reflector can be estimated from the time interval between pulse transmission and echo reception. For a uniform propagation speed, the distance is calculated as shown in (1) [14]:

$$d = \frac{vt}{2}, \tag{1}$$

where d is the distance between the transmitter and the reflector, v is the speed of sound in the propagation medium, and t is the measured round-trip time. The factor of two accounts for the outward and return paths of the pulse.

Modern diagnostic ultrasound systems use transmitted pulses and returning echoes. The arrival time of an echo contributes to the estimation of depth, while echo amplitude and spatial scanning contribute to image formation. For basic education, the complete imaging chain is not required. The distance relation in (1) is sufficient to introduce the principle that information about an object can be obtained without direct visual contact by measuring the return time of a reflected wave.

B. Conceptual Scope of the HC-SR04 Analogy

The HC-SR04 is an ultrasonic ranging module containing a transmitter, a receiver, and control electronics. According to its technical documentation, fig. 1 shows that the module emits an eight-cycle burst at approximately 40 kHz and returns an electrical pulse whose duration is proportional to the acoustic

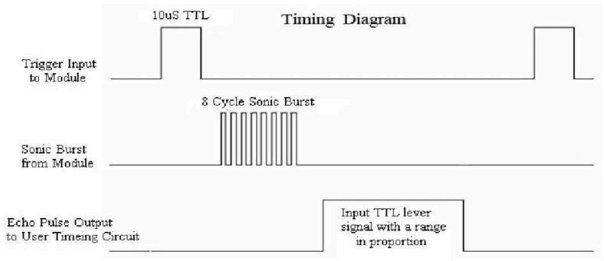

Fig. 1. Timing diagram of the HC-SR04 ultrasonic sensor, showing the 10 μs Transistor-Transistor Logic (TTL) trigger pulse, the 8-cycle ultrasonic burst, and the Echo output pulse whose width is proportional to the echo time-of-flight. Source: [15]

round-trip time. The manufacturer recommends a measurement cycle longer than 60 ms to reduce interference between successive measurements. The documented operating range is approximately 2 cm to 400 cm under suitable conditions [15].

The apparatus proposed in this work is a conceptual model of pulse-echo ranging and does not take into account many design aspects of medical ultrasound. Diagnostic ultrasound scanners use frequencies in range of 2 to 10 MHz, with specialized ultrasound applications up to 50 MHz. [14] In medical applications, ultrasound travels through the human body, which is composed of liquids, soft tissues and some solids, such as bone. The HC-SR04 operates in air at approximately 40 kHz. Medical image formation also requires beam steering or scanning, signal processing, amplitude encoding, and assumptions regarding tissue propagation speed [14]. These aspects are not reproduced by the HC-SR04 apparatus. Therefore, the analogy is restricted to the basic pulse-echo concepts of acoustic emission, propagation, reflection, reception, and round-trip time, without suggesting that the low-cost sensor reproduces a clinical ultrasound imaging system. These differences must be stated explicitly so that the analogy supports the intended physical concepts without suggesting that the low-cost sensor reproduces a clinical imaging system.

III. Methodology

A. Development of the Teaching Apparatus

The prototype was designed to provide an observable representation of an otherwise inaudible pulse-echo process. It was assembled using an Arduino Uno microcontroller, an HC-SR04 ultrasonic sensor, a breadboard, four light-emitting diodes (LEDs), resistors and jumper wires. Table I presents the estimated component cost at the time of construction.

The Arduino generates the trigger signal required by the sensor and measures the duration of the echo pulse. The round-trip time is converted into distance using (1), with the speed of sound in air used as the propagation speed (approximately 340 m/s). The measured value is then converted into a visible output through the LEDs, from 0 to 100 cm, with the four LEDs corresponding to 0 to 25 cm, 25 to 50 cm, 50 to 75 cm, and 75 to 100 cm, respectively. These LEDs provide an

TABLE I
APPROXIMATE COST OF THE COMPONENTS USED IN THE TEACHING APPARATUS

Component	Approximate Cost (R$)
Arduino Uno	45.00
HC-SR04 ultrasonic sensor	10.00
Breadboard	15.00
Light-emitting diodes (4 units)	2.00
Jumper wires	7.50
Resistors	4.00
Total	**83.50**

output reference for the distance being measured. The distance intervals associated with the LEDs can be modified in the source code according to the objectives of the activity. Fig. 2 summarizes the functionality of the code. In addition, an Arduino Serial Monitor output is displayed for the distance calculated and the time-of-flight measurement of the ultrasonic sensor.

Fig. 3 presents the circuit arrangement of Arduino with the ultrasonic sensor. Further details about the Arduino code and I/O connections were made available in the references [16].

B. Development of the Pedagogical Sequence

The pedagogical sequence was designed around two guiding questions:

1) How can a sensor operate using a sound that humans cannot hear?
2) How can the sensor estimate the distance to an object?

The conceptual progression of the class was organized in the following sequence:

everyday echo → animal echolocation → sound waves and frequency → pulse-echo ranging → medical ultrasound context

Table II summarizes a suggested lesson plan for a 50-minute class using a preassembled apparatus. The times are approximate and may be adapted to the school context.

The activity begins with the operation of the apparatus before a formal explanation is provided. Students may move an object in front of the sensor, observe changes in the visible output, and propose hypotheses regarding the type of signal used by the device. The teacher can then connect the observations to parking sensors, sonar systems, echoes in enclosed spaces, and animal echolocation.

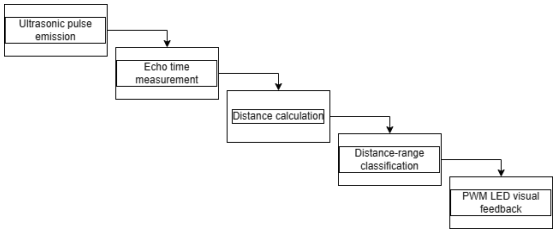

Fig. 2. Functional diagram of the ultrasonic distance-measuring apparatus.

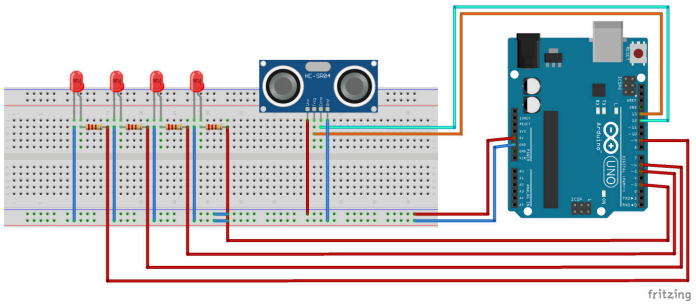

Fig. 3. Circuit arrangement of the proposed ultrasonic teaching apparatus Source: Authors.

Students may produce an initial representation through a drawing, a short written explanation, or an oral model of how the sensor operates. This representation is included as a formative pedagogical resource that helps the teacher identify ideas requiring discussion. It is not treated as research data in the present work.

The teacher can introduce the concept of wave reflection through the analogy of a ball traveling toward a wall and returning after impact. The analogy makes the outward and return paths visible, but the teacher should clarify that a sound wave is not a material object and that the analogy represents only propagation direction and reflection. Students may measure the time between throw and catch.

The teacher can introduce a discussion that addresses frequency and the limitations of human hearing. Audio signals of progressively higher frequency may be used to introduce the idea that sensory perception is limited and that inaudible sound can still be detected by an electronic device. Examples of animal communication and echolocation provide a transition to the HC-SR04 operating frequency: some whales communicate using low-frequency sounds (infrasound), while bats use high-frequency sounds (ultrasound) for echolocation.

The distance demonstration should connect the measured echo time to (1). A simple extension consists of positioning a flat object at different known distances and comparing the sensor reading with a ruler or measuring tape. This extension shifts the activity from demonstration towards a quantitative investigation, but requires additional time for data recording, calculation, comparison, and discussion.

TABLE II
SUGGESTED ORGANIZATION OF THE PEDAGOGICAL SEQUENCE.

Stage	Time
Exploration of the apparatus and guiding questions	5 min
Initial representation of the sensor operation	5 min
Everyday examples and animal echolocation	6 min
Ball-reflection analogy and discussion of echoes	7 min
Audible range, infrasound, and ultrasound	7 min
Pulse-echo distance demonstration and (1)	12 min
Revised representation and final discussion	8 min
Total	**50 min**

At the end of the sequence, students may revise their initial representation of how the equipment works. In the proposed pedagogical use, the revision is intended to promote self-explanation and teacher-mediated discussion.

C. Operational Implementation

A preassembled version of the apparatus and the proposed sequence were implemented during the teaching-practice component of the undergraduate course *NHT5013-15 (4-0-4) – Práticas de Ensino de Ciências e Matemática no Ensino Fundamental* at Universidade Federal do ABC (UFABC), taught by Prof. Caio de Castro e Freire in 2025.

A group of 14 seventh-grade students from a municipal public school located in the eastern region of the city of São Paulo visited UFABC to participate in the activity. Seventh-grade students in the Brazilian educational system are typically approximately 12 to 13 years old. The activity was designed and conducted by the first author under course supervision, with approximately 50 minutes available for its implementation.

The activity was conducted in a computer laboratory equipped with round tables. The students were divided into three groups. Only one preassembled apparatus was available during the session; therefore, each group approached the apparatus in turn to observe its operation and interact with it during the proposed activities. Despite the limited class time, all stages of the proposed pedagogical sequence were completed.

All lesson-plan materials and circuit arrangements were made available \cite{github} and can be adapted to different instructional contexts.

IV. Results

A. Prototype Operation and Cost

The apparatus was pre-assembled and used to demonstrate object detection based on ultrasonic pulse emission and echo reception. During operation, changes in the position of an object produced corresponding changes in the distance-dependent output of the system. The LEDs provided a visible response associated with the sensor measurement, allowing the teacher to discuss an acoustic process that is not directly audible to students.

The estimated component cost for the equipment was approximately R$83.50. This value should be interpreted as a local estimate rather than a fixed cost because component prices vary by supplier and date. The circuit uses commonly available components and can be assembled on a solderless breadboard, facilitating maintenance and modification.

B. Feasibility of the Pedagogical Sequence

With the apparatus assembled in advance, the central demonstrations and conceptual discussions could be accommodated within the available 50-minute session. The sequence allowed the teacher to relate the behavior of the US sensor with wave reflection, inaudible frequencies, animal echolocation, and time-of-flight distance estimation.

The limited class duration did not allow the implementation to include both a complete student-led circuit assembly and systematic quantitative investigation with repeated measurements and data analysis. Therefore, the single-session format is more appropriate for a guided demonstration and conceptual exploration. An additional class or extended workshop could include the construction of the complete ultrasound apparatus from its components. From this perspective, previous student contact with robotics activities in the school context facilitated the introduction of the basic elements: ultrasonic sensor, LEDs, and breadboard connections.

The classroom session also indicated the value of teacher mediation. The apparatus produces a distance measurement, but it does not independently explain why the echo time is related to distance, why the path is divided by two, or how the classroom sensor differs from a medical ultrasound scanner. These connections must be made explicit through questioning, diagrams, analogies, and mathematical discussion.

C. Technical and Pedagogical Limitations

The implementation of the circuit on a breadboard limits both student and instructor interaction with the apparatus. Although breadboards are well suited for static measurements, circuit prototyping, and direct demonstrations of sensors or microcontroller operation, they provide limited mechanical stability for activities that require physical manipulation of the device.

The apparatus should also be tested before each class to verify proper operation and should be used within a distance range that provides stable and reliable measurements under the environmental conditions of the classroom.

Another limitation regarding middle school classes is the limited class time. Considering that, several minutes are typically spent organizing students and taking attendance. Instructional time becomes a scarce resource. Although it would be ideal to have unlimited time for engaging discussions with active participation from all students, this is often not feasible within the constraints of a regular class period.

The comparison with medical ultrasound is limited to the general pulse-echo logic. The prototype does not produce anatomical images, does not operate in biological tissue, and does not reproduce the frequencies, transducers, beamforming methods, or signal-processing stages of diagnostic equipment. During the presentation, these topics were addressed only briefly. As the target audience consisted of middle school students, they were introduced primarily to clarify the limitations of the apparatus and to avoid an overly literal interpretation of the analogy.

V. Discussion

The main contribution of the proposed apparatus is to provide a physical bridge between an everyday distance sensor and the abstract pulse-echo principle. The HC-SR04 makes it possible to discuss emission, propagation, reflection, reception, and round-trip time using low-cost electronics. The apparatus also offers a point of connection among physics, basic

programming, sensor technology, and biomedical engineering without requiring the introduction of advanced ultrasound modalities.

The pedagogical proposal follows the BNCC progression by connecting sound transmission and reception with frequency classification and health-related technologies [1]. Nevertheless, its central content is wave physics rather than a comprehensive treatment of medical imaging. Medical ultrasound is used as a contextual application after the pulse-echo principle has been established.

From the teacher's perspective, one useful discussion point is the possibility that students initially interpret the sensor as a light-based or infrared device because many familiar object-detection systems are associated with visible or invisible light. This possible interpretation can be used pedagogically to contrast acoustic ranging with optical sensing and to prepare later comparisons between ultrasound and X-ray imaging. In this sense, the apparatus does not replace conceptual mediation; it creates a concrete situation in which the teacher can ask why an inaudible sound can still be emitted, reflected, received, and converted into a visible signal.

The 50-minute format imposes an important design choice. A preassembled apparatus permits more time for conceptual discussion, whereas student assembly can support electronics and programming objectives but reduces the time available for investigating the physical relationship between echo time and distance. Others experimental activities may also strengthen the investigative character of the sequence, as proposed by Martins and Lisbôa [12]. However, considering the target audience, the introduction of more complex activities should take into account students' prior knowledge and their familiarity with electronics, programming, and the physical concepts involved.

Although the proposed apparatus is based on low-cost and widely available components, its implementation in different school contexts may depend on factors beyond the cost of the materials. The availability of computers and electronic components, the school infrastructure, the time available for preparing the activity, and teachers' familiarity with electronics and programming may influence how the proposal is implemented. Therefore, adaptations may be necessary according to the resources and characteristics of each educational context. The work of Nunes and Rocha [6], for example, provides an alternative approach to the broader topic of "Radiations and their applications in health" through debates and a simulated jury in a school context characterized by limited resources and infrastructure. This example illustrates how different methodological approaches may be adopted according to the conditions of each educational context.

The inclusion of an evaluation with an initial and a revised representation of the apparatus functionality represents a pedagogically useful resource as it provides a structured opportunity for students to articulate and reconsider an explanatory model. However, in the present paper, these representations are components of the proposed lesson plan rather than data supporting educational claims. Therefore, although assessment activities may be incorporated into classroom practice, the present study does not provide evidence that the experimental resource improves students' conceptual understanding.

A study employing a more rigorous methodology could be implemented to systematically assess student learning through, for example, pre- and post-activity tests, questionnaires containing conceptual questions, or qualitative analysis of the explanations produced by students. Likert-scale instruments could also be used as a complementary approach to investigate aspects such as interest, engagement, or students' perceptions of the topic. An example of obtaining evidence of learning was presented by Nunes and Rocha [6], through the classification and analysis of transcripts of student interactions during the activity. The use of more systematic assessment procedures in future studies could provide more robust evidence regarding the contribution of the proposed experimental resource to the learning of the concepts addressed in the classroom.

Taken together, the implementation of the proposed activity highlights several practical lessons. First, the use of a preassembled apparatus makes it possible to prioritize conceptual discussion within a regular 50-minute class, whereas student-led construction requires additional instructional time. Second, the low cost of the apparatus alone does not ensure its applicability, since teacher preparation, infrastructure, and students' previous familiarity with electronics may influence its implementation. Finally, the apparatus is most appropriately used as a teacher-mediated conceptual model of pulse-echo rather than as a direct representation of diagnostic ultrasound. At the same time, important research gaps remain. The present study did not systematically evaluate student learning, conceptual change, or engagement, nor did it examine how students interpret the analogy between the HC-SR04 and medical ultrasound. Future studies should therefore investigate these aspects and replicate the activity across different school contexts.

VI. Conclusion

This work presented the development of a portable, low-cost ultrasonic teaching apparatus and a pedagogical sequence for introducing pulse-echo principles in middle school science classes. The prototype was assembled from commonly available components at an estimated cost of R$83.50 and was operationally suitable for demonstrating ultrasonic object detection and a simplified time-of-flight distance estimation.

A preassembled version of the apparatus can support the core sequence within a 50-minute class. However, student-led assembly and systematic distance measurements require additional time and are better suited to a second class or an extended workshop. The apparatus should be presented as a conceptual model of pulse-echo ranging, not as a reproduction of a diagnostic ultrasound imaging system.

These results support the feasibility of the proposed resource as a low-cost approach for introducing pulse-echo and time-of-flight concepts. However, educational effectiveness was not formally assessed in this study. Future work should include

technical calibration, classroom replication in different contexts, and formal pedagogical studies with learning assessment to investigate how students understand and use the proposed representations and measurements.

***Abstract*—Teaching biological, microbiological, and chemical concepts in Biomedical Engineering programs has traditionally relied on two-dimensional representations, which limit the understanding of complex morphologies, microarchitectures, and molecular structures. This paper presents the conceptual design of the *Inatel Museum of Biomedical Engineering*, a proposal for a permanent and traveling collection of three-dimensional educational models based on an additive manufacturing workflow previously validated by the same research group through the development of a DNA double-helix model fabricated using fused deposition modeling (FDM) [1]. The planned transition to photopolymer resin printing (MSLA) is expected to provide greater geometric accuracy, improved surface quality, transparency, color customization, and detachable components, enabling the production of educational models representing DNA, atomic orbitals, bacterial cell walls, viruses (HIV and SARS-CoV-2), and a macrophage performing phagocytosis. The collection also includes a flagship technological exhibit consisting of an articulated bacteriophage model equipped with LED lighting and a microcontroller to dynamically demonstrate the viral infection process. The museum is conceived as an educational walkthrough featuring exhibits protected by acrylic domes or displayed on interactive tactile stations accompanied by accessible explanatory texts. The proposal is discussed against a comparable Brazilian museum initiative and a critical review of its own technological choices. This paper presents the conceptual design and future implementation plan of the project rather than completed experimental results.**

***Index Terms*—Science Communication, Additive Manufacturing, Resin 3D Printing, Accessibility, Science Museum, Biomedical Engineering, Tactile Learning**

I. Introduction

Biomedical Engineering integrates concepts from biology, chemistry, physics, and medicine to develop technologies for healthcare applications. Many of these concepts—from the organization of bacterial cell walls to the three-dimensional conformation of viral proteins—are inherently spatial and therefore difficult to convey through static illustrations found in textbooks and lecture slides. This limitation has been discussed in previous work by the same research group, which identified additive manufacturing as an effective approach for producing manipulable educational models capable of enhancing spatial understanding [1].

As a proof of concept, a complete workflow for manufacturing three-dimensional educational models was previously developed and validated, encompassing biological data acquisition, digital modeling, slicing, fabrication, post-processing, assembly, and evaluation through the production of a DNA double-helix model using fused deposition modeling (FDM) [1]. This validated workflow established the methodological foundation upon which the present proposal is built.

Building upon that experience, and motivated by the superior resolution and geometric fidelity offered by masked stereolithography (MSLA) resin printing compared with FDM, the authors, together with the project supervisor, conceived a natural extension of the previous research: the creation of the **Inatel Museum of Biomedical Engineering**. The proposed museum consists of a physical, traveling, or hybrid collection of tactile three-dimensional educational models representing biological structures relevant to Biomedical Engineering curricula, pursuing three primary objectives:

1) promote science communication among students, children, and the general public;
2) enhance accessibility for visually impaired individuals through tactile educational exhibits;
3) strengthen the relationship between the institution and society while increasing academic and institutional visibility.

It is important to clarify the current stage of this project. While the DNA model produced using FDM has already been fabricated and experimentally evaluated [1], the museum proposed in this work—including the illuminated bacteriophage exhibit—remains a **conceptual proposal and future development plan** that has not yet been fully implemented. Therefore, this paper presents the conceptual design of the museum rather than reporting experimental results regarding the museum itself.

The main contributions of this work are summarized as follows:

1) the proposal of a conceptual layout for the museum based on an educational walkthrough;

2) the definition of an initial catalog of resin-printed educational models, together with their biological and pedagogical motivations;
3) the proposal of integrating additive manufacturing with embedded electronics to create interactive educational exhibits;
4) a discussion of the expected social, educational, and institutional impacts of the initiative, situated against a comparable Brazilian museum initiative and a critical review of the technological choices made.

II. Conception of the Museum

A. Format and Architecture

A hybrid museum format is proposed, combining a permanent installation—located in hallways and adjacent institutional spaces—with traveling modules that can be taken to schools, scientific events, and educational exhibitions. The central architectural concept is an **educational labyrinth**, in which visitors follow a sequential pathway beginning at the microscopic scale (the origin and diversity of bacteria), progressing through historical pandemics and the search for treatments, and culminating in a structural biology section where molecular and atomic structures are presented at larger scales and with greater detail. Fig. 1 illustrates the conceptual layout of the proposed educational pathway.

Fig. 1. Conceptual sketch of the proposed educational labyrinth for the Inatel Museum of Biomedical Engineering, guiding visitors from introductory microbiology to structural biology. Illustrative representation of the proposal, not yet physically implemented. Conceptual art generated by Artificial Intelligence.

B. Exhibition Modes

Two exhibition modalities are proposed, selected according to the fragility and educational purpose of each model:

- **Protected exhibits**, displayed under acrylic domes, intended for delicate models containing small detachable components or detailed painting;
- **Interactive exhibition benches**, featuring durable models designed for direct handling, particularly those intended for tactile learning and visitors with visual impairments.

Each exhibit is accompanied by accessible explanatory text covering three complementary dimensions: the biological nature of the represented structure, its functions or applications (for example, in industrial, biotechnological, or physiological processes), and, whenever applicable, the diseases or harmful effects associated with the represented organism or molecule.

C. Initial Collection of Models

The proposed initial collection consists of six educational models described below. With the exception of the DNA model—which has already been validated using FDM technology [1]—all remaining models are currently at the conceptual design stage.

1) Realistic DNA Model: A detailed double-helix model representing nucleotides, phosphate groups, and deoxyribose molecules. This model is an evolution of the FDM prototype previously fabricated and evaluated by the research group [1] and is intended to be reproduced using photopolymer resin to achieve greater geometric fidelity and detachable nucleotide components.

2) Schrödinger Atomic Model: A representation of electron probability clouds (s, p, and d orbitals) manufactured with translucent resin, allowing simultaneous visualization of the atomic nucleus and the spatial distribution of electron density—a concept that is traditionally difficult to understand in chemistry and physical chemistry courses.

3) Bacterial Cell Wall: Comparative tactile models of Gram-positive and Gram-negative bacteria, highlighting differences in peptidoglycan thickness, the presence of an outer membrane, and the location of lipopolysaccharides, thereby supporting the understanding of antibiotic mechanisms of action.

4) HIV and SARS-CoV-2 Models: Comparative virus models displaying the viral capsid and major surface proteins (gp120 glycoprotein for HIV and the *Spike* protein for SARS-CoV-2), illustrating their role in host-cell receptor recognition.

5) Macrophage Engulfing a Bacterium: A model representing the phagocytosis process, illustrating the innate immune response to invading microorganisms through a cross-sectional view that reveals phagosome formation.

6) Bacteriophage Model (Flagship Technological Exhibit): The centerpiece integrating Biomedical Engineering and Electronics, described in detail in Section III, consists of an articulated bacteriophage infecting a bacterium. The model is designed to incorporate LED lighting and a microcontroller capable of simulating, through sequential light patterns, the injection of viral genetic material into the bacterial host.

III. Technological Integration

A. Photopolymer Resin Manufacturing

The transition from FDM to masked stereolithography (MSLA) printing, already planned and partially supported by the acquisition of an Anycubic Photon Mono M7 Pro printer by the research group [1], provides the technical capability required to manufacture the high-resolution models proposed for the collection, particularly the translucent atomic model and the viral capsids. Standard, translucent, and flexible photopolymer resins are proposed for different models according to the transparency, flexibility, and mechanical strength required for each educational application.

The printer was acquired in August, and initial resin test prints have since begun; an early run was interrupted when the vat's build-plate film (FEP) was punctured, and a replacement is being sourced before fabrication of the collection's models proceeds. No museum exhibit has yet been produced on this equipment.

B. Embedded Electronics

For the bacteriophage model (Fig. 2), the integration of an addressable LED strip controlled by a low-cost microcontroller (Arduino- or ESP32-based) is proposed. The controller will execute a programmed lighting sequence designed to simulate, in an educational rather than literal manner, the injection of viral genetic material into the bacterial host. The model is conceived with articulated legs, allowing manual positioning over the bacterial surface. This is the only electromechanical and dynamic exhibit planned for the initial collection; its development, electrical safety testing, and durability validation remain future tasks that must be completed before any public exhibition.

Fig. 2. Artistic concept of the articulated bacteriophage model with LED illumination, designed to visually simulate the injection of viral genetic material into a bacterial host. The exhibit is currently at the conceptual design stage and is based on the 3D model designed by Leon Morlion [2].

C. Scalability and Modularity

As with the workflow previously validated for the DNA model [1], every new museum exhibit will follow the same sequence of scientific validation, digital modeling, manufacturing, post-processing, and educational evaluation. This standardized workflow enables the collection to expand incrementally without requiring a redesign of the manufacturing process for each new model, while also facilitating the future incorporation of educational models proposed by faculty members from other disciplines.

IV. Social Impact and Institutional Visibility

A. Accessibility and Inclusion

The availability of tactile educational models aims to provide visitors with visual impairments an alternative means of understanding the shape, spatial organization, and structural relationships of biological objects, consistent with previous evidence demonstrating the educational benefits of 3D-printed tactile resources for this audience [3], [4].

B. Science Communication and University Outreach

By welcoming elementary and high school students, families, and visitors during public events and weekend activities, the proposed museum is intended to serve as a continuous university outreach initiative, making advanced topics in structural biology and microbiology accessible to audiences that would otherwise have limited exposure to such scientific content.

C. Institutional Visibility

Initiatives of this nature have the potential to generate local and regional media coverage, strengthen partnerships with schools, and attract prospective undergraduate students to the institution. Although these outcomes are not the primary educational objective of the project, they contribute to its long-term institutional sustainability and visibility.

V. Implementation Plan

A. Proposed Timeline

Table I presents a preliminary four-phase implementation schedule, starting from the completion of the validated FDM manufacturing workflow.

TABLE I
Preliminary implementation schedule for the proposed museum

Phase	Planned Activities
1	Expansion of the digital catalog and resin fabrication of the first models (DNA, atomic orbitals, bacterial cell wall).
2	Acquisition and assembly of the exhibition infrastructure (acrylic display domes, interactive benches, and accessible signage).
3	Design, prototyping, and testing of the electromechanical bacteriophage model (LEDs and microcontroller).
4	Pilot opening of the collection and structured collection of feedback from visitors and faculty members.

B. Preliminary Resource Estimation

Table II presents a preliminary estimate of the additional resources required for the pilot phase, considering the materials already budgeted for the ongoing resin-printing project and the electronic components required for the bacteriophage model. These values are approximate and intended solely for planning purposes, and they remain subject to formal quotations before acquisition.

TABLE II
PRELIMINARY RESOURCE ESTIMATE FOR THE MUSEUM PILOT PHASE

Item	Estimated Cost (R$)
Additional resins (standard and transparent)	900.00
Acrylic display domes and exhibition supports	700.00
Microcontroller, LED strips, and wiring	350.00
Accessible signage (including Braille)	400.00
Assembly and finishing materials	250.00
Estimated Total (Pilot Phase)	**2,600.00**

VI. Discussion and Limitations

A. Comparison with Related Initiatives

Brazil already has a well-established example of a science museum built around microbiology and biomedical content: the Museu de Microbiologia Prof. Isaias Raw, part of Instituto Butantan's Parque da Ciência in São Paulo [8]. Open since 2002, it uses three-dimensional models, microscopes, and interactive media to guide visitors through the history and scale of microorganisms, and is explicitly accessible to visitors with disabilities, offering tactile models, enlarged specimens, audio description, and Braille materials. Its scale — a permanent, professionally staffed exhibition within a major public research institute — is far beyond what the present proposal can achieve as an undergraduate project, but it demonstrates that the core premise of this work, a microbiology-themed, tactile, accessible museum, is a proven and valued format in the Brazilian context rather than a speculative one. The present proposal differs mainly in scope and origin: a smaller, curriculum-specific collection built from synthetic, designed models (DNA, atomic structures, engineered viral models) rather than biological specimens, developed as part of a Biomedical Engineering undergraduate research project rather than a dedicated museum institution.

B. Critical Analysis of Technological Choices

The decision to move from FDM to resin (MSLA) printing, and to add embedded electronics to the bacteriophage exhibit, involves trade-offs worth stating explicitly. Resin offers finer detail than FDM — a property reported as the single strongest driver of museum visitors' preference for 3D-printed replicas [7] — which favors the translucent atomic model and viral capsids proposed in Section II-C. The same source, however, found robustness a meaningful secondary concern for handled objects, and resin parts are typically more brittle than FDM parts under the repeated handling expected on the interactive benches described in Section II-B; print technology may therefore need to be chosen per exhibit rather than applied uniformly. Likewise, the LED and microcontroller system is the collection's most technically ambitious element, and also its highest-risk one in cost, electrical-safety review, and maintenance under repeated public use, none of which apply to the collection's five static exhibits. A simpler, passive alternative, such as an audio- or QR-code-triggered explanation, would communicate the same infection sequence without embedded electronics. The more complex illuminated version was nonetheless chosen because peer review specifically identified it as the collection's clearest technical contribution to Biomedical Engineering, distinct from an education or outreach initiative.

C. Current Stage and Limitations

The main limitation of this work is its inherently propositional nature. With the exception of the DNA model, which has already been manufactured and evaluated using FDM [1], the remaining models in the proposed collection—particularly the LED-illuminated bacteriophage—have not yet been prototyped or experimentally tested, although initial resin test printing has begun (Section III-A). The technical feasibility of the electronic integration, electrical safety assessments, durability testing, and pedagogical validation with students and museum visitors remain subjects for future work.

Likewise, the values presented in Tables I and II represent planning estimates rather than measured data and should be revised according to actual quotations and any scope adjustments approved during project development.

Nevertheless, because the proposal is grounded on an additive manufacturing workflow that has already been experimentally validated [1], together with well-established literature on accessibility and three-dimensional educational resources [3]–[6], it goes beyond a purely speculative concept by providing a concrete and technically supported roadmap for expanding the undergraduate research project.

VII. Future Work

Because this paper reports a conceptual design together with the very early stages of physical implementation (Section III-A), most of the museum's technical and pedagogical validation remains ahead of it. A more concrete pilot plan, with systematic collection of pedagogical data, is described below to guide that work and to be reported in a follow-up publication.

A. Pedagogical Evaluation Plan

Once the bacteriophage exhibit and an initial set of resin models are fabricated, a preliminary pedagogical evaluation is planned using an anonymous questionnaire administered to a convenience sample of volunteer students, instructors, and, where possible, visually impaired users. The instrument will be applied before and after interaction with the exhibits and will cover three dimensions: comprehension (a small number of questions on the biological content represented, to estimate

learning gain), usability (Likert-scale items on the clarity of the models and, for the bacteriophage, its lighting sequence), and accessibility and educational perception (Likert-scale items on engagement, tactile clarity, and perceived educational value, with wording adapted for visually impaired respondents where needed). Anonymity is intended to encourage candid feedback, particularly on usability problems. As with the group's earlier DNA prototype [1], this evaluation is explicitly exploratory: with a convenience sample, it is meant to surface usability issues and a first, non-generalizable signal of learning gain and accessibility benefit, not to statistically validate the museum's pedagogical impact.

B. Fabrication and Technical Validation

Future work also includes completing resin fabrication of the five remaining exhibits, resolving the FEP-related interruption described in Section III-A and reporting fabrication time, material cost, and any print failures for each model at the same level of detail already reported for the group's FDM DNA prototype [1]; constructing and electrically safety-testing the bacteriophage's LED and microcontroller system before any public exhibition; and durability testing of both the resin models and the exhibition infrastructure (acrylic domes, interactive benches) under repeated handling.

C. Broader Directions

Beyond the initial collection, future work may extend the catalog with models proposed by faculty from other disciplines, formalize partnerships with local schools for recurring visits, and, if the pilot evaluation above indicates a learning or accessibility benefit, pursue a larger, more rigorously sampled study of the museum's educational impact.

VIII. Conclusion

This paper presented the conception of the Inatel Museum of Biomedical Engineering, a proposal for a tactile and interactive collection of three-dimensional educational models intended to support the teaching of biology, microbiology, and chemistry within Biomedical Engineering education. Building upon the additive manufacturing workflow previously validated by the research group through the FDM DNA model, the proposal introduces an initial catalog of six educational models, an architectural concept based on an "educational labyrinth," a flagship technological exhibit combining resin 3D printing with embedded electronics, and an implementation plan discussed against a comparable Brazilian museum initiative and a critical review of its own technological choices.

This paper accordingly presents a conceptual design and implementation plan rather than completed experimental results. Concrete progress toward execution has begun: the MSLA printer required for the collection was acquired in August, and initial resin test prints followed, though an early run was interrupted by a punctured build-plate film whose replacement is being sourced (Section III-A). No museum exhibit has yet been fabricated. Completing resin production of the collection, constructing and safety-testing the bacteriophage exhibit, and carrying out the pedagogical evaluation detailed in Section VII remain the next steps, to be reported in a follow-up publication.

***Abstract*—This study presents an integrative literature review on the impact of student-led scientific events as transformative learning ecosystems in Biomedical Engineering education. The analysis of 27 studies published between 2023 and 2026 demon-strates that these initiatives promote student leadership and the development of essential technical and socio-emotional skills. The findings indicate that such events articulate teaching, research, and outreach, aligning with Sustainable Development Goals (SDG 3, 4, and 9). A conceptual model is proposed, recognizing these events as structured pedagogical devices with the potential to transform academic training.**

***Index Terms*—Biomedical Engineering; Student-led Scientific Events; Learning Ecosystems; Pedagogical Innovation; Active Learning.**

I. Introduction

In recent decades, the healthcare sector has been deeply impacted by intensifying digitalization and the expanding use of Artificial Intelligence (AI)—a phenomenon directly linked to the exponential growth of healthcare data volume. This scenario, frequently termed the ”data era,” has enabled the development of systems capable of analyzing large clinical datasets, contributing to more accurate diagnoses, early risk identification, and therapeutic decision support. Such advance-ments have driven significant improvements in the quality, safety, and agility of healthcare [1]–[5]. In the Brazilian context, initiatives like the Digital Health Strategy for Brazil 2020–2028 reinforce this movement by proposing the inte-gration of information systems and the strengthening of the Unified Health System (SUS), expanding access and service efficiency. This research is intrinsically aligned with SDG 3 (Good Health and Well-being) by training professionals for the sector’s new technological demands, and SDG 4 (Quality Education) by proposing ecosystems that modernize higher education through student leadership [6]. Furthermore, the advancement of AI in areas such as telemedicine, hospital management, and predictive analysis highlights that the mere incorporation of technologies is insufficient to guarantee real impact on clinical practice. One of the main contemporary challenges lies in training professionals capable of under-standing, interpreting, and applying these tools in a critical, ethical, and efficient manner. In this sense, issues such as the explainability of AI systems and the reliability of algorithms become central, requiring a multidisciplinary approach that articulates technical, clinical, and social knowledge. Thus, higher education, especially in Biomedical Engineering, de-mands innovative pedagogical strategies that prepare students to handle complex and constantly transforming scenarios. This need for pedagogical adaptation reinforces Target 4.7 of SDG 4, which aims to ensure that all learners acquire the theoretical and practical knowledge needed to promote sustainable devel-opment and healthy lifestyles. In this scenario, active learning strategies gain prominence as effective alternatives to foster the development of essential 21st-century skills, such as critical thinking, problem-solving, creativity, and teamwork. By deal-ing with real challenges from industry and healthcare services, students are encouraged to integrate theoretical and practical knowledge, promoting a more meaningful and contextualized education. Approaches such as challenge-based learning and transdisciplinary experiential learning have demonstrated pos-

itive results in Biomedical Engineering education by bringing students closer to the real demands of healthcare systems and encouraging innovative solutions [14], [24]. The promotion of this educational technological innovation also dialogues with SDG 9 (Industry, Innovation, and Infrastructure) by strengthening scientific research and the technological capacity of the academic sector.

In parallel, the construction of collaborative educational ecosystems has become a fundamental element in the training of future professionals. These ecosystems involve the inte-gration of teaching, research, outreach, and extracurricular activities, fostering a dynamic environment for knowledge ex-change and continuous development. In this context, initiatives that strengthen academic mentoring, diversity, and inclusion contribute to expanding learning opportunities and stimulating student leadership—essential elements for consolidating more robust and innovative academic trajectories [18], [23]. By focusing on inclusion and equal educational opportunities, these initiatives support Target 4.5 of SDG 4, eliminating gender disparities and ensuring equal access to high-level vocational and professional training.

Therefore, it is within this framework that student-led scien-tific events emerge, configuring themselves as strategic spaces for active learning, interdisciplinary collaboration, and knowl-edge dissemination. These events enable practical experience in scientific endeavors, stimulate academic communication, and promote integration among different fields of knowledge. The Academic Symposium on Biomedical Engineering and In-novation (SABIO), for instance, represents a relevant initiative by articulating teaching, research, and innovation, allowing students to assume a central role in knowledge construction and in developing solutions for real healthcare challenges. This student-centered approach to solving complex public health problems directly contributes to Target 3.c of SDG 3 by helping to develop and train a skilled and technologically capable health workforce [3], [17].

However, despite the evident relevance of these forma-tive environments, studies that scientifically systematize and analyze the impact of student-led events on academic and professional training remain scarce. This gap highlights the need for investigations exploring how these experiences con-tribute to skill development, educational innovation, and the transformation of teaching-learning processes in Biomedical Engineering. Given this, it becomes essential to investigate this theme in a structured manner, recognizing that such events can serve as pillars for achieving Target 4.4 of SDG 4, which aims to substantially increase the number of youth with rele-vant skills for employment. Conducting an integrative review allows for the aggregation of available scientific evidence, the identification of gaps in knowledge, and the proposal of guidelines to strengthen the integration of innovative practices in higher education. Furthermore, these collaborative spaces contribute to forming more critical, reflective professionals prepared to act in a scenario of constant technological and social transformation, aligning with contemporary demands in healthcare and engineering.

Despite the growing valuation of active methodologies and learning ecosystems, there is a significant gap in the literature regarding the understanding of student-led scientific events as structured pedagogical devices. In particular, studies analyzing them as complex learning ecosystems that integrate pedagog-ical, organizational, and innovation dimensions are lacking.

II. RESEARCH PROBLEM

Despite advancements in teaching methodologies within Biomedical Engineering, a significant gap remains in the literature regarding the analysis of the impact and effectiveness of student-led scientific events as structured formative spaces. Although these events are increasingly frequent, their contri-bution to academic and professional development is seldom investigated systematically, particularly concerning the lack of clear guidelines for their implementation, monitoring, and evaluation.

Within this context, there is a clear need to understand how these events contribute to the development of technical and socio-emotional skills—such as leadership, communication, and teamwork—as well as to identify the primary challenges faced during their organization and management, including financial, structural, and institutional limitations. Furthermore, it is relevant to discuss which practices have proven most effective and how these spaces can be improved to maximize their integration with teaching, research, and the job market, thereby amplifying their impact on student training.

Consequently, the relevance of this study is linked to the necessity of generating knowledge that supports educational institutions, faculty, and students in understanding the trans-formative potential of these events. By advancing the sys-tematization of evidence and proposing parameters for their organization and evaluation, this work aims to contribute to consolidating these spaces as more structured, replicable learning ecosystems aligned with the contemporary demands of Biomedical Engineering education.

III. METHODOLOGY

A. Type of Research

This study was conducted as an integrative literature review based on the methodological recommendations of Whittemore and Knafl [27], Mendes, Silveira and Galvão [13], and Sousa et al. [25]. This approach was selected because it allows the integration of findings from qualitative, quantitative, mixed-methods, and descriptive studies. The review focused on student-led scientific events as learning ecosystems in Biomedical Engineering education, particularly their relationship with active learning, experiential learning, innovation, student leadership, scientific communication, competency development, and institutional support.

B. Research Question

The review was guided by the following question: How do student-led scientific events contribute to learning, competency development, and innovation in Biomedical Engineering education? The analysis considered the

organization and format of events, students' active participation, educational strategies, mentoring processes, technical and socioemotional competencies, and the institutional conditions that support or limit these initiatives.

C.Inclusion and Exclusion Criteria

Studies were included when they were full-text, peer-reviewed articles published between January 2023 and April 2026 in English, Portuguese, or Spanish. Eligible studies addressed student-led scientific or academic events, student research activities, active or experiential learning, scientific communication, leadership, mentoring, pedagogical innovation, or competency development in higher education, particularly in Biomedical Engineering, Bioengineering, Engineering, or related STEM fields. Editorials, opinion papers, conference abstracts, books, theses, dissertations, and studies that did not directly address the research question were excluded. Theses and dissertations were consulted only as complementary theoretical sources when relevant, without being included in the final sample.

D. Justification of the Period

The period from 2023 to April 2026 was selected to identify recent educational practices and emerging approaches associated with student participation, scientific events, digital transformation, interdisciplinary learning, and innovation in Biomedical Engineering education. Nevertheless, foundational publications published before 2023 were considered to support the theoretical discussion of active learning, experiential learning, engineering education, student leadership, and competency-based education. These earlier studies were used as conceptual references and were not necessarily included in the final sample.

E. Databases and Search Strategy

The searches were conducted in PubMed, SciELO, Scopus, Web of Science, IEEE Xplore, Engineering Village, and Google Scholar. The search strategy combined descriptors and related terms such as "student-led scientific events," "student-led academic events," "student-led conferences," "student research conferences," "biomedical engineering education," "bioengineering education," "engineering education," "active learning," "experiential learning," "transformative learning," "pedagogical innovation," "scientific communication," "student leadership," "mentoring," and "competency development." The Boolean operators AND and OR were used to combine the terms. The search procedures, databases, descriptors, and date of access were recorded to improve transparency and reproducibility.

F. Identification and Selection of Studies

The identification and selection process occurred in four stages. First, the studies were retrieved from the selected databases. Second, duplicate records were removed. Third, titles and abstracts were screened according to the previously established eligibility criteria. Finally, potentially relevant studies were assessed through full-text reading. Studies were excluded at the full-text stage when they did not address student-led scientific or educational practices, did not focus on higher education, lacked sufficient methodological information, or did not contribute to the research question. The selection process was organized according to the principles of PRISMA, with records of the number of identified, screened, excluded, and included studies.

G. Data Extraction

Data were extracted using a structured instrument developed for this review. The extracted information included authors, publication year, country, study design, educational context, participant characteristics, type and format of the scientific event, level of student leadership, learning strategies, mentoring activities, interdisciplinary collaboration, competencies developed, reported educational outcomes, assessment instruments, barriers, facilitating factors, methodological limitations, and DOI or other identification information. When available, the review also recorded whether the outcomes were assessed through qualitative perceptions, self-reported questionnaires, academic performance indicators, validated instruments, or objective measures of competency development.

H. Critical Appraisal

The methodological quality of the included studies was assessed according to their respective designs. Qualitative studies were examined regarding the clarity of their objectives, theoretical framework, participant selection, data collection, analytical procedures, and consistency between findings and interpretations. Quantitative studies were assessed according to sample description, measurement procedures, validity of instruments, statistical analysis, and clarity of results. Mixed-methods studies were evaluated based on the integration between qualitative and quantitative components. Descriptive studies and experience reports were analyzed for the clarity of the educational intervention, contextual description, evidence supporting the reported outcomes, and limitations. This assessment was used to interpret the strength and reliability of the available evidence.

I.Risk of Bias

Potential risks of bias were considered throughout the analysis, including selection bias, self-selection of participants, response bias, recall bias, publication bias, institutional bias, and limitations related to self-reported outcomes. Particular attention was given to studies conducted in a single institution, studies with small or non-probabilistic samples, and reports based mainly on students' perceptions. The review also distinguished between short-term outcomes, such as satisfaction, engagement, and perceived learning, and more objective or long-term outcomes, such as academic performance, sustained competency development, professional identity, and employability. These aspects were considered when comparing findings and discussing their generalizability.

J.Synthesis of Results

The findings were organized through thematic synthesis

into four categories: scientific event formats and student leadership; active, experiential, and collaborative learning processes; technical and socioemotional competency development; and institutional conditions, barriers, facilitating factors, and evaluation strategies. The results were compared according to similarities, differences, methodological characteristics, and the strength of the evidence. The synthesis also identified limitations in the existing literature, including the predominance of qualitative and self-reported data, the lack of standardized assessment instruments, the limited evaluation of long-term outcomes, and the restricted generalizability of single-institution studies. These gaps were used to indicate directions for future research on student-led scientific events as transformative learning ecosystems in Biomedical Engineering education.

IV. RESULTS

The initial database search identified 31 records. After title and abstract screening, four studies were excluded because they did not meet the eligibility criteria. Following full-text assessment, 27 studies were included in the final integrative review. The selection process should be presented in a PRISMA flowchart, detailing the number of records identified, duplicates removed, studies screened, full texts assessed, exclusions, and studies included in the final synthesis.The study selection process is illustrated in Fig. 1.

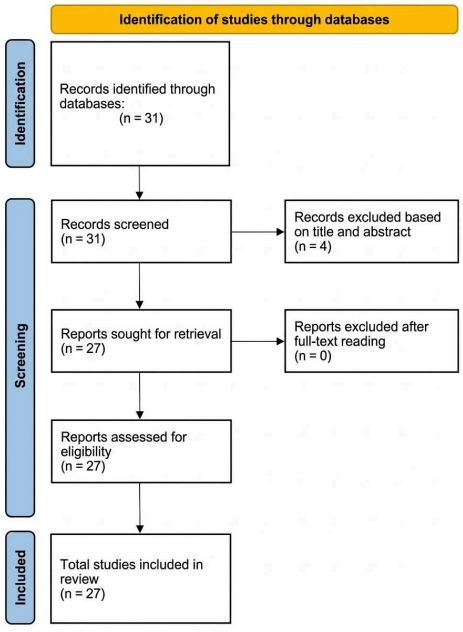

Fig. 1. PRISMA flow diagram detailing the identification, screening, and inclusion process of the reviewed studies.

An overall synthesis of the 27 selected studies was conducted to analyze their primary scope and contributions to the field. A detailed overview of each included study, including references, titles, and main focus, is presented in Table I.

TABLE I. Summary of the 27 Included Studies in the Integrative Review.

The included studies were predominantly conducted in international settings, especially in the United States, the United Kingdom, and China, with additional contributions from Latin American contexts. The methodological approaches were mainly qualitative, mixed-methods, descriptive, and exploratory. This pattern indicates that the field is still largely focused on understanding students' experiences, perceptions, engagement, and educational

processes rather than measuring long-term outcomes through standardized or objective instruments. Recent Biomedical Engineering literature emphasizes that student engagement involves behavioral, cognitive, and emotional dimensions and is influenced by active learning, mentoring, belonging, institutional support, and the organization of educational experiences.

The thematic analysis resulted in four categories: (i) characteristics and formats of student-led scientific events; (ii) learning, engagement, and competency development; (iii) mentoring, inclusion, and collaborative learning ecosystems; and (iv) challenges, enabling factors, and sustainability conditions. This organization expands the previous three-category structure by distinguishing the educational effects of the events from the institutional and relational conditions required for their implementation.

A. Characteristics and Formats of Student-Led Scientific Events

The studies identified different formats of student-led academic and scientific activities, including conferences, symposia, scientific workshops, hackathons, research presentations, interdisciplinary challenges, and project-based initiatives. These activities generally involve students in the planning, organization, communication, scientific production, and presentation of results. Their educational value is associated not only with participation in the event itself, but also with the process of preparing abstracts, developing projects, discussing research findings, presenting oral or poster communications, and interacting with peers, faculty members, and external professionals.

The reviewed literature indicates that these formats promote the integration of theoretical knowledge with practical and real-world problems. In Biomedical Engineering, this integration is particularly relevant because students must articulate knowledge from biology, medicine, engineering, mathematics, technology, and clinical practice. Student-led workshops and research activities may also reduce barriers to participation by offering structured opportunities for students to access scientific training, develop research skills, and establish relationships with mentors. For example, the Starting Undergraduate Research Experience initiative used interactive workshops, peer mentoring, and student leadership to support early undergraduate students and facilitate access to future research opportunities.

B.Learning, Engagement, and Competency Development

The findings suggest that student-led scientific events contribute to both technical and socioemotional development. Technical competencies include scientific writing, literature searching, research planning, data interpretation, scientific presentation, communication of results, and the application of specialized Biomedical Engineering knowledge. These activities also encourage students to understand the relationship between scientific evidence, technological innovation, and healthcare needs.

The development of socioemotional competencies was associated with leadership, teamwork, interpersonal communication, organization, autonomy, creativity, critical thinking, and problem-solving. By assuming responsibilities in the organization and execution of scientific activities, students move from passive recipients of information to active participants in the production and dissemination of knowledge. This finding is consistent with evidence supporting student-centered and active learning strategies as mechanisms for increasing participation, engagement, and learning opportunities in engineering education.

The results also indicate that engagement should not be understood only as attendance or participation in an event. It includes behavioral involvement, cognitive investment, reflection, self-regulation, interest, sense of belonging, and emotional connection with the educational environment. Therefore, student-led scientific events may function as learning ecosystems when they combine scientific production, collaborative interaction, mentoring, reflection, and opportunities for students to exercise autonomy and responsibility.

C.Mentoring, Inclusion, and Collaborative Learning Ecosystems

Mentoring and peer collaboration emerged as important elements for the success of student-led initiatives. The analyzed studies indicate that students benefit when they receive guidance from faculty members, more experienced peers, researchers, and institutional partners. Mentoring may support scientific learning, improve confidence, strengthen professional identity, and facilitate access to research networks and future academic or professional opportunities.

The reviewed evidence also highlights the importance of inclusive environments. Structured research activities, peer mentoring, and welcoming learning spaces can reduce inequalities in access to scientific experiences, particularly among students who have limited previous contact with laboratories, research groups, or professional networks. The literature on Biomedical Engineering education emphasizes that belonging, support, and participation are associated with students' engagement and academic development.

In addition, collaborative learning ecosystems extend beyond the event itself. They may involve partnerships among students, faculty members, research groups, professional organizations, innovation centers, and external institutions. Such networks create opportunities for knowledge exchange, interdisciplinary collaboration, scientific dissemination, and the development of projects connected to social and healthcare demands.

D.Challenges, Enabling Factors, and Sustainability

The main challenges identified were limited funding, insufficient infrastructure, lack of dedicated spaces, restricted access to technological resources, workload, dependence on voluntary student participation, and difficulties in maintaining institutional continuity. The sustainability of student-led initiatives may also be affected when activities depend on a small group of students or on individual faculty members without formal institutional mechanisms.

Conversely, the main enabling factors included faculty support, institutional recognition, mentoring, partnerships, access to laboratories and technological resources, collaborative networks, and the integration of teaching, research, and outreach. Evidence from studies on student-led initiatives indicates that mentoring and networking are perceived as high-impact mechanisms, whereas formal institutional structures and dedicated facilities may vary in availability and effectiveness.

The results further suggest that institutional support must include more than authorization to conduct an event. It should involve financial resources, access to infrastructure, training, dissemination support, recognition of student and faculty participation, and mechanisms for continuity between academic cycles. In Biomedical Engineering education, these conditions are especially important because scientific activities frequently require specialized equipment, interdisciplinary supervision, ethical considerations, and interaction with healthcare-related problems.

E. Overall Interpretation of the Findings

Overall, the evidence indicates that student-led scientific events can operate as transformative learning ecosystems by combining active participation, scientific communication, collaborative problem-solving, mentoring, and professional development. Their contribution is not limited to the acquisition of technical knowledge; they also support autonomy, leadership, teamwork, confidence, scientific identity, and the connection between academic learning and professional practice.

However, the strength of this conclusion must be interpreted cautiously. Much of the available evidence is based on qualitative reports, exploratory studies, institutional experiences, and self-reported perceptions. There remains a limited number of studies using validated instruments, control or comparison groups, longitudinal designs, and objective indicators of academic performance, competency development, employability, or professional insertion. The literature also presents limitations related to small samples, single-institution contexts, self-selection of participants, and differences in how engagement and learning outcomes are defined.

Therefore, although student-led scientific events show strong potential for promoting innovation and student development in Biomedical Engineering, further research is required to establish standardized evaluation models and to measure their short-, medium-, and long-term effects.

V. DISCUSSION

This integrative review demonstrates that student-led sci-entific events are consolidating as relevant spaces for skill development in higher education, especially in interdisci-plinary fields such as Biomedical Engineering. In light of active learning theories, these environments favor student participation as the central agent of the educational process, promoting greater engagement, autonomy, and meaningful knowledge construction [7], [21]. The literature points out that collaborative and interactive strategies directly contribute to better academic outcomes and to training more critical professionals prepared for complex challenges. In this regard, the discussion highlights that such ecosystems are fundamental to operationalizing the goals of SDG 3, 4, and 9 within daily academic practices.

When analyzing the historical evolution of engineering education, it is evident that initial innovation proposals were centered on curricular reformulation, seeking to align aca-demic training with market demands. Classical studies had already indicated the limitations of the traditional lecture-based model, highlighting the need to incorporate practical experiences and extracurricular activities. Currently, an advancement toward the conception of integrated educational ecosystems is observed, in which scientific events, hackathons, and technological challenges expand formative possibilities and strengthen interdisciplinarity [6], [8], [11], [15]. The anal-ysis of the studies demonstrates convergence regarding the role of these events as practical learning platforms for developing skills such as critical thinking and problem-solving.

However, there are divergences regarding how to measure these impacts, especially between international and national studies. While international literature tends to present more structured and quantitative evaluations, Brazilian studies still concentrate mostly on descriptive reports, which limits the comparability of results and the consolidation of robust evi-dence. This methodological disparity suggests a challenge for Target 9.5 of SDG 9, which encourages scientific research and an increase in the number of researchers, demanding greater analytical rigor in national productions by 2026 [2], [5], [19].

A critical appraisal of the 27 reviewed studies reveals significant methodological limitations and divergence in findings. The literature is predominantly reliant on cross-sectional, self-reported perception surveys, which introduces response, recall, and social desirability biases. Furthermore, potential publication bias is evident, as existing studies overwhelmingly report successful implementations and positive student outcomes, rarely documenting failed event models, logistical bottlenecks, or low engagement rates. Generalizability across diverse institutional and cultural contexts also remains constrained: educational frameworks implemented in highly funded North American or European institutions cannot be directly extrapolated to developing academic settings, such as Brazilian public universities, where infrastructure, funding availability, and integration with health systems (e.g., SUS) present unique operational constraints.

Regarding the implications for the Biomedical Engineering curriculum, the results indicate the need for greater integration between formal and non-formal learning activities. Incorporat-ing scientific events as complementary pedagogical strategies can contribute to developing skills that are not always fully addressed in traditional courses. Furthermore, the importance of faculty training focused on active methodologies and the creation of institutional policies that encourage student lead-ership becomes evident. The sustainability of these initiatives depends directly on institutional support, such as infrastructure and continuous funding—elements that still present challenges in the Brazilian context compared to the international scenario. Another relevant aspect concerns the dynamic nature of these learning ecosystems, which promote interaction among students, faculty, researchers, and the productive sector. This articulation strengthens interdisciplinary training and brings students closer to real-world demands in the

field. Moreover, these environments contribute to developing socio-emotional skills, such as leadership and adaptability, which are essential for contemporary professional practice. Despite the advance-ments, the review highlighted significant limitations, such as the scarcity of longitudinal studies and the lack of standardized instruments for impact evaluation.

Assessing the objective impact of student-led events on technical skill acquisition, academic performance, and long-term career insertion poses substantial evaluative challenges. Most current studies fail to isolate the specific causal effect of extracurricular event participation from standard curricular progression. To overcome these limitations, future research must transition from non-standardized feedback forms to validated measurement instruments. Competency growth can be quantified using established frameworks such as the AAC&U VALUE Rubrics (for critical thinking, teamwork, and problem-solving), the Motivated Strategies for Learning Questionnaire (MSLQ), or validated STEM Professional Identity Scales. Implementing pre- and post-test designs paired with control groups would provide the empirical rigor necessary to validate these informal learning spaces.

Based on the findings of this review, a conceptual model is proposed that conceptualizes student-led scientific events as transformative learning ecosystems structured across four interdependent dimensions: (i) inputs, which include institu-tional support, financial resources, and academic mentoring (ii) processes, related to the adoption of active methodolo-gies, interdisciplinary collaboration, and real-world problem-solving; (iii) products, represented by the development of tech-nical and socio-emotional skills; and (iv) outcomes, associated with qualified professional training, innovation, and impact on healthcare systems. This model contributes to understanding these events not merely as extracurricular activities, but as structured pedagogical devices with the potential to transform Biomedical Engineering education.

VI. CONCLUSION

This integrative review synthesized evidence reinforcing the role of student-led scientific events as transformative ecosystems in Biomedical Engineering education. From this synthesis, key lessons learned emerge regarding their pedagogical value: first, student leadership in event management shifts learners from passive knowledge consumers to active educational architects; second, robust mentoring ecosystems involving faculty, senior peers, and industry partners are essential to sustain event quality and student engagement; and third, these events serve as vital practical devices bridging technical bioengineering concepts with real-world healthcare demands, thereby directly advancing SDG target alignments.

Despite these contributions, critical research gaps remain in the current literature. Most available evidence relies on short-term, single-institution qualitative reports, leaving a major gap regarding the long-term impact of these events on academic retention, graduation rates, and professional career insertion. Furthermore, there is a notable absence of multicenter comparative studies and quantitative evaluation models capable of measuring the specific educational return on investment or skill acquisition isolated from standard curricular progression. To address these gaps, future research priorities must focus on implementing longitudinal cohort designs, multicenter evaluations across diverse institutional and socioeconomic contexts, and validated quantitative measurement models to rigorously substantiate the transformative potential of student-led learning ecosystem.

***Abstract*—The growing adoption of generative Artificial Intelligence (AI), such as Large Language Models (LLMs), has introduced a disruptive paradigm in scientific communication, with sensitive implications for Biomedical Engineering and the Health Sciences, fields in which published knowledge serves as direct input for medical devices, diagnostic algorithms, and clinical protocols. This scenario exposes the paradox of assisted writing: productivity gains contrast with risks of authorial homogenization, factual hallucinations, and the erosion of academic integrity. This work investigates this paradox in the submission processes of conferences and journals in Biomedical Engineering and the various Health Sciences fields, from a historical and predictive perspective, through a literature review and critical analysis of empirical studies on AI detection systems, focusing on false positives, systemic failures, and resilience mechanisms used to evade plagiarism detection. The results show that verification technologies are statistically unstable: both algorithms and human reviewers fail to reliably distinguish organic from synthetic text, unjustly accusing authentic researchers. A survey of biomedical literature indexed in PubMed identified a tenfold increase in the rate of fabricated references, surging to one in fewer than 280 papers by early 2026, evidencing measurable contamination of the evidence base in health sciences. Unregulated AI adoption also exacerbates structural disparities in science, and absolute prohibition policies prove ineffective. Projecting the future of publishing through 2035, this study concludes that the "Academic Ecosystem" must transition toward guidelines of radical transparency and ethical-use regulation. This shift is essential to preserve the reliability of the knowledge base that underpins the transfer of technology from academia to the market. To this end, evaluation criteria must safeguard researchers' critical reasoning and methodological accountability.**

***Index Terms*—Generative Artificial Intelligence, Academic Integrity, LLM, Biomedical Engineering, Synthetic Content Detection, Scientific Writing.**

I. Introduction

The evolution of scientific communication and research support tools has reached a disruptive milestone with the adoption of generative Artificial Intelligence and Large Language Models (LLMs), altering the foundations and validation processes of academic knowledge synthesis [1]. These architectures use natural language processing to generate text with fluency and coherence, mimicking human writing to the point of challenging even experienced evaluators to distinguish it [2].

The substantial productivity gains in scientific writing have, however, introduced the paradox of AI-assisted writing, in which technological efficiency directly contrasts with the risks of homogenized thinking, loss of authorial integrity, and the emergence of synthetic plagiarism [3]. The rationale for investigating this phenomenon lies in the tension experienced by journals and scientific conference committees, particularly within Biomedical Engineering and the Health Sciences, which face a growing volume of submissions containing factual inaccuracies or algorithmic hallucinations, often masked by scientifically plausible rhetoric [4].

In response, automated tools for detecting AI-generated content have been developed, but the stability and effectiveness of these platforms remain statistically questionable. This fragility translates into frequent false positives, capable of unjustly incriminating the original work of human researchers and deepening the disparities already inherent to the publishing ecosystem [5]. Strict prohibition of these tools disregards their potential for co-creation, requiring the community to urgently transition toward policies grounded in transparency and responsible, ethical use [6].

This work aims to investigate the paradox of generative AI-assisted academic writing within the scientific community, focusing on submission processes in Biomedical Engineering conferences and journals. To this end, the study adopts a historical and predictive approach. The research analyzes technological evolution, evaluates the methodological flaws of current detection systems, and discusses the ethical implications for the future of scientific publishing. Finally, it proposes that evaluation guidelines be adapted to preserve critical reasoning in the face of inevitable automation.

II. Methodology

To comprehensively investigate the impact of LLMs on academic integrity, this study adopted a narrative evidence-synthesis methodology rather than a systematic review protocol. Sources were identified through exploratory searches in the Google Scholar, PubMed, and Web of Science databases, conducted between February and July 2026. The search expressions combined key terms, including "Generative AI," "ChatGPT," and "Large Language Models," crossed with "academic integrity," "peer review," "authorship," and "scientific publishing." Sources were selected based on their relevance to the paradox investigated, prioritizing peer-reviewed articles, institutional guidelines, and official regulatory documents that directly addressed the ethical implications, structural impacts, or detection of synthetic content in academic writing. A total of 145 sources were retrieved through the initial database searches, of which twelve core references were retained for qualitative analysis [1]–[12]. This narrative approach, rather than a systematic protocol with fixed inclusion and exclusion screening at each stage, is acknowledged as a methodological limitation in Section V.

The review was organized into three main analytical axes: an analytical and historical review of documentary evolution, a critical synthesis of empirical studies on detection tools, and an analysis of the incidence of false positives in AI detection systems [4].

Important methodological clarification: this work did not conduct its own empirical tests with AI detectors or synthetic text generation. Instead, it adopted an evidence-synthesis approach, compiling and critically analyzing the results of empirical studies already published in high-impact scientific literature [2], [3]. This methodological choice enabled a comprehensive and comparative view of the state of the art without the need to replicate already robustly documented experiments.

Initially, a methodological mapping was carried out of the transition from traditional documentary support technologies to current natural language processing architectures, contextualizing the ethical implications, copyright restrictions, and emerging editorial policies in light of these innovations [5]. This theoretical foundation allowed for an in-depth structuring of the debate on the paradox of human-machine co-creation in the scientific writing process [1].

In the second axis, the research focused on the critical synthesis of empirical studies on originality-verification technologies designed to identify synthetic content. The study was based on an analysis of the resilience of traditional and AI-focused detectors against evasion strategies, that is, techniques employed by authors to bypass detection, such as successive text rewriting by another AI (recursive paraphrasing) and linguistic prompt optimization [3]. Based on data compiled from the literature, the performance of algorithmic classifiers was examined when confronted with mixed datasets composed of rigorously authentic research abstracts and artificially generated abstracts [2].

The third axis consisted of investigating the intrinsic limitations of algorithmic behavior and human evaluation, focusing on classification failure rates. Trials were synthesized in which blinded human reviewers, together with plagiarism detection platforms, evaluated academic material to identify the machine's signature [2]. Attention was primarily directed toward quantifying the impact of the false-positive phenomenon, an alarming situation in which entirely human-authored texts are unjustly flagged as synthetic plagiarism [2].

This methodological triangulation, crossing the evolutionary history of artificial intelligence with the synthesis of practical tests of its effectiveness and detection, provided the necessary substrate to understand the instability of current control mechanisms and to ground a responsible approach to the use of AI within the publishing ecosystem [6].

III. Results

A. Historical Evolution of Academic Writing Tools

To grasp the magnitude of the current paradox, it is essential to trace the historical evolution of writing technologies in academia, which can be periodized into three distinct eras:

Era 1: Typographic and Mechanical Assistance (1960-1995). In this phase, tools such as the typewriter and, later, the first word processors (WordStar, Microsoft Word), operated exclusively in formatting and editing. The researcher was the sole generator of ideas and text. The technology reduced physical effort and facilitated revisions but did not alter the genesis of scientific thought. Authorship was unquestionably human.

Era 2: Information Retrieval and Originality Policing (1995-2022). With the internet and the digitization of journals, the challenge shifted from production to information retrieval and verification. Unlimited access to articles gave rise to the problem of digital plagiarism and "salami science." Academia's historical response was the development of textual similarity detection software (Turnitin, iThenticate, Copyscape). The focus of the technology was to control originality, requiring the human to prove that the text was theirs through the absence of overlap with existing databases. Authorship remained exclusively human but now had to be "certified" by algorithms.

Era 3: Probabilistic Generation and Algorithmic Co-authorship (2022-Present). Generative AI broke the previous paradigm. The tool no longer merely retrieves or formats text; it generates text based on statistical probabilities learned from vast text corpora. The paradox sets in: the very tool used to "police" originality can now perfectly simulate it. Academia has moved from a posture of assistance to a crisis of authorship, in which the boundary between "productivity tool" and "ghost co-author" becomes systemically blurred.

B. Instability of Detection Systems and False Positives

The results extracted from the synthesis of empirical studies reveal that the ability to discriminate between human writing and synthetic content is highly flawed, both for human evaluators and algorithmic systems [3]. In a blinded evaluation involving 50 original and 50 ChatGPT-generated abstracts from five high-impact medical journals (*Nature Medicine*,

JAMA, *NEJM*, *BMJ*, and *The Lancet*), four human reviewers correctly identified only 68% of artificially generated texts and, alarmingly, incorrectly classified 14% of strictly authentic abstracts as AI-produced [2]. In the same study, an automated AI output detector achieved an area under the ROC curve of 0.94, indicating that algorithmic tools, while imperfect, outperformed unaided human judgment under these specific experimental conditions [2]. This documented incidence of false positives in the literature evidences a harmful distrust instilled in the peer-review process, in which human originality is frequently placed under unwarranted suspicion [2].

Additionally, contemporary synthetic-content detection tools were found to exhibit acute vulnerabilities and drastic drops in effectiveness when confronted with structured evasion techniques. In a controlled experiment, an 11-billion-parameter paraphrasing model (DIPPER) was used to rewrite text generated by large language models including GPT3.5; this evasion strategy collapsed the detection accuracy of the DetectGPT classifier from 70.3% to 4.6% at a fixed false-positive rate of 1%, without appreciably altering the semantic content of the text [13]. This vulnerability to paraphrase-based evasion is consistent with the broader survey findings on detector fragility [3]. Another severe impact observed in academic production generated by these architectures was the occurrence of hallucinations, resulting in nonexistent bibliographic citations and entirely fabricated numerical data that nonetheless perfectly mimic the structure and plausibility of real studies [4].

C. Specific Impact on Scientific Conferences

Scientific conferences, as rituals of social validation and rapid knowledge dissemination, have felt the impact of this paradox in specific and concerning ways:

Flood of Synthetic Abstracts. Between 2021 and 2023, quantitative analyses of submissions to major international conferences and scientific journals identified a measurable increase in AI-generated content, both in oncology conference abstracts [14] and in artificial intelligence conferences such as NeurIPS and ICLR [15].

Crisis of Peer Review at Events. Reviewers began using LLMs to summarize and evaluate full conference papers, often without organizers' permission, leaking confidential data to third-party servers and compromising the confidentiality of the evaluation process.

Devaluation of the Poster Format. With the ease of generating visually flawless posters and dense text via AI, the poster format has lost part of its value as an indicator of the researcher's synthesis effort and content mastery.

Asymmetry in Oral Presentations. Researchers who used AI to prepare presentation scripts demonstrated artificially elevated fluency, while researchers native to non-hegemonic languages, even when experts in the content, continued to face linguistic barriers unresolved by simple automated translation.

D. Structural and Ethical Impacts

The findings also reveal impacts of a structural and ethical nature on the dissemination of science. It was found that unregulated adoption of automated writing carries the intrinsic risk of propagating biases consolidated in the vast training databases, threatening the diversity of thought [5]. Furthermore, it was observed that AI's predictive behavior tends to exacerbate phenomena of academic inequality, such as the Matthew Effect, by systematically favoring the recommendation and citation of already widely referenced works to the detriment of more recent output or research from peripheral researchers [5]. The convergence of this data strongly indicates that the current infrastructure for submission and verification at conferences and in journals is technologically outdated for ensuring content integrity. This fragility not only allows sophisticated fraud to circulate but also penalizes legitimate scientific labor [1].

E. The Specific Case of Biomedical Engineering and Health Publications

Biomedical Engineering has an essentially applied character, in which published knowledge frequently serves as direct input for the development of medical devices, diagnostic algorithms, and clinical protocols. For this reason, the paradox of AI-assisted writing takes on particularly high-risk contours in this field. A survey published in The Lancet, which audited approximately 2.5 million biomedical articles indexed in PubMed Central between January 2023 and February 2026, identified the proportion of articles containing at least one fabricated bibliographic reference. The data are striking: such articles grew more than tenfold during this period. While in 2023 a researcher had to scan nearly 3,000 publications to find a single paper with a fabricated reference, by early 2026 this density had surged, requiring the review of fewer than 280 papers to encounter one, with the sharpest inflection coinciding with the popularization of generative AI writing tools from 2024 onward [7]. The same study found that literature review articles, a category widely used to inform clinical guidelines and care protocols, presented a reference-fabrication rate 57% higher than that of original research articles, amplifying the risk of systemic contamination of the evidence bases used in health decision-making [7].

Vulnerability is not restricted to the writing of primary articles: the integrity of the peer-review process itself in Biomedical Engineering journals has also been directly compromised. In a letter to the editor published in the journal Annals of Biomedical Engineering, researchers reported identifying hidden textual instructions deliberately inserted into preprint manuscripts, designed to manipulate reviewers using AI assistants during review by instructing the system to issue a favorable opinion regardless of the work's scientific merit [8].

In response to analogous risks, funding agencies such as the National Institutes of Health (NIH) and the National Science Foundation (NSF) have formally prohibited the use of generative AI in the peer-review process for research proposals, recognizing the confidentiality and integrity of evaluation as non-negotiable assets [9], [10]. On the national scale, this rigor was consolidated with the publication of Ordinance No.

2,664/2026 by the Brazilian National Council for Scientific and Technological Development (CNPq) [11]. According to an interpretation raised in recent academic debate by researcher Fernanda Scussel [12], the explicit prohibition on inputting third-party projects into AI tools for drafting reviews implies, in practice, a restriction on the use of automated detectors as well. This is because detection platforms require the upload of others' manuscripts for analysis on third-party servers, violating the confidentiality guaranteed by the regulation. This legal perspective directly dialogues with the empirical evidence that such tools are statistically unstable. Given that detectors generate false positives [2], [3] and that legislation itself restricts the transit of third-party data on these platforms [11], it becomes untenable to keep scientific evaluation focused solely on textual policing. In light of this, the urgency is reinforced for a transition in how reviews are conducted, shifting them toward a context focused more on data auditing and methodological transparency.

These findings have direct implications for the theme of this conference edition, "Building Bridges Between Academia and the Market": the transfer of scientific knowledge into the development of health technologies presupposes that this knowledge base be traceable and verifiable at its source. Contamination of the literature by fabricated citations or undetected synthetic data compromises, above all, the very raw material of technological innovation in health, constituting a risk that transcends the strictly academic sphere and directly affects the reliability of the products, devices, and processes derived from it.

IV. Discussion and Predictive Implications (2026-2035)

A. The Organic versus Synthetic Paradox

The scenario outlined by the results evidences the consolidation of the "organic versus synthetic" paradox, in which the boundary between a legitimate co-creation tool and authorial fraud becomes increasingly blurred in academia [1]. The key insight for understanding this phenomenon lies in the observation that the current punitive stance of most journals and conference committees rests on a systemically fragile premise; after all, if a discovery or textual formulation possesses rigor, originality, and scientific value, the purely artificial nature of its genesis should not be the sole criterion for its invalidation [6]. The introduction of these tools does not create ethical problems but rather acts as a magnifying glass that exposes the structural fractures of an academic system historically anchored in the "publish or perish" culture [1], [5].

B. The Unsustainability of the Technological Arms Race

The predictive implications for the future of publishing indicate that the technological arms race between text-generation platforms and detection software is unsustainable and unproductive. Since detectors generate false positives and are easily fooled by paraphrasing, trust in the peer-review process will suffer severe strain if it relies exclusively on algorithmic audits [3].

C. Projections for the Academic Ecosystem (2026-2035)

The four transformations projected below were derived through analytical extrapolation by the authors, based on the structural fractures identified in the empirical evidence discussed in Section III (namely, the instability of detection systems [2], [3], [13], the fabrication crisis documented in biomedical literature [7], and the regulatory responses already adopted by funding agencies [9]–[11]). Unlike the findings reported in Section III, these projections do not derive directly from empirical studies; rather, they represent the authors' reasoned interpretation of where current trends are likely to lead. No formal forecasting method (such as a Delphi panel or structured scenario analysis) was employed, and this speculative nature is further addressed as a limitation in Section V. Given the above, it is projected that journals and scientific events will need to urgently migrate from blind-prohibition policies toward requiring radical methodological transparency. Specifically, four major transformations are anticipated through 2035:

1) Redefinition of Authorship and "Epistemic Origin Seals" [authors' projection]. The requirement for an "AI use declaration" will cease to be a footnote and become a mandatory, auditable metadata field. The creation of "Epistemic Origin Seals" is anticipated, whereby researchers must map exactly what percentage of ideation, writing, and data analysis was delegated to AI. AI "co-authorship" will continue to be denied by major journals, but conferences will create hybrid presentation categories (Human + AI Agent), with specific transparency requirements.
2) Migration from Text to Data Auditing [extrapolated from the detector-instability evidence in Section III-B [2], [3], [13]]. As written text loses its value as proof of competence (since anyone can generate a flawless article with AI), academic evaluation will shift focus to what AI cannot easily falsify: raw data, programming code, laboratory protocols, and the methodological decision tree. In the specific context of Biomedical Engineering, this auditing will translate into the traceability of biosignal databases (such as ECG and EEG), the verification of medical image repositories, and the availability of open-source code for the diagnostic algorithms employed. The article itself will come to function strictly as an "executive summary" of an underlying database, one that is traceable and subject to audit.
3) Rebirth of the Oral Defense at Conferences [authors' projection]. The paradox of writing will trigger a pendulum reaction: the revaluation of orality. Scientific conferences will cease to be showcases for read-aloud texts and will become arenas for the defense of thought. Q&A sessions will be rigorously expanded. A researcher's ability to debate, improvise, and defend their premises against challenges from peers (and auditing AIs) will become the true proof of authorship and understanding.
4) Peer Review Hybridized with AI "Devil's Advocates"

[extrapolated from the regulatory precedents in Section III-E [9]–[11]]. Peer review at conferences will become fully hybridized. AIs will not replace reviewers but will act as pre-programmed "Devil's Advocates," tasked with finding logical flaws, statistical biases, and literature gaps before the article even reaches the human reviewer. In this new arrangement, the expert is repositioned: rather than acting as the manuscript's "primary reader," the expert assumes the role of "auditor of audits." Far from constituting a demotion, this transition elevates the expert to the indispensable status of guardian of scientific ethics and common sense, focusing on questions of relevance and impact that require contextual judgment. This human role will be crucial precisely to catch possible algorithmic hallucinations or biases generated by the evaluating AI itself, since the same architecture capable of fabricating references when writing can also "hallucinate" a nonexistent methodological flaw when evaluating, making it the human reviewer's responsibility to ensure that the AI's critique actually makes sense.

D. Radical Transparency and Open Science

The evaluation ecosystem will need to focus on the open declaration of AI use, requiring that final responsibility, data curation, and the validation of critical reasoning remain inalienable duties of the human researcher, while simultaneously strengthening open science practices [4], [6]. Transparency will no longer be an ethical option but an epistemic requirement for the validity of the knowledge produced.

V. Study Limitations

This study presents certain limitations that should be weighed when interpreting its results and projections. First, from a methodological standpoint, the work is grounded in a narrative evidence synthesis rather than a systematic review protocol; database search results were not exhaustively screened with fixed inclusion and exclusion counts at each stage, and it did not conduct primary empirical tests (such as generating original synthetic texts or novel testing of detection algorithms). Second, given the exponential pace of updates to Large Language Models (LLMs) and verification tools, the empirical data on detector effectiveness represent a temporal snapshot that may become rapidly obsolete. Finally, the quantitative analysis of bibliographic contamination and fabricated references focused primarily on the Health Sciences and Biomedical Engineering databases (such as PubMed, IEEE Xplore, Scopus, and Web of Science), meaning the exact magnitude of the phenomenon may vary if extrapolated to other fields of knowledge, such as the Humanities or Exact Sciences.

Regarding the predictive implications outlined for the academic ecosystem (2026-2035), it is necessary to acknowledge their inherently speculative nature. As explicitly noted in Section IV-C, these four transformations were derived through the authors' analytical extrapolation from documented structural fractures, without recourse to a formal forecasting method such as a Delphi panel or structured scenario analysis. The projected transformations, such as the implementation of origin seals and the hybridization of peer review, constitute logical extrapolations based on current trends and structural fractures within the publishing system. The definitive realization of these scenarios is not deterministic and remains subject to unpredictable variables, such as the pace of updates to current legislation, the commercial policies of major publishing conglomerates, and the degree of cultural acceptance of these new norms within the scientific community itself.

VI. Conclusion

It is concluded that the symbiosis between researchers and generative artificial intelligence models is an irreversible and profoundly transformative technological reality. The demonstrated instability and high failure rate of synthetic content detectors show that the preservation of scientific integrity will not be achieved through banning or imprecise automated tracking. The historical approach demonstrated that academia has always absorbed and domesticated new communication technologies, but generative AI represents a qualitative rupture, as it is not merely an assistance tool but a probabilistic generation agent that challenges the very foundations of authorship. The predictive projections indicate that the future of scientific communication will depend on restructuring evaluation methods and formulating ethical guidelines that prioritize radical transparency, originality of methodological reasoning, and the non-transferable human responsibility over generated knowledge. Scientific conferences, in particular, will have the opportunity to reclaim their lost essence: live debate, the confrontation of ideas, and the oral defense of knowledge. For publications and conferences to maintain their relevance and reliability, systemic adaptation that transcends mere policing of tool use is imperative. The future of academia does not belong to those who write best with the help of machines, but to those who think most clearly to guide them. In the specific field of Biomedical Engineering, this systemic adaptation is a necessary condition for the bridge between Academia and the Market, proposed as the theme of this conference edition, to be built on a verifiable evidence base, rather than on a silent accumulation of fractures in scientific integrity.

Acknowledgments

The authors thank the Faculdade de Tecnologia of the Universidade Estadual de Campinas (UNICAMP) for institutional support and the faculty for their critical contributions that enabled the maturation of this ethical debate. Rafael Fabre Rodrigues e Souza also thanks the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) for granting an institutional scholarship quota (CAPES/DS Scholarship), fundamental for the subsistence and exclusive dedication to graduate academic research.

AI Use Declaration

The authors acknowledge the use of generative artificial intelligence tools in this work. Google's Gemini 3.1 Pro was

used as an auxiliary resource for exploratory research, initial idea structuring, spelling review, textual cohesion enhancement, and translation. Anthropic's Claude Sonnet 5 was used solely to perform a critical review of the manuscript after its finalization. All ideas, analyses, interpretations, results, and final content were reviewed, validated, and remain the sole and exclusive responsibility of the researchers.

***Abstract*— The low representation of women in Science, Technology, Engineering, and Mathematics (STEM) fields highlights the need for initiatives that increase girls' and women's contact with these fields and raise their visibility in academic and professional careers. This study analyzes three live streams organized by the Girls in Technology Project – North Connection, covering topics related to Assistive Technology, Biomedical Engineering, and Biomedicine. The evaluation took into account the reach of promotional posts on Instagram, the number of views of the YouTube streams, the age distribution of the audience, and the questions asked by viewers. The posts received a total of 10,581 views on Instagram, while the live streams reached 333 views on YouTube. The discussions covered the training of educators in the use of assistive technology, career prospects in biomedical engineering, and the challenges faced by an Indigenous student in science. The results provide a preliminary mapping of the digital reach of these initiatives and identify specific instances of audience engagement based on recorded interactions related to training, career opportunities, and women's academic and professional trajectories in technology and health.**

Keywords*— Science promotion; women in science; health technologies; STEM.

I. INTRODUCTION

Women's presence in science, technology, engineering, and mathematics (STEM) is still marked by inequalities, with barriers related to entering and remaining in higher education, as well as to entering the workforce [1]

In engineering degree programs in Brazil, for example, there is still a significant male predominance [2]. However, this situation cannot be attributed solely to female students' individual choices regarding these programs, since their paths are also influenced by gender stereotypes, prejudice, isolation, insufficient institutional support, and a lack of visible female role models [1], [2]

Biomedical Engineering is a relatively recent interdisciplinary field in Brazil, with its first undergraduate program established in 2001 by the University of Vale do Paraíba (UNIVAP) [3]. By integrating knowledge from engineering, the exact sciences, the biological sciences, and the health sciences, the field is interdisciplinary in nature and focuses on the development of techniques, equipment, and technologies for diagnosis, treatment, rehabilitation, and other health-related applications [4].

In this context, scientific outreach and public engagement initiatives can influence perceptions of STEM careers and increase the visibility of female scientists and engineers as professional role models [5]. Thus, presenting the fields of study, career opportunities, and the professional trajectories of women in these areas can also broaden female students' knowledge and bring them closer to the applications of engineering in healthcare [6], [7].

As ways to broaden the reach of science dissemination, social media and digital platforms make it possible to share scientific content with geographically dispersed audiences [8]. In this regard, Phillips et al. [9] found that an initiative carried out on Instagram brought visibility to female researchers of different racial identities and nationalities, highlighting the potential of these channels to showcase female role models to international audiences.

Habibi and Salim also observed that scientific content presented in dynamic formats garnered greater engagement than static posts [8]. In this regard, live streams constitute a format for scientific outreach capable of combining content presentation, sharing academic and professional experiences, and interaction with audiences from different institutions and locations.

In this context, the Girls in Technology Project—North, South, and Northeast Connection was launched, a collaborative initiative among universities in these three Brazilian regions, developed with the goal of promoting participation and increasing the visibility and representation of women in the fields of exact sciences, engineering, and technology.

As part of North Connection, the project carries out initiatives to disseminate scientific knowledge and engage with students, promoting the sharing of academic and professional experiences among women working in STEM fields. This inter-institutional collaboration fosters the exchange of practices and experiences focused on gender equity in science and technology, while also increasing the visibility of women and encouraging the participation of girls and women in these fields.

Among the activities carried out by the project, three live streams were selected for analysis based on their thematic relevance to the intersections of technology, engineering, and health. The study aims to analyze the reach and thematic

contributions of these activities, taking into account the number of views, the content presented, and the questions raised by the audience.

In addition, the study seeks to discuss the potential of these activities to increase female representation and bring girls and women closer to STEM fields, particularly at the intersections of engineering, technology, and health.

II. METHODOLOGY

The methodology was structured into four stages: 1) defining topics related to STEM fields; 2) selecting participants and organizing the team; 3) planning and conducting live streams; and 4) monitoring indicators and audience feedback. These stages made it possible to assess the potential of the activities and their contributions to encouraging greater female participation in engineering.

The project team, shown in Fig. 1, consists of professors and undergraduate and postgraduate students from various fields of study, including Electrical Engineering, Biomedical Engineering, and Chemical Engineering, which contributes to the multidisciplinary nature of the initiatives carried out.

Fig. 1. Girls in Technology Project Team - North Connection

A. *Themes definition*

The events were streamed live on YouTube and lasted an average of 60 minutes. Launched in May 2025, the initiative covered various themes related to inclusion, leadership, accessibility, science, and technology.

The selection of topics for the livestreams was largely guided by suggestions and comments from the participating audience, who identified topics of interest for future editions, thereby fostering a program aligned with the community's needs. In addition, the project team prioritized topics recognized for their scientific and educational relevance, especially those focused on promoting health, inclusion, and technological development.

To this point, the project has held 14 live streams, three of which are included in the scope of this study because they address topics related to biomedical engineering, titled: "Accessibility and Assistive Technology in Professional and Technological Education"; "Women in Health Innovation: Challenges and Opportunities in the Field of Biomedical Engineering"; and "Between Traditional Knowledge and Biomedicine: The Journey of an Indigenous Student in Science."

B. *Selection of Participants*

After the topics were chosen, the selection of participants prioritized professionals whose academic, scientific, and social activities were aligned with the themes addressed in each broadcast. Accordingly, preference was given to female researchers and professionals from the North Region with proven experience in teaching, research, extension, or the development of projects related to biomedical engineering, accessibility, assistive technology, innovation in health, and social inclusion.

In addition to academic background and technical-scientific output, consideration was given to involvement in initiatives with social impact, participation in research and outreach projects, and the representativeness of their professional trajectories, in order to promote discussions grounded in scientific evidence and practical experience.

C. *Live Stream Planning*

The planning and execution of the live streams followed the methodological workflow presented in Fig. 2, structured in three stages. The pre-broadcast stage included defining the theme, selecting the speakers, organizing the team, and preparing support and promotional materials.

During the transmission, the moderator led the session and the technical script was followed. The post-transmission phase involved issuing certificates and collecting feedback from participants, which informed the evaluation of the project's activities.

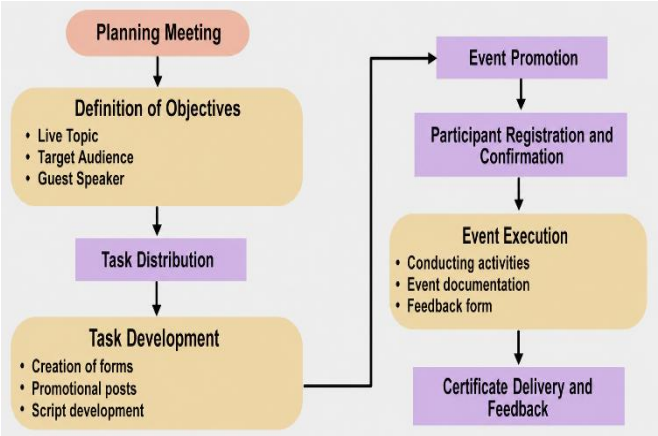

Fig. 2. Planning Flowchart

To expand the reach of the activities, the events were promoted on Instagram—the project's primary communication channel—using promotional graphics, as shown in Fig. 3. The live streams were hosted on YouTube, with technical support and management provided by StreamYard software, which facilitated interaction among participants and the simultaneous broadcast of the event.

Fig. 3. Promotional material for the live streams.

D. *Indicators and Feedback*

In this study, the analysis of the live streams was based on metrics generated by Instagram and YouTube, which allow for an assessment of the reach of the content among followers and non-followers, the demographic profile of the audience (age group and gender), the number of views, and engagement metrics such as likes, shares, comments, and other recorded interactions.

In the case of live streams, comments and interactions that occurred during the broadcast were also considered, making it possible to analyze the level of viewer participation and engagement with the topics discussed. In addition, the feedback forms completed at the end of each live stream were quantitatively analyzed.

The analysis considered the respondents' demographic and educational profiles, the communication channel through which they learned about the live streams, and their evaluations of the organization, clarity of language, fulfillment of expectations, and contribution of the activities to their interest in STEM fields. The rating-scale responses were analyzed using descriptive statistics, including frequencies and percentages, while open-ended responses were considered as complementary qualitative information.

III. RESULTS

The indicators obtained from the three live streams are presented in Table I. On Instagram, the reach of the posts used to publicize the initiatives was analyzed, while the YouTube data corresponds to the views of the live streams. Thus, Instagram metrics were considered indicators of reach and dissemination, whereas YouTube views were used to characterize audience participation in the live broadcasts.

TABLE I. PROJECT LIVESTREAMS

Theme	*Instagram Post Views*	*YouTube Live Views*
Accessibility and Assistive Technology in Vocational and Technological Education	3.888	77
Women in Health Innovation: Challenges and Opportunities in the Field of Biomedical Engineering	3.578	81
Between Traditional Knowledge and Biomedicine: The Journey of an Indigenous Student in Science.	3.115	175

The three promotional posts analyzed reached a total of 10,581 views on Instagram, with an average of 3,527 views per post. The corresponding live streams recorded 333 views on YouTube, comprising 77 views for the Accessibility and Assistive Technology initiative, 81 for Biomedical Engineering, and 175 for Biomedicine. These results show that the publications achieved broad dissemination on Instagram, while the live broadcasts reached a more specific audience on YouTube. Therefore, the two indicators provide complementary information: Instagram reflects the visibility achieved through the dissemination strategy, whereas YouTube views provide an indication of participation in live activities.

Among the Instagram publications, the initiative on Accessibility and Assistive Technology accounted for 36.7% of the views, followed by Biomedical Engineering, with 33.8%, and Biomedicine, with 29.4%. The relatively close distribution of views among the three themes indicates consistent interest in different relationships between technology and health, including accessibility, innovation, professional education, and diversity in science.

The live broadcast entitled "Accessibility and Assistive Technology in Vocational and Technological Education" addressed the relationship between technology, inclusion, and professional education. Among the questions raised by viewers during the broadcast, two stood out:

> "Many educators lack the training and knowledge required to use Assistive Technology in education, which limits the effectiveness of including students in educational practices. How can this situation be changed?"

> "Do you believe that accessibility is considered from the beginning of research projects, or does it still tend to appear as a subsequent adaptation?"

These questions directed the discussion toward two aspects highlighted in the literature: the need for teacher training for the appropriate selection and use of Assistive Technology, and the adoption of universal design approaches, in which accessibility is considered in advance during the planning of educational practices and resources, thereby reducing the need for subsequent adaptations [10], [11]. In this context, the initiative presented Assistive Technology as a field of research and professional practice committed to developing more inclusive solutions.

During the live broadcast entitled "Women in Health Innovation: Challenges and Opportunities in the Field of Biomedical Engineering," which highlighted female

participation at the intersection of engineering, innovation, and health, questions such as the following were recorded:

> "What distinguishes Biomedical Engineering from Engineering Physics?"

> "What is the job market like for biomedical engineers?"

These questions indicate an interest in understanding the identity of the field and its professional opportunities. The responses made it possible to present professional activities related to research, development, management, and healthcare technologies. These activities are consistent with the professional competencies of Biomedical Engineering established in Article 8 of CONFEA Resolution No. 1,156/2025, in conjunction with the professional activities defined in Article 5 of Resolution No. 1,073/2016 [12], [13].

By sharing the guest speaker's academic and professional journey, the live broadcast also increased the visibility of women working in engineering and research. This aspect is consistent with studies that emphasize the importance of visible female role models in encouraging girls to identify with STEM fields [5].

The live broadcast entitled "Between Traditional Knowledge and Biomedicine: The Journey of an Indigenous Student in Science" recorded the highest number of views on YouTube and Instagram. Most of the audience consisted of non-followers, accounting for 83.7% of the total.

During the broadcast, participants asked:

> "What were the greatest challenges you faced when entering and remaining in the scientific field as an Indigenous student?"

> "What were the greatest cultural or scientific shocks you experienced when entering university?"

These questions broadened the discussion to include the challenges faced by Indigenous women in accessing and remaining in higher education, as well as the relationships among academic education, cultural identity, and a sense of belonging. These aspects are discussed in the literature as important elements of the university experiences of Indigenous women [14]. By presenting the guest speaker's journey, the live broadcast also increased the visibility of women and Indigenous and Amazonian individuals within scientific and academic environments. This is consistent with studies that associate such representation with empowerment, the recognition of traditional knowledge, and the strengthening of ethnic identity [14].

Furthermore, the age distribution indicated that the Instagram content reached audiences from different age groups, as illustrated in Fig. 4.

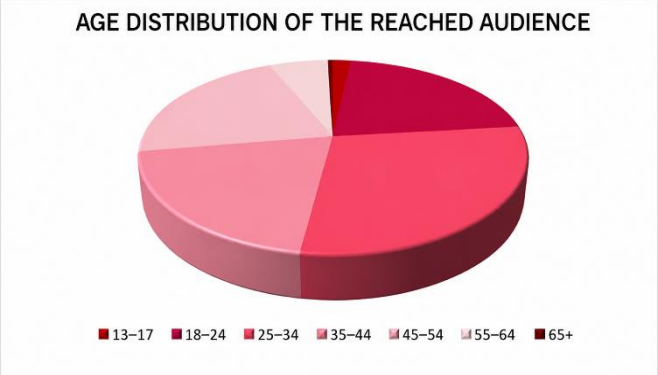

Fig. 4. Age distribution associated with the promotional posts for the three Instagram live broadcasts.

In Assistive Technology, the 45–54 age group stood out, accounting for 46.7% of the audience. In Biomedical Engineering, 67.0% of the audience was between 25 and 44 years old, whereas in Biomedicine, 73.0% was between 18 and 34 years old. This variation suggests that the topics attracted individuals at different stages of their academic education and professional careers.

The combined analysis allows the identification of three main contributions: the discussion on the inclusive application of technologies, the dissemination of professional opportunities at the intersection of engineering and health, and the recognition of diverse female trajectories in science.

The quantitative analysis of the feedback forms, completed by a total of 28 participants, complemented the indicators obtained from the digital platforms, allowing the characterization of the participants' profiles and their evaluation of the activities. Among the respondents, 57.1% were women and 42.9% were men. Regarding educational level, undergraduate students predominated (82.1%), followed by secondary school students (14.3%), while postgraduate participation was lower (3.6%). Most respondents reported that they had learned about the live streams through Instagram, reinforcing the relevance of this platform as a dissemination channel for the activities.

Regarding the evaluation of the live streams, 92% of respondents positively assessed the organization of the activities. In the overall evaluation, 95% assigned the highest score, while the remaining 5% assigned a score of 4, corresponding to a "good" rating. The feedback forms also recorded predominantly positive evaluations regarding the clarity of the language, fulfillment of expectations, and the contribution of the activities to interest in STEM fields. These quantitative results indicate a high level of acceptance among the participants who completed the feedback forms and complement the reach and participation metrics obtained from Instagram and YouTube.

In addition, records of audience participation during the live broadcasts, particularly through comments and questions, complement the digital metrics by identifying specific topics that generated audience interaction. Within the scope of the data collected, these results indicate point

instances of engagement with topics related to accessibility, professional opportunities, and women's trajectories in science, engineering, and health.

IV. CONCLUSION

The study provided a preliminary mapping of the digital reach of scientific outreach initiatives related to female participation in technology and health. The analysis of Instagram and YouTube metrics, feedback forms, and audience interactions allowed the identification of specific instances of engagement with topics related to accessibility, professional opportunities, and diverse female trajectories in science. It is important to highlight that this information is limited to the interactions recorded during the analyzed activities, which restricts broader interpretations regarding female participation in STEM fields.

V. FUTURE WORKS

As a next step toward improving the project, it is proposed to expand the analysis by including a larger number of participants and live streams, as well as longitudinally monitoring their academic and professional trajectories. It is also intended to investigate whether exposure to the live streams and female role models in STEM fields is associated with students' interest in and persistence in Engineering programs over the years. For future evaluations, quantitative metrics and statistical validation methods are recommended to enable a more robust assessment of the impacts of these initiatives. These improvements may contribute to a broader understanding of their effectiveness in promoting women's participation and supporting academic and professional pathways in STEM fields.

***Abstract*—Mental health content about disorders like anorexia and bulimia has grown rapidly on platforms such as TikTok and Instagram, especially among adolescents, but the sheer volume makes it hard to distinguish reliable information from misleading content. This study presents a pipeline to automatically classify short videos into three categories (useful, misleading, and personal experience), combining mobile-based collection, transcription, expert annotation, and supervised classification. Inter-annotator agreement (Fleiss' Kappa) was incorporated into model training via sample weighting. Since the annotated corpus was small and imbalanced (33 videos, no misleading examples), a three-stage synthetic augmentation pipeline was built using LLM-generated seed texts, BERTimbau embeddings, class-conditional GANs, and LLM paraphrasing. Four classifiers (Logistic Regression, Random Forest, SVM, Naive Bayes) were trained on TF-IDF features with Kappa-oriented Grid Search, achieving 0.885–0.893 accuracy and 0.817–0.840 Kappa, surpassing per-disorder baselines and comparable literature. Logistic Regression was selected for deployment for its low inference cost and calibrated probabilities, and integrated into a real-time web interface that classifies videos by URL, reporting a confidence score adjusted by inter-annotator reliability and a semantic-affinity indicator per disorder.**

***Index Terms*—Mental Health; Natural Language Processing; Machine Learning; Eating Disorders; Interrater Agreement; Data Augmentation; Social Media.**

I. Introduction

Mental disorders are recognized as a major public health concern due to their substantial impact on quality of life, functioning, and mortality [1]. Among the conditions that demand particular attention are anorexia and bulimia, eating disorders associated with severe physical, emotional, and behavioral harm that affect millions of people worldwide [2]. Early identification of symptoms, access to reliable information, and adequate follow-up are essential to prevent worsening and to promote mental health.

In parallel, social media platforms have become central to the production, sharing, and consumption of health-related information [3]. Platforms such as TikTok and Instagram have consolidated themselves as major digital communication channels, allowing users to publish personal experiences, opinions, guidance, and educational content in accessible, rapidly disseminated formats. Short-form videos have become one of the primary means of information consumption, reaching millions of views daily and significantly influencing how people seek knowledge on a wide range of topics [4].

Although these platforms contribute to democratizing access to information and foster discussion of previously underaddressed topics, they also raise challenges related to the quality and reliability of published content. The absence of effective validation mechanisms allows inaccurate, misleading, or decontextualized information to spread at scale, often reaching visibility comparable to that of content produced by qualified professionals [5], [6]. For sensitive topics such as eating disorders, the circulation of inadequate information can reinforce stigma, normalize harmful behaviors, and contribute to misconceptions about diagnosis, treatment, and prevention; recent experimental evidence shows that even brief exposure to pro-anorexia short-form video content produces measurable declines in body image satisfaction among young women [7].

The sheer volume of published content makes manual analysis infeasible, motivating automated approaches to identify, organize, and classify this information. Natural Language Processing (NLP) and Machine Learning (ML) techniques have shown potential to support the analysis of large volumes of data in a fast, consistent, and scalable manner [8].

This work aims to develop machine-learning-based computational tools to collect, transcribe, and classify short videos published on Instagram and TikTok related to anorexia and bulimia, and to assess the reliability of the information shared on these platforms by measuring agreement among human evaluators. Specific objectives include: collecting short videos related to the disorders under study on both platforms; building a dataset through human classification of the collected videos; designing a text preprocessing pipeline for the collected content; training machine learning models for automatic validation and classification informed by inter-annotator agreement; analyzing model performance and the reliability of the generated classifications; and developing a web interface to make the classification system available.

II. Methodology

A. Data Collection

Short videos were collected from TikTok and Instagram Reels using Appium-based mobile automation [9]. The collection targeted hashtags related to anorexia and bulimia in both female- and male-oriented contexts, evenly distributed across the two platforms. To ensure sufficient public reach, only videos meeting a minimum engagement threshold of 10k views on Instagram or 10k likes on TikTok were considered.

Audio was extracted using the Python `youtube-dl` library. Videos containing excessive background noise, dominant music, or other audio characteristics unsuitable for textual analysis were filtered using TensorFlow's YAMNet model [10] in combination with Fourier-domain signal analysis, retaining only those in which the audio was predominantly classified as speech. The remaining audio was converted to WAV format and transcribed using the Python `SpeechRecognition` library. The resulting transcripts were stored together with each video's original metadata.

Initially, 400 videos were collected for each disorder, comprising 200 videos associated with female-oriented hashtags and 200 with male-oriented hashtags. After automated audio filtering and manual verification of topical relevance and language (Portuguese only), only 19 anorexia-related videos and 14 bulimia-related videos satisfied the final inclusion criteria. This substantial reduction highlights the challenge of identifying directly relevant content on social media, as many videos employed the target hashtags only incidentally or in contexts unrelated to eating disorders.

Videos were labeled by expert judges from the Alagoas Psychometrics and Psychological Assessment Laboratory (LAPAP) into three categories: useful, misleading, and personal experience (adapted from [11]). Two independent panels of judges (n = 10 for anorexia, n = 11 for bulimia) rated all videos, and the inter-annotator agreement was quantified with Fleiss' Kappa, both overall and per category. The study was approved by the UFAL Research Ethics Committee (protocol No. 7.587.554).

B. Class imbalance and synthetic data augmentation

As shown in Table I, no videos were labeled as misleading for either disorder, resulting in a severe class imbalance that precluded reliable supervised learning. Expanding the dataset through additional rounds of manual annotation was deemed impractical due to the time required and the limited availability of domain experts. To address this limitation, a three-stage synthetic data augmentation pipeline was developed. It must be stated explicitly that, because not a single real, human-annotated example of the *misleading* category was available, the classifier's performance on this class cannot be validated against any held-out real-world sample. Consequently, the reported metrics for this category should be interpreted strictly as a proof-of-concept (PoC) demonstration of the proposed pipeline's feasibility, rather than as evidence of generalization to real.

TABLE I
DISTRIBUTION OF CLASSIFICATION CATEGORIES

Category	**Disorder**	
	Anorexia	***Bulimia***
Useful	5	6
Misleading	0	0
Personal Experience	14	8

The first stage consisted of seed generation. Ten synthetic misleading texts were created for each disorder using the Gemini large language model (LLM). A structured prompt instructed the model to assume the role of a digital content creator and produce pseudoscientific narratives that promoted or normalized behaviors associated with anorexia or bulimia. Students with relevant domain knowledge manually reviewed all generated texts before being incorporated into the dataset.

In the second stage, all available texts were encoded into 768-dimensional embeddings using BERTimbau (`neuralmind/bert-base-portuguese-cased`), with the representation extracted from the final hidden layer. These embeddings were used to train class-conditional Generative Adversarial Networks (GANs), which generated synthetic embeddings for the underrepresented class.

In the final stage, each synthetic embedding was mapped back to text. When the cosine similarity between a synthetic embedding and its nearest real embedding was greater than or equal to 0.70, the corresponding original text was used directly. Otherwise, the closest synthetic seed text was rewritten by the Gemini LLM using the prompt: "Rewrite the following sentence using different words while preserving its original meaning, without translating it into English." This procedure increased lexical diversity while maintaining semantic consistency.

In this initial study, the data augmentation pipeline expanded the anorexia dataset from 29 to 329 samples (+1034.5%) and the bulimia dataset from 24 to 324 samples (+1250%), resulting in datasets that were approximately balanced across the three classification categories. This amount was empirically determined and used to increase other mental disease databases used by our research group.

Text was tokenized and stop words were removed before feature extraction. Data were split 80/20 into development and held-out test sets before synthetic augmentation, ensuring the test set reflects real-world, independent data (though it does include the manually added misleading seed texts). Each classifier (Logistic Regression, Random Forest, SVM, Naive Bayes) was wrapped in a scikit-learn Pipeline that combined TF-IDF vectorization with the classifier, so the vectorizer was fit only on training folds, preventing data leakage.

Each training sample was weighted according to

$$w_i = 0,8 + \kappa_c \tag{1}$$

where κ_c is Fleiss' Kappa of the category to which the sample belongs. The 0.8 floor was implemented to ensure that categories with near-zero agreement still contribute to training rather than being effectively excluded.

Hyperparameters were tuned via Grid Search with 3-fold stratified cross-validation (chosen given the small dataset size to avoid folds with fewer than four examples per class), using Cohen's Kappa as the optimization metric—more appropriate than raw accuracy under class imbalance. Table II lists the hyperparameter grids evaluated.

TABLE II
HYPERPARAMETER GRIDS USED IN GRID SEARCH

Model	Evaluated Hyperparameters
Logistic Regression	**C**: 0.01, 0.1, 0.5, 1.0, 10.0 **penalty**: 11,12 **solver**: liblinear
Random Forest	**n_estimators**: 10, 50, 100, 200 **max_depth**: 1, 10, 20, 50 **min_samples_split**: 2, 5, 10, 20 **min_samples_leaf**: 1, 5, 10, 20 **max_features**: sqrt, log2
SVM	**C**: 0.01, 0.1, 1.0, 10.0 **gamma**: scale, auto **kernel**: linear, rbf
Naive Bayes	**alpha**: 0.01, 0.1, 0.5, 1.0, 10.0 **fit_prior**: True, False

We performed a complementary analysis on the unified dataset using Rocchio-style TF-IDF centroids per disorder [12], computed exclusively on the training subset. Cosine similarity between each text and both centroids was normalized to a percentage semantic-affinity score, which was later exposed to end users.

C. Deployment interface

The selected model (Logistic Regression, trained on the unified augmented dataset with isotonic probability calibration) was integrated into a Python/Gradio web application. Given a video URL, the pipeline downloads audio, transcribes it with OpenAI Whisper (chosen over `SpeechRecognition` for its greater robustness to variable real-world audio quality and noise), applies the same TF-IDF/preprocessing steps, classifies the content, and computes an adjusted confidence score:

$$C_{aj} = \alpha \cdot p_m + \beta \cdot \hat{\kappa}_c \tag{2}$$

where p_m is the calibrated model probability for the predicted class, κ_c is Fleiss' Kappa of that class normalized by the maximum observed category Kappa, and α = 0.7, β = 0.3 were set empirically to prioritize model sensitivity while still incorporating annotation reliability. Scores at or below 0.40 (the "fair" threshold on Altman's scale) trigger an automatic low-confidence visual warning recommending expert review. The interface also reports the semantic-affinity indicators using a separate TF-IDF vectorizer fitted to the combined vocabulary of both disorders.

It should be acknowledged that the weighting coefficients were set empirically rather than derived from a formal statistical calibration procedure. As a direct consequence, given that the *misleading* category consistently exhibits the lowest Fleiss' Kappa across both disorders ($\kappa \approx 0.09$–0.15), the resulting adjusted confidence score for this class is systematically pulled below the 0.40 alert threshold by construction, regardless of the model's own predicted probability. This behavior should therefore be understood as a hardcoded business rule designed to flag inherently low-reliability categories for human review, rather than as a probabilistically calibrated estimate of the true likelihood that a given prediction is correct.

III. RESULTS AND DISCUSSIONS

A. Anorexia dataset

Overall Fleiss' Kappa reached 0.659 (SE = 0.0033, 95% CI [0.595, 0.724]), indicating *good* inter-rater agreement according to Altman's scale. Category-level agreement was also classified as *good* for the personal experience ($\kappa = 0.719$) and useful ($\kappa = 0.717$) classes. In contrast, the misleading category achieved only *very weak* agreement ($\kappa = 0.150$), reflecting both its limited representation in the original dataset and the greater ambiguity associated with identifying misleading content.

Following the three-stage LLM-based synthetic data augmentation process described in Section II, the dataset increased from 29 to 329 samples. This increase in both class balance and textual diversity created more favorable conditions for learning discriminative patterns, particularly for the originally underrepresented classes.

The expanded dataset substantially improved the performance of most classifiers. As shown in Table III, Random Forest exhibited the largest relative gain, with Kappa increasing from 0.368 to 0.795 and accuracy improving from 0.667 to 0.864. Logistic Regression and Naive Bayes also benefited from the augmented dataset, both achieving Kappa values above 0.79 and accuracies exceeding 86%, demonstrating that the synthetic samples effectively enriched the training set without compromising overall predictive consistency.

TABLE III
CLASSIFICATION PERFORMANCE BEFORE AND AFTER LLM-BASED SYNTHETIC DATA AUGMENTATION FOR THE ANOREXIA DATASET.

Model	Metric	Original Data	Augmented Data
Logistic Regression	Accuracy	0.8333	0.8788
	F1-score	0.6190	0.8808
	Precision	0.5833	0.8899
	Recall	0.6667	0.8800
	Kappa	0.7000	0.8181
Random Forest	Accuracy	0.6667	0.8636
	F1-score	0.4722	0.8588
	Precision	0.5333	0.8668
	Recall	0.5000	0.8613
	Kappa	0.3684	0.7952
SVM	Accuracy	1.0000	0.8939
	F1-score	1.0000	0.8958
	Precision	1.0000	0.9056
	Recall	1.0000	0.8945
	Kappa	1.0000	0.8407
Naive Bayes	Accuracy	0.8333	0.8636
	F1-score	0.8222	0.8647
	Precision	0.8333	0.8833
	Recall	0.8889	0.8649
	Kappa	0.7500	0.7958

Although SVM presented a reduction in Kappa from 1.000 to 0.841 after augmentation, this decrease should not be interpreted as a deterioration in predictive performance. Instead,

it reflects the elimination of the optimistic bias introduced by overfitting on the original test set, which contained only four samples. Consequently, the post-augmentation results provide a more realistic estimate of the classifier's performance on unseen data.

Overall, the results indicate that LLM-based synthetic data augmentation improved not only predictive performance but also the stability of the learning process. The most expressive gains were observed for Random Forest, suggesting that this algorithm was particularly sensitive to the increased volume and diversity of training examples. In contrast, the more modest improvements achieved by Logistic Regression and Naive Bayes indicate that these models were already capable of capturing part of the underlying textual patterns in the original dataset. However, they still benefited from the improved class balance.

B. Bulimia dataset

Inter-rater reliability was assessed using Fleiss' Kappa, yielding an overall coefficient of 0.655 (SE = 0.0033, 95% CI [0.590, 0.719]), which corresponds to *good* agreement according to Altman's scale. Agreement was strongest for the personal experience ($\kappa = 0.708$) and useful ($\kappa = 0.673$) categories, whereas the misleading category achieved only *very weak* agreement ($\kappa = 0.090$). As observed in the anorexia dataset, the lower agreement on misleading content is likely due to its limited representation in the original corpus and the greater subjectivity involved in identifying misleading health-related information.

Following the three-stage LLM-based synthetic data augmentation process described in Section II, the dataset expanded from 24 to 324 samples, providing a substantially larger and more balanced corpus for supervised learning.

Table IV summarizes the classification results before and after augmentation. In contrast to the anorexia dataset, all four classifiers produced the same performance on the original dataset, achieving an accuracy of 0.800 and a Kappa coefficient of 0.667. This uniform behavior is unlikely to reflect equivalent learning capabilities; instead, it is a consequence of the extremely small test set, where the limited number of evaluation samples constrained the classifiers to identical prediction outcomes.

The expanded dataset produced consistent improvements across all evaluated algorithms. Logistic Regression and Random Forest achieved the best overall performance, with accuracies of 0.985 and Kappa coefficients of 0.977. At the same time, SVM and Naive Bayes obtained accuracies of 0.954 with Kappa values close to 0.931.

Taken together, these findings indicate that the proposed LLM-based augmentation strategy effectively mitigated the limitations imposed by the small and initially imbalanced dataset. Besides improving predictive performance across all classifiers, the expanded corpus enabled a more reliable assessment of model generalization.

TABLE IV
CLASSIFICATION PERFORMANCE BEFORE AND AFTER LLM-BASED SYNTHETIC DATA AUGMENTATION FOR THE BULIMIA DATASET.

Model	Metric	Original Data	Augmented Data
Logistic Regression	Accuracy	0,8000	0,9846
	F1-Score	0,6000	0,9848
	Precision	0,5556	0,9855
	Recall	0,6667	0,9848
	Kappa	0,6667	0,9769
Random Forest	Accuracy	0,8000	0,9846
	F1-Score	0,6000	0,9845
	Precision	0,5556	0,9855
	Recall	0,6667	0,9841
	Kappa	0,6667	0,9769
SVM	Accuracy	0,8000	0,9538
	F1-Score	0,6000	0,9545
	Precision	0,5556	0,9559
	Recall	0,6667	0,9538
	Kappa	0,6667	0,9307
Naive Bayes	Accuracy	0,8000	0,9538
	F1-Score	0,6000	0,9542
	Precision	0,5556	0,9551
	Recall	0,6667	0,9538
	Kappa	0,6667	0,9308

C. Unified dataset

The anorexia and bulimia datasets were merged to evaluate cross-disorder generalization, using averaged per-category Fleiss' Kappa (Useful: 0.695; Misleading: 0.120; Personal experience: 0.713). The unified corpus initially comprised 53 annotated samples and, after the three-stage LLM-based synthetic augmentation process, expanded to 653 samples with an almost perfectly balanced class distribution.

Unlike the individual datasets, the original merged corpus already produced competitive performance for three of the four evaluated classifiers, with accuracies ranging from 0.818 to 0.909, as shown in Table V. Only Random Forest exhibited noticeably lower performance (0.636), suggesting that the linguistic characteristics shared among disorder-related content already yield relatively consistent discriminative patterns, even before synthetic augmentation.

After augmentation, all classifiers converged to a narrow performance range, with accuracies between 0.885 and 0.893. Compared with the original dataset, the variation in accuracy across models decreased from 0.273 to only 0.008, indicating that synthetic augmentation not only improved predictive performance but also reduced variability among different learning algorithms. Logistic Regression, Random Forest, and SVM all benefited from the expanded dataset, whereas Naive Bayes showed a slight decrease in some evaluation metrics. One possible explanation is that the richer semantic relationships introduced by the synthetic texts partially violate the conditional independence assumption on which Naive Bayes relies.

To place these findings into context, they were compared with the results reported by Benítez-Andrades *et al.* cite benitezandrades. In their study, Random Forest achieved an accuracy of 73.7% with an F1-score of 49.2%. At the same time, a RoBERTa-based model achieved 84.4% accuracy in classifying English-language eating-disorder posts as informative or non-informative. The proposed approach achieved

TABLE V
CLASSIFICATION PERFORMANCE BEFORE AND AFTER LLM-BASED SYNTHETIC DATA AUGMENTATION FOR THE UNIFIED DATASET.

Model	Metric	Original Data	Augmented Data
Logistic Regression	Accuracy	0,8182	0,8855
	F1-Score	0,7852	0,8861
	Precision	0,8667	0,8872
	Recall	0,7667	0,8861
	Kappa	0,7027	0,8282
Random Forest	Accuracy	0,6364	0,8779
	F1-Score	0,4667	0,8780
	Precision	0,4222	0,8852
	Recall	0,5333	0,8790
	Kappa	0,3889	0,8168
SVM	Accuracy	0,8182	0,8931
	F1-Score	0,7852	0,8934
	Precision	0,8667	0,8954
	Recall	0,7667	0,8931
	Kappa	0,7027	0,8396
Naive Bayes	Accuracy	0,9091	0,8931
	F1-Score	0,8586	0,8931
	Precision	0,9444	0,8943
	Recall	0,8333	0,8946
	Kappa	0,8493	0,8397

competitive performance despite relying on conventional machine learning classifiers and a substantially smaller annotated corpus, with classification results exceeding those reported for both the Random Forest and RoBERTa-based models in terms of accuracy. Nevertheless, these comparisons should be interpreted with caution because of differences in language, social media platforms, annotation protocols, and classification objectives.

The learning curve obtained for Logistic Regression (Fig. 1) on the augmented unified dataset provides additional evidence of the benefits of synthetic augmentation. A persistent gap between the training and validation curves was observed until approximately 400 training samples, with the validation F1-macro remaining close to 0.59 while the training score exceeded 0.80. Beyond approximately 420 samples, however, both curves began to converge while continuing to improve, suggesting that the availability of additional synthetic samples progressively mitigated intermediate-stage overfitting. This trend also indicates that incorporating more real annotated data could further improve the model's generalization capability.

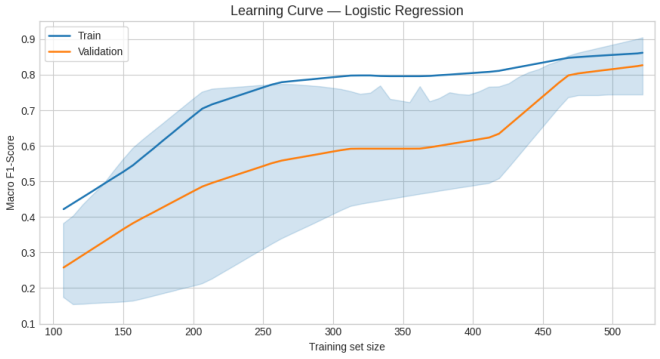

Fig. 1. Learning curve for the Logistic Regression classifier.

Prediction confidence exhibited a behavior consistent with the annotation reliability analysis. After applying the confidence adjustment defined in (2), predictions belonging to the useful and personal experience classes remained strongly concentrated near the maximum confidence level, both before and after augmentation. In contrast, confidence scores for the misleading class were considerably more dispersed, with most predictions concentrated between 0.70 and 0.75 after augmentation. This behavior is consistent with the low inter-rater agreement observed for the misleading category (Fleiss' Kappa = 0.120), suggesting that annotation uncertainty propagates into the classifier's confidence estimates.

Finally, semantic-affinity analysis based on Rocchio centroids revealed high within-disorder relevance, reaching 80.5% for anorexia and 76.6% for bulimia, whereas cross-disorder relevance remained substantially lower (19.2–23.4%). These findings indicate that, although both disorders share eating disorder-related vocabulary, each exhibits a distinct semantic profile. This semantic separation helps explain the strong classification performance achieved on the merged dataset and supports the feasibility of both disorder-specific and cross-disorder text classification.

D. Deployed Interface

Initially developed to analyze Portuguese-language videos, the application was designed with a focus on validating the user experience. The workflow begins with the initial input screen (Figure 2), where users can submit the URL of an Instagram or TikTok video for classification. Upon submission, the system processes the video and presents the comprehensive analysis on the output screen (Figure 2).

Fig. 2. Results screen displaying the predicted class.

This interface details the outcome of the Natural Language Processing (NLP) pipeline, reporting the predicted class, the base model probability, the Fleiss' Kappa of the predicted class, and an adjusted confidence score with its corresponding Altman interpretation. Additionally, it displays the full video transcript alongside the semantic-affinity percentages toward specific disorders (Figures 3 and 4).

To demonstrate this functionality, the figures include an illustrative example using an Instagram Reels URL. In this case, the system predicted the "personal experience" class with a 71.2% model probability and a 79.9% adjusted confidence score (Fleiss' Kappa = 0.713). Furthermore, the semantic

Fig. 3. Results screen displaying the model probability, adjusted confidence, and the video transcript.

analysis revealed an affinity of 55% toward bulimia and 45% toward anorexia.

Fig. 4. Detailed metrics screen illustrating the semantic-affinity percentages for the analyzed video.

IV. Conclusion

This work presented a complete pipeline for the automatic classification of eating disorder-related short-form video content, encompassing automated data collection, expert annotation, LLM-based synthetic data augmentation, supervised learning, and a deployed reliability-aware classification interface. Unlike conventional approaches that provide only a predicted label, the proposed system explicitly incorporates inter-rater agreement through Fleiss' Kappa.

Experimental results demonstrated that synthetic data augmentation substantially improved classifier performance and produced more stable estimates of model generalization. Across the anorexia, bulimia, and unified datasets, the augmented corpora consistently outperformed their original counterparts, with the unified dataset achieving up to 0.893 accuracy and a Kappa coefficient of 0.840 using classical machine learning classifiers.

Despite these promising results, several limitations should be acknowledged. The manually annotated corpus remained relatively small after language and relevance filtering, making the reported performance dependent on synthetic data whose ability to generalize to broader real-world scenarios still requires further validation. In addition, the consistently low inter-rater agreement observed for the misleading category suggests that this class requires a more precise operational definition to improve annotation consistency. Finally, the study was restricted to Brazilian Portuguese, and the automatic transcription process remains sensitive to factors such as audio quality, regional accents, and code-switching.

A further methodological concern is a mismatch between the transcription method used to build the training corpus and the one used at deployment. The training dataset was transcribed with the `SpeechRecognition` library, whereas the deployed interface uses OpenAI Whisper; the latter was used only for testing and will be replaced by an API in future work, with `SpeechRecognition` as the main library.

Another weak point of this study is that none of the 33 collected videos was classified as "Misleading". Future work will remake the video collection process looking for this class, thereby increasing both the volume and diversity of the corpus. Additional annotation rounds will refine the definition of misleading content and investigate alternative annotation protocols. From an application perspective, future versions of the proposed system will include mechanisms for collecting feedback on model predictions and support for direct text and audio submissions without requiring URLs from external social media platforms. Overall, the proposed framework provides a practical foundation for developing reliable decision-support tools to help identify and analyze eating disorder-related content on social media while maintaining transparency about prediction reliability.

***Abstract*— University hospitals play a strategic role in fostering innovation by integrating healthcare delivery, education, research, and technological development. This study describes the experience of the Hospital de Clínicas de Porto Alegre (HCPA) in establishing a healthcare innovation ecosystem through the Health Technology and Innovation Park (HCPATec), including the pre-incubation, incubation, and intrapreneurship programs promoted by the Starts-HCPA Technology-Based Business Incubator. A cross-sectional observational study was performed based on institutional records from the Starts-HCPA innovation programs conducted between 2023 and 2025. During this period, nearly 30 entrepreneurial initiatives were supported, covering areas such as artificial intelligence, digital health, medical devices, wearables, mental health, pharmaceuticals, rehabilitation, and assistive technologies. The programs engaged more than 150 participants and contributed to the creation and consolidation of technology-based healthcare startups. The results demonstrate the potential of university hospitals as hubs for open innovation, technology transfer, and the generation of socioeconomic impact.**

Keywords—healthcare innovation; university hospital; entrepreneurship; startups; business incubation; technology transfer.

I. INTRODUCTION

Innovation has been widely recognized as a key driver for addressing the contemporary challenges faced by healthcare systems. Population aging, increasing demand for healthcare services, and the rapid incorporation of emerging technologies require organizational models capable of translating scientific and technological knowledge into practical healthcare solutions with meaningful clinical and societal impact [1].

In this context, university hospitals occupy a strategic position by integrating patient care, education, and research, thereby providing an ideal environment for identifying real-world healthcare challenges and developing technologies tailored to users' needs [2]. In addition to concentrating clinical, academic, and scientific activities, university hospitals possess characteristics that make them particularly conducive to intrapreneurship. Although hierarchical structures, regulatory requirements, and patient safety concerns may constrain experimentation, the inherent complexity of healthcare delivery creates opportunities for innovation in processes, services, and organizational models. International evidence demonstrates that structured intrapreneurship programs foster clinical leadership, interdisciplinary collaboration, and the development of solutions aligned with institutional needs [3][4][5].

Within this context, the Hospital de Clínicas de Porto Alegre (HCPA), an academic hospital affiliated with the Federal University of Rio Grande do Sul (UFRGS), established its healthcare innovation ecosystem through the creation of the HCPATec Health Technology and Innovation Park. Located within the hospital premises, HCPATec promotes synergies between long-established scientific research activities and a technology-driven innovation approach, fostering collaboration with industry while supporting the creation of new healthcare-focused companies. To further stimulate innovation-driven

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

entrepreneurship, HCPA established the Starts-HCPA Technology-Based Business Incubator, which operates pre-incubation, incubation, and intrapreneurship programs.

Against this background, this study describes HCPA's experience in developing a healthcare innovation ecosystem through HCPATec, including the pre-incubation, incubation, and intrapreneurship programs promoted by the Starts-HCPA Incubator. To achieve this objective, a cross-sectional observational study based on institutional records from the Starts-HCPA innovation programs conducted between 2023 and 2025 was performed, as detailed in the methodology section. The results are presented according to the selected evaluation indicators, followed by a discussion highlighting the role of university hospitals as key actors within innovation ecosystems and as drivers of technology transfer. Finally, the study concludes by discussing the main contributions of this experience and its implications for strengthening healthcare innovation ecosystems.

A. HCPA's Innovation Ecosystem

HCPA's innovation model was developed based on the principles of open innovation, scientific entrepreneurship, and healthcare needs-driven technological development. To support this strategy, the HCPATec Health Technology and Innovation Park was established in 2022 to serve as a hub connecting the multiple stakeholders of the Quadruple Helix of Innovation [6] [7] within the healthcare sector, including healthcare professionals, researchers, students, startups, companies, investors, government agencies, and other relevant partners.

The international literature has emphasized that healthcare innovation ecosystems rely not only on scientific production but also on structured mechanisms capable of transforming knowledge into practical solutions. Innovation, incubation, and technology venture development programs foster capacity building, collaborative networks, and stronger connections among academia, industry, and society, thereby enhancing the ability of institutions to generate economic and social impact [8][9]. University hospitals are uniquely positioned within this context because they combine research infrastructure, highly qualified professionals, and direct access to real healthcare challenges, creating favorable conditions for innovation generation and technology transfer [3][5].

HCPA promotes innovation through a structured innovation pathway composed of five sequential stages:

1. Problem Identification: This stage focuses on recognizing concrete challenges within clinical care, hospital operations, academic activities, or healthcare management. The objective is to identify inefficiencies, risks, costs, limitations in patient care, and opportunities for process improvement. Innovation opportunities may arise from healthcare professionals, researchers, students, managers, patients, or entrepreneurs, particularly when they originate from unmet needs identified in clinical practice or institutional routines.

2. Solution Development: During this stage, research groups or multidisciplinary teams transform validated problems into potential healthcare products, services, processes, software applications, medical devices, digital platforms, or other technological solutions by developing a Minimum Viable Product (MVP). Activities include defining the value proposition, technical requirements, solution design, prototype development, functional specifications, feasibility assessment, and adaptation to the intended use environment. Healthcare innovation projects must also address ethical and regulatory requirements, patient safety, data protection, interoperability, and compatibility with clinical workflows.

3. Pre-incubation: During pre-incubation, teams receive guidance to further refine both the identified problem and the proposed MVP. This stage includes business model development, market assessment, identification of potential users and customers, cost estimation, risk analysis, and strategic planning for subsequent development phases. Pre-incubation serves as a preparatory stage in which early-stage projects are structured to evolve into more robust and sustainable innovations. It also enables the identification of initiatives with the greatest technical, institutional, commercial, or social potential to advance through the innovation pipeline. At this stage, participants are not required to have an officially registered company.

4. Incubation: The incubation program is designed for projects and startups that have reached a more advanced level of technological and business maturity. Participants receive structured support for technology consolidation, business development, legal incorporation, mentoring, networking with strategic partners, fundraising, user validation, and market entry. The primary objective is to reduce technical and commercial uncertainties, strengthen execution capabilities, and increase the long-term sustainability of the venture through the value-added services provided by the incubator. Within the HCPATec and Starts-HCPA ecosystem, this stage plays a critical role in supporting the transition from pre-incubation—whether conducted within or outside HCPA—to technology-based healthcare startups and companies.

5. Scaling: Once a solution has demonstrated initial technical and commercial feasibility, its potential for expansion to other departments, healthcare organizations, institutions, or markets is evaluated. Scaling involves process standardization, technological robustness, operational capacity, commercialization strategies, revenue models, financial sustainability, regulatory compliance, and adaptation to different implementation contexts. Within the HCPATec ecosystem, this stage may occur during the incubation period or subsequently if the startup becomes a resident company within the Technology Park.

In 2025, HCPA also launched its first Intrapreneurship Program, specifically designed for hospital employees. This initiative expanded internal innovation activities while strengthening the institutional culture of developing solutions for organizational challenges. The program complements the activities of HCPATec and the Starts-HCPA Incubator by creating structured mechanisms to identify and address improvement opportunities emerging directly from the hospital environment. Consequently, HCPA's innovation ecosystem now encompasses both the development of technology-based startups and the promotion of internal innovation initiatives

aimed at improving healthcare processes, services, and organizational practices, further reinforcing the integration of patient care, research, education, and innovation.

II. METHODOLOGY

The study employed an observational, cross-sectional design based on documentary analysis. It was considered cross-sectional because the available data were analyzed as a snapshot of the innovation programs conducted during the study period, with the consolidation of the variables available for each year.

The unit of analysis comprised each team, startup, incubated company, or intrapreneurship project registered within the innovation programs. The variables analyzed included the year in which each program cycle began, type of initiative, technological area, number of participants, completion or continuation status, formal business registration, and evidence of progression through the innovation pipeline, particularly the transition from pre-incubation to incubation.

III. RESULTS

A. *Evolution of the Starts-HCPA Innovation and Intrapreneurship Programs*

Between 2023 and 2025, the Starts-HCPA programs included pre-incubation, incubation, and intrapreneurship initiatives, covering projects in digital health, artificial intelligence, medical devices, wearable technologies, mental health, rehabilitation, biotechnology, and pharmaceuticals.

During the study period, the following were identified:

- 38 teams applied to the Pre-incubation Program, of which 20 were selected through the competitive selection process, while 3 (three) teams decided to forsake..
- 11 startups applied to the Incubation Program, of which 8 were selected during the study period.
- 11 teams applied to the 2025 Intrapreneurship Program, with 3 teams selected to participate in that year's activities.

Considering all the teams and startups that have applied, there were more than 150 participants directly involved in the innovation programs, supported by 25 institutional mentors and more than five partner companies, which contributed expertise, mentoring and value-added services throughout the programs.

TABLE I. EVALUATION OF PARTICIPATION IN THE STARTS-HCPA INNOVATION AND INTRAPRENEURSHIP PROGRAMS

Year	*Pre-incubation*	*Incubation*	*Intrapreneurship*
2023	11 teams	–	–
2024	3 teams	5 startups	–
2025	3 teams	3 startups	3 teams
Total	**17 teams**	**8 startups**	**3 teams**

The incubation program attracted fewer applicants than the pre-incubation program. This difference reflects the operational model adopted by the Starts-HCPA Incubator, which emphasizes intensive support for incubated ventures through structured mentoring, regular follow-up meetings, and continuous monitoring of startup development indicators.

In 2024, five startups were admitted to the incubation program, which has an expected duration of 18 months. In 2025, three additional startups joined the program, bringing the total number of supported companies to eight during the study period. Unlike the pre-incubation program, which has an educational focus and accommodates a larger number of teams, the incubation program concentrates resources on a smaller portfolio of ventures, enabling individualized support and closer monitoring of business development.

The results demonstrate the effectiveness of this strategy. By the end of 2025, three startups had successfully completed their first incubation cycle and had their residency renewed for 2026 to continue executing their business development plans. In addition, one startup successfully completed the graduation process after achieving its planned milestones, illustrating the progressive maturation of companies supported by the incubator. These findings highlight the incubator's role not only in attracting innovative initiatives but also in fostering the consolidation and growth of technology-based healthcare businesses.

B. *Distribution of Initiatives by Technological Area*

Approximately 60% of the initiatives focused on software, digital health, and artificial intelligence, highlighting the alignment of HCPA's innovation ecosystem with the ongoing digital transformation of the healthcare sector.

TABLE II. DISTRIBUTION OF INITIATIVES BY TECHNOLOGICAL AREA (2023-2025)

Technological Area	Number of Initiatives
Software / Digital Health	18
Artificial Intelligence	5
Digital Mental Health	4
Medical Devices and Wearables	3
Pharmaceuticals and Biopharmaceuticals	4
Therapeutic Virtual Reality	1
Healthcare Marketplaces and Digital Platforms	1
Rehabilitation	1
Social Technologies	2

C. *Participation of Professionals and Entrepreneurs*

The innovation programs engaged multidisciplinary teams composed of healthcare professionals, researchers, students, managers, and entrepreneurs.

TABLE III. NUMBER OF PARTICIPANTS BY YEAR

Year	*Participants*
2023	87
2024	21
2025	47
Total	**155**

The results demonstrate HCPA's growing integration into the regional innovation ecosystem through the activities of HCPATec and the Starts-HCPA Incubator. This integration is evidenced by the active participation of professionals from medicine, nursing, pharmacy, physiotherapy, psychology,

nutrition, engineering, information technology, and several other disciplines, reinforcing the multidisciplinary nature of healthcare innovation.

D. Startup Generation and Business Formation

The structured training pathway and continuous mentoring provided by the innovation programs enabled several pre-incubation teams to naturally progress to the incubation stage.

Among the incubated startups are:

- Florence Artificial Intelligence: home-based self-monitoring platform for multiple health parameters.
- Artpsy Software: digital platform providing group therapy for mental health treatment.
- Formula3D: personalized medicine pills manufactured using 3D printing technology.
- Lumen Corporate Mental Health: digital mental health application for organizations.
- Warux Health: software for post-discharge patient monitoring and follow-up.
- Otus Solutions: software for the management and monitoring of healthcare research projects.
- Alora: cosmetic products for skin and oral ailments from oncology treatment.
- Move Sapiens: exergame solutions for complementary treatment for ADHD.

Several initiatives evolved into formally established companies during or after participation in the innovation programs.

The progression from pre-incubation to incubation and subsequently to company formation demonstrates the effectiveness of HCPA's innovation model in fostering technology-based entrepreneurship within the healthcare sector.

E. Intrapreneurship Program

In 2025, HCPA launched its first dedicated Intrapreneurship Program. There were 15 participants organized into three project teams. The initiatives developed included:

- Precision Care: a system for monitoring the volume of contrast agents administered during endovascular procedures, contributing to improved patient safety.
- Biobankers: a digital platform designed to optimize the operational processes of the HCPA Biobank.
- Supplier Management: a system for automating supplier registration, qualification, and performance evaluation processes.

The successful implementation of the program demonstrates its ability to generate innovation directly from institutional needs, reinforcing a culture of continuous improvement within the hospital.

IV. Discussion

The findings demonstrate the progressive maturation of HCPA's healthcare innovation ecosystem.

The diversity of supported initiatives reflects strong alignment with global trends in digital health, artificial intelligence, medical devices, personalized medicine, and the digital transformation of healthcare services.

The results also reveal the existence of a structured innovation pipeline, in which ideas originating from the hospital environment evolve into research projects, startups, and incubated companies. Examples such as Florence AI, Formula3D, Artpsy, and Lumen illustrate the program's ability to foster technology-based ventures addressing real healthcare challenges.

These findings highlight the importance of institutional structures capable of supporting the entire innovation journey—from problem identification to market-ready healthcare solutions. HCPA's experience demonstrates that integrating a university hospital, a technology park, a business incubator, and structured entrepreneurship programs creates a sustainable healthcare innovation pipeline. Beyond supporting startup creation and business development, this model strengthens the connection between research, clinical practice, and technological development, expands opportunities for knowledge transfer to society, and reinforces the role of university hospitals as drivers of economic and social transformation.

It also reinforces the perspective presented by ANPROTEC [10] which recognizes innovation environments as strategic platforms that integrate research, entrepreneurship, technology transfer, and institutional collaboration, enabling innovative ideas to progress from early-stage development to market-ready solutions with societal impact.

Overall, HCPA's experience confirms that university hospitals are not only centers for healthcare delivery, education, and research but also strategic actors within innovation ecosystems and important facilitators of technology transfer.

V. Conclusion

HCPA's experience demonstrates that university hospitals can serve as structured environments for innovation, entrepreneurship, and technological development.

Between 2023 and 2025, HCPATec's innovation programs supported dozens of innovative initiatives spanning multiple healthcare domains, including artificial intelligence, medical devices, digital health, and personalized medicine.

The findings indicate that combining a health technology park with structured pre-incubation, incubation, and intrapreneurship programs represents an effective strategy for transforming unmet clinical and organizational needs into technological solutions with the potential to generate significant clinical, social, and economic impact.

The innovation ecosystem developed at HCPA may serve as a model for other healthcare institutions seeking to strengthen innovation capacity, promote technology transfer, and foster entrepreneurship.

ACKNOWLEDGMENT

The authors gratefully acknowledge the financial support provided by the Brazilian Funding Authority for Studies and Projects (FINEP), Grant number 0384/22, and the Research Support Foundation of the State of Rio Grande do Sul (FAPERGS) – Grant number 25/2551-0002188-0. Their support was essential for the development of this work and the advancement of the innovation initiatives described in this study.

***Abstract*—Vancomycin therapeutic monitoring based on the AUC/MIC ratio is recommended to guide antimicrobial exposure, but interpreting the pharmacokinetic concepts involved may pose an educational challenge. This study aimed to develop the VancoLearn web platform as a support resource for teaching clinical pharmacokinetics and AUC/MIC-based vancomycin therapeutic monitoring. A responsive application was implemented featuring four sequential educational modules, deterministic pharmacokinetic simulation, automated calculation, concentration-time curve visualization, guided activities, and conversational support. The implementation enabled the demonstration, in hypothetical scenarios, of the influence of clinical and anthropometric variables on estimated clearance, 24-hour AUC, trough concentration, and the AUC/MIC ratio. The presented results are functional and demonstrative, and do not constitute evidence of educational effectiveness or clinical validation. In conclusion, VancoLearn presents initial functional viability as an educational environment. The evaluation of usability, acceptance, and learning with students and professionals constitutes the next phase of the research, which has already been approved by the Research Ethics Committee.**

***Index Terms*—Vancomycin, Therapeutic Drug Monitoring, Pharmacokinetics, AUC/MIC Ratio, Medical Education, Digital Learning.**

I. Introduction

Vancomycin is a glycopeptide antimicrobial agent used in the treatment of severe infections caused by Gram-positive bacteria, including methicillin-resistant Staphylococcus aureus (MRSA) [1]–[3]. Its clinical management requires careful attention to systemic exposure, as insufficient concentrations may compromise the therapeutic response, whereas elevated exposures are associated with an increased risk of nephrotoxicity [4]–[6]. In this context, therapeutic drug monitoring (TDM) facilitates the integrated interpretation of pharmacokinetic and clinical parameters.

Historically, vancomycin monitoring relied on serum trough concentrations, typically obtained prior to the subsequent dose [6], [7]. The consensus guidelines published in 2020 shifted toward recommending the estimation of exposure using the ratio of the 24-hour area under the concentration-time curve to the minimum inhibitory concentration (AUC/MIC), particularly for severe MRSA infections [6], [8]. For the scenarios addressed by these guidelines, an AUC range of 400 to 600 mg·h/L is utilized as a target to balance antimicrobial exposure and the risk of toxicity [6].

The application of AUC/MIC-based monitoring involves concepts such as clearance, volume of distribution, half-life, exponential decay, and concentration-time curve integration [4], [5]. The literature reports difficulties among students and healthcare professionals in learning and applying quantitative content related to drug administration [7], [9], [10]. Digital resources and simulations can support the representation of these concepts, allowing for the observation of how alterations in physiological and dosing variables modify calculated outcomes [11], [12]. However, the educational effects of these strategies depend on empirical evaluation with the target audience.

Given this context, this study aimed to develop and describe the initial functional viability of VancoLearn, an educational web platform designed for teaching clinical pharmacokinetics and AUC/MIC-based vancomycin therapeutic monitoring. The proposed system integrates theoretical content, data visualization, simulation of hypothetical scenarios, guided activities, and conversational support within a single environment. The platform was designed exclusively for educational purposes and does not constitute a validated tool for prescription or

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brasil (CAPES) - Finance Code 001.

dose adjustment in patients.

II. Materials and Methods

A. Study Design

This work is characterized as a methodological study of technological development with a quantitative and deterministic approach. The study encompassed architecture specification, interface implementation, pharmacokinetic modeling, and the organization of a simulated educational environment [5]. At this stage, the evaluation was restricted to the implementation and functional demonstration of the components; usability, acceptance, cognitive load, and learning were not measured.

B. Platform Development

The platform was developed as a responsive web application, with a separation between the interface, the processing of simulated parameters, and the visualization of results. The technological choices aimed to enable the immediate updating of values and curves during the exploration of hypothetical scenarios, as well as to facilitate access across different devices:

1) User Interface (Front-end): The React library with TypeScript was utilized, a combination that enables reusable components, reactive interface updating, and static data type checking. These features were selected to mitigate implementation inconsistencies and allow changes in scenario parameters to be reflected without a page reload [12].
2) Instructional Design Support and Doctor AI: Google AI Studio (https://aistudio.google.com/) was employed as an auxiliary resource for the ideation and the textual and visual refinement of the educational pathways; its suggestions were subjected to review by the authors and did not constitute an autonomous source of scientific content. The Doctor AI chatbot was included as conversational support for inquiries regarding the content presented on the platform. Its responses are generated by a language model and, therefore, may contain inaccuracies, omissions, or outdated information. The resource is identified as educational, does not replace bibliographic sources or professional judgment, and displays a disclaimer advising that clinical decisions should not be made based on its responses. The definition of a restricted knowledge base, periodic content curation, and systematic evaluation of the responses constitute measures planned for subsequent stages.
3) Graphical visualization: The Recharts library (https://recharts.org/) was utilized to represent the concentration-time curves and update the graphs following parameter modifications. This choice allows for visually correlating the scenario inputs with the calculated outcomes, without assuming, at this stage, any learning gains [12].
4) Deployment and availability: The application was hosted on the Vercel platform. The hosting enables public access (https://vancolearn.mathematicalmodels.app/) to the demonstrative version; performance, scalability, and compatibility with different access conditions remain to be systematically evaluated.

C. Educational Modules

The content was organized into four sequential modules to progress from introductory concepts to application in simulated scenarios: pharmacokinetic fundamentals, principles of TDM, interpretation of the AUC/MIC ratio, and interactive simulation. This sequence was adopted to present definitions prior to their mathematical representation and, subsequently, to allow for the manipulation of variables. The guided activities and visual feedback were designed as strategies for guided exploration [12]. At this stage of development, no formal evaluation of the pedagogical architecture by external experts was conducted; this aspect will be incorporated into the subsequent validation phase.

Module 1 – Fundamentals of Vancomycin Pharmacokinetics

Presents the first-order linear one-compartment model and the definitions of volume of distribution (V_d), clearance (Cl), elimination half-life ($t_{1/2}$), and steady state [4], [5]. The module provides the conceptual foundation necessary to interpret the subsequent simulations.

Module 2 – Therapeutic Drug Monitoring (TDM)

Presents the principles of TDM and discusses the relationship between exposure, therapeutic response, and the risk of nephrotoxicity. The content contrasts traditional monitoring based on trough concentration with the AUC/MIC-based approach and contextualizes the AUC range of 400 to 600 mg·h/L within the situations covered by the guidelines [6], [13].

Module 3 – AUC/MIC Ratio

Explores the definition and interpretation of the ratio between the 24-hour AUC and the MIC. Relates this indicator to current monitoring recommendations, highlighting that the values presented on the platform are educational estimates and not individualized treatment guidance [4], [6].

Module 4 – Interactive Simulation

Allows the input of real or hypothetical values for sex, age, weight, serum creatinine, dose, dosing interval, and MIC. These variables were selected because they participate in the implemented estimations and allow exploring, in a controlled manner, relationships between renal function, dosing regimen, and exposure. The system generates concentration-time curves and calculated indicators for comparison between scenarios [5], [6].

D. Mathematical Modeling

For instructional purposes, the computational engine implements first-order deterministic relationships and a simplified one-compartment representation [1], [5]. The calculation assumes constant parameters over the simulated interval, linear kinetics, instantaneous distribution, and the absence of

interindividual variability not represented by the inputs. Vancomycin clearance estimation utilizes a linear relationship with creatinine clearance ($CrCl$), with conversion from mL/min to L/h using the factor 0.06, according to Equation (1) [11]. The model does not incorporate Bayesian inference, population pharmacokinetic models, additional covariates, observed serum concentrations, or adjustments for special clinical situations. For these reasons, it is intended for the demonstration of mathematical relationships and not for individualized clinical calculation.

$$CL = 0.8 \times CrCl \times 0.06 \tag{1}$$

The 24-hour AUC is estimated by the ratio between the total dose administered in the period and clearance, according to Equation (2) [5]. This approximation assumes linear kinetics and conditions compatible with steady state. The implementation was verified for dimensional consistency and the direct reproduction of the presented equations; however, external validation against reference clinical software or an independent set of cases was not performed at this stage.

$$AUC = \frac{Dose}{CL} \tag{2}$$

The AUC/MIC ratio is obtained by dividing the estimated exposure by the provided MIC, according to Equation (3) [6]. The result serves to compare educational scenarios and illustrate the interpretation of the indicator. It should not be employed as a dosing recommendation or a substitute for TDM and clinical evaluation.

$$TR = \frac{AUC}{MIC} \tag{3}$$

III. Results

A. Platform Architecture

The implementation resulted in a functional web application that receives user-defined parameters, processes the described mathematical relationships, and updates the indicators and visualizations without a page reload. Fig. 1 presents the flow between the interface, the deterministic processing, and the visualization layer. The results in this section describe the observed operation of the developed version, without inferring scalability, clinical performance, or educational effectiveness.

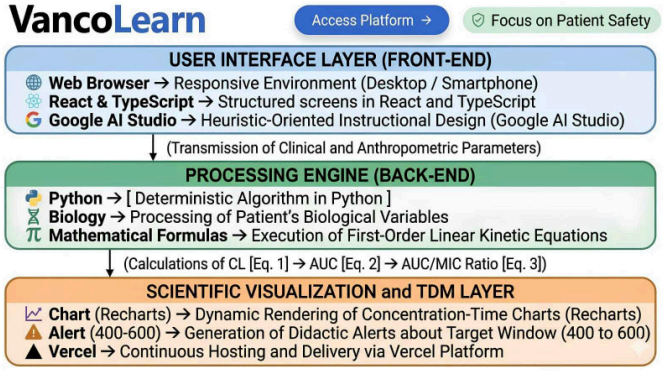

Fig. 1: General architecture and data flow of the VancoLearn platform.

Alterations in dose or physiological parameters of the virtual patient update the estimated values and displayed curves. The platform presents disclaimers regarding its exclusively educational purpose and has neither been designed nor validated to support prescription, dosage adjustment, or clinical decision-making. The perceived responsiveness of the interface updates was not subjected to formal performance testing.

B. User Interface

The interface was organized to consolidate related inputs, explanations, and results within a single visual sequence. Sliders, informational cards, and graphs were employed to explicitly demonstrate the relationship between the manipulated variables and the calculated outcomes. The suitability of this organization, its accessibility, and its effect on cognitive load have yet to be evaluated with users.

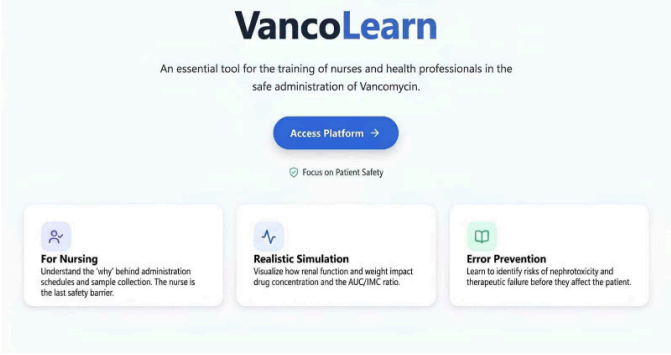

Fig. 2: Initial welcome and navigation screen of the platform.

The simulator (Fig. 3) allows for the configuration of biological sex, age, total body weight, serum creatinine, dose, dosing interval, and MIC within hypothetical scenarios. Sliders and selectors constrain input values and update the calculated outcomes. Based on sex, age, weight, and creatinine, the system estimates creatinine clearance using the Cockcroft-Gault method and presents an educational categorization of renal function. These results do not substitute for laboratory or clinical evaluation.

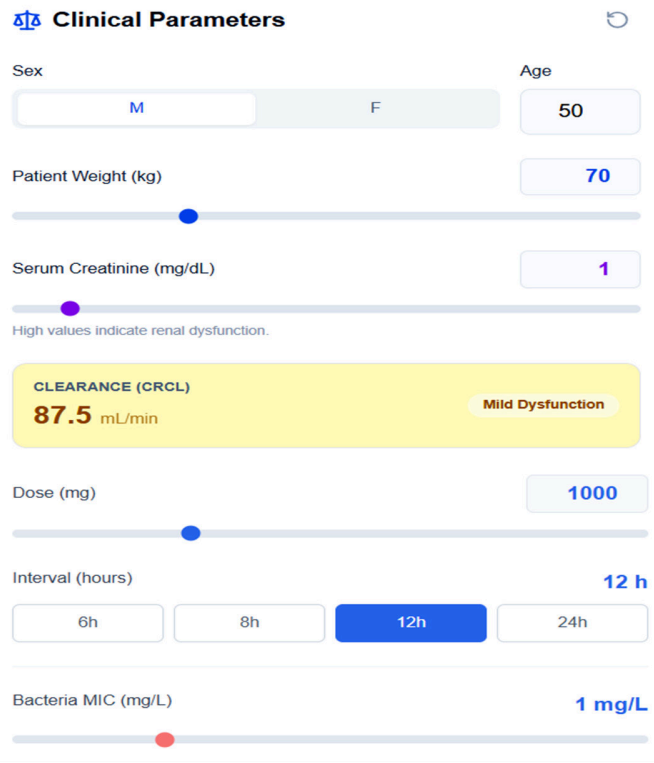

Fig. 3: Interface of the practical pharmacokinetic simulator.

The Fig. 4 demonstrates the visualization of the concentration-time curve and the calculated indicators for the configured scenario. The panel consolidates three informational cards updated following modifications to the inputs:

AUC/MIC Card: displays the calculated ratio and indicates its position relative to the reference range of 400 to 600, utilized in the module for educational interpretation purposes [6].

Trough Concentration Card: presents the estimated concentration prior to the subsequent dose and allows for its comparison, within the simulated scenario, with values traditionally utilized in monitoring [6], [7].

AUC (24h) Card: presents the estimated 24-hour exposure, in mg·h/L, utilized as the numerator for the AUC/MIC ratio and as an element for quantitative exploration [5].

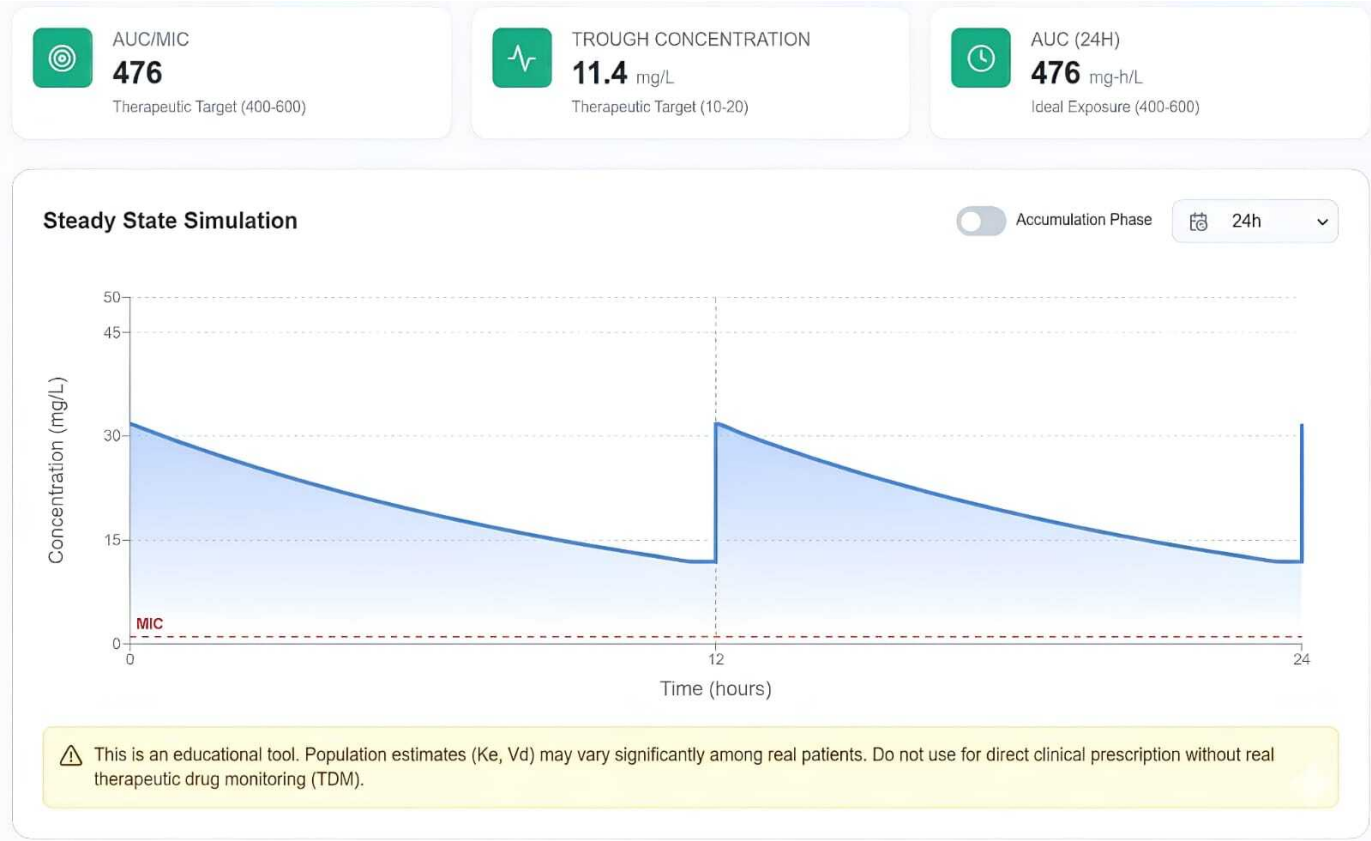

Fig. 4: Dynamic graph of the plasma concentration-time curve and PK/PD indicator panel of the VancoLearn platform.

C. Implemented Features

The platform consolidates calculation, visualization, and guided exploration routines. Table I summarizes the implemented features and their educational purpose. The presence of these components demonstrates the functional integration of the prototype, but it does not allow for the conclusion that it produces knowledge gain, reduces math anxiety, or promotes active learning.

TABLE I: Analysis and Description of the Features Implemented in the Platform

Feature	Description
AUC Calculation	Automated estimation of the 24-hour Area Under the Curve [5].
Clearance Estimation	Deterministic pharmacokinetic calculation based on renal function [11].
Concentration Curves	Interactive and dynamic plots of temporal decay [4].
Clinical Scenarios	Educational simulations based on the patient's biological and anthropometric variation.
Educational Activities	Three practical guides integrated into the "Activities" page, intended for the guided exploration of concepts [10].
AI Support (Chatbot)	Doctor AI module for conversational support, subject to the limitations of AI-generated responses and restricted to educational use.
Scenario Interpretation	Visual indication of the AUC/MIC ratio relative to the reference range, without clinical recommendation [6].

IV. Discussion

The proposed differential for VancoLearn does not reside in the creation of new pharmacokinetic equations, but in the integration, within a single educational environment, of sequential content, variable manipulation, deterministic calculation, graphical visualization, guided activities, and conversational support. This organization allows exploring the relationships between renal function, dosing regimen, and exposure indicators. The pedagogical utility of this integration remains a hypothesis to be tested with the target audience [4], [5], [12].

Platforms such as DoseMeRx and InsightRX are directed toward clinical support and utilize population models and Bayesian methods, whereas SimPHARM adopts simulations in pharmacology education [3], [7], [9], [15]. VancoLearn distinguishes itself through its specific focus on teaching AUC/MIC-based vancomycin monitoring and through the articulation between conceptual explanation, manipulable scenarios, and immediate visualization. This comparison pertains to scope and educational strategy; it does not constitute a demonstration of superiority. Doctor AI broadens the forms of interaction, but generative responses may be incorrect or outdated, requiring usage disclaimers, source review, and systematic reliability evaluation prior to any expansion of its educational role.

Limitations include the absence of empirical validation with students, faculty, or professionals, of pedagogical comparison, of usability and accessibility metrics, of objective learning assessment, and of external validation of the mathematical model against a reference clinical tool. The simplified model does not represent all pharmacokinetic variability nor special clinical situations. The experience across different student profiles, devices, and connectivity conditions, the hosting scalability, and the update process in light of new recommendations also remain to be evaluated. The next phase, already approved by the Research Ethics Committee, entails a study with students and healthcare professionals to evaluate usability, acceptance, user experience, and learning indicators. Its results will guide pedagogical, technical, and accessibility revisions.

V. Conclusion

This study described the development and demonstrated the initial functional feasibility of VancoLearn as an educational web environment for teaching vancomycin pharmacokinetics and AUC/MIC-based monitoring. The platform integrated conceptual modules, deterministic simulation, automated calculation, graphical visualization, guided activities, and conversational support, preserving the distinction between educational exploration and clinical decision-making. The results do not allow for the assertion of educational effectiveness, cognitive load reduction, or a proven contribution to professional training. The next phase of the research, already approved by the Research Ethics Committee (CAAE: 97742926.7.0000.5497), will evaluate the platform with the target audience through usability, acceptance, experience, and learning metrics.

VI. Acknowledgment

The authors express their sincere gratitude to the Universidade de Mogi das Cruzes (UMC) and the Graduate Program in Biomedical Engineering for the institutional support, infrastructure, and technical assistance that made the development of this research possible, as well as to the faculty, students, and collaborators who contributed to the conception and initial refinement of the VancoLearn platform. This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brasil (CAPES) - Finance Code 001 (Process No. 88887.254418/2026-00), and the Teaching, Research and Extension Support Fund (FAEP).

***Abstract*—Introduction: Dosimetry and quality control in pediatric computed tomography (CT) require physically realistic phantoms that replicate the radiological properties of the developing cranial bone. Objective: To validate PLA and PLA Stonefill materials, processed by FDM 3D printing at 220 °C, for simulation of the cranial bone of a 2-year-old child, characterizing the Hounsfield Units (HU) as a function of the filling percentage from 10% to 100% and digitized on a Canon Aquilion Prime SP CT scanner (80, 100 and 120 kVp; 200 mA; 100 mAs) with FC21 and FC30 kernels. The analysis included volumetric ROI, linear modeling HU = a·(%filling)+b, and spatial line profiles. Results: Both materials showed a significant linear correlation with the infill (R^2 = 0.956 for PLA; R^2 = 0.966 for PLA Stonefill), with slope coefficients of ≈10 HU/% and ≈14 HU/%, respectively. The inter-kVp variation at 100% filling was 29.5% (Δ = 130.17 HU) for the PLA Stonefill. Inter-kernel variation was less than 15 HU (PLA) and less than 39 HU (Stonefill). Line profiles confirmed the absence of structural voids at 100% filling, with a plateau difference of 325 HU between the two materials. Conclusion: 100% filling of PLA Stonefill reproduces the cortical bone of the pediatric skull (300–600 HU; 80 kVp: +440.7 HU); 80% and 90% fillings simulate muscle tissue and trabecular bone, respectively. Conventional PLA covers lung tissue (10–30%), adipose tissue (≈90%), and dense soft tissue (100%). The linear model allows for fine-tuning of attenuation with each 1% increase in filling.**

***Index Terms*—3D printing, PLA, PLA Stonefill, pediatric phantom, computed tomography, Hounsfield Units, cranial bone, FDM, tissue equivalence.**

I. Introduction

Computed tomography (CT) plays a relevant role in pediatric diagnostic imaging, particularly in cranial evaluation of children under 3 years of age [1]. Optimizing pediatric computed tomography (CT) protocols requires anthropomorphic phantoms that mimic the attenuation properties of developing tissues, thus enabling better quality control and reducing patient exposure to ionizing radiation [2]. In pediatric patients, especially around two years of age, the calvaria presents very different radiological characteristics from those of an adult. In this age group, the structure is predominantly monocortical, transitioning to the adult trilaminar configuration (outer table, diploë, and inner table). Diploë identifiable by CT scan is present in more than 90% of cases and only from 3 to 5 years of age in the frontal and posterior parietal regions [3]. The average calvaria thickness in this age group is between 3.7 mm (anterolateral) and 3.9 mm (posterolateral) [4], with a thickness of less than 3 mm in 85–92% of patients under 4 years of age [5]. Liu et al. [6] developed a normative model based on 2,068 individuals (0–10 years) with a predictive uncertainty on the Hounsfield scale of 76.7 ± 91.5 HU, reflecting the high heterogeneity of this segment. Gajawelli et al. [7] confirmed, using structural MRI in a three-dimensional model of 56 children (0–3 years), that cranial thickness and geometry vary with age and anatomical location. Delye et al. [8] demonstrated that cranial bone density increases at an accelerated rate in the first 3 years of life without reaching a plateau until the third decade of life.

From a densitometric point of view, the calvaria at 2 years of age presents a mosaic of Hounsfield Units (HU): Yamada et al. [9] documented an upward trajectory of density from birth, with a plateau around 20 years of age with a HU value around 1,164 ± 143 HU; in the parietal and frontal regions of children aged 1–3 years, the values are predominantly in the range of 300–600 HU [6], [9]. Takahashi et al. [10] identified that only specific regions such as the mastoid reach 1000 HU around 1.7 years. Rowbotham et al. [11] documented adult neurocranial variation from 78 to 1323 HU, a range that the pediatric cranial bone still traverses throughout development. The consolidated reference ranges for adjacent tissues are: inflated lung tissue between −500 and −1000 HU; adipose tissue between −50 and −100 HU; muscle tissue between +10 and +40 HU; spongy bone between +100 and +300 HU; dense cortical bone between +300 and +1000 HU [12]–[14].

Fused deposition modeling (FDM) additive manufacturing allows for fine-tuning of the effective density of phantoms through control of the percentage of internal filling [15], [16]. Hatamikia et al. [16] obtained a range of −482 to 968 HU with a single filament; Arnold et al. [17] achieved an increase of 196 HU by weight percent with PLA/bismuth oxide composites; Okkalidis et al. [18] confirmed the feasibility of bone tissue replication by FDM; and Mei et al. [19] reproduced bone marrow with differences smaller than 15 HU using calcium-doped filament. Conventional PLA ($\rho \approx 1.24$ g/cm3) is the most widely used

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

thermoplastic in medical physics applications, being characterized as equivalent to soft tissue in certain configurations [20], but with limitations for bone simulation even at 100% filling [20]. Mineral-filled composite filaments expand this range: Ahmed, Buschmann, et al. [15] reported values of 57 to 460 HU with mineral PLA, and Lai et al. [22] obtained 547 HU with PLA supplemented with calcium carbonate for adult skull simulation.

Despite these advances, a gap persists in the specific validation of FDM materials for cranial bone simulation, particularly in the 2-year-old age range [6]. Given this scenario, the present study aims to validate two FDM 3D printing materials — conventional PLA and PLA Stonefill — for simulating pediatric skull bone at 2 years of age, through their characterization in Hounsfield Units under the kVp variation of the pediatric skull protocol in CT and reconstruction algorithms.

II. Methodology

A. Printout of Test Specimens

Test specimens were manufactured by FDM additive manufacturing (Fused Deposition Modeling) using two commercial filaments with a diameter of 1.75 mm, both produced by Earth Renewable Technologies — ERT (Curitiba, PR, Brazil). Each piece was printed in the form of a cylinder 20 mm in diameter by 20 mm high, for a total of 20 cylinders (10 of conventional PLA and 10 of PLA Stonefill), with infill densities ranging from 10% to 100%, in 10% increments.

1) Conventional PLA: bio-based resin FC 10030 [23], with a nominal density of 1.24 g/cm³, tensile modulus of 3500 MPa and tensile strength of 50 MPa (ISO 75-1/2). The manufacturer's datasheet establishes a maximum processing temperature of 230 °C; the extrusion temperature adopted in this study (220 °C — Table I) respects this limit with a safety margin of 10 °C, avoiding thermal degradation of the polymer chain and ensuring rheological stability during deposition.

TABLE I. FDM 3D Printing Parameters

Parameter	Specification
Slicing Software	Creality Print V2.10.4414
Nozzle Diameter	0.6 mm
Filament Diameter	1.75 mm
Filament Density (PLA)	1.24 g/cm3
Filament Density (PLA Stonefill)	1.35 g/cm3
Extruder Temperature	220 °C
Table Temperature	50 °C
Chamber Temperature	35 °C
Number of Layers	83
Maximum Height Z	20 mm
Contraction / Shrinkage Comp.	1.5 mm / F2400
Fill Pattern	Gyroid

2) PLA Stonefill: FC 50325 composite [24], formulated from a physical blend of PLA with an antiblocking additive based on calcium carbonate ($CaCO_3$), giving it a marble-like texture and a nominal density of 1.35 g/cm³. The material has a tensile strength of 16 MPa and an elongation at break of 400% (ASTM D638-22). The maximum processing temperature limit is also 230 °C, respected by the adopted extrusion temperature of 220 °C. The presence of $CaCO_3$ in the polymer matrix is primarily responsible for shifting the attenuation values to higher ranges of Hounsfield Units compared to pure PLA, due to the effective atomic number of the composite.

The printing parameters were standardized as per Table I. The relationship between filling density and HU values was modeled by simple linear regression, described by the model:

$$HU = a \cdot (\%filling) + b \qquad (1)$$

where a represents the slope coefficient (HU/%), corresponding to the change in HU per percent unit of filling, and b is the linear intercept corresponding to the HU value extrapolated to 0% infill (i.e., contribution of the polymer matrix and residual air).

B. CT Acquisition Protocols

The acquisitions were made using the computed tomography equipment model Canon Medical Systems Aquilion Prime SP (EBSERH-UFPR). For acquisition, the CRANIO 0–2 YEARS protocol was used with tube voltage variation as per Table II. The images were reconstructed using two algorithms: FC21 (soft) and FC30 (bone).

TABLE II. CT Acquisition Parameters by Protocol

Parameter	Prot. 1	Prot. 2	Prot. 3
Voltage (kVp)	80	100	120
Current (mA)	200	200	200
Exposure (ms)	500	500	500
Charge (mAs)	100	100	100
Rotation (s)	0.5	0.5	0.5
Collimation (mm)	20	20	20
Thickness (mm)	1.0	1.0	1.0
Kernel	FC21/FC30	FC21 (soft)	FC21 (soft)
Filter	Al-Cu	Al-Cu	Al-Cu

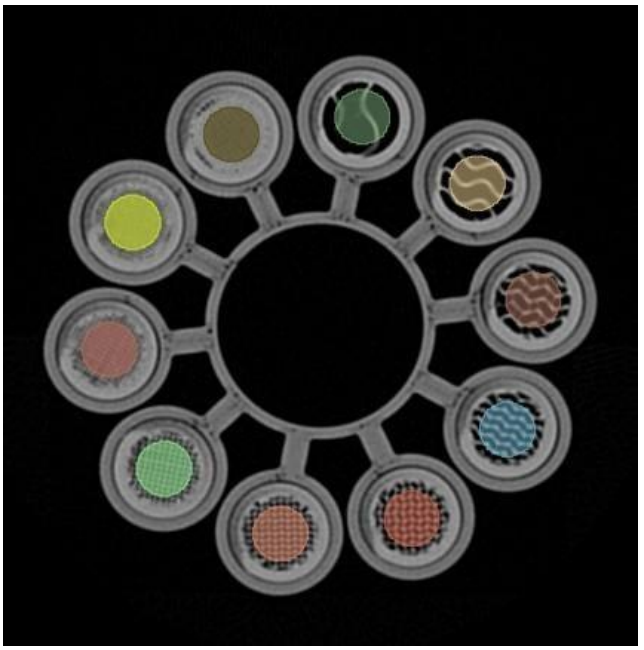

Fig. 1. Axial CT scan of ten PLA and PLA Stonefill specimens showing the ROI regions for evaluation.

C. Data Analysis

HU values were extracted from regions of interest (ROI), as shown in Fig. 1, segmented in each specimen using the free software 3D Slicer, version 5.12.0. The mean and standard deviation were determined for each combination of material, filler, protocol, and reconstruction kernel. The measurements obtained with the soft kernel (FC21) were compared with the bone kernel (FC30) to evaluate the influence of the reconstruction algorithm on the quantitative values of HU. The results were correlated with reference values of biological tissues [12], [13] and with published data on pediatric cranial bone density [6], [8], [10].

III. Results

A. Gradual Progression of Radiopacity in the Test Specimens

Fig. 2 shows the ten PLA test specimens distributed across their respective filling levels, visually illustrating the density spectrum produced by the parametric variation.

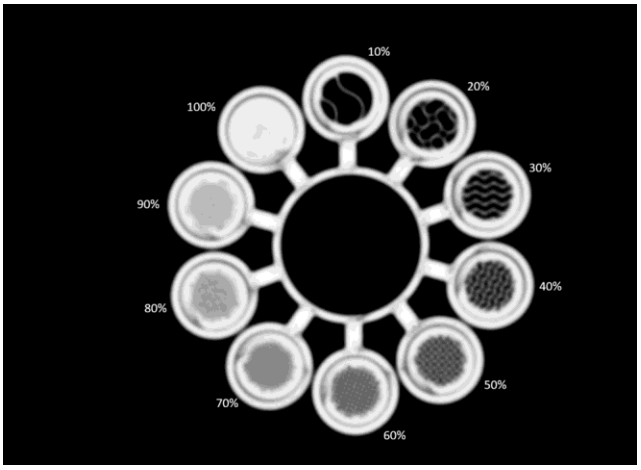

Fig. 2. Axial CT slice of the ten PLA specimens. The gradual progression of radiopacity — translucent pattern (10%) to homogeneous and dense appearance (100%) — demonstrates the sensitivity of the FDM method in modulating radiological density, as in the model of Eq. (1).

B. HU Values — PLA and PLA Stonefill (Soft Kernel, 80 kVp)

Table III presents the mean values and standard deviations of HU at all ten fill levels acquired at 80 kVp, with FC21 soft-kernel reconstruction for PLA and PLA Stonefill materials.

A monotonic relationship was observed between the percentage of filling and the HU value for both materials. PLA Stonefill showed systematically higher values than conventional PLA, with an increasing difference: from 51.40 HU at 10% to 332.51 HU at 100%. The linear fit by Eq. (1) produced coefficients of determination of $R^2 = 0.956$ for PLA and $R^2 = 0.966$ for PLA Stonefill, confirming that the linear model describes with high fidelity the densitometric response of the materials in the evaluated range. Fig. 3 presents the experimental data with uncertainty bars (±SD) and their respective regression lines.

TABLE III. Tissue Equivalence of Filling Materials (80 kVp)

Infill (%)	PLA (HU)	Stonefill (HU)
10	−904.98 ± 155.84	−853.58 ± 205.06
20	−801.31 ± 161.17	−719.09 ± 215.94
30	−698.04 ± 125.97	−603.71 ± 164.89
40	−592.88 ± 79.84	−473.33 ± 108.07
50	−493.36 ± 42.17	−349.52 ± 62.71
60	−388.81 ± 19.92	−223.50 ± 40.12
70	−280.85 ± 12.85	−90.40 ± 38.62
80	−177.70 ± 12.04	+36.15 ± 31.49
90	−87.89 ± 11.46	+148.99 ± 32.79
100	+108.22 ± 14.25	+440.73 ± 43.52

C. Tissue Equivalence by Filling Range

The HU values obtained were compared with the reference ranges for biological tissues (Table IV).

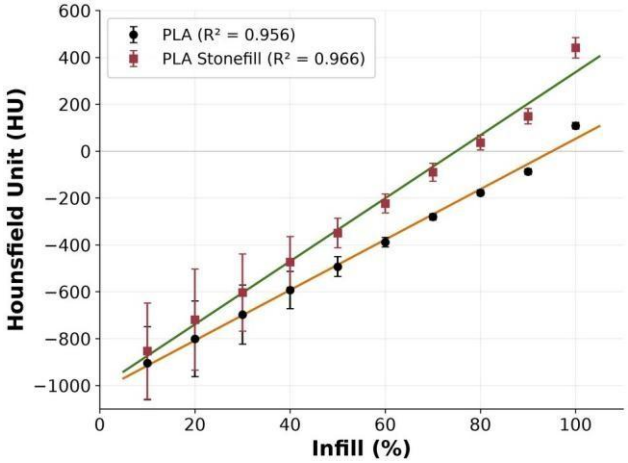

Fig. 3. Linear regression between percentage of filling and mean HU values (80 kVp, kernel FC21) for PLA (black circles, orange line, $R^2 = 0.956$) and PLA Stonefill (red squares, green line, $R^2 = 0.966$). Error bars represent ±1 SD. The greater slope of the Stonefill line (a ≈ 14 HU/%) reflects the contribution of $CaCO_3$ to the attenuation coefficient.

TABLE IV. Tissue Equivalence of Materials by Filling Range (80 kVp)

Infill (%)	PLA (HU)	Stonefill (HU)
10–30	Lung tissue (−698 to −905 HU)	Lung tissue (−604 to −854 HU)
40–60	Lung/adipose transition (−389 to −593 HU)	Pulmonary/adipose transition (−224 to −473 HU)
70	Adipose transition (−281 HU)	Adipose tissue (−90 HU)
80	Adipose (−178 HU)	Soft tissue/muscle (+36 HU)
90	Adipose (−88 HU)	Trabecular bone (+149 HU)
100	Dense soft tissue (+108 HU)	Pediatric cortical bone (+441 HU)

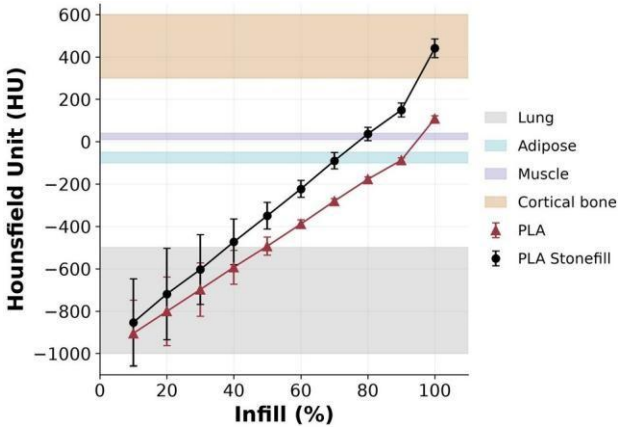

Fig. 4. Tissue equivalence as a function of filling percentage (80 kVp, kernel FC21). Red triangles: conventional PLA; black circles: PLA Stonefill. Colored bands delimit reference ranges in HU: inflated lung (gray, −500 to −1000 HU), adipose tissue (green, −50 to −100 HU), muscle/soft tissue (blue, +10 to +40 HU) and pediatric cortical bone tissue (beige, +300 to +600 HU) [6], [9]. Stonefill reaches the bone range from 90% filling, while PLA remains below dense soft tissue throughout the evaluated range.

It is noteworthy that PLA Stonefill at 80% filling (+36.15 HU) is located exactly in the muscle/soft-tissue range (+10 to +40 HU) [5]. Conventional PLA at 90% (−87.89 HU) corresponds to the adipose tissue range (−50 to −100 HU) [13]. Fig. 4 graphically summarizes this correspondence, superimposing the experimental values onto the reference ranges of the main biological tissue groups.

D. Qualitative and Spatial Analysis of Homogeneity

Fig. 5 shows an axial CT image of ten specimens with different percentages of filling identified directly in the samples, acquired with a bone kernel (FC30). The numerical

indication allows for the correlation between the printing configuration and the radiological density, highlighting an increase in radiopacity. Fig. 6 shows an axial CT scan of a phantom containing a sample of PLA Stonefill at ten filling levels, highlighting the internal geometric macrostructure of the specimens and allowing a qualitative assessment of the spatial distribution of the material in each infill configuration.

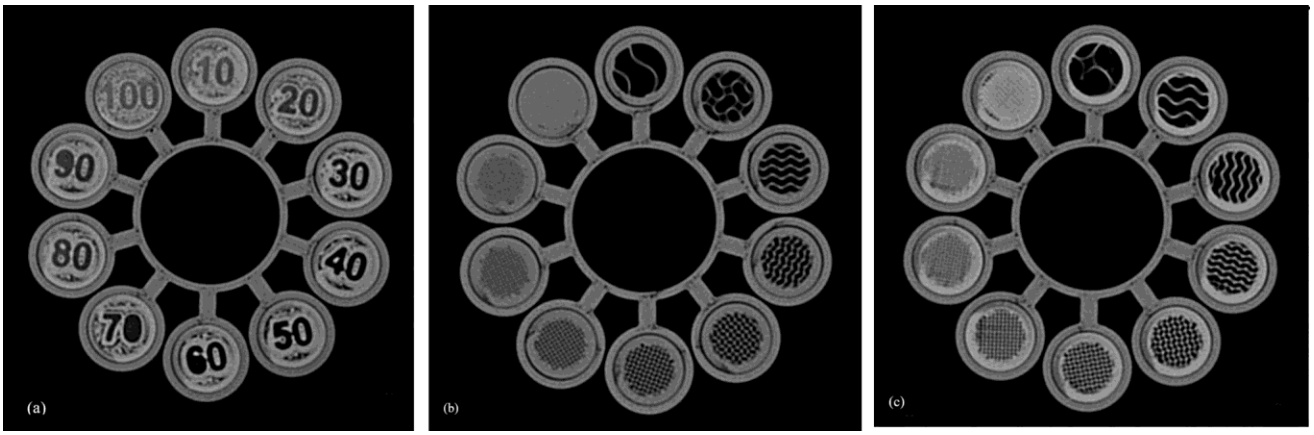

Fig. 5. Axial CT image (bone kernel — FC30) of the ten specimens. (a) Percentage of filling recorded on each disc (10% to 100%); (b) PLA specimens at the ten filling levels — the bone kernel shows the microstructure of the infill pattern at intermediate percentages (40–70%), where the filament network is clearly distinguishable from the interstitial air space, while in high-density samples (90–100%) the appearance is uniform with no discernible internal structure; (c) PLA Stonefill specimens at the ten filling levels — the greater radiopacity of the calcareous compound ($CaCO_3$) is evidenced by the more intense brightness in the filaments even at low percentages, contrasting strongly with the interstitial air space. In fillings above 80%, the appearance approaches the homogeneity of pediatric cortical bone, consistent with the HU values in Table III.

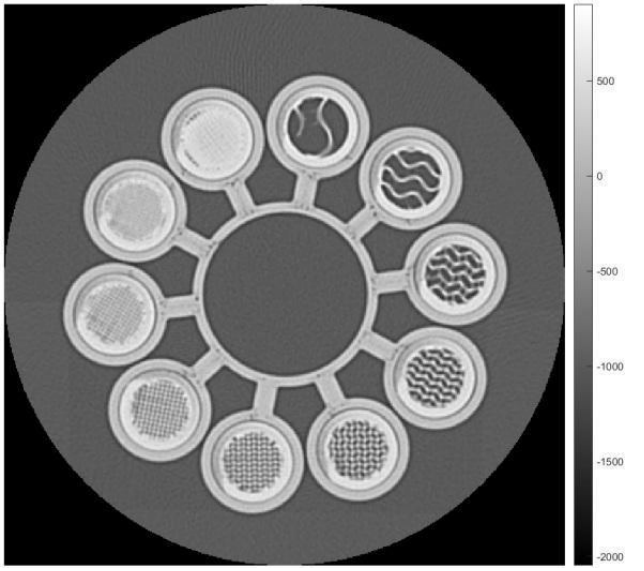

Fig. 6. Axial CT scan of the ten specimens showing the geometric macrostructure of the filling patterns at the ten levels of infill (grayscale sidebar).

A continuous progression of apparent radiological density (grayscale) is observed from the lowest fillings (10% and 20%) — a clearly defined reticular pattern with ample interstitial air space — up to 100%, where the appearance is close to a solid filling. The visual distinction of the internal layers in the 40–70% fillings confirms that the CT scanner individually differentiates the material layers and air spaces, so that the HU values measured by ROI express the weighted average between the two phases, as described by Bustillo et al. [25].

Figs. 7 and 8 show the spatial line attenuation profiles obtained in MATLAB. For the analysis, the total diameter of the 100%-filling specimens was evaluated for PLA and PLA Stonefill. These attenuation profiles demonstrate that there are no abrupt depressions (negative values in the plateau region), confirming the absence of structural voids in the test specimens. Direct comparison reveals an important point: the perimeter peaks of PLA (~450–490 HU) numerically coincide with the internal plateau of Stonefill (~433 HU), demonstrating that the overlapping perimeter walls of PLA reach a radiopacity equivalent to Stonefill in solid configuration — a value more than four times higher than the internal plateau of PLA itself. This intrasectional heterogeneity, inherent to FDM phantoms, should be considered when defining ROIs for quantitative measurements and when designing thin-walled geometries [25]. At the same time, Stonefill 100% confirms its suitability to simulate the monocortical architecture of the 2-year-old pediatric calvaria — with perimeter peaks in the cortical range and an internal plateau in the trabecular/lower-cortical bone range [9], [10] — while PLA 100% remains in the dense soft-tissue range (+108 HU), suitable for simulating non-bone tissues [12], [13].

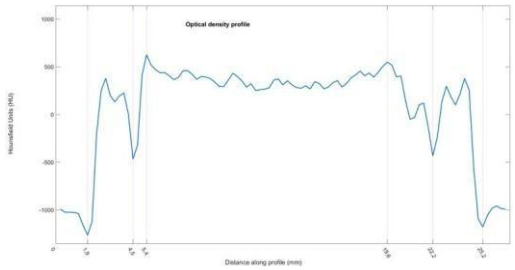

Fig. 7. Spatial line profile of the 100% PLA Stonefill sample at 80 kVp. Perimeter peaks (627 and 550 HU) correspond to the walls (shells) and a homogeneous central plateau with a median of 433 HU. Horizontal axis: distance along the profile (mm).

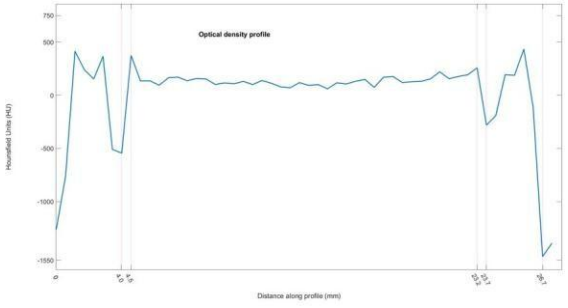

Fig. 8. Line profile of the 100% PLA sample at 80 kVp. Perimeter peaks (450 and 490 HU) correspond to the walls (shells) and a homogeneous central plateau with a median of ≈108 HU. Horizontal axis: distance along the profile (mm).

E. Voltage Dependence — PLA

Table V presents the average HU values of PLA at the three kVp values. PLA showed low energy dependence: maximum variation of 8.91 HU between 80 and 120 kVp (for 100% filling). At other filling levels, the variation was less than 7.5 HU. Thus, we observed that PLA has an effective atomic number close to that of water [13], [17].

TABLE V. AVERAGE HU VALUES OF PLA AS A FUNCTION OF KVP (KERNEL FC21)

Infill (%)	80 kVp	100 kVp	120 kVp
10	−904.98	−898.93	−900.89
20	−801.31	−798.73	−796.90

100	+108.22	+115.03	+117.13

F. Voltage Dependence — PLA Stonefill

Table VI presents the average HU values of PLA Stonefill at the three kVp values. PLA Stonefill exhibited pronounced energy dependence, with a variation of up to 130.17 HU between 80 and 120 kVp (at 100% infill), corresponding to a 29.5% reduction. This effect became progressively more intense with increasing infill, indicating a growing contribution from the photoelectric effect of the filament additive [13], [17].

TABLE VI. AVERAGE HU VALUES OF PLA STONEFILL AS A FUNCTION OF KVP (KERNEL FC21)

Infill (%)	80 kVp	100 kVp	120 kVp
10	−853.58	−858.18	−873.62

G. Comparison between Reconstruction Kernels — PLA

Table VII compares the HU values of PLA obtained with a soft kernel (FC21) and a bone kernel (FC30) at 80 kVp.

The difference between kernels for PLA ranged from 0.25 HU (100% fill) to 14.19 HU (10% fill), demonstrating high agreement between the reconstruction algorithms, especially at high fill values.

TABLE VII. PLA COMPARISON: SOFT KERNEL (FC21) VS. BONE KERNEL (FC30) AT 80 KVP

Infill (%)	FC21 (HU)	FC30/bone (HU)	|Δ| (HU)
10	−904.98	−890.79	14.19
20	−801.31	−791.69	9.63
30	−698.04	−692.58	5.46
40	−592.88	−584.03	8.84
50	−493.36	−484.63	8.73
60	−388.81	−382.74	6.07
70	−280.85	−276.21	4.64
80	−177.70	−174.03	3.67
90	−87.89	−87.45	0.44
100	+108.22	+107.96	0.25

H. Comparison between Reconstruction Kernels — PLA Stonefill

Table VIII compares the HU values of PLA Stonefill with a soft kernel vs. bone kernel at 80 kVp. For PLA Stonefill, the difference between kernels ranged from 0.02 HU (80% fill) to 38.45 HU (100% fill). Agreement was excellent at intermediate fills (60–80%), with the most pronounced divergence at 100% fill.

TABLE VIII. COMPARISON OF PLA STONEFILL: SOFT KERNEL (FC21) VS. BONE KERNEL (FC30) AT 80 KVP

Infill (%)	FC21/soft (HU)	FC30/bone (HU)	|Δ| (HU)
10	−853.58	−845.64	7.94
20	−719.09	−707.64	11.90
30	−603.71	−591.59	12.12

60	−223.50	−221.01	2.49
70	−90.40	−88.65	1.75
80	+36.15	+36.17	0.02
90	+148.99	+142.90	6.10
100	+440.73	+402.29	38.45

IV. DISCUSSION

A. Suitability of Materials for the Simulation of Biological Tissues

The results demonstrate that the two materials evaluated allow coverage of a wide range of the HU spectrum of biological tissues. Considering the reference values consolidated in the literature — inflated lung tissue (−500 to −1000 HU), adipose tissue (−50 to −100 HU) and muscle tissue (+10 to +40 HU) [12], [13] — a quantitative correspondence with a good degree of agreement is identified.

Conventional PLA in 10–30% fillings produced averages of −905.0 ± 155.8 to −698.0 ± 126.0 HU (coefficient of variation, CV = 17.2% to 20.1%), placing it within the range of inflated lung tissue. The absolute difference between the average obtained at 10% (−905.0 HU) and the upper limit of the lung range (−500 HU) is 405 HU, demonstrating that fillings of 30–40% can be adjusted to simulate partially inflated or emphysematous lungs. At 90% filling (−87.89 ± 11.5 HU, CV = 13.1%), PLA coincides with the central range of adipose tissue (−50 to −100 HU), with an absolute mean deviation of only 12.1 HU from the midpoint of the range (−75 HU). At 100% (+108.22 ± 14.2 HU, CV = 13.2%), it is positioned in the transition between dense soft tissue and trabecular bone. These values are consistent with Walt et al. [20], who characterize PLA as equivalent to soft tissue, and with Kamomae et al. [26], who reported 126 ± 18 HU for a PLA phantom wall — a difference of only 17.8 HU (< 14%) compared to the 100% PLA in this study.

PLA Stonefill exhibits a shifted equivalence range toward higher densities with systematically more variable behavior (CV = 9.9% to 24.1%). At 70% (−90.40 ± 38.6 HU), it is located in the adipose-tissue range with 79.3% overlap with the reference interval. At 80% (+36.15 ± 31.5 HU), it reaches agreement with muscle tissue (+10 to +40 HU): the average of +36.15 HU is located only 11.2% from the upper limit of the muscle range, with an overlap of ±1 SD fully covering the target range. At 90% (+149.0 ± 32.8 HU), it corresponds to the cancellous-bone range. At 100% (+440.7 ± 43.5 HU at 80 kVp), it falls within the pediatric cortical-bone range.

B. Statistical Analysis with Pediatric Cranial Bone

Validating PLA Stonefill as a pediatric cranial-bone simulator for the 2-year-old age group requires quantitative comparison with densitometric data available in the literature for this age.

Pediatric reference range. Yamada et al. [9], in a study with 495 individuals (ages ranging from months to 80 years), documented that the peak cranial-density histogram gradually increases from birth, reaching an adult plateau of

1164 ± 143 HU (women, 20–30 years). The developmental curve indicates that children aged 1 to 3 years are in the range of 300–600 HU for parietal and frontal regions [6], [9]. Delye et al. [8], in a cohort of 187 individuals (0–20 years), indicate that the rate of mineralization is highest in the first 3 years of life, corresponding to approximately 25–50% of the adult plateau in that time window.

C. Quantitative Agreement

PLA Stonefill at 100% filling at 80 kVp (440.73 ± 43.5 HU) is located at the 47th percentile of the pediatric reference range (300–600 HU), with an overlap of ±1 SD (397–484 HU) covering 62% of the target range. At 100 kVp (359.86 ± 38.4 HU), the material moves to the 20th percentile of the same range, and at 120 kVp (310.57 ± 33.8 HU) it approaches the lower limit. Taking the pediatric midpoint of 450 HU (estimated from the curves of Yamada et al. [9] for the age of 2 years), the absolute deviation of PLA Stonefill at 80 kVp is only −9.27 HU (2.1%), indicating excellent agreement.

Regional heterogeneity. Takahashi et al. [10] demonstrated that only the lateral surface of the mastoid reaches ∼1000 HU by around 1.7 years of age, while the parietal and frontal regions remain significantly below this value. Rowbotham et al. [11] documented adult neurocranial variation from 78 HU (mastoid) to 1323 HU (temporal squama). The 310–441 HU range of PLA Stonefill (depending on kVp) is therefore specifically suited for simulating the parietal and frontal regions — anatomically more relevant for pediatric cranial phantom structures in radiological-protection and neurosurgical-planning studies [14], [26].

Comparison with phantoms for adult skulls. Lai et al. [22] obtained 547 HU with PLA/calcium carbonate for adult skull simulation — a value 24.1% higher than PLA Stonefill at 80 kVp and 76.1% higher at 120 kVp, a difference consistent with lower pediatric mineralization. Kim et al. [27] reported 680 HU for a PLA-plaster phantom (adult skull), representing a difference of 54.3% compared to PLA Stonefill at 80 kVp. Ahmed, Buschmann, et al. [15] reported 57 and 460 HU with PLA of variable mineral load. The value of 440.73 HU found in the present study is close to the upper limit of that research (460 HU), showing a difference of only 4.4%. These data confirm that PLA Stonefill is positioned in the pediatric densitometric window, distinct from the values reported for mature-bone simulation.

Variability and precision. The coefficient of variation of PLA Stonefill 100% (CV = 9.9% at 80 kVp) is lower than the predictive error of the normative model of Liu et al. [6] (76.7 ± 91.5 HU, CV > 100% in children under 3 years old), indicating that the reproducibility of the printed material is superior to interindividual biological variability. The standard deviation of 43.5 HU for Stonefill 100% at 80 kVp corresponds to only 30% of the target-range amplitude (300 HU), suggesting adequate stability for use as a reference in calibration protocols.

D. Energy Dependence and Spectral Behavior

The variation of 130.17 HU (29.5%) observed for PLA Stonefill 100% between 80 and 120 kVp (Δ = 440.73 − 310.57 HU) is clinically relevant, since pediatric protocols frequently use 80 to 100 kVp for dose reduction [26]. This spectral behavior is attributed to calcium carbonate ($CaCO_3$) in the Stonefill filament: the high effective atomic number of calcium (Zeff ≈ 14.0) increases the photoelectric contribution ($\propto Z^4/E3$) at low energies, mimicking biological bone (hydroxyapatite, Zeff ≈ 13.8) [13], [17]. For comparison, pediatric cranial bone also exhibits energy dependence: Yamada et al. [9] used 120 kVp in their reference measurements, while values obtained at 80 kVp in pediatric clinical studies are typically 20–30% higher [15]. The 29.5% variation of PLA Stonefill between 80 and 120 kVp is consistent with this magnitude, suggesting that the material replicates not only the absolute density but also the spectral behavior of mineralized pediatric cranial bone.

Conventional PLA showed a variation of only 8.91 HU (8.2%) between 80 and 120 kVp at 100% filling, behaving as a near water-equivalent material (Zeff ≈ 7.0). The inter-kVp coefficient of variation of 4.1% is lower than that observed for biological soft tissue (∼5–8%) [13], confirming the spectral stability of pure PLA. This spectral difference between the two materials (8.2% vs. 29.5%) is analogous to the difference between soft tissue and biological bone [17].

E. Influence of the Reconstruction Kernel

The comparison between soft (FC21) and bone (FC30) kernels at 80 kVp revealed distinct behaviors depending on the material and the filling level.

For PLA, the correlation between the means of the two kernels was excellent for all levels ($r > 0.999$), and the maximum difference of 14.19 HU represents only 1.4% of the total dynamic range of the material (−905 to +108 HU). In clinical terms, this agreement indicates that PLA measurements in phantoms are virtually independent of the selected reconstruction kernel.

For PLA Stonefill, inter-kernel agreement was equally high at intermediate fillings (40–90%, $|\Delta| < 7$ HU), but divergent at the extremes: 7.94 HU at 10% and 38.45 HU at 100%. The divergence of 38.45 HU (8.7% of the average value) for Stonefill 100% indicates that the bone kernel (FC30) systematically underestimates the density of this material in solid configuration. Concomitantly, the standard deviation obtained with FC30 (74.6 HU) was 71.4% higher than that obtained with FC21 (43.5 HU), suggesting that the bone kernel — optimized for edge enhancement in biological bone with hydroxyapatite [20] — amplifies the textural heterogeneity of $CaCO_3$ in the polymer matrix.

The interpretation of these differences is relevant for clinical protocols: at low fillers, the geometric heterogeneity of the filler pattern generates air/polymer interfaces with a high contrast gradient, highlighted differently by the algorithms [16]. It is therefore recommended to use the soft kernel (FC21) for quantitative HU measurements in phantoms with PLA Stonefill 100%, avoiding negative bias and artificially high dispersion.

F. Implications for the Construction of Pediatric Cranial Phantoms

The combination of the two materials in selected fillings allows for the replication of pediatric cranial microarchitecture at 2 years of age with radiometric fidelity.

- a) Pediatric cortical bone (300–600 HU in the frontal-parietal region [6], [9]): PLA Stonefill 100% (310–441 HU as per kVp) — 73–100% agreement with target range.
- b) Trabecular bone/diploë (100–300 HU [13]): PLA 100% (+108 HU) or PLA Stonefill 90% (+149 HU) — both within the reference range.
- c) Periosteal/pericranial soft tissue (+10 to +40 HU [5]): PLA Stonefill 80% (+36.15 HU) — deviation < 4 HU from the midpoint.

- d) Subdural space/CSF (~0 to +15 HU [13]): PLA Stonefill 80% can be calibrated via fine fill adjustment (78–82%).

According to the linear model described by Eq. (1), the slope coefficient quantifies the intrinsic calibration of each material: a ≈ 10 HU/% for PLA and a ≈ 14 HU/% for Stonefill. This coefficient allows for the accurate prediction of the HU value for any intermediate infill percentage, giving the system fine-tuning capability in 1% increments. This predictive resolution constitutes a significant advantage over commercial phantoms with fixed densities [15], [16]. Huang et al. [3] demonstrated that diploë is inconsistent in children under 3 years of age; therefore, for phantoms representing the 2-year-old calvaria, a 100% Stonefill monolayer configuration with a thickness of 3.7–3.9 mm (according to Garfin et al. [4]) is more reliable than the adult trilaminar configuration.

G. Limitations and Perspectives

The cylindrical geometry of the specimens does not replicate the pediatric cranial curvature, which may influence the beam-material interaction in clinical protocols with angulation. Comparison with reference data from the literature is limited by the interindividual variability of pediatric cranial mineralization (CV > 100% according to Liu et al. [6]), by the absence of age-stratified HU tables specifically for 2 years [9], and by the dependence on a single CT scanner, which prevents assessment of inter-scanner variability — known to be relevant in cranial densitometry [21]. Future studies should: (1) manufacture phantoms with anatomical cranial geometry derived from pediatric statistical models [14]; (2) validate on multiple low-dose clinical instruments and protocols; (3) evaluate mechanical properties (Young's modulus, Vickers hardness) to verify biomechanical equivalence in addition to radiological equivalence; and (4) investigate the temporal stability of the radiological properties of PLA Stonefill under prolonged storage conditions.

V. Conclusion

This study aimed to demonstrate the feasibility of FDM 3D printing with PLA and PLA Stonefill filament for fabricating phantoms simulating biological tissues across a wide range of Hounsfield Units (HU), with specific application to simulating pediatric cranial bone at 2 years of age. The main findings were:

- 1) PLA Stonefill at 100% infill (310–441 HU, depending on kVp) simulates pediatric cranial cortical bone, falling within the 300–600 HU range reported for 2-year-old children.
- 2) PLA Stonefill at 80% fill (+36.15 HU) shows precise equivalence with muscle/soft tissue (+10 to +40 HU).
- 3) Conventional PLA at 90% infill (−87.89 HU) simulates adipose tissue (−50 to −100 HU), and at 100% (+108.22 HU) it positions itself as dense soft tissue/trabecular bone.
- 4) Energy dependence: PLA Stonefill (130 HU between 80–120 kVp) mimics the spectral behavior of biological bone. Conventional PLA is almost energetically independent (< 9 HU).
- 5) The agreement between reconstruction kernels (soft vs. bone) was high for both materials, with differences of less than 15 HU in most fillings.

The combination of the two materials in distinct fillings provides a quantitative basis for the construction of low-cost, multicompartmental pediatric phantoms, applicable to dosimetry and quality assurance in pediatric cranial CT.

***Abstract*—The publication of Anvisa Collegiate Board Resolution No. 611/2022 (RDC No. 611/2022) introduced new regulatory requirements for the arrangement, operation, and quality control of diagnostic and interventional radiology services. This study aimed to describe the process of adapting a public dental radiology service to RDC No. 611/2022 and to critically discuss regulatory issues related to dental practice. This descriptive case study used a mixed qualitative-quantitative approach and involved document analysis of technical reports, dosimetry records, quality control tests, radiometric surveys, and the institution's radiation protection plan (RPP). Nine imaging units were assessed: six intraoral units, two extraoral units, and one cone-beam computed tomography scanner, along with ten lead protective garments. Radiometric surveys, protective garments, and eight of the nine units complied with the applicable requirements. One intraoral unit failed the tube voltage accuracy and exposure time accuracy tests and was referred for corrective maintenance. Occupational dosimetry readings remained below the service's monthly recording level. This finding was consistent with the radiometric surveys and quality control tests, although dosimetry alone cannot establish a causal relationship with the effectiveness of the protection measures in place. The service team prepared the RPP and descriptive report at no additional cost to the institution. Overall, the service had largely met the requirements of RDC No. 611/2022; however, the periodic training program and the installation of red warning lights above the examination room doors were still pending at the time of assessment. Document organization, technical follow-up, and staff engagement facilitated progress toward compliance with RDC No. 611/2022. The analysis also highlighted potential regulatory tensions between Brazilian requirements and recent international recommendations on the use of lead protective garments in dental imaging, particularly in examinations where shielding may interfere with the acquisition field or automatic exposure control (AEC).**

***Index Terms*—Quality control, public health management, radiation protection, dental radiology, RDC No. 611/2022.**

I. Introduction

According to the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR), medical exposures are the main artificial source of human exposure to ionizing radiation. Approximately 1.1 billion dental radiology examinations are performed worldwide each year, representing a 130% increase compared with the previous report, published in 2010. Dental radiology accounts for 26.3% of human exposures to ionizing radiation but only 0.2% of the total collective dose [1].

In Brazil, SVS/MS Ordinance No. 453/1998 was replaced by RDC No. 611/2022 in 2022. This regulatory update was needed to modernize radiation protection requirements and keep pace with technological advances, particularly the expansion of digital image acquisition and processing systems. Ordinance No. 453/1998 had limitations regarding newer technologies and included requirements and equipment assessment parameters that could overlap with other standards, creating uncertainty about which regulation applied.

In addition to updating regulatory requirements for radiology services, RDC No. 611/2022 aligned its provisions with specific technical and regulatory standards, including guide-

lines issued by the Brazilian Nuclear Energy Commission (CNEN) [3], [5].

The dental radiology service evaluated in this study comprises two settings: the Dental Radiology Service and the Imaging Teaching and Research Laboratory (LABIM). The Dental Radiology Service has one room equipped with an ORTHOCEPH extraoral X-ray unit and one cubicle containing an XDENT X70 intraoral unit. LABIM has five cubicles with five intraoral/periapical units—three DABI ATLANTE SPECTRO 70 X units and two XDENT X70 units—one room with an ORTHOCEPH extraoral unit, and one examination room with an ICAT cone-beam computed tomography scanner. Extraoral radiographs are performed in the Dental Radiology Service. At LABIM, cone-beam computed tomography examinations and extraoral radiographs are performed, and practical intraoral radiology classes are provided to undergraduate dentistry students. In 2025, the service performed 5,708 extraoral radiographs and 1,345 cone-beam computed tomography examinations.

This study aimed to describe the process of adapting a public dental radiology service to RDC No. 611/2022 and to critically evaluate selected regulatory requirements.

II. Methodology

A descriptive case study with a mixed qualitative-quantitative approach was conducted through document analysis of technical reports, institutional records, occupational dosimetry reports, quality control tests, radiometric surveys, and the radiation protection plan of a public dental radiology service. The analysis compared the service records with the requirements established by RDC No. 611/2022 and by the Normative Instructions applicable to extraoral and intraoral dental radiology. The analysis included the assessment results for six intraoral X-ray units, two extraoral X-ray units, and one cone-beam computed tomography scanner. Ten lead aprons were also evaluated according to the performance and integrity criteria established by RDC No. 611/2022 and the applicable Normative Instructions. For the intraoral units, the following parameters were assessed: tube voltage indicator accuracy; exposure time indicator accuracy; half-value layer; air kerma rate linearity; air kerma rate reproducibility; field size; focus-to-skin distance; representative dose value; image artifacts; image quality; darkroom sealing; effectiveness of the erasure cycle in digital processing; room radiometric survey; and leakage radiation. For the extraoral X-ray units and the cone-beam computed tomography scanner, the following parameters were assessed: accuracy and reproducibility of the tube voltage indicator; accuracy and reproducibility of the exposure time indicator; half-value layer; air kerma rate reproducibility; field size; representative dose value; dose indicator accuracy; presence of image artifacts; indicative computed tomography (CT) number value; image uniformity in cone-beam computed tomography; noise and image uniformity in direct or computed radiography; effectiveness of the erasure cycle; and radiometric surveys of the rooms.

III. Results

The radiation protection plan (RPP) includes the professional team, work instructions, team training, signage system, warning signs and controls, area monitoring program, description of protective garments, description of the record system, standard operating procedures, quality assurance program, and accident procedures. The document contains seven appendices: the architectural design of the facility; quality control test and radiometric survey reports; the list of staff members and personal dosimetry reports; work procedures and examination techniques; archived information on periodic training; investigations of events related to occupational risk; and records of changes to the physical structure and equipment.

The examination room doors are fitted with lead-glass viewing windows for visual monitoring of the patient during examinations. They are identified with the international radiation symbol and the warning signs recommended by RDC No. 611/2022 and RDC No. 50/2002 [3], [4].

Analysis of the monthly occupational dosimetry reports showed that readings remained below 0.2 mSv per month, corresponding to the recording level adopted in the reports evaluated, with no readings above this level during the period analyzed [3], [5].

The radiometric surveys of all examination rooms were considered compliant with the regulation.

The assessment results for the extraoral X-ray units and the cone-beam computed tomography scanner were considered compliant with the applicable regulatory requirements.

Among the six intraoral units, only one XDENT X70 unit was found to be noncompliant in the tube voltage accuracy and exposure time accuracy tests. The unit underwent corrective maintenance and will be reevaluated.

All ten lead aprons were considered compliant with the regulation in terms of integrity and the quantity available in each examination room.

The periodic training program was still being implemented, with activities scheduled for the following two months.

Table I summarizes the degree of compliance with the requirements evaluated.

IV. Discussion

Although dental radiology examinations involve low individual doses compared with other radiological modalities, the high frequency of these procedures supports the continued use of quality assurance programs, dose control, protocol optimization, and periodic staff training. In this context, the principles of justification and optimization remain essential to reduce unnecessary exposures and avoid repeat examinations [6]–[8].

Ordinance No. 453/1998 needed to be replaced because it had become outdated in relation to newer technologies and overlapped with other standards, including Regulatory Standard No. 32 of the Brazilian Ministry of Labour and Employment (NR 32), CNEN Standard NN 3.01, which serves as the national reference for occupational dose limits, and some state and municipal laws. In the state of Paraná, State Law No.

TABLE I
SUMMARY OF COMPLIANCE WITH THE REQUIREMENTS EVALUATED

Requirement	Observed status	Status
RPP and documentation	Elements and records described in the RPP available	Met
Radiometric surveys	All rooms evaluated were compliant	Met
Extraoral equipment and CBCT	Test results compliant	Met
Intraoral equipment	Five of six compliant; one under maintenance and pending reevaluation	Partially met
Lead protective garments	Integrity and quantity considered compliant	Met
Occupational monitoring	No readings above the recording level in the reports evaluated	Met
Periodic training	Program under implementation	Pending
Red warning light	Not installed above the examination room doors	Pending

19,125/2017 also requires the availability and use of thyroid collars and lead shielding barriers to protect radiosensitive organs such as the gonads, thyroid, and lens of the eye, without explicitly accounting for examination-specific technical factors [2], [5], [9], [10].

Under RDC No. 611/2022, companions must use personal protective equipment when their presence in the examination room is indispensable. During radiological examinations, the gonads, lens, and thyroid must be protected when these organs are directly exposed to the primary radiation beam or located within 5 cm of it, provided that such protection does not obscure or degrade relevant diagnostic information or increase patient dose [3].

In contrast, recent international recommendations have questioned the routine use of patient shielding in dental imaging. The 2024 ADA recommendations no longer advocate the routine use of thyroid collars or lead aprons during dental radiographic examinations because shielding may interfere with the primary beam, obscure relevant anatomy, generate artifacts, or lead to repeat exposures [13].

Similar concerns have been raised for imaging systems using automatic exposure control (AEC), because highly attenuating material within the acquisition field may interfere with exposure regulation. However, the present study did not include experimental measurements of dose or image quality; therefore, this issue should be interpreted as a regulatory and technical concern rather than as an effect demonstrated in the service evaluated. [11]–[13].

The issue is presented here as a regulatory comparison between national requirements and international recommendations, not as an effect verified through dose or image-quality measurements obtained in the service evaluated in this study.

The situation is further complicated by the requirement in RDC No. 611/2022 to post a notice instructing patients to request protective garments. This requirement may call for additional explanations from professionals and complicate communication with patients, since technical guidance may appear to conflict with the institutional notice required by regulation. Standardized notices that do not distinguish among imaging modalities and technologies may therefore make patient communication more difficult and increase operational uncertainty for the team. The examination room doors display the warnings required by RDC No. 611/2022 and have lead-glass viewing windows that allow observation of the patient during examinations. At the time of the assessment, however, the red warning lights above the examination room doors had not yet been installed. They remain a pending item in the adaptation process [3], [4].

Another gap identified in RDC No. 611/2022 is the absence of a definition of the professional categories qualified to assume technical responsibility and radiation protection supervision, unlike Ordinance No. 453/1998. By using the term "legally qualified professionals," RDC No. 611/2022 leaves this definition to professional councils and local health surveillance authorities. This may create administrative and legal uncertainty, as well as professional disputes over which specialties or professionals have the legal authority to sign reports and assume responsibility for the service [3].

RDC No. 611/2022 is also complemented by Normative Instructions that specify technical requirements and the quality control tests applicable to each imaging technology. In dental radiology, operating routines must follow Normative Instruction No. 94/2021 (IN 94) for extraoral equipment parameters and Normative Instruction No. 95/2021 (IN 95), which establishes the minimum constancy tests for intraoral dental radiography equipment [3], [14], [15].

Regarding quality assurance, the institutional assessment showed compliance after the institution hired an external specialized company in 2025. This enabled the issuance of radiometric survey reports for all physical barriers, quality control test reports, and leakage radiation measurements for all X-ray units. Although technical outsourcing is permitted under the current regulation, it introduces costs that radiology services may find difficult to absorb. Dosimeter readings remained below 0.2 mSv per month throughout the period analyzed, corresponding to the recording level adopted in the evaluated reports. Radiometric surveys demonstrated compliance with the shielding barriers, while periodic quality control tests assessed equipment performance [3], [5].

The dental radiology staff prepared the descriptive report and RPP at no cost to the institution. Because these documents were developed specifically for the service rather than using generic commercially prepared templates, they provided detailed information on the infrastructure, waste management, and dosimetry control.

V. CONCLUSION

The service's experience showed that systematic document organization, staff involvement, technical monitoring, and quality control contributed to progress toward compliance with

RDC No. 611/2022. Full adaptation had not yet been achieved during the study period: one intraoral unit was noncompliant and required corrective action, while the periodic training program and red warning lights remained pending. Because this was a case study of a single service with its own institutional characteristics, the findings should not be generalized to other institutions. The analysis also highlighted regulatory issues related to the use of lead protective garments in AEC equipment; their effects on dose, image quality, and repeat examinations require additional data and specific investigation. Regulatory guidance tailored more closely to dental radiology may help reduce operational and legal uncertainty while preserving quality of care and continuity of services.

***Abstract*—Ultraviolet radiation (UVR) is a significant factor correlated with various ocular pathologies, making the geometry of sunglass frames a essential element for peripheral blocking. This study presents a comparative analysis between two techniques designed to assess the efficacy of sunglass frames in UVR: an experimental measurement system assembled from a polystyrene sphere internally irradiated by a UVA source from 385 to 395 nm, with a tolerance of plus or minus 5 nm, over a mannequin headform, and a computational image processing system based on mathematical modeling of the visual field of view. The methodologies were applied to five distinct sunglass samples, each characterized by a different frame geometry. The results indicate a consistent qualitative agreement between the two systems in ranking and identifying the relative blocking capability across the samples. While differences in absolute values were observed, they can be attributed to the physical sensor's 80-degree acceptance angle compared to the 100-degree temporal angle considered in the computational model. Furthermore, both methodologies provide a preliminary comparative approach within controlled environments to support future measurement procedures.**

***Index Terms*—eye protection, scattered light, sunglasses, sunglass frames.**

I. Introduction

Studies indicate that ultraviolet radiation (UVR) is a significant factor correlated with ocular pathologies affecting the cornea, lens, and retina [1]–[5]. While the use of sunglasses is fundamental, their protective efficacy is not solely defined by the UV transmittance of the lenses.

The vast diversity of protective eyewear models on the market highlights the necessity of considering both frame geometry and material to characterize the contribution to ocular radiation blocking. This consideration may be essential because peripheral radiation incidence becomes highly significant in environments with high levels of diffuse and reflected UVR, as demonstrated by Parisi *et al.* [6], Sliney [7], and Rosenthal *et al.* [8].

Supported by FAPESP and CAPES

Based on extensive literature in this field, the guidelines published by the International Commission on Non-Ionizing Radiation Protection (ICNIRP) [9] establish safe UVR limits for an 8-hour exposure period. These guidelines specify that the maximum radiant exposure—encompassing the UV-C (100 nm–280 nm), UV-B (280 nm–315 nm), and UV-A (315 nm–400 nm) bands weighted against the spectral efficacy curve—must not exceed 30 J/m^2.

The work published by Backes *et al.* [10] simulated solar exposure environments to isolate the fractions of direct, diffuse, and reflected radiation incident on the eyes of a computer-modeled human head. Their study utilized three sunglass models with distinct geometries to quantify the UVR incident on the ocular and periorbital regions. Furthermore, these evaluations were categorized according to the season, time of day, and head tilt of the user.

The primary objective of this study is to provide a comparative analysis of two techniques currently under development at the Ophthalmic Instrumentation Laboratory (LIO-EESC/USP). Although independently introduced in preliminary works [11], [12], both methodologies are applied in this work to a new set of sunglass samples to assess their efficacy in blocking UVR.

The first approach is experimental [11], utilizing a physical setup composed of UV-A LEDs as the radiation source, paired with a photodiode sensor sensitive to the UV-A spectrum. In contrast, the second strategy is computational [12], employing digital image processing techniques alongside mathematical modeling to map the optical paths of radiation reaching the human eye. Although currently under development, both protocols aim to establish a standardized measurement procedure within a controlled environment to ensure consistent testing conditions in future work.

II. Methodology

To compare the methods, both the experimental and computational techniques were applied to evaluate the same group of sunglass frames. This section outlines the implementation

of both protocols [11], [12]. The following subsections present the physical development of the experimental setup, followed by the algorithmic steps of the computational image-based model.

A. Measurement System

To achieve the objective of measuring scattered UVR within a controlled diffuse UV-A exposure environment, a set of optical instruments was selected to develop an electronic apparatus capable of conducting measurement tests on sunglass frames of various geometries.

A polystyrene sphere (Fig.1) was employed to establish a controlled UVR exposure environment, containing a headform with its eye positions centered within the sphere. An array of four high-power LEDs, emitting at 385 ± 5 nm and 395 ± 5 nm, was positioned behind the headform at a zenith angle of $60°$. Photodiode sensors were integrated at the eye locations of the headform to measure the incident irradiance, featuring an $80°$ acceptance half-angle, covering from $-80°$ to $+80°$ (Fig. 2). The laboratory-developed apparatus is illustrated in Fig.3.

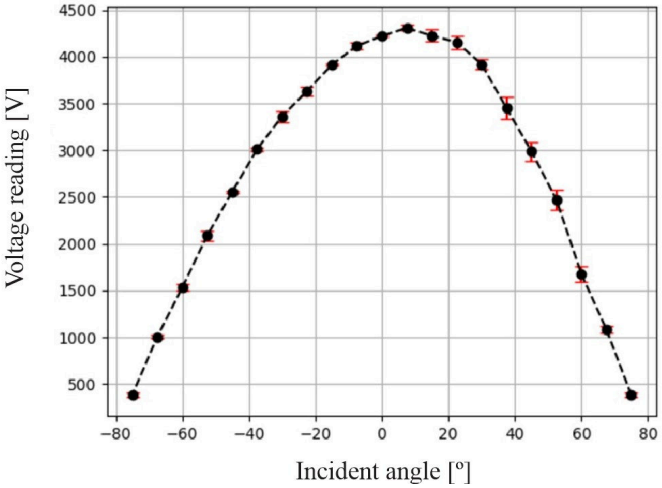

Fig. 2. Sensor incidence angle response.

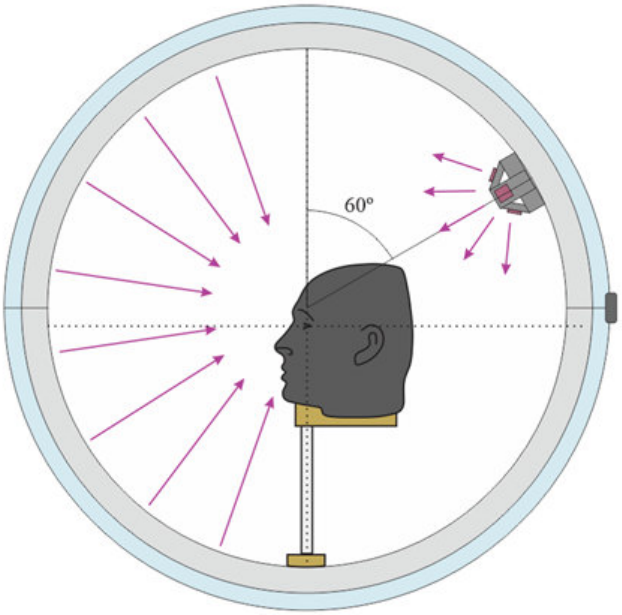

Fig. 1. Prototype of the spherical environment used to create a controlled diffuse UV-A source.

Fig. 3. Developed physical prototype of the measurement system.

Furthermore, an embedded system was developed based on an ESP8266 microcontroller to integrate the instrumentation and communicate with a custom graphical user interface (GUI). This software application ensures ease of use and efficiency during testing, displaying the processed results from the irradiance readings.

The UVR blocking measurement (B_{m}) is automatically calculated through auxiliary calibration steps that quantify the irradiance detected by the sensor under minimum and maximum exposure baselines, denoted as E_{off} (sources turned off) and E_{on} (sources turned on without the sunglasses), respectively. The irradiance incident through the gaps of the frame (E_{frame}) is measured by positioning the sunglasses on the headform. The blocking percentage is then computed according to (1). It is important to highlight that an opaque material was applied to the inner surface of the lenses to eliminate any transmitted or reflected optical contributions from the lenses, thereby isolating the geometric blocking capacity of the frame.

$$B_{\text{m}} = 100 \cdot \left(1 - \frac{E_{\text{frame}} - E_{\text{off}}}{E_{\text{on}} - E_{\text{off}}}\right) [\%] \tag{1}$$

B. Computational Image-Based Method

This computational method for estimating the percentage of light blocking caused by sunglass frames integrates three primary components: a trigonometric projection model, an image acquisition system, and a digital processing pipeline. The objective of this procedure is to propose a standardized metric capable of quantifying the light blocking capacity provided by the frame's geometry across the user's visual field of view (FOV).

At the core of this methodology is mathematical modeling, which is essential for accurately delimiting the regions of interest (ROIs) on the image plane corresponding to the physiological limits of the human FOV. This critical step ensures standardization when evaluating luminous obstruction from both frontal and lateral perspectives. The specific ROIs are derived by performing trigonometric projections of the physiological FOV boundary angles, specifically $60°$ superior, $75°$ inferior, and $100°$ temporal [13], onto the two-dimensional (2D) view plane, accounting for the physical distances between the sunglasses and the ocular surface of the headform.

The image acquisition setup was mounted on an optical bench. Images were captured using a Bright 2k WC577 camera with a resolution of 2560×1440 pixels, placed at a fixed distance of 40 cm from a yellow headform (Fig.4) to maximize contrast against the sunglass frames. Furthermore, a white LED ring light was employed to ensure uniform illumination throughout the experiments.

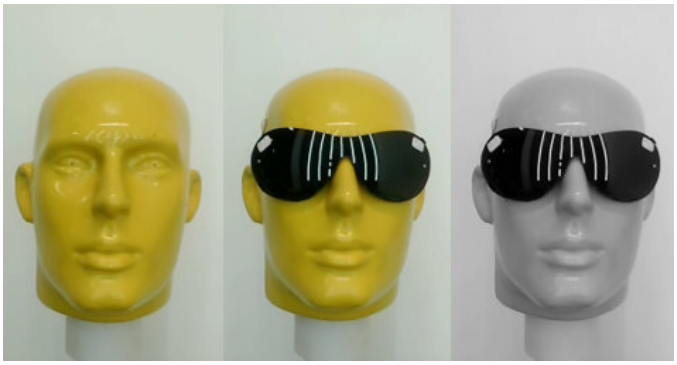

Fig. 4. Headform images from frontal perspective showing baseline setup and sample placement.

The captured images are processed through a custom Python-based software pipeline. The workflow begins with system calibration, where a feature of known physical dimensions on the headform is measured in pixels to establish a spatial scale (px/mm). Using this scale, the software applies the mathematical projection model to automatically segment the ROI. The segmented ROI is then converted into a binary image using color-based thresholding to isolate the frame (represented by white pixels) from the background (black pixels). Subsequently, morphological operations (Fig.5) are applied to reduce noise, such as shadows and unwanted reflections.

Finally, the percentage of light blockage obtained via image processing (B_{i}) is quantified by calculating the ratio of the blocked pixel area (comprising the frame and lens region, considering 100% light blockage, equivalent to the opacified lenses in the physical method) to the total pixel area of the ROI. Additionally, the results analyzed from the frontal and lateral viewpoints are assigned distinct weighting factors. This proportional allocation is determined by the percentage of the total visual field that each perspective encompasses for each eye, establishing the frontal contribution at 81% and the lateral contribution at 19%.

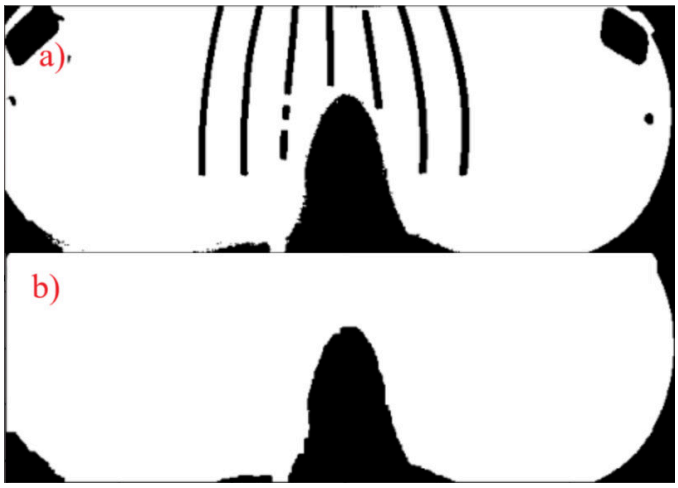

Fig. 5. Morphological filter application: (a) unfiltered image and (b) filtered image.

III. Results

The methodologies were applied to five distinct sunglass samples, each characterized by different frame geometries, as depicted in Fig. 6. These samples represent a new dataset evaluated specifically for this comparative study, distinct from the preliminary sets reported in [11] and [12].

The experimental results obtained from the measuring system are presented in Table I. The data includes the blockage percentages for the right eye, left eye, and the mean value for each sample.

TABLE I
EYE BLOCKAGE RESULTS OBTAINED BY THE MEASURING SYSTEM.

Sample	$B_m[\%]$		
	Right Eye	Left Eye	Mean
I	91.89	92.91	92.40
II	92.69	94.80	93.74
III	89.25	89.75	89.50
IV	93.82	95.02	94.42
V	91.24	91.59	91.41

Table II presents the results obtained through the computational image-based method. This technique calculates the radiation blockage within the projected physiological FOV for the right eye, the left eye, and the mean value for each sample.

The mean blockage percentages obtained from both the physical measurement system and the computational image-based method are summarized in Table III. The data include the absolute difference between the two approaches.

Fig. 6. The five distinct sunglass samples evaluated in the study, showcasing diverse frame geometries.

TABLE II
EYE BLOCKAGE RESULTS OBTAINED BY THE COMPUTATIONAL IMAGE-BASED METHOD

Sample	B_i (%)		
	Right Eye	Left Eye	Mean
I	86.74	87.81	87.27
II	87.26	89.87	88.56
III	82.76	83.08	82.92
IV	91.78	93.15	92.46
V	85.41	86.02	85.72

Both methodologies consistently identified Sample IV as the most effective and Sample III as the least effective in blocking radiation. Under the physical measurement system, Sample IV achieved a mean blockage of 94.42%, compared to 89.50% for Sample III. A similar trend was observed in the computational method, with Sample IV reaching 92.46% and Sample III obtaining 82.92%. Overall, the experimental measurement system consistently yielded higher blockage values than the computational image-based method across all evaluated samples.

TABLE III
COMPARISON OF THE MEAN BLOCKAGE RESULTS BETWEEN BOTH METHODS

Sample	B_m (%)	B_i (%)	Difference (%)
I	92.40	87.27	5.13
II	93.74	88.56	5.18
III	89.50	82.92	6.58
IV	94.42	92.46	1.96
V	91.41	85.72	5.69

IV. DISCUSSION

The comparative analysis between the two systems reveals a consistent agreement in ranking the efficacy of the samples, demonstrating that both methodologies successfully distinguish blocking differences among distinct frame geometries. Both methodologies identified Sample IV as providing the highest coverage and Sample III as the least effective. This qualitative agreement demonstrates the initial potential of the computational image-based method for evaluating frame geometry.

While the ranking trends are consistent, the quantitative results show that the physical measurement system consistently recorded higher blockage percentages than the computational method. This offset may be partly explained by the difference between the physical sensor's acceptance angle and the FOV limits modeled in the software. As detailed in Section II-A, the photodiode sensors possess an acceptance angle of $80°$. In contrast, the computational method is modeled to evaluate blockage up to a temporal limit of $100°$. Although both methodologies aim to estimate the total radiation percentage blocked by the frames, they approach it through different mechanisms. The physical system measures the percentage blockage of UV-A irradiance, while the computational method models the projected geometric occlusion of the visual field to approximate the actual measured blocking.

An additional point of agreement is observed in the lateral asymmetry of the results. In both Table I and Table II, the blockage values differ between the right and left eyes across all samples. This systematic difference suggests a slight asymmetry in the positioning of the sunglasses on the headform during the tests. The fact that both systems detected the same variation with a similar magnitude between the eyes indicates congruent results between the physical measurements and the computational model.

V. CONCLUSION

This study presented a comparative analysis between a physical measurement system and a computational image-based method, both developed to assess the efficacy of sunglass frames in blocking peripheral ultraviolet radiation.

While the computational method requires further parameter refinement to enhance absolute quantitative accuracy, it offers a non-destructive testing methodology that eliminates the need for physical sample preparation, thereby accelerating the evaluation throughput. In contrast, although the physical measurement system provides reliable direct irradiance readings, it requires temporary lens opacification to isolate the geometric blocking contribution of the frame and eliminate any transmitted or reflected optical contributions from the lenses.

Ultimately, although based on preliminary results, this study demonstrates that both methodologies under development show potential to establish standardized measurement procedures within controlled environments. By minimizing external variables, both protocols aim to provide consistent testing conditions across the evaluated samples, representing

complementary methodologies under development for sunglasses frame analysis.

Abstract* — This study evaluated the acoustic power output of a dermatological ultrasound device operating at frequencies of 5.5 and 10.10 MHz. Three applicators with different effective radiating areas (ERAs) were analyzed using a calibrated radiation force balance with up-to-date preventive maintenance. Ten consecutive measurements were performed at each nominal power level to assess measurement accuracy and repeatability. Accuracy was evaluated using the mean relative error between the measured and reference values, whereas repeatability was quantified using the standard deviation and coefficient of variation. Overall, the acoustic power values measured using a radiation force balance showed good agreement with the corresponding reference values, with most results falling within the ±20% interval adopted as a comparative criterion with reference to IEC 61689:2022, although the evaluated frequencies are outside the scope of the standard. In general, measurement accuracy was lower at the one or two lowest nominal power settings**. *The applicators* **with a nominal ERA of 3 cm² showed high repeatability (CV < 2%), whereas the applicators with a nominal ERA of 1 cm² exhibited greater dispersion at lower power settings. At the lowest nominal power setting (0.3 W), the relative error was negative and exceeded 20% in magnitude, indicating that the measured acoustic power was higher than the nominal value and could therefore result in greater acoustic energy delivery for a given exposure time. These findings underscore the importance of periodic acoustic power assessment and performance monitoring to ensure the safety and reliability of dermatological ultrasound applications.

I. Introduction

The increasing incorporation of electromedical technologies into healthcare services has heightened the need for robust quality control, calibration, and performance assessment programs for medical devices [1]. The reliability of the physical parameters generated by these devices is fundamental to ensuring patient safety, treatment effectiveness, and the reproducibility of clinical and scientific results [2–4]. In this context, metrology applied to biomedical engineering plays an essential role by providing methods and criteria for verifying whether devices operate in accordance with the specifications established by manufacturers and international technical standards [5].

Among the devices used in clinical practice, therapeutic ultrasound (TUS) is an electrophysical modality frequently employed in physical therapy, including both rehabilitation and dermatofunctional applications [6]. Its physiological effects on biological tissues result from the propagation of acoustic waves and their interaction with the medium, producing thermal and non-thermal responses. However, the effects of TUS also depend on tissue properties, such as density, perfusion, and absorption coefficient, as well as treatment parameters, including frequency, operating mode, pulse duration, exposure time, acoustic intensity, and acoustic power [7,8].

When there is a discrepancy between the dose indicated by the equipment and the dose actually delivered, both the treatment outcome and patient safety may be compromised [9,10].

To promote measurement reliability and support the safe and effective use of therapeutic ultrasound, international bodies have established standards for the metrological evaluation of TUS equipment [11]. The IEC 61689 standard [12] stipulates that the power emitted by TUS equipment may vary by up to approximately ±20% relative to the values indicated by the device. Despite the existence of international standards defining calibration and verification procedures, studies have reported discrepancies between the programmed nominal power and the power actually emitted by equipment in clinical use [13,14].

One of the most commonly used methods used for measuring acoustic power is the radiation force balance, in which a conical target positioned in the path of the ultrasound beam. The radiation force exerted on the target is employed to determine the acoustic power output of the equipment. Measurement repeatability is also essential for obtaining consistent results and ensuring their reliability [15,16]. Thus, the accuracy of the acoustic power output of the equipment is critical to ensuring that the planned therapeutic dose is effectively delivered to the patient [14].

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

In this context, the aim of this study was to evaluate the output power of a therapeutic ultrasound device operating at two nominal frequencies (5.5 and 10.10 MHz) by comparing the measured values with the corresponding nominal settings. The findings were also used to emphasize the importance of periodic performance assessment and proper maintenance as part of quality assurance for dermatological ultrasound (DUS) equipment.

II. Methods

A. Acoustic power measurement

A new ILIFT therapeutic ultrasound device (Ibramed, Amparo, Brazil) was evaluated in its first use. The device included three applicators with distinct electroacoustic characteristics. Output power was measured using a UPM-DT-1000PA acoustic radiation force balance (OHMIC Instruments Inc., St. Charles, USA), which had a valid calibration and up-to-date preventive maintenance at the time of the measurements.

The tests were conducted over two consecutive days, with five hours of operation per day. During the measurements, the applicators was secured in a mounting fixture, centered and partially submerged in the water reservoir of the acoustic radiation force balance, with its emitting surface perpendicular to the metal cone. A fixed distance of 3 cm was maintained between the emitting surface and the cone throughout the tests. The water was replaced at the beginning of both test days and allowed to stabilize for 1.5 hours before testing.

To monitor the thermal conditions during the experiments, water and ambient temperatures were recorded at the beginning and end of each test period. Water temperature was measured using a TM-947SD thermometer (Lutron Electronic Enterprise Co., New Taipei, Taiwan), whereas a digital thermometer was used for ambient temperature. Other potential sources of interference were also controlled: the air conditioning remained off during testing, and the ultrasound device was placed on a separate table from the acoustic radiation force balance to minimize the transmission of mechanical vibrations.

The ILIFT device comprises three applicators operating at 5.5 or 10.10 MHz, with different ERAs and maximum output powers, as summarized in Table 1. Output power was measured individually for each applicator at all available nominal power settings.

TABLE I. Operating characteristics and output power settings evaluated for the three ILIFT dermatological ultrasound applicators

	Applicator 1	**Applicator 2**	**Applicator 3**
Frequency (MHz)	5.5	10.10	10.10
Nominal ERA (cm^2)	3	3	1
Maximum output power (W)	9	9	3
Power range evaluated (W)	0.3–9.0	0.3–9.0	0.1–3.0
Increment (W)	0.3	0.3	0.1

The obtained data were entered and organized into Microsoft Excel® spreadsheets, where an automated procedure was also developed to calculate the acoustic power accuracy test, as expressed in equation (1). This test is well-established in the literature for evaluating therapeutic ultrasound equipment and consists of comparing the measured acoustic power with the nominal power specified by the manufacturer [6]. The relative error was calculated as the percentage difference between the measured and nominal output power values. A ±20% interval, based on IEC 61689:2022, was adopted as a comparative criterion; however, the operating frequencies evaluated in this study fall outside the scope of the standard.

$$E = \left(\frac{P_{Medida} - P_{Nominal}}{P_{Nominal}}\right) \times 100 \quad (1)$$

B. Analysis of the repeatability of sound power measurements

For each nominal power setting of each DUS applicators, 10 consecutive measurements were performed under the same experimental conditions. The mean relative error (MRE) and standard deviation of the relative error (SDE) were calculated to characterize the average deviation from the nominal power and the dispersion of the relative errors, respectively, following the approach described by Costa Júnior et al. [17]. The coefficient of variation (CV) was also calculated to evaluate the repeatability of the output power measurements. These parameters are defined in Eqs. (2)(4). Data analysis was performed using MATLAB® software (Version R2019a; Mathworks, Natick, USA) and Microsoft Excel. MRE and SDE were calculated and the figures were generated in MATLAB, whereas the remaining parameters were obtained using Microsoft Excel.

$$MRE = \frac{1}{n}\sum_{i=1}^{n}(E_i) \quad (2)$$

$$SDE = \sqrt{\frac{\sum_{i=1}^{n}(E_i - MRE)^2}{n - 1}} \quad (3)$$

$$CV = \frac{s}{\bar{x}} \times 100 \quad (4)$$

where E_i is the relative error associated with the ith measurement for a given applicator and nominal power setting, $\bar{x}$ is the mean output power obtained from the repeated measurements, and s is the standard deviation of these measurements.

III. Results

All measurements were performed at night. Throughout the experiments, the water temperature ranged from 26.0 to 27.9 °C, whereas the ambient temperature decreased from 25.9 to 25.1 °C.

Figure 1 presents the results obtained for the applicators with a nominal frequency of 5.5 MHz and a nominal ERA of 3 cm². The top panel shows the mean relative error in acoustic power as a function of the selected nominal power, along with the ±20% tolerance limits specified by the IEC standard for therapeutic ultrasound equipment. The bottom panel shows the standard deviation of the relative error in acoustic power, thereby allowing measurement repeatability to be assessed.

Figure 2 presents the same analysis for an applicator with a nominal effective radiating area of 3 cm² operating at a

nominal frequency of 10.10 MHz. Figure 3 presents the corresponding results for an applicator with a nominal frequency of 10.10 MHz and a nominal effective radiating area of 1 cm². The top panel shows the mean relative error in acoustic power, while the bottom panel presents the corresponding standard deviation.

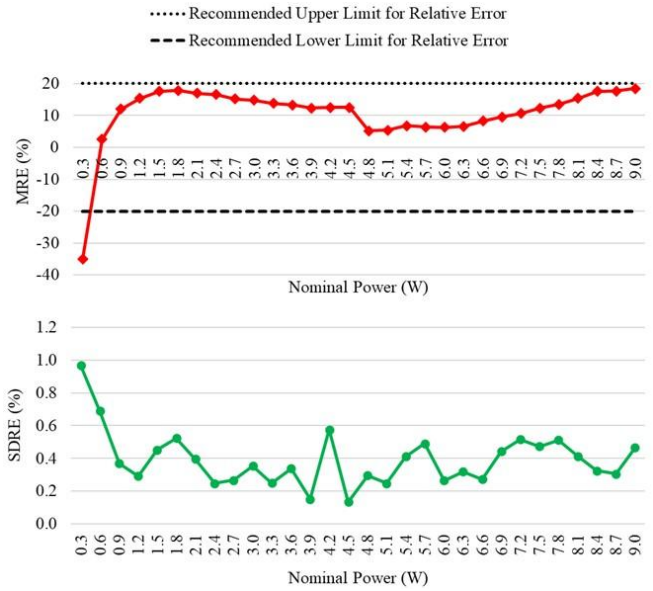

Fig. 1. Mean relative error in acoustic power (top panel) and corresponding standard deviation (bottom panel) as a function of nominal power for an applicator with a nominal frequency of 5.5 MHz and a nominal ERA of 3 cm².

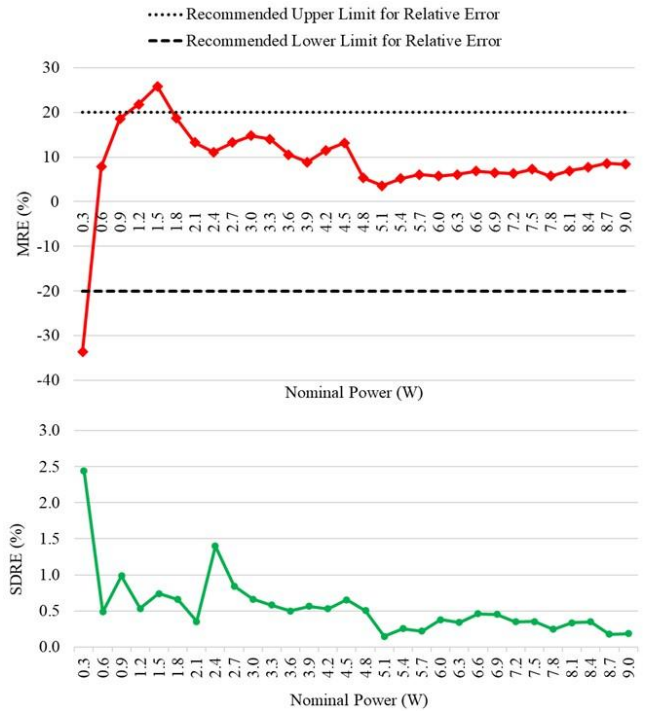

Fig. 2. Mean relative error in acoustic power (top panel) and corresponding standard deviation (bottom panel) as a function of nominal power for an applicator with a nominal frequency of 10.10 MHz and a nominal ERA of 3 cm²

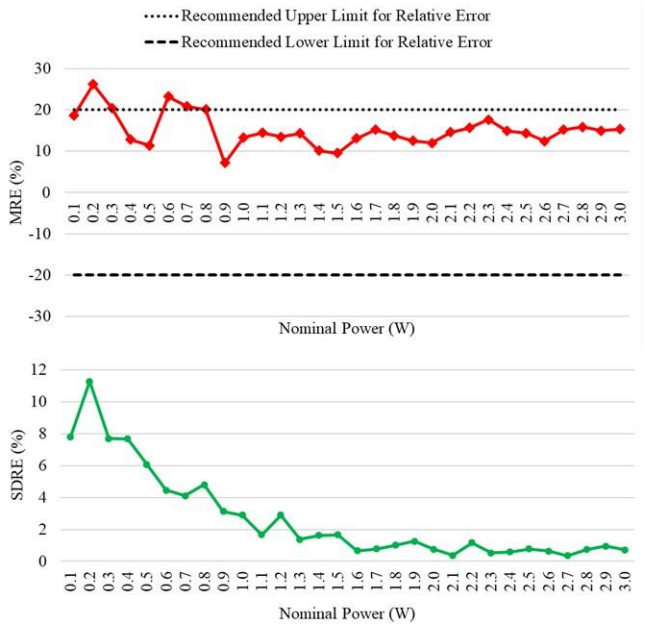

Fig. 3. Mean relative error in acoustic power (top panel) and corresponding standard deviation (bottom panel) as a function of nominal power for an applicator with a nominal frequency of 10.10 MHz and a nominal ERA of 1 cm²

Figure 4 presents the coefficient of variation of the acoustic power measurements as a function of nominal power for the three applicators evaluated. Overall, the CV remained below 2% for the applicators with a nominal acoustic response area (ARA) of 3 cm², regardless of the operating frequency, indicating high measurement repeatability across most of the investigated power range.

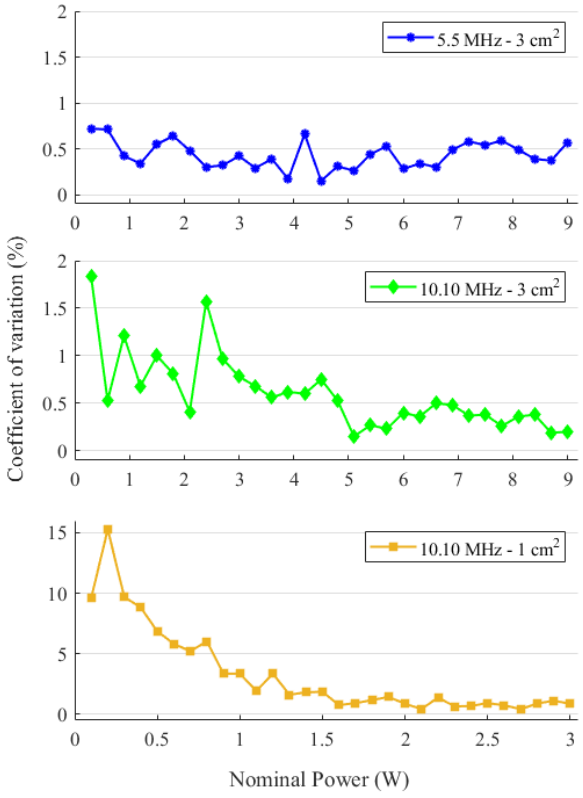

Fig. 4. Coefficient of variation of acoustic power measurements as a function of rated power for the applicators evaluated.

In contrast, the applicators with a nominal frequency of 10.10 MHz and a nominal acoustic area (ERA) of 1 cm² exhibited substantially higher coefficient of variation (CV) values at low power levels, reaching approximately 15% at the lowest power settings evaluated. However, variability decreased markedly as nominal power increased, approaching 2% at power levels above approximately 1.1 W. This behavior suggests a reduction in measurement uncertainty as the emitted acoustic power increases, which is consistent with the improvement in signal-to-noise ratio typically observed at higher power levels.

Overall, the results demonstrate satisfactory repeatability of the radiation force balance measurements, particularly for applicators with a nominal ERA of 3 cm². The greater variability observed for the 1 cm² applicators at low power levels is likely due to its lower acoustic output power and the consequent reduction in measurement system sensitivity under these operating conditions.

IV. Discussion

This study evaluated the metrological performance of dermatological ultrasound equipment operating at 5.5 and 10.10 MHz based on the agreement between measured and nominal output power values and the repeatability of measurements obtained using a radiation force balance. Overall, the three applicators demonstrated measured acoustic output power within the ±20% reference criterion derived from IEC 61689 across most of the operating range, although deviations were observed at low power levels. Under these conditions, the combination of high repeatability and reduced accuracy indicates the predominance of systematic errors, a pattern typically observed in radiation force measurements when the forces exerted on the target are small [16,18].

Because the operating frequencies of the dermatological ultrasound equipment (5.5 and 10.10 MHz) are outside the 0.5–5 MHz frequency range specified in IEC 61689:2022 for physiotherapy ultrasound systems, this standard was not considered an applicable conformity standard. In addition, no specific standard applicable to the type of non-focused dermatological ultrasound equipment evaluated in the present study was identified. Nevertheless, the ±20% criterion specified in IEC 61689:2022 was adopted as a reference for comparison with the measured acoustic output power.

The results corroborate previous findings showing that the acoustic power output of therapeutic ultrasound equipment may not remain uniform throughout the entire operating range. Several studies have reported discrepancies between programmed and measured values, which have been attributed to the electroacoustic characteristics of the applicators, operating conditions, and wear resulting from clinical use [14,15,19,20].

However, unlike the equipment evaluated in previous studies, the device tested here was new and had not been used previously, which may have contributed to the close agreement between the measured and nominal output power values. This result reinforces the fact that periodic calibration, preventive maintenance, and quality control programs play a decisive role in the metrological reliability of the equipment [6,21].

The literature also highlights the importance of assessment at multiple points across the operating range. While Artho et al. [19] found that approximately 39% of the evaluated devices exhibited acoustic power levels outside acceptable limits at least one intensity setting, Nascimento et al. [6] found deviations between measured and nominal acoustic power even in devices undergoing preventive maintenance, with some measurements exceeding the limits established by IEC 61689. These results indicate that periodic maintenance alone does not ensure adequate metrological performance, underscoring the need for regular performance assessments and calibration.

A distinguishing feature of this study is the evaluation of applicators operating at frequencies above those commonly used in therapeutic applications. Most previous studies have focused on devices operating at 1 and 3 MHz, whereas data on therapeutic ultrasound equipment operating between 5 and 10 MHz remain limited [19, 15, 22]. This lack of data warrants further investigation of the metrological performance of these applicators, particularly at low power levels.

Differences in accuracy and precision were observed among applicators with different effective radiating areas. The applicator with an ERA of 3 cm² generally exhibited higher accuracy and precision across the operating range, whereas lower accuracy and greater variability at low power levels were observed for the applicator with an ERA of 1 cm². Although these findings do not establish a causal relationship between ERA and measurement performance, the differences may be partly associated with the lower acoustic output of applicators with a smaller radiating area. At a given intensity, a smaller ERA results in lower total acoustic power and, therefore, a lower radiation force. At low output levels, instrumental effects account for a larger proportion of the measured signal and may contribute to the lower accuracy and precision observed. [23].

The observed deviations were predominantly concentrated at the lower nominal power levels. For the 5.5 MHz applicators, only the 0.3 W power setting exceeded the ±20% limit established by IEC 61689, although repeatability remained high. A similar trend was observed for the 10.10 MHz applicators with a 3 cm² ERA, where variability progressively decreased as power increased. In contrast, the 10.10 MHz applicators with a 1 cm² ERA exhibited greater dispersion at lower power levels but also showed progressive improvement in repeatability as power increased. These results reinforce that the observed limitations are primarily associated with the low magnitude of radiation force at low power levels, a condition that reduces the signal-to-noise ratio of the measurement system [24].

A notable finding was observed at the lowest nominal power setting (0.3 W), for which the mean relative error was approximately −35%. The negative error indicates that the measured acoustic power exceeded the nominal value, falling outside the recommended lower limit of −20%. This discrepancy is clinically relevant because an acoustic output greater than intended may increase tissue exposure and potentially compromise treatment safety and dosimetric accuracy.

From a biomedical engineering perspective, the results reinforce that the metrological assessment of ultrasound equipment should not rely on accuracy testing at a single power setting, as performance may vary across the operating

range. Quality control procedures conducted during maintenance and calibration should therefore include acoustic power measurements at multiple output levels to detect deviations that might otherwise go unnoticed. Regular performance testing, combined with appropriate maintenance and calibration, is important for the safety and reliability of therapeutic ultrasound equipment [15, 23].

This study has limitations, as only one unit of a single commercial model from one manufacturer was evaluated, precluding an assessment of unit-to-unit variability and limiting the generalizability of the results. Moreover, the ultrasound device was new, and the measurements reported here were obtained during its first use. The results may therefore differ from those obtained with equipment subjected to routine clinical use, maintenance, or calibration over time. Future studies should include multiple units of the same model and manufacturer to assess inter-unit variability, as well as models from other manufacturers. Investigations covering a broader range of operating frequencies, applicators, and power settings are also needed for a more comprehensive characterization of the metrological performance of high-frequency therapeutic ultrasound equipment.

In summary, the results demonstrate that dermatological ultrasound equipment operating at frequencies above 5 MHz can exhibit satisfactory metrological performance when subjected to appropriate calibration, although evaluation at low power levels requires greater attention due to the increased influence of uncertainties inherent to the measurement method. These findings contribute to expanding knowledge regarding the metrological characterization of high-frequency therapeutic ultrasound devices and provide a basis for improving quality control programs and future normative recommendations applicable to this class of devices.

A. Limitations

The present study evaluated a single unit of one model of dermatological ultrasound equipment. Therefore, the results cannot be used to distinguish device-specific characteristics from variations associated with the technology as a whole. Despite this limitation, previous studies have evaluated the acoustic output power and/or acoustic output intensity of multiple physiotherapy ultrasound devices, with each study including a single model of equipment [10, 25]. In particular, Guirro and Santos [25] evaluated multiple physiotherapy ultrasound devices that were new and had not been previously used, providing a precedent for assessing the acoustic output of new equipment of a specific model. The equipment evaluated in the present study is also a recently introduced system, which began commercial distribution in April 2026, limiting the availability of units with different periods of use at the time of this study. Further investigations involving multiple units of the same model and, when available, units with different periods of use are necessary to assess inter-unit variability and long-term stability.

V. CONCLUSION

This study demonstrated that the dermatological ultrasound equipment evaluated complied with the accuracy limits established by IEC 61689 across most of its operating range, showing satisfactory metrological performance following calibration. The observed deviations were limited to the lower nominal power settings, underscoring the need for assessments across the entire operating range. Furthermore, this work makes an original contribution to the literature by evaluating the acoustic power of therapeutic applicators operating at frequencies of 5.5 MHz and 10.10 MHz, given that existing studies focus predominantly on 1 MHz and 3 MHz equipment. Thus, the results highlight the importance of periodic calibration and proper maintenance as essential strategies for ensuring equipment reliability, patient safety, and the quality of therapeutic ultrasound treatments

***Abstract*—Este trabalho tem a intenção de fortalecer e complementar a cadeia de rastreabilidade brasileira para a grandeza campo elétrico de baixa frequência, detalhando o desenvolvimento de um sistema e a comparação experimental de um padrão para calibração de medidores de campo elétrico de baixa frequência, baseado no sistema de placas paralelas conforme a norma IEC 61786-1. Durante o processo, testamos o procedimento recomendado pela norma, até os limites de exposição estabelecidos por organismos internacionais como a International Commission on Non-Ionizing Radiation Protection (ICNIRP). O sistema montado no Instituto de Pesquisas Tecnológicas do Estado de São Paulo, com placas de alumínio de 1,5 m x 1,5 m e distância de separação de 0,6 m, foi avaliado quanto às principais componentes de incerteza: tensão aplicada (divisor de tensão e multímetro digital), distância entre placas, não uniformidade do campo, efeitos de borda, deslocamentos do sensor e alinhamento. A incerteza expandida de calibração obtida foi de 1,2% (k=2), resultando em "Test Uncertainty Ratio" (TUR) de aproximadamente 4 vezes em relação à incerteza típica dos medidores comerciais (5%), valor dentro da faixa recomendada para atender aos requisitos da maioria dos usuários que necessitam de rastreabilidade no Brasil. Além disso, este trabalho visa futuramente preencher a lacuna existente na Rede Brasileira de Calibração, que atualmente não possui laboratório acreditado para essa grandeza.**

***Index Terms*—Metrologia, Medidores, Campo Elétrico, Campo Magnético, limite de exposição, calibração, placas paralelas, incerteza de medição**

I. Introdução

A expansão da infraestrutura elétrica no Brasil, com o aumento do número de linhas de transmissão e subestações [3], tem intensificado a preocupação com a exposição da população a campos elétricos e magnéticos de baixa frequência. Como resultado, normas nacionais [1] e regulamentações [3] estabeleceram limites de exposição e requisitos para instrumentos de medição. Entretanto, até o momento, não há laboratório acreditado pela Rede Brasileira de Calibração (RBC) para calibração de medidores de campo elétrico em baixa frequência [7], nem estrutura de rastreabilidade em campos elétricos, levando parte dos medidores usados no Brasil a ser enviada para calibração fora do país, com mais custos e prazos maiores, o que motivou o desenvolvimento deste trabalho. Este trabalho apresenta o desenvolvimento de um padrão baseado em placas paralelas no Instituto de Pesquisas Tecnológicas do Estado de São Paulo (IPT), bem como a validação do procedimento de calibração, visando suprir essa lacuna e a conformidade com os requisitos normativos.

II. Efeitos biológicos e Limites de exposição

Os limites de exposição a campos elétricos e magnéticos de baixa frequência, estabelecidos por normas como a ABNT NBR 25415 e agências reguladoras, como a Agência Nacional de Energia Elétrica (ANEEL) e Agência Nacional de Telecomunicações (ANATEL), são fundamentados em diretrizes internacionais de proteção radiológica não ionizante [8]. Estas diretrizes visam evitar efeitos adversos comprovados, como a estimulação de nervos e músculos e o surgimento de correntes induzidas no corpo humano (em baixas frequências) e aquecimento excessivo de tecidos (em altas frequências). Embora estudos subsequentes [9], [10], [11] continuem a investigar possíveis efeitos de longo prazo e lacunas de conhecimento, o consenso científico atual, corroborado por pareceres em comitês científicos de risco ambiental e à saúde [10], é de que não há evidências convincentes de riscos à saúde para exposições dentro dos limites estabelecidos. A Tabela I apresenta os níveis de referência para 50Hz e 60Hz, adotados pela regulamentação brasileira [3].

Os limites de exposição são definidos por comitês internacionais de saúde "International Commission on Non-Ionizing Radiation Protection" (ICNIRP) e Organização Mundial da Saúde (OMS) e adotados pela norma nacional de referência ABNT NBR 25415 e normas (portarias) publicadas pelas agências reguladoras nacionais (ANEEL e ANATEL).

Tais limites visam evitar prioritariamente os efeitos adversos já comprovados, além de evitar os efeitos de exposição a longo prazo que ainda estão sendo estudados.

TABLE I
Níveis de referência de exposição a campos elétricos e magnéticos

Frequência	**50 Hz**		**60 Hz**	
Campo	**Elétrico (kV/m)**	**Magnético (μT)**	**Elétrico (kV/m)**	**Magnético (μT)**
Público em Geral	5,00	200,0	4,17	200,0
População Ocupacional	10,0	1000,0	8,33	1000,0

III. Requisitos da Norma Brasileira para Medição e Calibração

A norma ABNT NBR 25415 — versão brasileira da IEC 61786-1 [2] — estabelece métodos de medição e níveis de referência para exposição a campos elétricos e magnéticos nas frequências de 50Hz e 60Hz. A norma também define os requisitos para instrumentação de medição e os procedimentos recomendados para calibração.

O foco deste trabalho foi o desenvolvimento de um procedimento de calibração de medidores de campo elétrico de baixa frequência (50Hz e 60Hz) até 40 kV/m, grandeza para a qual não há laboratório acreditado pela RBC. A calibração desses instrumentos, utilizados em medições em ambientes industriais, subestações e linhas de transmissão, é essencial para assegurar a rastreabilidade da medidas, o cumprimento dos limites de exposição estabelecidos e a segurança da população exposta.

Vale destacar que, para campos magnéticos, o IPT já oferece serviço de calibração de medidores de campo magnético AC e DC, com escopo acreditado pela RBC nas faixas de amplitude e incertezas exigidas pela norma.

A. Medidores de Campo Elétrico

Segundo a norma ABNT NBR 25415, os medidores de campo elétrico utilizados nas medições de exposição humana a campos devem ter incertezas de ±(10% + 2V/m) ou menores. Entretanto, os medidores mais novos comumente encontrados no mercado, têm incerteza de 5% ou melhor.

B. Padrão de Campo Elétrico

Para a calibração dos medidores de campo elétrico, a norma ABNT NBR 25415 referencia diretamente a norma IEC 61786-1, para que seja seguida.

Dentre as possibilidades de padrões para calibração de campo elétrico recomendadas na norma IEC 61786-1 [2], escolhemos uma das mais utilizadas no mundo, o Sistema de placas paralelas. Esse sistema tem a vantagem de permitir calibrar todos os tipos de medidores, além da possibilidade de calibrar sensores com dimensões maiores, devido ao tamanho do dispositivo construído no IPT.

A norma contém descrições de dimensões e proporções mínimas do sistema de placas paralelas, para que possa ser utilizada a incerteza recomendada.

Para esse tipo de sistema, o cálculo do campo elétrico teórico vem da equação básica do capacitor de placas planas e paralelas, $E = Vaplicado/D$, onde E é o campo elétrico do sistema, $Vaplicado$ é a tensão aplicada nas placas e D é a distância de separação entre elas.

IV. Incerteza da Medição de Campo Elétrico

A incerteza da medição de campo elétrico com o sistema de placas paralelas é calculada a partir da combinação de incertezas dos principais padrões envolvidos.

A seguir, discutiremos as principais componentes de incertezas (efeitos) que foram consideradas no cálculo final do sistema construído, Fig.1.

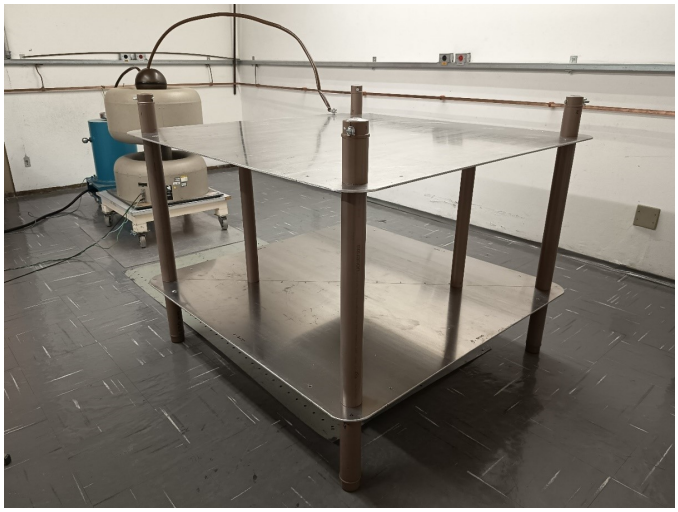

Fig. 1. Arranjo experimental para calibração de medidores de campo elétrico: sistema de placas paralelas com placas de alumínio de 1,5 m × 1,5 m com separação de 0,6 m (relação D/L = 0,4), instalado no IPT. Ao fundo, observa-se o aplicador de tensão (fonte de tensão) e divisor de tensão padrão.

A. Incerteza da tensão aplicada ($Vaplicado$)

Para o sistema montado, as incertezas relacionadas à tensão aplicada ao mesmo vêm de 2 fontes principais: um divisor resistivo de tensão de relação de 100000:1 e um multímetro digital 6 ½ dígitos.

A incerteza recomendada pelo fabricante do divisor de tensão usado com tensão AC é de 0,05% da relação, enquanto a incerteza recomendada pelo fabricante do multímetro digital para a medição de 60 mV, equivalente à leitura de 6 kV com o divisor, é igual a 0,13%. Essa é a amplitude de tensão necessária para o ponto de 10 kV/m, com distância de 0,6m.

B. Incerteza da distância entre as placas (D)

A incerteza relacionada à distância entre as placas paralelas é devido à régua graduada utilizada para a medição da distância. A régua graduada utilizada tem incerteza de 0,5 mm em toda a extensão de medição, o que representa 0,083% no ponto de medição de 0,60 m de separação entre as placas.

C. Incerteza do dispositivo de placas paralelas (k)

Considerando as proporções recomendadas na norma e o tamanho típico dos medidores comerciais (normalmente menores que um cubo de (0,1 m x 0,1 m x 0,1 m) e maior diagonal menor que 0,23 m), foi montado um capacitor com 2 placas paralelas, de alumínio com dimensões (L) de 1,5m x 1,5m, com distância de separação entre elas (D) de 0,6 m, que segundo a norma, seria suficiente para ter uma incerteza de 1%, somente devido ao dispositivo gerador de campo.

Segundo a norma, a incerteza do dispositivo será da ordem de 1%, desde que a relação entre a distância das placas (D) e o seu lado (L) deve ser $D/L \leq 0,5$. O sistema construído possui L= 1,5 m e D= 0,6 m, resultando em uma relação $D/L = 0,4$, que é ainda mais conservadora que a recomendada.

A não planicidade e não paralelismo das placas, devido às imperfeições geométricas na construção das placas, causam variações no campo elétrico gerado. Embora essas componentes sejam geralmente pequenas quando as placas estejam bem construídas, elas podem ser avaliadas durante a medição do espaçamento das placas e devem ser consideradas na análise de incerteza.

Uma correção k, referente à variável do dispositivo, pode ser levada em consideração, com os efeitos empíricos do dispositivo montado.

D. Validação da incerteza do dispositivo de placas paralelas

Para a validação da incerteza do dispositivo, foi utilizado um medidor de campo elétrico com o princípio de placas paralelas com dimensões de aproximadamente 17 cm x 7 cm e espaçamento de 4 cm entre as placas. Durante a validação, esse medidor teve resolução de 0,1% ou melhor.

Por causa de suas dimensões, esse "probe" mede um campo elétrico médio, mas que já está inserido no volume central dentro do dispositivo com campo uniforme.

A uniformidade do campo, devido à presença do medidor, com suas dimensões controladas (relação entre a dimensão do medidor, as dimensões da placa e o espaçamento entre elas, fornece uma incerteza de 0,5% [4].

Deslocando o "probe" do centro, em relação ao eixo X ou Y (paralelamente às placas) em distâncias de até 100 mm, o campo indicado pelo medidor variou até 0,1%.

Deslocando o "probe" do centro, em relação ao eixo Z (aproximando de alguma das placas energizadas) em +20 mm, o campo indicado pelo medidor variou -0,6% e em -20 mm, o campo indicado pelo medidor variou +0,6% (comportamento simétrico).

Também relevante, é a incerteza devido ao efeito das bordas finitas das placas, que tem um efeito de aproximadamente +0,3% e que esse efeito seria "compensado" pelo efeito de proximidade do sensor com as placas -0,4% [5].

Por fim, o ângulo de inclinação do sensor em relação às placas paralelas é importante e deve ser considerado um sistema de alinhamento do mesmo. Para uma incerteza no alinhamento de até 5°, isso resulta em uma incerteza de aproximadamente 0,31% [6].

Na tabela II, apresentamos as principais componentes relacionadas ao dispositivo de placas paralelas. Nela, também apresentamos a incerteza combinada calculada do dispositivo para comparação com o valor proposto na norma.

TABLE II
ORÇAMENTO DE INCERTEZAS PARA O DISPOSITIVO DE PLACAS PARALELAS

Componente de incerteza	**Incerteza (%)**	**Distribuição**
Não uniformidade do campo	0,50	Retangular
Variação no eixo X ou Y	0,10	Retangular
Variação no eixo Z	0,60	Retangular
Dimensão finita das placas	0,40	Retangular
Alinhamento do sensor e das placas	0,31	Retangular
Incerteza combinada	0,54	-
Incerteza expandida (k=1,732)	**0,94**	**Retangular**

Considerando os efeitos avaliados experimentalmente, juntamente com outros efeitos relevantes da literatura, obtivemos uma incerteza de medição de 0,94%, valor levemente inferior à incerteza recomendada pela norma IEC 61786-1 [2].

Embora as medidas tenham sido executados com somente um tipo de medidor (em 2 medidores de fabricantes distintos), esse resultado reforça a adoção de 1% da proposto na norma.

E. Cálculo da Incerteza final

A incerteza final de calibração de um medidor de campo elétrico com o sistema de placas paralelas é calculada a partir da combinação de incertezas dos principais padrões envolvidos; além da variabilidade e resolução dos padrões e do próprio instrumento sob calibração.

Como vimos, a disposição e a geometria do sistema influencia também no valor do campo elétrico de referência e, desta forma a equação de medição do campo elétrico deriva para $E = k * (Vaplicado/D)$, onde E é o campo elétrico da medição, k é a correção aplicada de acordo com o dispositivo, o $Vaplicado$ é a tensão aplicada nas placas e D é a distância de separação entre elas.

Para simplificação da tabela de componentes de incertezas, omitimos as componentes relativas à variabilidade (0,05%) e resolução dos padrões (0,01%) e do instrumento sob calibração (0,1%), por serem consideradas de menor magnitude e não impactarem a incerteza final. Dessa forma, apresentamos apenas as principais componentes relacionadas ao sistema, conforme visto na tabela III.

A incerteza expandida de medição foi calculada como a incerteza padrão combinada, multiplicada pelo fator de abrangência k=2, supondo variação normal, correspondente a uma probabilidade de abrangência de aproximadamente 95% [12]. Resultando numa incerteza de calibração de medidores de campo elétrico de 1,2 % para o sistema montado, Fig.2.

Ressaltando que, a garantia da rastreabilidade do campo elétrico no sistema montado no IPT se dá por duas frentes; a primeira relativa à metodologia utilizada no laboratório ser conforme o descrito na norma e a segunda, devido à rastreabilidade de todos os instrumentos envolvidos: o divisor de tensão padrão, o multímetro 6 ½ dígitos e a régua graduada (nas grandezas e escalas utilizadas durante o procedimento de calibração) terem sido calibrados em laboratórios acreditados pela Coordenação Geral de Acreditação (Cgcre - RBC).

TABLE III
ORÇAMENTO DE INCERTEZAS PARA CALIBRAÇÃO DE CAMPO ELÉTRICO

Componentes de incerteza	**Incerteza (%)**	**Distribuição**	**Incerteza padrão (%)**
Divisor de tensão (medição da tensão)	0,05	Retangular	0,029
Multímetro digital na saída do divisor (medição da tensão)	0,13	Retangular	0,075
Distância entre placas - D (régua graduada)	0,08	Retangular	0,048
Dispositivo de placas paralelas	1,00	Retangular	0,577
		Incerteza combinada	0,58
		Incerteza expandida (95%, k=2)	**1,2**

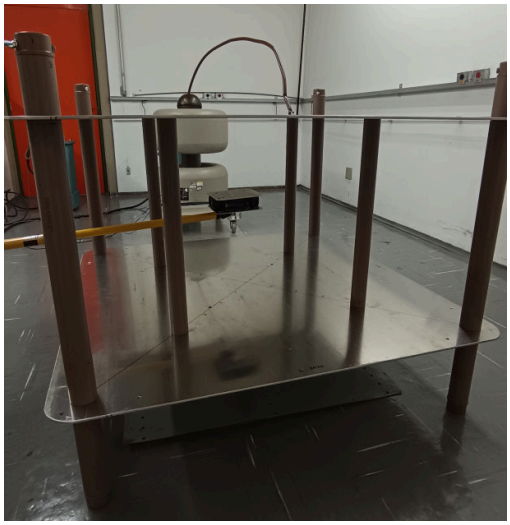

Fig. 2. Sistema de placas paralelas montado do IPT, com um sensor posicionado no centro, pronto para calibração

Um ponto importante, verificado durante as medições executadas, é que a proximidade de pessoas e objetos ao dispositivo, interfere nos valores medidos (provavelmente pela distorção das linhas de campo elétrico).

Outro ponto chave é o suporte do medidor de campo elétrico, que também fica sob efeito do campo de referência, podendo alterar o valor indicado pelo medidor. Por isso, é recomendado o uso do suporte do próprio medidor sob calibração, que também será utilizado nas medidas em externas. Caso contrário, será uma nova componente de incerteza.

V. Conclusão

Recomenda-se que a relação de incertezas entre um instrumento sob calibração e um padrão utilizado nessa calibração "Test Uncertainty Ratio" (TUR) seja entre 3 a 10 vezes.

Como os medidores de campo elétrico utilizados nas medições de exposição humana a campos têm normalmente incertezas de cerca 5%, e que a incerteza de medição calculada do sistema foi de 1,2%, chegamos na relação TUR próxima de 4 vezes, valor dentro da recomendação para oferecer o serviço de calibração para a maioria dos clientes que necessitem de rastreabilidade para as medições de campo elétrico no Brasil.

Conforme relatado, temos a linha de rastreabilidade ininterrupta e a metodologia aprovada pelas normas (nacional e internacional), por isso já estamos oferecendo para qualquer cliente do IPT, o serviço de calibração de Campos Elétricos de baixa frequência rastreado ao Sistema Internacional (SI).

VI. Próximos Passos

Como próximos passos, pretendemos solicitar a acreditação do serviço de calibração de medidores de campo elétrico em baixa frequência para a Cgcre.

Para tanto, uma comparação interlaboratorial com algum laboratório já acreditado pela norma ABNT NBR ISO/IEC 17025, uma garantia da confiabilidade dos resultados obtidos [13], se faz necessária.

Adicionalmente, buscaremos aprimorar o sistema desenvolvido, testando também outros tipos de medidores de campo elétrico, com o objetivo de entender cada componente de incerteza envolvida na instrumentação, a fim de poder reduzir a incerteza de medição, aplicando fatores de correção onde for possível.

Agradecimentos

Gostaria de agradecer principalmente ao engenheiro mecânico Ramon Valls Martin do IPT, pela construção do dispositivo de placas paralelas, que através de sua habilidades, conseguiu montar o dispositivo de acordo com as proporções recomendadas nas normas, mantendo assim as características elétricas esperadas.

Por fim, gostaria de agradecer à chefia do Laboratório de Metrologia Elétrica do IPT e à gerencia do mesmo, por acreditar e investir em uma capacitação tão importante para a segurança das pessoas no entorno das instalações elétricas de alta tensão.

***Abstract*—Proton therapy offers a dosimetric advantage through the concentrated energy deposition at the Bragg peak, but its biological response remains insufficiently characterized and is still managed clinically using a fixed Relative Biological Effectiveness (RBE = 1.1) that does not capture its true variability. Developing more accurate RBE models requires experimental data collected under well-controlled physical conditions. This preliminary study aimed to develop and initially validate an experimental protocol for in vitro radiobiological studies using a low-energy (2.6 MeV) proton beam. MG-63 cells, derived from a human osteosarcoma, were irradiated, the absorbed dose was estimated through Monte Carlo simulations using the PHITS code, and cell viability was assessed by MTT assay at different incubation periods. The 48-hour protocol showed a strong, significant negative correlation between absorbed dose and cell viability, whereas the 6-day protocol showed no consistent relationship, supporting the selection of the 48-hour incubation period for the proposed experimental protocol. These results support the initial validation of the proposed methodology and demonstrate its feasibility for obtaining dose-dependent biological responses using a low-energy research accelerator, providing an experimental foundation for subsequent radiobiological studies and future RBE estimation.**

***Index Terms*—radiobiology, cell culture, low-energy proton beam, cell viability**

I. Introduction

Clinical access to proton therapy has expanded considerably over the past decades, establishing it as a relevant treatment

modality for aggressive tumors, particularly for complex tumor locations or pediatric patients, where preserving healthy tissue is essential [1]. Its main physical advantage stems from the Bragg peak, where protons deposit most of their energy near the end of their range, followed by a sharp drop in dose beyond that point [2]. Because the depth of this peak depends on the initial beam energy and the properties of the traversed medium, dose can be concentrated within the tumor volume while minimizing exposure of surrounding structures, reducing the risk of late toxicity and radiation-induced secondary malignancies [3].

Despite these clinical advances, the biological response induced by protons is still not fully understood [4]. Current radiotherapy planning relies on a fixed Relative Biological Effectiveness (RBE = 1.1), defined as the ratio between the dose of a reference radiation (typically photons) and the proton dose required to produce the same biological effect. Although widely used in clinical practice, this value was derived from experimental studies conducted under specific conditions [5]. Recent studies, however, indicate that RBE varies with parameters such as LET, dose per fraction, cell type, and tissue radiosensitivity [6], [7]. This variability can lead to tumor underdosing or healthy-tissue overdosing, compromising treatment safety and efficacy, particularly in the distal beam region where LET is higher.

Several studies point to the need for mechanistic models capable of predicting RBE by integrating physical parameters, such as cellular dose and LET, with biological characteristics specific to each cell type [8]. Advancing these models, however, depends on experimental data obtained under rigorously controlled physical conditions [9], [10]. Accordingly, there is a growing effort within the scientific community to clarify the relationship between LET and RBE through in vitro experiments, computational simulations, and clinical analyses, aiming to develop more accurate radiobiological models that can be incorporated into proton therapy planning [11].

Obtaining this experimental data, however, depends on the availability of experimental platforms capable of irradiating cell cultures under well-defined physical conditions [6]. Although radiobiology studies are often conducted at clinical proton therapy centers or dedicated biological research facilities, access to this equipment remains limited [12], [13]. In this context, research accelerators represent an important alternative for expanding the production of experimental radiobiology data. Adapting in vitro experiments to these platforms, however, involves significant technical challenges due to the horizontal beam geometry and the short range of low-energy protons. These factors impose constraints on the experimental geometry, cell culture conditions, and control of the physical irradiation parameters, requiring the development of specific protocols capable of ensuring rigorously controlled physical conditions and reliable, reproducible quantitative data that can serve as a reference for radiobiology studies and for validating predictive models.

Within this context, this study evaluated the effect of low-energy proton irradiation, produced by the accelerator at the Laboratory of Materials Analysis by Ion Beams of the University of São Paulo (LAMFI-USP), on the viability of tumor cell lines, investigating the consistency and reproducibility of the biological responses, as well as the adequacy of the experimental adaptations required to use this platform for in vitro radiobiology studies. These results aim to establish criteria and standardize the experimental protocol for obtaining consistent quantitative experimental data, capable of supporting the development of mechanistic models for RBE estimation.

II. Materials and Methods

This section describes the experimental protocol developed for the in vitro irradiation of tumor cells with low-energy protons and the evaluation of their biological effects through viability assays. The protocol was established and optimized throughout the study, including the definition of culture and plating conditions and the standardization of the irradiation and MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] viability assay steps.

Fig. 1 illustrates the experimental workflow adopted, from cell culture and seeding through proton irradiation and subsequent viability assessment. Each step is described in detail in the following subsections.

A. Pre-irradiation

1) Cell culture: The cell line used as the primary model for the irradiations was MG-63, derived from a human osteosarcoma, widely used as in vitro models for tumors that are difficult to control therapeutically, characterized by high growth and invasive capacity [14], [15].

MG-63 cells were cultured in low-glucose (1 g/L) Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum (FBS) and 1% penicillin-streptomycin (pen-strep). The cells were kept in T-75 culture flasks in an incubator at 37°C with a 5% CO_2 atmosphere, with medium changes three times per week and trypsinization once confluence (the percentage of the culture surface occupied by adherent cells) reached 80%.

2) Sample preparation: Cell cultures were prepared in 33 mm Petri dishes (KASVI, model K13-0035, growth area = 8.5 cm^2), allowing the culture medium to be removed immediately before irradiation while keeping the cells adhered to the dish surface as a monolayer, oriented toward the beam, as shown in Fig. 2. The cell suspension volume was adjusted to yield 9×10^5 cells per dish, a concentration previously defined to reach approximately 80–90% confluence at the time of irradiation. The cell suspension was prepared in a sufficient volume of culture medium to dispense 1.5 mL per dish, homogenized, and then distributed into the Petri dishes. Finally, to ensure a homogeneous cell distribution, the dishes were vortexed at 250 rpm for 2 min.

Twenty-four hours after plating, the dishes showing the highest confluence and most homogeneous cell distribution were selected for irradiation. Samples were then sealed with parafilm and transported from Faculdade Israelita de Ciências

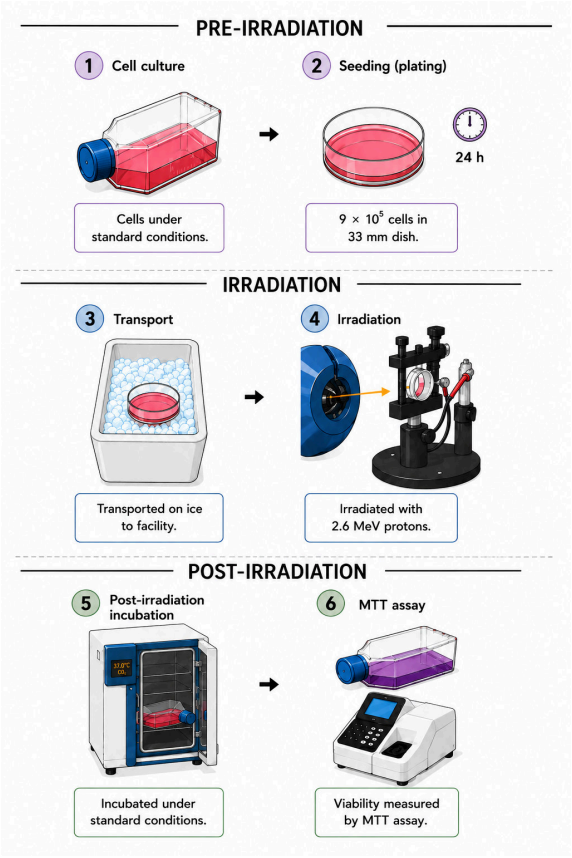

Fig. 1. Schematic flowchart of the experimental protocol steps. The pre-irradiation stage comprises (1) maintaining cells under standard culture conditions and (2) plating 9×10^5 cells in a 33 mm dish 24 h before irradiation. The irradiation stage includes (3) transporting the dishes on ice to LAMFI-USP and (4) irradiation with a 2.6 MeV proton beam. Post-irradiation: (5) incubating samples under standard culture conditions and (6) assessing cell viability using the MTT assay.

da Saúde Albert Einstein (FICSAE) to LAMFI-USP in an insulated container with crushed ice, to preserve cell viability during transport.

B. Proton irradiation

1) Experimental irradiation platform: Irradiations were performed using the proton beam available at the Laboratory of Materials Analysis by Ion Beams of the University of São Paulo (LAMFI-USP). Experiments were conducted on a 5SDH Pelletron-tandem electrostatic accelerator, with a beam energy of 2.6 MeV selected for corresponding to the equipment's most operationally stable energy range. The charge delivered in each irradiation was monitored using a charge integrator coupled to the sample holder.

The irradiation line has a horizontal geometry, requiring the culture dishes to be positioned vertically, with the cell monolayer perpendicular to the beam direction. Since the beam has a 1 mm diameter, a distance of 97.44 mm was adopted between the beam exit and the cell monolayer to increase the irradiated area of the Petri dish and, consequently, the number of cells exposed to the beam, as shown in Fig. 2.

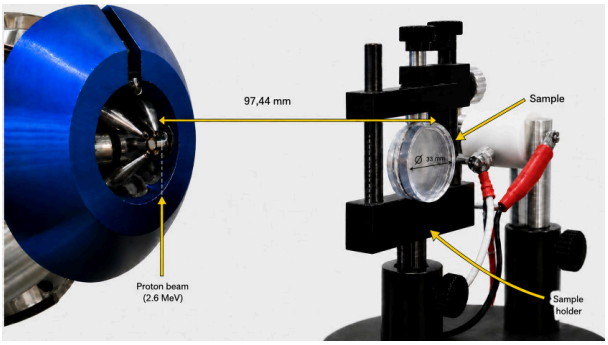

Fig. 2. Schematic representation of the irradiation experimental setup.

Given the limited range of 2.6 MeV protons in the culture medium, approximately 117.6 μm according to the PSTAR database (National Institute of Standards and Technology - NIST) [16], the culture medium was completely removed and the dishes were left uncovered during irradiation to avoid attenuating the beam before it reached the cell monolayer. After irradiation, 1 mL of culture medium was added, and the dishes were sealed with parafilm for transport.

2) Experimental design: Samples were divided into two experimental groups, control and irradiated, with all conditions evaluated in technical duplicate. The control group was subdivided into C0 and C1, while the irradiated group comprised different irradiation conditions, defined by the delivered proton beam charge.

The C0 control group remained in incubation throughout the entire experimental procedure, without undergoing transport or the irradiation steps, and was used as the biological reference control for comparing cell viability results.

The C1 control group underwent the same experimental conditions as the irradiated groups, including transport to LAMFI-USP, removal of the culture medium, and time spent in the experimental environment corresponding to the longest irradiation performed (4 minutes), but without exposure to the proton beam. This group was used exclusively to assess possible systematic effects arising from the experimental protocol itself, such as sample transport, handling during irradiation preparation, and the temporary absence of culture medium.

The irradiated group was subdivided into different exposure conditions, with charges ranging from 0.12 to 4.8 μC, obtained by combining beam current (2 to 20 nA) and irradiation time. In this study, a replicate was defined as a full irradiation session, using technical duplicate samples for each dose condition within that session. However, due to experimental uncertainties in the proton beam during irradiation, the effectively delivered integrated charge showed small variations between samples, including between technical duplicates. The integrated charge was therefore recorded individually for each sample.

C. Post-irradiation

1) Post-exposure cell handling and maintenance: After irradiation, samples were transported on ice over a 20-minute trip from LAMFI to FICSAE. They were then trypsinized

and transferred to a T25 flask with 5 mL of medium, and incubated under standard culture conditions for subsequent viability assessment. Two protocols were tested, one with a 6-day incubation period and another with 2 days, to account for late effects of radiation-induced damage [17], [18]. During incubation, cells were kept under standard culture conditions for the period corresponding to each protocol.

In the 6-day incubation protocol, samples were checked after 72 hours, if confluence exceeded 80%, they were transferred to T75 culture flasks or simply had their medium changed, to prevent excessive confluence from restricting cell proliferation and altering cell metabolism, which could interfere with the viability assessment. In the 2-day incubation protocol, due to the shorter culture period, cells remained in T25 flasks throughout.

2) Cell viability assessment: Cell viability was assessed using the colorimetric MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] assay, which estimates the metabolic activity of viable cells through the formation of formazan crystals. For this, the culture medium was discarded and 2 mL of a solution containing 10% MTT solution – prepared by dissolving the salt in PBS at 5 mg/mL – and 90% culture medium was added. Samples were incubated for 3 hours to allow formazan crystal formation.

Colorimetric quantification was performed using a Kasvi K37-VIS spectrophotometer at a wavelength of 570 nm. To keep sample readings within the equipment's detection limit, the formazan solution was diluted in isopropyl alcohol, maintaining a final volume of 2 mL for all readings. The aliquot volume used for dilution was defined according to the intensity of sample coloration, so that more concentrated samples were subjected to higher dilution factors, aiming for absorbance readings of up to 1.5.

To correct for the dilution effect during data analysis, the obtained absorbance values were multiplied by the ratio between the final solution volume (2 mL) and the aliquot volume used for dilution. The corrected values were then normalized relative to the C0 control group, considered as 100% cell viability.

Given the variations in absorbed dose observed between technical duplicates, each sample was analyzed individually by evaluating the correlation between dose and the corresponding cell viability response for each irradiation experiment. Because of the small sample size and the lack of normality in the data, Spearman's correlation test was used, with the correlation coefficient (r) calculated independently for each irradiation (GraphPad Prism, version 11.0.2). The r coefficient was used to assess the strength of the association between variables, while the p-value was used to determine the statistical significance of that association, adopting a 5% significance level ($p < 0.05$).

Samples grouped by absorbed dose were then compared against C0 using the non-parametric Kruskal-Wallis test, followed by Dunn's post hoc teste for multiple comparisons. The analysis included four independent irradiation experiments ($N = 4$). The Kruskal-Wallis test was used to determine whether significant differences existed among the groups, while Dunn's test was subsequently applied to identify specific pairwise differences. A significance level of 5% ($p < 0.05$) was adopted. Given the limited number of independent experiments, the statistical analysis was interpreted within the context of an exploratory pilot study aimed at the initial validation of the proposed experimental protocol.

D. Absorbed dose estimation

The absorbed dose corresponding to each experimental condition was estimated through Monte Carlo simulation using the PHITS (Particle and Heavy Ion Transport code System) code, version 3.35. The irradiation geometry was faithfully reproduced, using the same experimental conditions described in Section II-B, including the irradiation line configuration, the composition and dimensions of the materials, the position of the cell monolayer relative to the beam, and the source proton energy.

The absorbed dose was estimated for a representative region of the cell monolayer using the T-Deposit estimator, which calculates the energy deposited per unit mass in the region of interest, in units of Gy per source particle. Since the integrated beam charge was monitored during each irradiation by the LAMFI-USP acquisition system, the total number of source particles for each condition was obtained by dividing the integrated charge by the elementary proton charge (1.602×10^{-19} C). The total absorbed dose in the cell monolayer, in Gy, was then calculated by multiplying the dose per source particle estimated by PHITS by the number of source particles derived from the integrated charge.

This approach made it possible to convert the experimentally measured electric charge into absorbed dose within the cell monolayer, allowing the biological assay results to be quantitatively correlated with the estimated absorbed dose.

III. Results and Discussion

A. Morphological assessment

Fig. 3 shows MG-63 cell images obtained with an EVOS M5000 microscope (Thermo Fisher Scientific), taken immediately after irradiation (40× magnification) and 48 hours after irradiation (10× magnification), for the C0 control group and the C1 control group.

The 40× images, taken after the experimental procedure, show that the C1 control group preserved the same spindle-shaped morphology and adhesion pattern observed in the C0 control group, with no evident structural alterations resulting from transport, handling, or the temporary absence of culture medium. Similarly, the 10× images, taken 48 hours later, show comparable confluence and cell distribution between the two groups.

Fig. 4 shows MG-63 cell images obtained with an EVOS M5000 microscope (Thermo Fisher Scientific), taken immediately after irradiation (40× magnification) and 48 hours after irradiation (10× magnification), for the C0 control group and two irradiated groups at different absorbed doses.

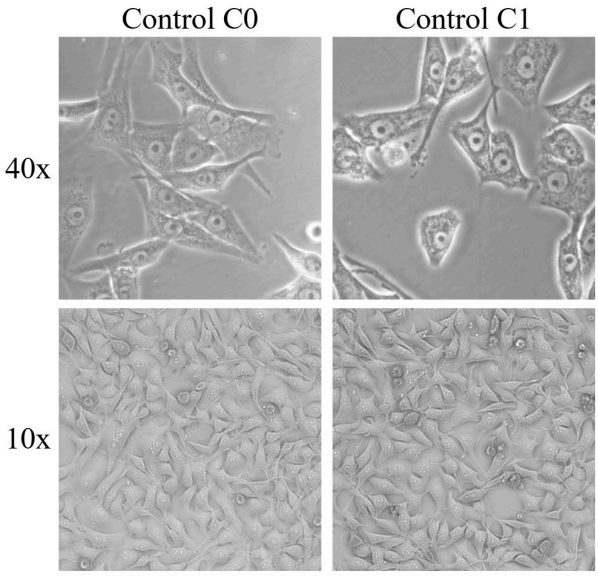

Fig. 3. Microscope images comparing the control groups, as indicated in the image. The top row shows samples immediately after irradiation at 40× magnification.The bottom row shows samples 48 hours after irradiation at 10× magnification; Columns represent the different groups: control C0 and control C1.

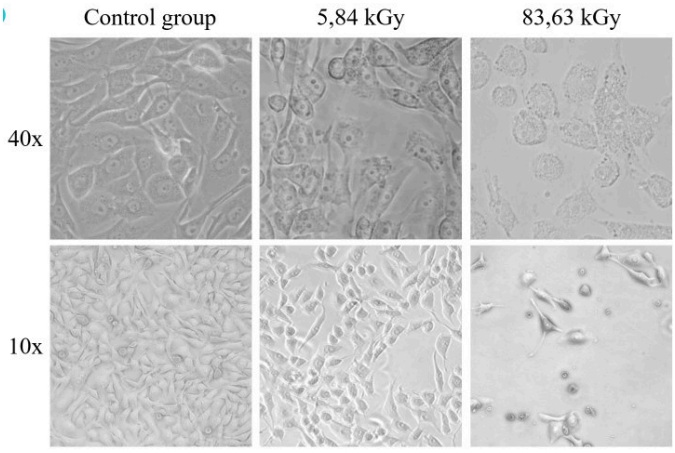

Fig. 4. Microscope images comparing the control group with the irradiated groups, as indicated in the image. The top row shows samples immediately after irradiation at 40× magnification.The bottom row shows samples 48 hours after irradiation at 10× magnification; Columns represent the different groups: control and different absorbed doses.

The 40× images, taken immediately after irradiation, reveal the initial morphological changes induced by proton beam exposure. The lower-dose group preserved the spindle-shaped morphology and adhesion pattern characteristic of the MG-63 line, with no evident structural changes compared to the control group, consistent with the absence of visible morphological alterations at this early stage. In contrast, the higher-dose group showed more retracted and rounded cells compared to the control, suggesting an acute cellular response to irradiation. These morphological changes precede the reduction in confluence observed after 48 hours, indicating that structural modifications may represent one of the earliest manifestations of the biological response to proton beam exposure.

The 10× images, taken 48 hours after irradiation, allow the effect of dose on cell confluence to be assessed. The control group shows high confluence and the characteristic spindle-shaped morphology of the MG-63 line, with cells well adhered and organized into a monolayer. This behavior confirms the stability of the culture conditions under incubation. In the lower-dose group (5.84 kGy), morphology similar to the control was observed, with no evident alterations, although confluence was slightly reduced. This pattern suggests that this dose induces damage insufficient to substantially compromise cell viability, allowing part of the cell population to survive and maintain partial confluence. In contrast, the higher-dose group (83.63 kGy) shows a more pronounced reduction in confluence progression, consistent with the increased cell death observed in this group.

The absorbed dose values obtained, on the order of kGy, are related to the extremely small mass of the irradiated cell monolayer. Since absorbed dose corresponds to energy deposited per unit mass, depositing energy in a region of extremely small mass results in numerically high dose values. This order of magnitude therefore does not, by itself, indicate excessive energy deposition in absolute terms, but rather reflects the normalization of that energy by the small cellular mass. For this reason, the dose values estimated in this experiment should not be directly compared to doses used in clinical practice, which are determined for macroscopic tissue volumes and under different irradiation conditions.

B. Biological response as a function of absorbed dose

The biological response was assessed using the MTT assay at two distinct time points after irradiation. Results obtained after six days of incubation are presented first, following the approach commonly adopted in the literature, followed by the results obtained two days after irradiation.

1) Cell viability 6 days after irradiation: The C1 control group showed a mean relative deviation in cell viability of $(26 \pm 21\%)$ compared to C0, which may be associated with the experimental conditions preceding irradiation, including transport and the period without culture medium. The relatively high standard deviation indicates considerable variability in the relative difference between C1 and C0 across the four independent experimental sessions.

Fig. 5 shows a scatter plot of MG-63 cell viability as a function of absorbed dose. Each point represents the mean of an irradiated experimental group, and the horizontal and vertical error bars correspond to the standard deviation of the absorbed dose and cell viability, respectively.

Fig. 5 shows that cell viability varied among the experimental groups across the different absorbed doses. Overall, higher doses were associated with lower viability compared to groups irradiated with lower doses. However, this reduction did not occur uniformly, and no clear dose-dependent trend was observed.

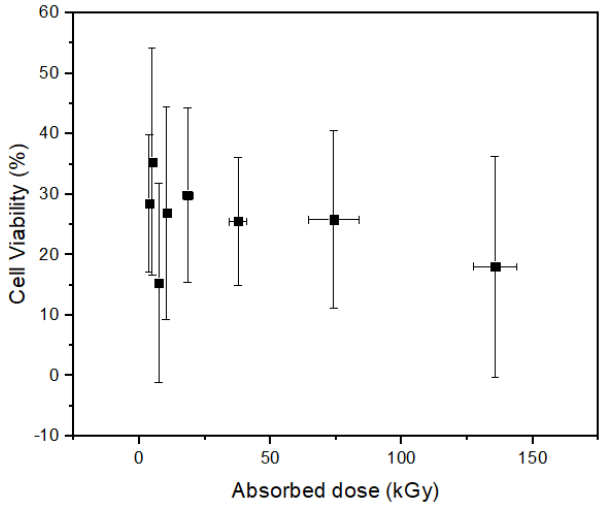

Fig. 5. MG-63 cell viability as a function of absorbed dose, determined by the MTT viability assay 6 days after irradiation. Data represent the mean viability of the experimental groups, normalized to the corresponding non-irradiated control group, set as 100% viability. Horizontal error bars indicate the standard deviation of the absorbed dose, and vertical error bars represent the standard deviation of cell viability.

The reproducibility of the absorbed dose was assessed by comparing technical duplicates irradiated during the same experimental session. Duplicates showed a mean relative difference in absorbed dose of $(7.0 \pm 0.6)\%$, representing the uncertainty associated with the irradiation procedure. This variability contributes to the dispersion observed among the experimental groups and should be taken into account when interpreting the biological results.

Spearman correlation analysis yielded the following values: irradiation 1 ($r = 0.16$; $p = 0.66$), irradiation 2 ($r = 0.22$; $p = 0.50$), irradiation 3 ($r = -0.42$; $p = 0.12$), and irradiation 4 ($r = 0.05$; $p = 0.89$). These results indicate no relationship between increasing absorbed dose and decreasing cell viability after 6 days of incubation.

The Kruskal-Wallis test indicated a significant difference among groups ($H = 31.55$; $p = 0.0001$). Dunn's test identified significant differences between the control and several groups: the intermediate-dose groups (63.38 kGy, $p = 0.0001$; 31.69 kGy, $p = 0.0006$; and 15.85 kGy, $p = 0.0177$), the higher-dose groups (253.53 kGy, $p = 0.0074$, and 126.77 kGy, $p = 0.0032$), and the lower-dose groups (12.67 kGy, $p = 0.0006$; 7.92 kGy, $p = 0.9601$; and 6.34 kGy, $p = 0.0609$). Despite these significant differences, no ordered relationship between increasing dose and decreasing viability was found. These results indicate that, with a 6-day incubation period, no direct relationship between beam exposure and biological effect could be observed.

The absence of correlation between absorbed dose and cell viability is related to the prolonged incubation period, which favors biological processes that modify the radiation response. Although irradiation initially induces cell cycle arrest, part of the surviving cells resume proliferation while another fraction enters radiation-induced senescence, remaining metabolically active despite losing proliferative capacity [19], [20]. Since the MTT assay reflects cellular metabolic activity, these processes can attenuate the relationship between absorbed dose and the biological response observed after a longer incubation period.

The 6-day interval between irradiation and the MTT assay was initially adopted based on studies described in the literature for evaluating radiobiological responses in cell cultures [21]. However, the results obtained did not show a consistent relationship between absorbed dose and cell viability. In addition, daily monitoring of the cell cultures revealed that morphological changes were visually more evident in the first days after irradiation. Accordingly, the incubation period before the viability assay was reduced to 2 days.

2) Cell viability 2 days after irradiation: The C1 control group showed a mean relative deviation in cell viability of $(22 \pm 2\%)$ compared to C0, which may be associated with transport and experimental handling. The lower standard deviation compared with the 6-day protocol indicates greater consistency in the relative difference between C1 and C0 across the four independent irradiation sessions using the 2-day incubation protocol.

Fig. 6 shows a scatter plot of MG-63 cell viability as a function of absorbed dose for a 2-day incubation period. Each point represents the mean of an irradiated experimental group, and the horizontal and vertical error bars correspond to the standard deviation of the absorbed dose and cell viability, respectively.

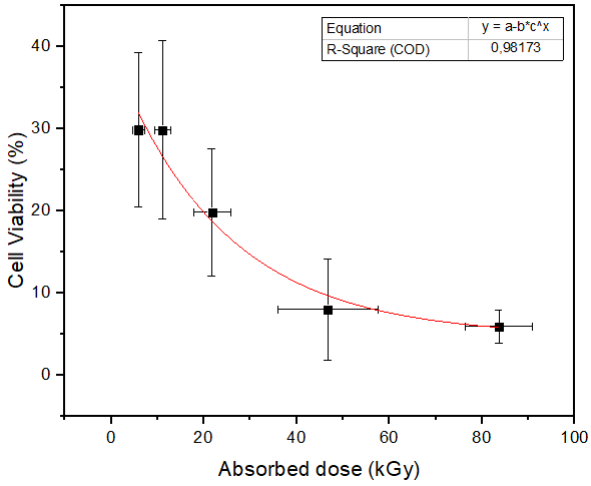

Fig. 6. MG-63 cell viability as a function of absorbed dose, determined by the MTT viability assay 2 days after irradiation. Data represent the mean viability of the experimental groups, normalized to the corresponding non-irradiated control group, set as 100% viability. Horizontal error bars indicate the standard deviation of the absorbed dose, and vertical error bars represent the standard deviation of cell viability.

Fig. 6 shows a progressive reduction in cell viability with increasing absorbed dose. Groups exposed to lower doses showed higher viability compared to those irradiated at higher doses. Unlike the 6-day results in Fig. 5, this dataset shows

a clearer, approximately exponential decline in viability as absorbed dose increases.

Spearman correlation analysis showed a strong, statistically significant negative correlation: irradiation 1 ($r = -0.87$; $p = 0.0022$), irradiation 2 ($r = -0.77$; $p = 0.0126$), irradiation 3 ($r = -0.89$; $p = 0.0011$), and irradiation 4 ($r = -0.89$; $p = 0.0011$), indicating a progressive and consistent reduction in cell viability with increasing absorbed dose.

The Kruskal-Wallis test indicated a significant difference among groups ($H = 38.66$; $p < 0.0001$). Dunn's post-test revealed a significant reduction in viability in the higher-dose groups relative to the C0 control: 126.77 kGy ($p < 0.0001$), 63.38 kGy ($p < 0.0001$), and 31.69 kGy ($p = 0.0064$). In contrast, the lower-dose groups, 15.85 kGy ($p = 0.27$) and 7.92 kGy ($p = 0.23$), showed a trend toward reduced viability without reaching statistical significance.

A clear trend of decreasing cell viability with increasing absorbed dose was observed. In addition, the mean relative difference between duplicates was $(4.2 \pm 1.8)\%$, indicating good experimental reproducibility. This behavior suggests that, in the first days after irradiation, the cellular response is dose-dependent, since the immediate effects of radiation on viability have not yet been influenced by cellular adaptation mechanisms, such as the resumption of proliferation by surviving cells. These results validate the choice of the 48-hour protocol as the most suitable for assessing the relationship between absorbed dose and biological response under the adopted experimental protocol.

In addition to the MTT assay, direct counting of viable cells was performed using trypan blue exclusion, to verify whether the trend observed by MTT was consistent with an independent viability assessment method. Fig. 7 shows the mean number of viable cells as a function of absorbed dose for each experimental group.

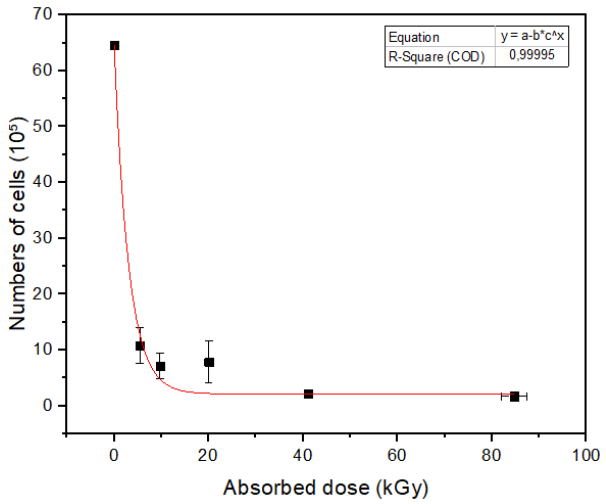

Fig. 7. Number of viable MG-63 cells as a function of absorbed dose, determined by trypan blue counting, 2 days after irradiation. Horizontal error bars indicate the standard deviation of the absorbed dose, and vertical error bars represent the standard deviation of the cell number.

Fig. 7 shows a reduction in the number of viable cells with increasing absorbed dose. This behavior is consistent with the results obtained by MTT 2 days after incubation, confirming agreement between the two methods used to assess the cellular response to irradiation.

Overall, these results show that the 2-day incubation protocol allowed for a consistent analysis of the relationship between dose and cell viability, yielding an appropriate dose-dependent biological response. These findings demonstrate that the proposed experimental protocol is capable of generating reproducible biological data under well-defined physical irradiation parameters. This established protocol therefore enables progression to the next stage of the pilot study, consisting of clonogenic assays and subsequent RBE determination.

IV. Conclusion

The results obtained support the initial validation of the experimental protocol established for irradiating cells at LAMFI-USP and its ability to produce consistent biological data for cell cultures irradiated with low-energy protons. Assessment of MG-63 cell viability showed that the 2-day MTT viability protocol is the most suitable for establishing the relationship between absorbed dose and biological response, showing a strong and consistent negative correlation across the independent experiments. In contrast, the 6-day protocol proved less suitable for this purpose, as no consistent relationship between absorbed dose and cell viability was observed under the evaluated conditions. Overall, these results show that, despite the inherent limitations of using low-energy proton beams at research accelerators, it is possible to establish an experimental platform capable of generating quantitative radiobiological data under well-characterized physical conditions. Considering the exploratory nature and the limited number of independent experiments, these findings represent an initial validation of the developed protocol. As a next step , additional independent experiments wiil be performed to strengthen its validation, and the characterization of the cellular response will be complemented by the clonogenic assay, a method that evaluates reproductive survival after radiation exposure. Accordingly, the methodology developed in this pilot study can be applied in future investigations integrating biological measurements, Monte Carlo simulations, and radiobiological models, enabling the application of mechanistic models for RBE estimation.

***Abstract*—This preliminary study aims to assess the feasibility of an experimental procedure that enables the adaptation of cell culture techniques, using different tumor cell lines, for irradiation with a low-energy proton beam originally intended for nuclear physics research. Considering the physical constraints imposed by the beam and the experimental setup, different conditions were investigated to determine whether cell cultures could be maintained under the procedure required for irradiation and to assess their influence on cell viability independently of radiation exposure. The results provide an initial methodological basis for establishing a reproducible pre-irradiation protocol, enabling subsequent radiobiological experiments with the proton beam and supporting future microdosimetric investigations**

***Index Terms*—proton therapy, cell culture, low-energy proton beam, radiobiology**

I. Introduction

Proton therapy has become clinically consolidated as a high-precision alternative to conventional radiotherapy, owing to its ability to concentrate the therapeutic dose within the target volume while sparing surrounding healthy structures [1]. Its rise is sustained by an expanding global infrastructure, which currently exceeds the milestone of 100 active clinical centers worldwide, according to data from the Particle Therapy Co-Operative Group (PTCOG) [2].

The main advantage of this technique lies in the proton dose deposition profile, characterized by the Bragg peak, a region in which protons deposit most of their energy abruptly, sparing adjacent tissues. However, from a biological standpoint, important gaps persist, particularly regarding parameters such as Linear Energy Transfer (LET), a physical quantity that indicates the average rate and spatial density at which the particle dissipates its kinetic energy along its microscopic path, and Relative Biological Effectiveness (RBE), which expresses the dose ratio required for protons and a reference radiation to produce the same level of cellular damage [3] [4].

Clinical practice adopts a constant RBE of 1.1, comparing the efficacy of proton therapy relative to the use of photons. However, current studies show that these factors vary depending on tissue type, depth, and dose, and can influence both tumor response and adverse effects [5] [6]. Thus, variations in the response of different cell lines to the treatment, such as the mechanisms of response and DNA damage induced by protons, are not considered [7] [8]. However, the actual biological variations resulting from the increase in LET, especially in the distal region of the Bragg peak, present critical gaps that demand investigation [9]. In this scenario, *in vitro* assays constitute the primary tool for generating controlled experimental data, providing the necessary basis to validate biological models and refine microdosimetric approaches [9] [10].

One of the main obstacle to expanding these assays is the limited access to suitable irradiation infrastructure. The majority of *in vitro* studies are conducted in clinical proton therapy centers or in facilities dedicated exclusively to radiobiology [11]. Under these conditions, the experimental geometry is already compatible with cell culture parameters, and the beam possesses high energy, sufficient to penetrate isolation windows, physical supports, and culture medium layers. However, access to this type of facility remains restricted and limited worldwide [2], particularly in Brazil, compromising the advancement of exploratory and pre-clinical studies.

In order to mitigate this restriction, linear accelerators designed for basic research in nuclear physics emerge as a

promising alternative to expand the capacity for investigating fundamental interactions between protons and biological systems [1]. On the other hand, because they were not designed for biomedical applications, the use of these facilities imposes methodological challenges, such as the low energy of the beam. The reduced range of these particles requires the adaptation of biological cell culture conditions to ensure that the beam reaches the cellular target [12]. However, these adaptations may themselves introduce cellular stress and affect cell viability independently of radiation exposure. Therefore, before investigating proton-induced biological effects, it is necessary to determine whether cells remain viable under the experimental conditions required for irradiation.

In this context, the proton accelerator at the Laboratory of Materials Analysis with Ion Beams (LAMFI) of the University of São Paulo (USP) represents a potential platform for this type of investigation [13]. Although the system exhibits excellent beam stability and precision, its maximum energy of approximately 5.1 MeV imposes significant constraints on the biological preparation of samples; under these conditions, conventional cell culture protocols must be adjusted to enable irradiation.

Against this backdrop, this preliminary study aimed to evaluate the feasibility of adapting adherent cell cultures for irradiation with a low-energy proton beam from an accelerator originally designed for nuclear physics research. To this end, the main experimental factors capable of influencing cell viability independently of radiation were systematically investigated, including exposure time without culture medium, cell concentration, homogeneous cell seeding, and the conditions required to allow direct beam incidence on the cells. The results are intended to provide an initial methodological basis for establishing a reproducible pre-irradiation procedure, minimizing biological effects associated with the adaptations required for subsequent proton irradiation experiments.

II. Materials and Methods

A. Experimental platform

The development of the experimental methodology was based on the characteristics of the proton beam available at USP's LAMFI. This facility features a Pelletron-tandem electrostatic accelerator, model 5SDH, originally designed for research in Nuclear Physics and Materials Science, which is capable of accelerating different ionic species with energies up to 5.1 MeV [13]. The system delivers beams with high operational stability, excellent reproducibility, and rigorous control of irradiation parameters, characteristics that make it suitable for experiments demanding high precision in dose delivery. Beam energy control is performed by a closed-loop electronic feedback system that is periodically calibrated, while fluence is monitored by a charge integrator connected to the sample holder, allowing control of the delivered charge in each irradiation. For this study, an energy of 2.6 MeV was used, corresponding to the operating range that exhibits the greatest stability of the accelerator.

LAMFI's irradiation beamline has a horizontal configuration, such that the beam impinges laterally on the experimental region. This characteristic imposes constraints on the positioning of cell cultures and constitutes one of the challenges in developing the experimental platform employed in this study. To ensure that the cell growth surface remained parallel to the beam incidence direction, the culture plates were positioned vertically in the sample holder, with their bottom perpendicular to the ground, as shown in Fig. 1. Due to these conditions, the cultures were necessarily performed using adherent cells in monolayers.

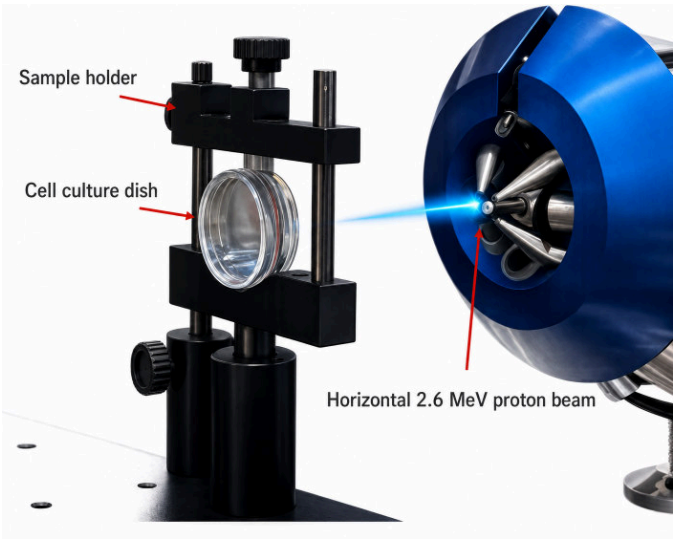

Fig. 1. Experimental geometry adopted in the LAMFI irradiation beamline. The horizontal incidence of the proton beam requires the vertical positioning of the culture plate in the sample holder during irradiation.

The limited penetration depth of low-energy protons represented a second challenge for the development of the experimental methodology. At 2.6 MeV, the range of protons in water, and consequently in culture medium,is approximately 117.6 μm, according to data from the PSTAR database (National Institute of Standards and Technology – NIST) [14].

The depth-dose curve presented in Fig. 2A demonstrates that the Bragg peak occurs very close to the surface of the irradiated medium. Under conventional culture conditions, cells remain adhered to the bottom of the culture plate, covered by a layer of culture medium with a thickness on the order of millimeters (Fig. 2B). However, at the available energy, the proton range is insufficient to penetrate the medium and reach the cells adhered to the plate, as illustrated in Fig. 2C. In order for the Bragg peak to reach the cell surface, complete removal of the culture medium was required during the irradiation period.

B. Cell culture

All biological experiments were conducted at the Cell and Tissue Culture Laboratory of the Albert Einstein Israelite College of Health Sciences (LCCT-FICSAE) under standardized culture conditions. Based on the imposed limitations, the

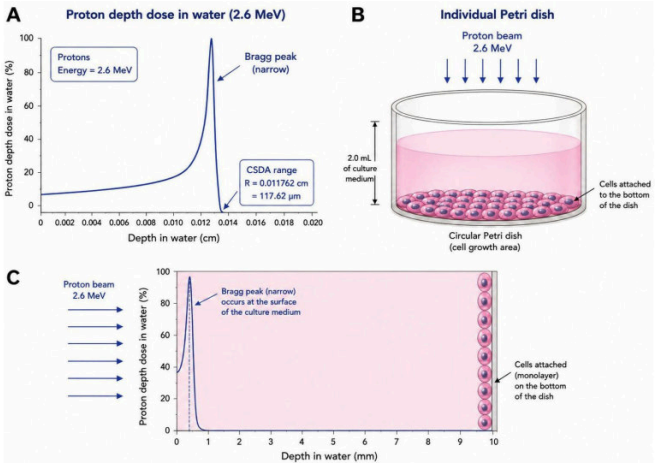

Fig. 2. Physical justification for the development of the experimental methodology. (A) Depth-dose curve (DDC) in water for 2.6 MeV protons, highlighting the Bragg peak. (B) Conventional configuration of a cell culture plate, in which cells remain adhered to the bottom of the plate and covered by a layer of medium. (C) Illustration of the culture plate in the irradiation position, with the bottom positioned vertically, parallel to the beam incidence direction. Inset: the position of the Bragg peak relative to the cells, demonstrating that the proton range is insufficient to penetrate the culture medium and reach the cells.

chosen experimental methodology was the culture of adherent monolayers, using the human osteosarcoma cell line MG-63, and subsequently validated with the MDA-MB-231 line (human breast adenocarcinoma) to evaluate its reproducibility across different cellular models.

Cells were cultured in T75 flasks, maintained at 37 °C in a humidified atmosphere containing 5% CO_2, with culture medium replenishment every two days. Upon reaching high confluence, the cultures were washed with phosphate-buffered saline (PBS), trypsinized, and prepared for the experiments according to the protocols recommended by the American Type Culture Collection [15] [16]. The specific culture conditions for each cell line are presented in Table I.

For all assays described herein, a standard protocol was established to plate cells between 20 and 24 hours before irradiation, an interval defined based on the time required for cell adhesion and the operational logistics of the laboratories. All described samples were seeded in culture petri dishes with a diameter of approximately 33 mm, using models K13-0035 and K12-006 from KASVI.

TABLE I
CULTURE CONDITIONS USED IN THIS STUDY

Cell line	Origin	Culture medium	Supplements
MG-63	Human osteosarcoma	DMEM Low Glucose	10% FBS + 1% Penicillin-Streptomycin
MDA-MB-231	Human breast adenocarcinoma	DMEM Low Glucose	10% FBS + 1% Penicillin-Streptomycin + 0.1 mM NEAA

C. Employed methodology

The physical limitations described in Section II-A required the development of a specific experimental protocol for culturing adherent cells. To this end, the maximum exposure time of cells without culture medium, the cell concentration required to obtain a uniform monolayer, and the homogeneity of cell distribution in the irradiation area were systematically evaluated. The procedures adopted for each stage are described below.

1) Evaluation of exposure time without culture medium: To investigate the feasibility of exposing cells without culture medium to a non-sterile environment and the impact of exposure time on their viability, an experimental protocol was developed and divided into three sequential stages, as illustrated in Fig. 3.

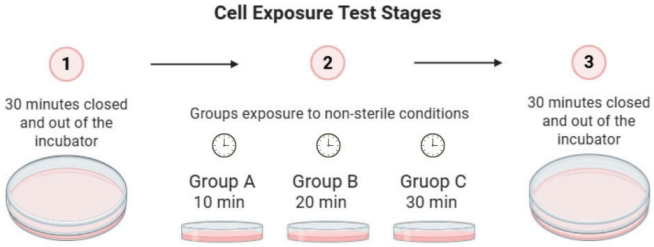

Fig. 3. Workflow and timeline of the experimental stages evaluated during the cell exposure test.Group A was exposed for 10 minutes, group B, for 20 minutes and group C, for 30 minutes.

Cells previously plated with 1.5 mL of culture medium were sealed and kept outside the incubator for 30 minutes, simulating the transport time between laboratories. Subsequently, the culture medium was completely removed, and the adhered cells remained exposed to the environment for different exposure times: Group A (10 minutes), Group B (20 minutes) and Group C (30 minutes). The selected times were longer than those typically required to perform the irradiations at LAMFI, thus representing a conservative condition for cell viability assessment.

At the end of the exposure period, 1 mL of culture medium was added to each well. The plates were sealed again and remained outside the incubator for an additional 30 minutes, reproducing the return transit to the LCCT laboratory after irradiation at LAMFI. In parallel, a control group was maintained, in which cells remained with 1.5 mL of culture medium in the incubator under optimal conditions of temperature, humidified atmosphere, and CO_2 supply.

Following 48 hours of incubation, the MTT assay was performed, which is based on the metabolic capacity of viable cells to reduce the tetrazolium salt (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) by the action of mitochondrial enzymes, forming insoluble formazan crystals [17]. The amount of formazan formed is proportional to the number

of metabolically active cells, allowing the estimation of cell viability compared to the control group and the quantification of the impact of the stress conditions imposed by the experimental protocol. Following the incubation period with the reagent, the formed crystals were solubilized in isopropyl alcohol, and the absorbance of the solutions was determined using a Kasvi K37-VIS spectrophotometer.

2) Optimization of cell concentration: To investigate the cell concentration required to achieve approximately 80% confluence, that is, 80% of the plate area occupied by cells after the incubation period preceding irradiation, concentrations ranging from 1.4×10^5 cells/well to 1.0×10^6 cells/well were evaluated.

Sample preparation consisted of trypsinizing T75 flasks, followed by cell counting. The volume of cell suspension to be added to each well (in μL) was calculated using Equation (1), utilizing the mean concentration obtained from the cell count, followed by the addition of culture medium to a final volume of 1.5 mL.

$$V_{\text{cells}} = \left(\frac{\text{Desired concentration}}{\text{Mean count}} \right) \times 1000 \qquad (1)$$

Following approximately 24 hours of incubation, the cultures were observed under an optical microscope to verify the level of confluence of the monolayer across the culture surface. Optimal confluence should represent a continuous monolayer, maximizing the utilization of the irradiated area without cellular overlap. Analysis allowed the determination of the optimal seeding concentration and the evaluation of the efficiency of the employed homogenization strategies.

3) Monolayer homogeneity evaluation: To evaluate cell homogeneity after seeding, two distinct homogenization techniques were tested. In the conventional protocol, the volume of cell suspension was dispensed directly into the well of the culture plate. Subsequently, culture medium was added to reach a final volume of 1.5 mL, without performing any prior homogenization step. After seeding, gentle manual shaking of the plate was performed with the objective of promoting cell spreading over the entire culture surface, as illustrated in Fig. 4A.

In the adapted protocol, a pre-homogenization step for the cell suspension was incorporated. In this method, the calculated volume of the cell suspension and the volume of culture medium required to reach 1.5 mL were combined in a conical tube. The mixture was homogenized by mechanical resuspension (pipetting up and down) and by mechanical vortex agitation for 2 minutes at a constant speed of 250 rpm, as shown in Fig. 4B.

III. Results and Discussion

A. Maximum exposure time without culture medium

Cell viability was initially evaluated to verify whether the temporary removal of the culture medium could be incorporated into the experimental protocol without compromising cell integrity. Fig. 5 presents the means and standard deviations

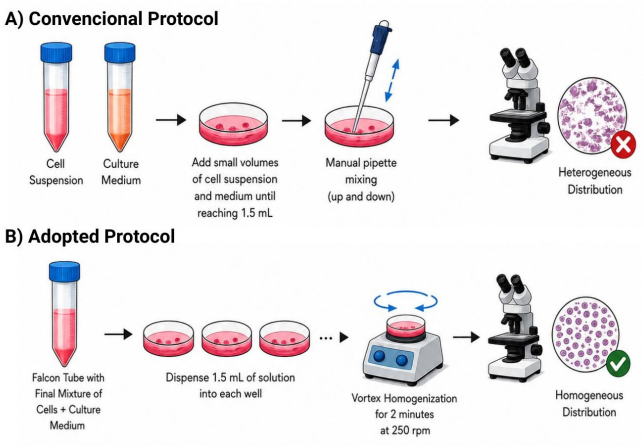

Fig. 4. Comparison between the conventional (A) and adapted (B) cell homogenization methods.

of the absorbance values for each group, which were normalized by the control group. Technical replicates (duplicates) were condensed into their respective means prior to the inter-assay analysis. The final mean and variability of each group were calculated strictly based on the number of independent experiments (N=4).

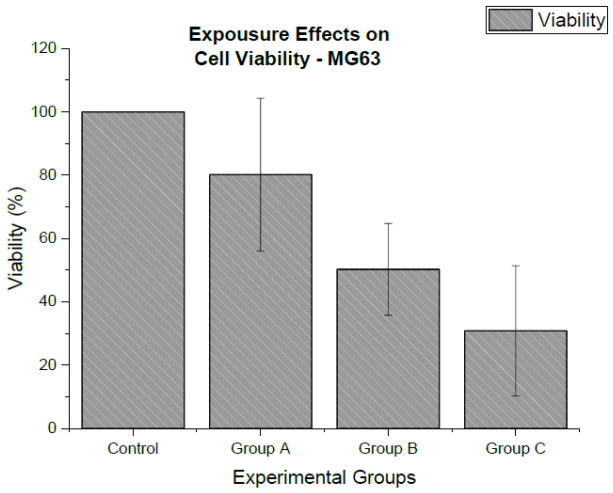

Fig. 5. MTT assay results for MG-63 cell groups A, B, and C previously defined. Data are presented as mean and standard deviation (SD) from two independent experiments, each performed in technical duplicate (n = 4 independent experiments × 2 technical replicates).

Fig. 5 presents the results of the MTT assay performed on the MG-63 cell line. As expected, cell viability decreased with increasing exposure time. For the statistical analysis, two non-parametric tests were performed. First, the Kruskal–Wallis test was used to evaluate the null hypothesis that no differences existed in cellular response among the different exposure times and the control group. Subsequently, Dunn's multiple comparisons test was applied as a post hoc analysis to assess the hypothesis that each exposure time (10, 20, and 30

minutes) would individually exhibit a statistically significant difference in response compared with the control group.

The Kruskal–Wallis test yielded a p-value of 0.0013, indicating a statistically significant difference among the groups. Graphical analysis and Dunn's post hoc test indicated that that cell viability was maintained at approximately control levels for exposure times of up to 10 minutes, with a viability of $(80.18 \pm 24.12)\%$ and the highest p-value in Dunn's multiple comparisons test ($p > 0.999$). In contrast, longer exposure times had a greater impact on cell viability. As shown in the graph, Group B (20-minute exposure) exhibited approximately a 50% reduction in viability , reaching $(50.25 \pm 14.49)\%$, whereas Group C (30-minute exposure) showed a viability of only $(30.18 \pm 20.58)\%$. When compared with the control group, Dunn's test yielded p-values of 0.0744 and 0.0083 for Groups B and C, respectively.

Given the promising results obtained with the MG-63 cell line, the same experimental protocol was replicated using MDA-MB-231 cells, as shown in Fig. 6.

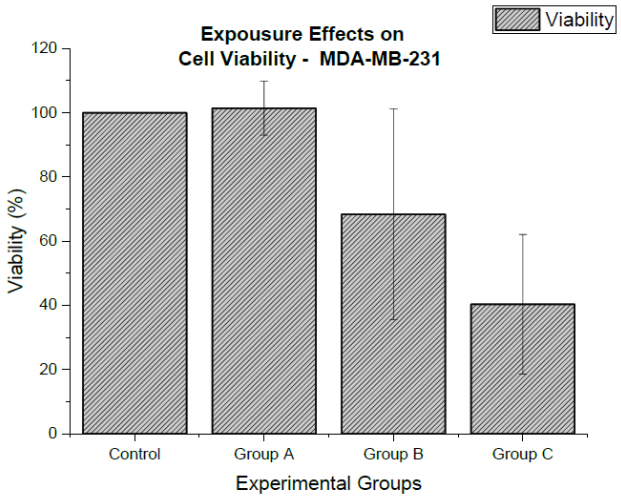

Fig. 6. MTT assay results for Groups A, B, and C of the MDA-MB-231 cell line. Data are presented as mean and standard deviation (SD) from two independent experiments, each performed in technical duplicate (n = 4 independent experiments × 2 technical replicates).

Fig. 6 presents the results obtained for the MDA-MB-231 cell line. The Kruskal–Wallis test indicated a statistically significant differences among the groups ($p = 0.0014$). To further investigate these findings, Dunn's multiple comparisons test was also performed. Group A showed the greatest similarity to the control group, with a cell viability of $(101.40 \pm 8.38)\%$ and a p-value greater than 0.9999 in Dunn's test. Graphical analysis again revealed a decline in cell viability for Groups B and C, reaching $(68.34 \pm 32.86)\%$ and $(40.32 \pm 21.74)\%$, respectively. However, the post hoc analysis yielded p-values of 0.3485 for Group B and 0.0407 for Group C, indicating that neither group differed significantly from the control.

Statistical analysis showed no significant difference between Group A and the control group for either cell line in Dunn's post hoc test ($p > 0.9999$ for both the MG-63 and MDA-MB-231 cell lines). These findings suggests that exposure for up to 10 minutes under the evaluated experimental conditions did not significantly affect cell viability. To provide an additional margin for subsequent irradiation experiments, a safety factor of 2 (Fs = 2) was applied to this exposure time, establishing 5 minutes as the maximum exposure time adopted during proton irradiation.

B. Cell seeding concentration

The different cell concentrations evaluated for the MG-63 cell line resulted in distinct patterns of culture surface coverage. Following a preliminary screening, lower cell concentrations were found to produce areas with incomplete cellular coverage, whereas higher concentrations promoted cell overlap.

Fig. 7 presents representative microscopic images of cultures seeded at concentrations of 8.0×10^5, 9.0×10^5, and 1.0×10^6 cells/well after 24 hours of incubation. The images were acquired using the Cell AutoCount tool of the EVOS M5000 microscope (Thermo Fisher Scientific) at 4× magnification.

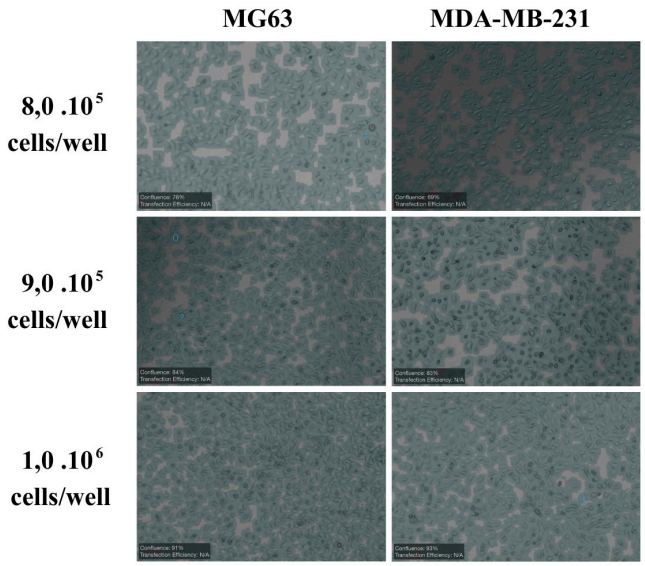

Fig. 7. Relationship between cell seeding concentration and culture surface coverage for the different cell lines, by the AutoCout confluence result. Representative images were acquired 24 hours after cell seeding.

In Fig. 7, the first column displays the different cell seeding concentrations for the MG-63 cell line, while the second column presents the corresponding concentrations for the MDA-MB-231. For both cell lines, the concentration of 8.0×10^5 cells/well did not achieve the target confluence, (MG63=78%, MDA-MB-231=69%) as evidenced by the presence of large cell-free areas. In contrast, the concentration of 1.0×10^6 cells/well exceeded the desired confluence (MG63=91%, MDA-MB-231=93%). This effect was particularly evident in the MG-63, where cell overlap and limited intercellular space indicated excessive cell density.

Finally, a cell seeding concentration of 9.0×10^5 cells/well produced a uniform cell monolayer with minimal cell overlap while maximizing the use of the available culture surface, achieving 84% for MG63 cells and 83% for MDA-MB-231. Therefore, this concentration was considered optimal and was adopted for all subsequent experiments.

C. Cell monolayer homogeneity

Fig. 8 illustrates the difference in monolayer homogeneity between the conventional cell homogenization protocol and the optimized protocol developed in this study, 24 hours after MG-63 cells seeding.

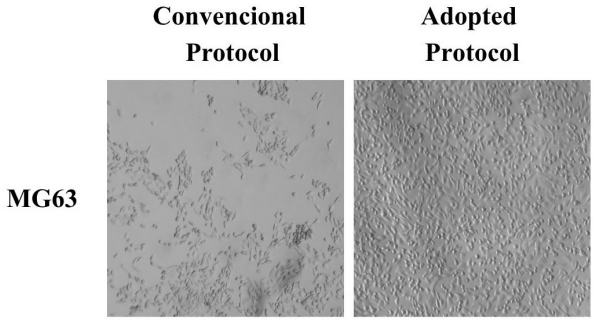

Fig. 8. Microscopic analysis of the impact of cell homogenization techniques on the distribution of MG-63 cells.

The optimized protocol produced a homogeneous cell monolayer throughout the irradiation area, minimizing local variations in cell density that could influence the biological response to the proton beam. In contrast, the conventional protocol resulted in cell accumulation at the center of the well, followed by a gradual decrease in cell density toward the periphery. These findings demonstrate that the proposed modifications were effective in achieving a homogeneous monolayer. Moreover, the optimized protocol improved the reproducibility of the experimental procedure while reducing the potential for human error.

The establishment of a homogeneous cell monolayer is a fundamental requirement for irradiation experiments using low-energy proton beams. A homogeneous monolayer ensures that all cells are located at approximately the same distance from the incident beam and receive a comparable radiation dose, thereby minimizing geometric variations in energy deposition.

D. Final experimental protocol

Table. II presents the final flowchart of the protocol developed throughout this preliminary study. The experimental design was conceived to establish compatibility between cell culture and the available proton beam by selecting adherent cell lines and using culture wells with a diameter of 33 mm. To adapt the experimental conditions to the irradiation geometry, the proposed protocol defines the cell seeding density (9.0×10^5 cells/well), the volume of culture medium (1.5 mL/well), the cell homogenization procedure during seeding, and the incubation time and conditions. Finally, the results showed that, under the evaluated conditions, the adaptations required by the physical constraints of the proton beam did not significantly compromise cell viability, supporting the feasibility of the proposed pre-irradiation procedure.

TABLE II
FINAL IRRADIATION CONDITIONS

Culture Conditions	Adherent Cells in 33 mm diameter plate
Seeding Density	9.0×10^5 cells/well
Monolayer Homogeneity	Use the adapted protocol, available in Section II-C-2
Expousure Time	5 minutes Without Culture Medium

IV. CONCLUSION

This study presented a preliminary evaluation of an experimental methodology as the first stage of adapting cell cultures to irradiation with a low-energy proton beam generated by an accelerator primarily intended for nuclear physics research.The proposed protocol was designed to address the physical limitations of the beam, including its low energy and spatial configuration.

Adherent cell culture was selected as the most suitable approach to satisfy the physical constraints imposed by the irradiation system. Based on this strategy, experimental procedures were evaluated to define an appropriate cell seeding density, obtain homogeneous cell monolayers within the region reached by the proton beam, and assess the effects of the experimental conditions required for irradiation on cell viability, resulting in an initial protocol for sample preparation.

The results indicate that cell culture, transport and exposure procedures can be performed without significantly compromising cell viability under the evaluated conditions. These findings support the feasibility of the proposed pre-irradiation procedure and provide an initial methodological basis for subsequent radiobiological studies using low-energy protons.

This preliminary assessment represents the first stage of a broader research project aimed at determining the absorbed dose at the cellular level, performing the microdosimetric characterization of the proton beam, and ultimately estimating the RBE in different tumor cell lines. As the next steps, a parametric analysis of the microscopic results presented in Sections III-B and III-C will be performed, followed by pilot irradiations using the LAMFI proton beam according to the proposed protocol. These experiments will evaluate the biological response under the established irradiation conditions and provide the experimental basis for subsequent quantitative radiobiological investigations.

Abstract*— This project aims to develop and characterize a low-cost bone-equivalent phantom for brachytherapy applications using commercially available materials. Because brachytherapy employs low-energy radioactive sources that generate steep dose gradients, accurate experimental dosimetry remains challenging, making tissue-equivalent phantoms essential for quality assurance and dosimetric validation. To address this need, several formulations based on plaster, epoxy resin with hardener, and PLA powder were produced and experimentally characterized by gravimetric analysis, density measurements, energy-dispersive X-ray spectroscopy (EDS), and scanning electron microscopy (SEM). Their dosimetric performance was further investigated through Monte Carlo simulations. The combined experimental and computational approach enabled the evaluation of the physical, morphological, elemental, and dosimetric properties of the proposed materials, demonstrating their potential for use in brachytherapy research and quality assurance.

***Index Terms*— brachytherapy, low-cost phantoms, dosimetry, bone tissue-equivalent materials, bone phantoms**

I. Introduction

Brachytherapy (BT) is a radiotherapy modality based on the use of sealed radioactive sources positioned inside or near the treatment region, allowing the administration of high radiation doses in a highly localized manner [1]. The growing precision of calculation algorithms and planning systems has increased the need for experimental validation of dose distributions, as recommended by the TG-186 report of the American Association of Physicists in Medicine (AAPM) [2].

In this context, physical phantoms play a fundamental role in dosimetric studies, quality control, and the validation of computational models. For experimental measurements to be representative, these devices must reproduce not only the geometry of the irradiated region but also the radiological properties of the biological tissues of interest [3].

This characterization becomes particularly important in brachytherapy applications using low-energy brachytherapy sources, where radiation interactions strongly depend on the elemental composition of the medium due to the predominance of the photoelectric effect. [4]. Consequently, small differences in density, effective atomic number, and energy absorption coefficients can produce significant changes in the dose distribution. This behavior is especially relevant for bone tissue, whose high concentration of calcium and phosphorus, associated with the variability between different bone types, complicates the development of equivalent materials capable of adequately reproducing its radiological properties.

Although several bone phantoms have been reported in the literature using polymeric and ceramic materials, as well as additive manufacturing techniques, many exhibit high manufacturing costs, complex fabrication processes, or limited characterization for brachytherapy applications involving low-energy sources. Consequently, there remains a need for

* These authors contributed equally to this work

alternative materials that combine low cost, ease of fabrication, and radiological equivalence to bone tissue [5].

In this context, the present study aims to develop and characterize low-cost bone phantom formulations based on plaster, high-viscosity epoxy resin, and polylactic acid (PLA) [6]. Their physical, morphological, and elemental properties were evaluated to assess their suitability for dosimetric studies involving low-energy brachytherapy sources.

II. Materials and Methods

A. Preparation of Bone Phantom Formulations

Four bone phantom formulations were developed using three commercially available materials: plaster (Fortaleza), high-viscosity epoxy resin (Real Epoxi) with its corresponding hardener, and microparticulated polylactic acid (PLA). Plaster and epoxy resin were selected because of their ability to reproduce the density and radiation attenuation properties of bone tissue, while PLA powder was incorporated into the formulations as a porosity-controlling and density-modifying agent.

The formulations were prepared by manually homogenizing the components according to the mass proportions presented in Table I.

The mass of each component was measured using an analytical balance with a resolution of 0.0001 g, maintaining a total mass of 10 g for all specimens. To facilitate the discussion of the results, the formulations were designated according to the relative proportions of their main constituents: G (plaster), R (epoxy resin), and P (PLA). Accordingly, four formulations were defined and organized into two groups, as summarized in Table I.

TABLE I
IDENTIFICATION AND COMPOSITION OF THE SAMPLES

Sample	Composition (g)			
	Plaster	Resin	Hardener	PLA
7G3R	7.000	2.000	1.000	-
4G4R1P	4.125	3.000	1.500	1.375
3G4R3P	3.000	2.670	1.330	3.000
7G2R	7.500	1.670	0.830	-

After homogenization, the samples were placed in silicone molds (Figure 1) and kept at room temperature (~20 °C) for 24 hours for curing.

Subsequently, to ensure complete curing in the internal part and the removal of residual water, the samples were subjected to drying in a muffle furnace. The thermal cycle was programmed starting from room temperature, with a controlled heating rate of 1 °C/min, until reaching the maximum temperature of 100 °C for 12 h, followed by natural cooling to room temperature. After cooling, the specimens were removed and weighed to obtain the total mass after complete drying.

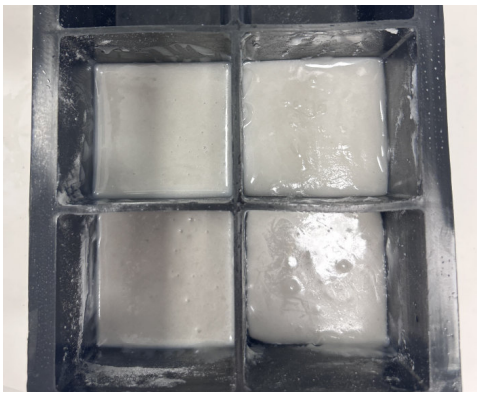

Fig. 1. Homogenized samples placed in silicone molds for room temperature curing.

B. Gravimetric Analysis

With the purpose of quantifying the mass variations resulting from the heat treatment and curing stages, gravimetric analysis was performed on both the isolated commercial plaster and the manufactured complete formulations.

Initially, the finished structures were weighed before and after thermal curing, which allowed for the determination of the total mass post-drying. Measurements were performed using an analytical balance, with an error of 0.0001 g, and the percentage mass loss was calculated using (1):

$$\Delta m\% = \frac{mi - mf}{mi} \times 100 \quad (1)$$

Subsequently, the plaster matrix was subjected to the same muffle furnace thermal cycle used in the production of the samples in order to determine the degree of hydration of the raw material.

Additionally, after the complete curing and drying process, the experimental density of each manufactured formulation was determined based on Archimedes' principle using the liquid displacement method. The volume of each sample was obtained by measuring the displaced volume of water, and the experimental density was subsequently calculated by its final mass by the measured volume.

C. Scanning Electron Microscopy (SEM)

The microstructural characterization of the specimens was performed using a Scanning Electron Microscopy (SEM) system, model JSM-6010LA (JEOL), applying a voltage of 8 kV, which allowed the evaluation of the surface morphology and homogeneity of the matrix formed by the constituent materials.

The samples were initially cut using a diamond disc cutter into dimensions of 10 mm x 10 mm, obtaining a uniform surface suitable for microscopic analysis.

D. Energy-Dispersive X-ray Spectroscopy (EDS)

Chemical composition analyses were performed using energy-dispersive X-ray spectroscopy (EDS) coupled with SEM. Three complementary approaches were conducted:

EDS spectra for the quantitative determination of the elemental composition of each sample, in order to distinguish the main elements present in each formulation; elemental mapping (EDS Mapping) to examine the spatial distribution of chemical elements along the sample surface; and morphological-compositional correlation, correlating the SEM images with the results obtained by EDS, aiming to relate morphological characteristics to the observed elemental distributions. The quantitative data obtained were compared with X-ray attenuation data from NIST XCOM.

E. Computational Simulation Using the Monte Carlo Method

To complement the experimental characterization and evaluate the dosimetric behavior of the developed formulations, Monte Carlo simulations were performed using the MCNP6.3 (Monte Carlo N-Particle Transport) code [7].

The computational model consisted of a homogeneous cylindrical phantom with a diameter of 4.0 cm, representing the material under investigation (Figure 2). The elemental composition of each formulation was defined according to the experimental results obtained by energy-dispersive X-ray spectroscopy (EDS). Furthermore, the experimental density values obtained via Archimedes' principle for each sample were directly applied to the material definitions in the MCNP6.3 input. For comparison, commercially available bone-equivalent materials from CIRS (Tissue Simulation & Phantom Technology) were also simulated using their reference compositions, together with the ICRP cortical bone standard, whose elemental composition was validated against the NIST database.

A Ho-166 brachytherapy source was modeled as a circular disk with a diameter of 0.2 cm positioned in direct contact with the phantom surface, as illustrated in Figure 2. The radionuclide was represented by the emission of β^- particles with a mean energy of 0.665 MeV, while secondary photon transport was also taken into account. Coupled electron-photon transport was performed using the physics models available in MCNP6.3, employing the MCPLIB08 library for photon transport and the e303 library for electrons.

The energy deposited within the phantom was calculated using the *F8 tally, which estimates the energy deposited in each cell as a result of particle interactions. To obtain the percentage depth dose (PDD) distribution, the phantom was subdivided into fifteen adjacent parallelepiped regions aligned with the direction of radiation incidence, as shown in Figure 2. The energy deposited in each region was then used to determine the depth-dependent energy deposition profile.

To quantitatively evaluate this dosimetric equivalence, the mean relative error between the doses deposited in the developed phantoms and the reference materials was calculated for the depth range of 0.01 - 0.11 cm.

All simulations were carried out on a workstation equipped with an Intel® Core™ i9-14900KF processor. The number of primary particle histories was adjusted to ensure statistical uncertainties below 1.0% (Type A, $\pm 1\sigma$) for all calculated quantities.

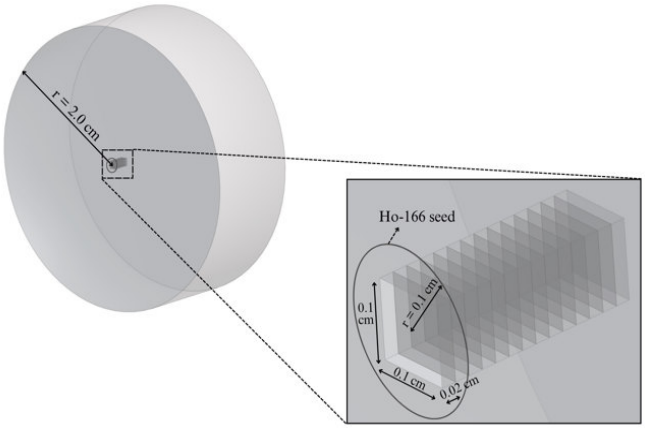

Fig. 2. Three-dimensional representation developed for simulations. On the left, the isometric view of the cylinder with a 2.0 cm radius. On the right, magnified detail of the central region, demonstrating the Ho-166 source and the arrangement of the 14 blocks used.

III. Results and Discussion

A. Gravimetric Analysis and Mass Loss Evaluation of the Specimens

The gravimetric characterization of the sample formulations was performed after the thermal cycle in the muffle furnace. The mass quantification of the specimens pre- and post-treatment provided the measurement of the percentage magnitude of the loss (m%), primarily associated with dehydration and the release of remaining volatile fractions from the ceramic matrix. The obtained experimental data are summarized in Table II.

TABLE II
GRAVIMETRIC PROPERTIES OF THE FORMULATIONS PRE- AND POST-MUFFLE FURNACE HEAT TREATMENT

Sample	Initial mass (g)	Final mass (g)	Mass loss (%)
7G3R	10.00	7.21	27.93
4G4R1P	10.00	5.47	45.33
3G4R3P	10.00	6.10	38.96
7G2R	10.00	8.27	17.27

The gravimetric profiles obtained in Table II demonstrate a general decrease in the mass of all specimens, corroborating the occurrence of kinetic processes of water elimination and volatile byproducts during the proposed thermal cycle. It is also observed that the magnitude of the percentage mass loss was directly influenced by the composition of each system, especially in systems with a higher fraction of resin, indicating that volatile organic compounds evaporated during the drying processes. The final experimental densities determined for the developed formulations are summarized in Table III.

TABLE III
EXPERIMENTAL DENSITY OF THE MANUFACTURED FORMULATIONS

Sample	Experimental Density (g/cm³)
7G3R	2.04
4G4R1P	1.93
3G4R3P	1.94
7G2R	2.67

B. Morphological Characterization via SEM

Figure 3 presents the scanning electron micrographs of the four developed formulations, allowing the influence of composition on the surface morphology and internal organization of the composite matrix to be qualitatively evaluated. In general, formulations composed only of plaster and epoxy resin exhibited a more compact and homogeneous microstructure, whereas the incorporation of PLA produced noticeable changes in surface morphology and in the spatial distribution of the constituent phases.

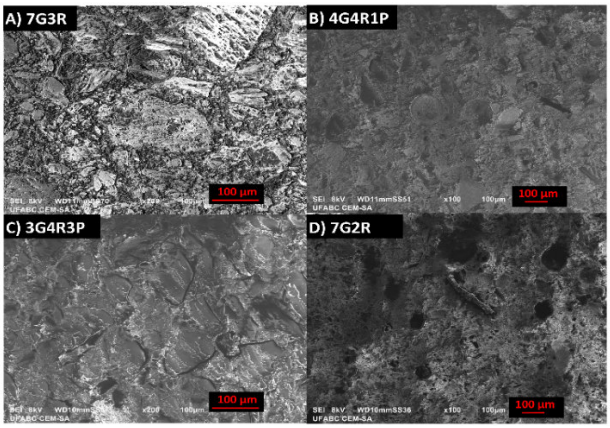

Fig. 3. SEM showing the surface morphology and topography of fragments from the developed formulations. The interpenetration domains of the organic and ceramic phases are observed, as well as the presence of porosities with predominantly spheroidal geometry and micrometric voids. Images obtained under an acceleration voltage of 8 kV.

The 7G3R (Figure 3A) and 7G2R (Figure 3D) formulations, composed exclusively of plaster, epoxy resin, and hardener, exhibited a continuous and relatively homogeneous matrix. In sample 7G2R, predominantly spheroidal pores were observed, heterogeneously distributed across the analyzed surface. These voids are likely associated with air entrapment during the mixing process and/or the evaporation of residual moisture during the curing and drying stages, phenomena commonly observed in plaster-based composite materials.

In contrast, the formulations containing PLA (4G4R1P and 3G4R3P) exhibited rougher surfaces and a higher density of micrometric interfaces than the formulations without this additive. These observations indicate that the incorporation of PLA modifies the organization of the composite matrix during curing, promoting a more heterogeneous distribution of the ceramic and polymeric phases and reducing the matrix continuity observed in the other formulations.

The microstructural differences revealed by SEM demonstrate that the formulation composition directly influences the internal architecture of the developed composites. Considering their intended application as bone-equivalent phantoms for brachytherapy, these morphological characteristics may affect relevant physical properties, such as density, elemental homogeneity, and radiation transport. Therefore, the SEM observations complement the gravimetric, compositional, and Monte Carlo analyses, providing a more comprehensive understanding of how each formulation influences the overall performance of the proposed phantom materials.

C. Chemical Characterization by EDS

The elemental composition of the developed formulations was investigated by energy-dispersive X-ray spectroscopy (EDS) in order to evaluate the influence of each constituent material on the chemical composition of the composites. Figure 4 presents the EDS spectra obtained for the four formulations, while Figure 5 shows the corresponding elemental distribution maps.

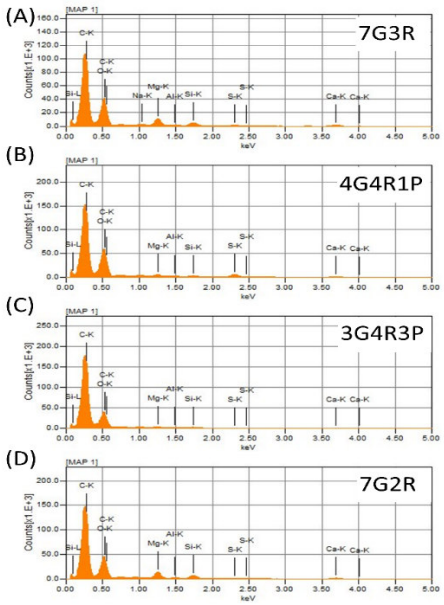

Fig. 4. EDS spectra of the developed formulations, showing the peaks of each identified element in the different compositions.

The generated spectra confirmed the presence of characteristic energy peaks of the elements theoretically expected from the raw materials used, including carbon (C), oxygen (O), magnesium (Mg), aluminum (Al), silicon (Si), sulfur (S), and calcium (Ca). Carbon and oxygen concentrations were identified in the lower energy regions of the spectrum, likely corresponding to the organic fraction of the polymeric base derived from the resin and PLA, as well as emission lines related to sulfur and calcium, presumably derived from the mineral phases of the commercial plaster. Furthermore, a residual presence of magnesium, aluminum, and silicon was detected

distributed across the samples, likely due to impurities in the raw materials, which are for industrial or commercial use and therefore do not possess high purity. The average elemental composition obtained for each of the formulations, along with their respective standard deviations, is presented in Table IV.

TABLE IV
MEAN AND STANDARD DEVIATION OF ELEMENTS PER SAMPLE

Sample	C	O	Mg	Al	Si	S	Ca
7G3R	57.4 ± 6.8	29.0 ± 1.0	4.1 ± 1.3	0.5 ± 0.1	2.7 ± 1.0	1.5 ± 1.3	4.8 ± 3.5
4G4R1P	63.1 ± 3.2	28.6 ± 1.3	2.2 ± 0.5	0.4 ± 0.2	1.5 ± 0.4	1.8 ± 1.6	2.5 ± 1.7
3G4R3P	70.1 ± 0.4	26.3 ± 0.1	1.4 ± 0.2	0.5 ± 0.1	1.1 ± 0.2	0.2 ± 0.02	0.4 ± 0.3
7G2R	57.0 ± 1.9	29.2 ± 1.9	4.8 ± 0.5	0.6 ± 0.1	2.9 ± 0.6	0.8 ± 0.3	4.8 ± 1.1

It can be observed that the chemical composition varied among the formulations due to the distinct proportions of each matrix used. Regarding the identification of the expected elements, the analyses pointed out that the calcium concentration was lower than the predicted nominal content, due to the volume of the ceramic matrix added during the manufacturing process. The elemental mapping by EDS presented in Figure 5 allows for the evaluation of the spatial distribution of the elements in the samples.

The EDS spectra confirmed the presence of the major elements expected from the raw materials used in the formulations, namely carbon (C), oxygen (O), magnesium (Mg), aluminum (Al), silicon (Si), sulfur (S), and calcium (Ca). Carbon and oxygen were predominantly associated with the polymeric constituents (epoxy resin and PLA), whereas calcium and sulfur originated mainly from the calcium sulfate phase of the commercial plaster. Minor amounts of magnesium, aluminum, and silicon were also detected in all formulations, most likely due to naturally occurring impurities present in the commercial-grade raw materials.

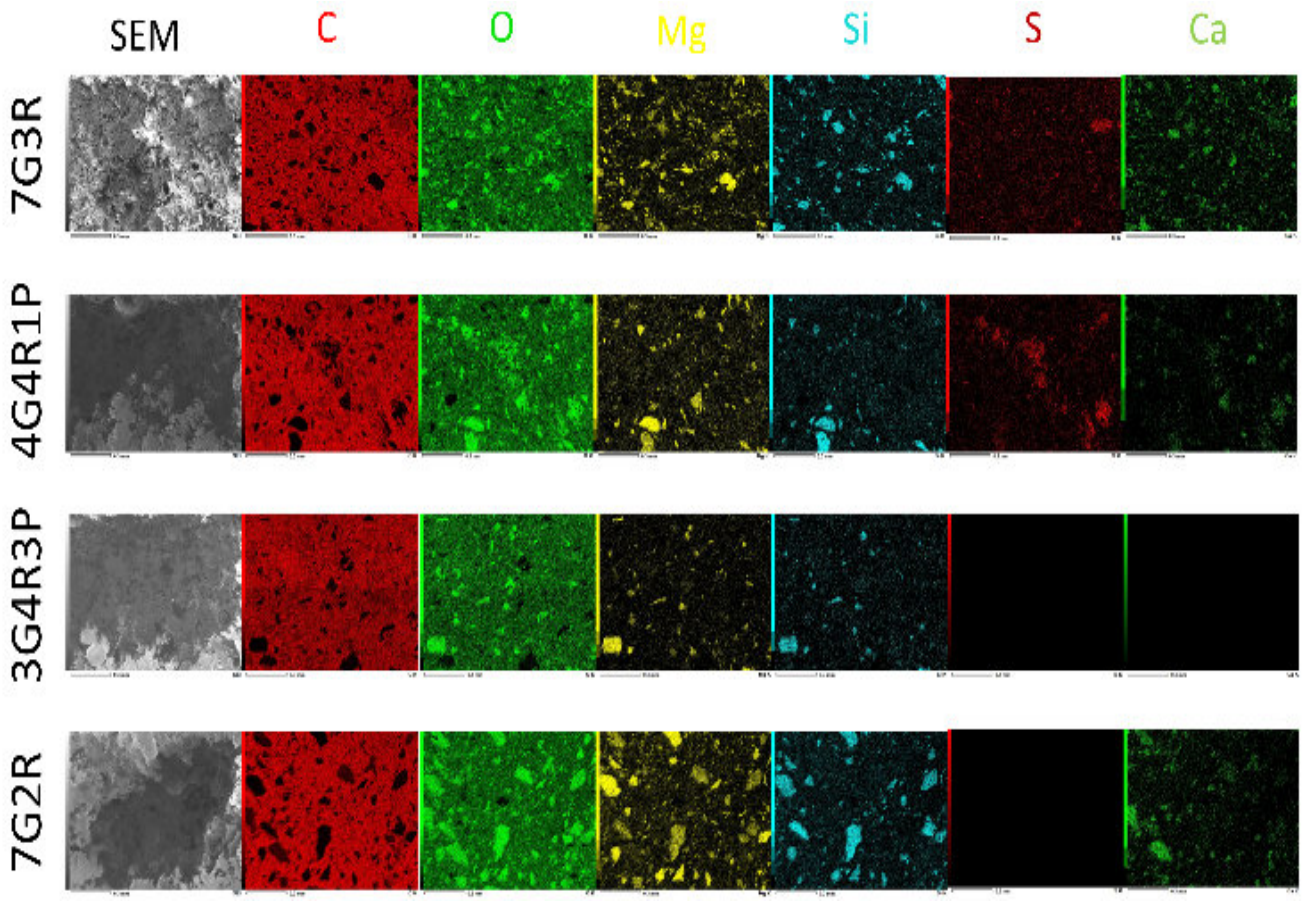

Fig. 5. Elemental mapping by energy-dispersive X-ray spectroscopy (EDS Mapping) of the surfaces of the developed formulations: (a) 7G3R, (b) 4G4R1P, (c) 3G4R3P, and (d) 7G2R." The spatial distributions correspond to the characteristic signals of Carbon (C), Oxygen (O), Magnesium (Mg), Silicon (Si), Sulfur (S), and Calcium (Ca).

The average elemental composition of each formulation, together with the corresponding standard deviations, is presented in Table IV. As expected, differences in elemental composition were observed among the formulations, reflecting the varying proportions of plaster, epoxy resin, and PLA used during fabrication. In particular, formulations containing higher amounts of polymeric material exhibited an increase in the relative carbon content, accompanied by a decrease in the relative concentrations of calcium and sulfur, consistent with the lower proportion of plaster incorporated into these composites.

The elemental maps shown in Figure 5 revealed a homogeneous spatial distribution of the detected elements throughout the analyzed regions, with no evidence of significant elemental segregation or phase clustering. This result indicates that the manufacturing process promoted adequate dispersion of the constituent materials within the composite matrix, contributing to the chemical homogeneity of the developed formulations.

From the perspective of phantom development for brachytherapy applications, this chemical homogeneity is particularly important because the interaction of ionizing radiation with matter depends directly on its elemental composition. Therefore, the EDS results demonstrate that the proposed manufacturing process produced chemically homogeneous phantoms, supporting the reliability of the subsequent Monte Carlo simulations and dosimetric evaluations.

D. Monte Carlo Dosimetric Analysis

With the purpose of evaluating the dosimetric equivalence of the manufactured formulations in relation to the reference bone materials, the ratio between the dose deposited in each proposed sample and the dose obtained in the simulated reference materials was calculated. The dose ratio was determined point-by-point along the radiation penetration depth.

Comparisons were made between each of the four manufactured specimens and the bone materials from the literature adopted as references, with densities ranging between 1.161 and 2.150 g/cm3. The analysis was conducted limited to depths between 0.01 and 0.11 cm, since, for greater depths, the dose deposited by the Ho-166 source decreases significantly due to the limited range of the particles, resulting in values with a negligible contribution to the evaluation.

Figure 6 presents the Percentage Depth Dose (PDD) curves for the different simulated materials, comparing the proposed formulations to the bone materials cited in the literature with distinct densities. The reference materials from CIRS are represented in green, while the developed formulations are shown in their respective colors.

Overall, the developed formulations exhibited depth-dose profiles comparable to those of the reference bone-equivalent materials. Nevertheless, differences in the position of the dose fall-off were observed, reflecting the influence of material density and composition on beta-particle transport and energy deposition within the materials. Among the investigated formulations, 7G2R exhibited the earliest dose fall-off, indicating a more rapid reduction in the deposited dose with depth. In contrast, formulations 7G3R, 4G4R1P, and 3G4R3P displayed very similar depth-dose profiles throughout the region of interest, suggesting comparable radiological behavior despite differences in their compositions.

To further quantify these differences, Figures 7A–D present the ratio between the dose deposited in each developed formulation and that calculated for the CIRS reference materials with known densities. A dose ratio close to unity indicates greater agreement between the developed formulation and the corresponding reference material.

At shallow depths (up to approximately 0.05 cm), all formulations exhibited dose ratios close to unity, indicating excellent agreement with the reference bone materials in this region. As the depth increased, larger deviations from unity became evident, particularly for the higher-density reference materials. This behavior is associated with the limited penetration range of the beta particles emitted by the Ho-166 source. As the deposited dose decreases rapidly with depth, small differences in material composition and density become more pronounced in the deeper regions.

Within the analyzed depth range (0.01-0.11 cm), formulation 7G3R (Figure 7A) exhibited the closest agreement with the reference materials of densities 1.820 and 1.850 g/cm³, presenting mean relative errors of 4.56% and 5.07%, respectively. Additionally, formulations 4G4R1P (Figure 7B) and 3G4R3P (Figure 7C) demonstrated the highest dosimetric equivalence with the 1.660 g/cm³ reference material, yielding mean relative errors of 3.68% and 4.20%, respectively. The similar behavior observed for these formulations suggests that the incorporation of PLA did not significantly modify the depth-dose characteristics of the developed composites, preserving their radiological behavior relative to the reference materials.

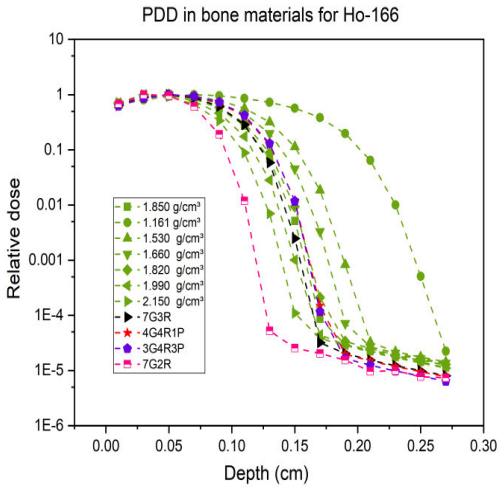

Fig. 6. Percentage Depth Dose (PDD) curves obtained via Monte Carlo simulation for the developed samples and reference materials with different densities.

In contrast, formulation 7G2R (Figure 7D) exhibited a progressive decrease in the dose ratio beyond approximately 0.06 cm for most of the reference materials, indicating a greater deviation from the expected dose deposition profiles. This behavior suggests that differences in its composition and density resulted in a distinct beta-particle transport pattern compared with the reference materials.These observations indicate that formulations 7G3R, 4G4R1P, and 3G4R3P more closely reproduce the radiological behavior of the selected CIRS bone-equivalent reference materials over the investigated depth range, whereas formulation 7G2R exhibits a distinct dose deposition profile.

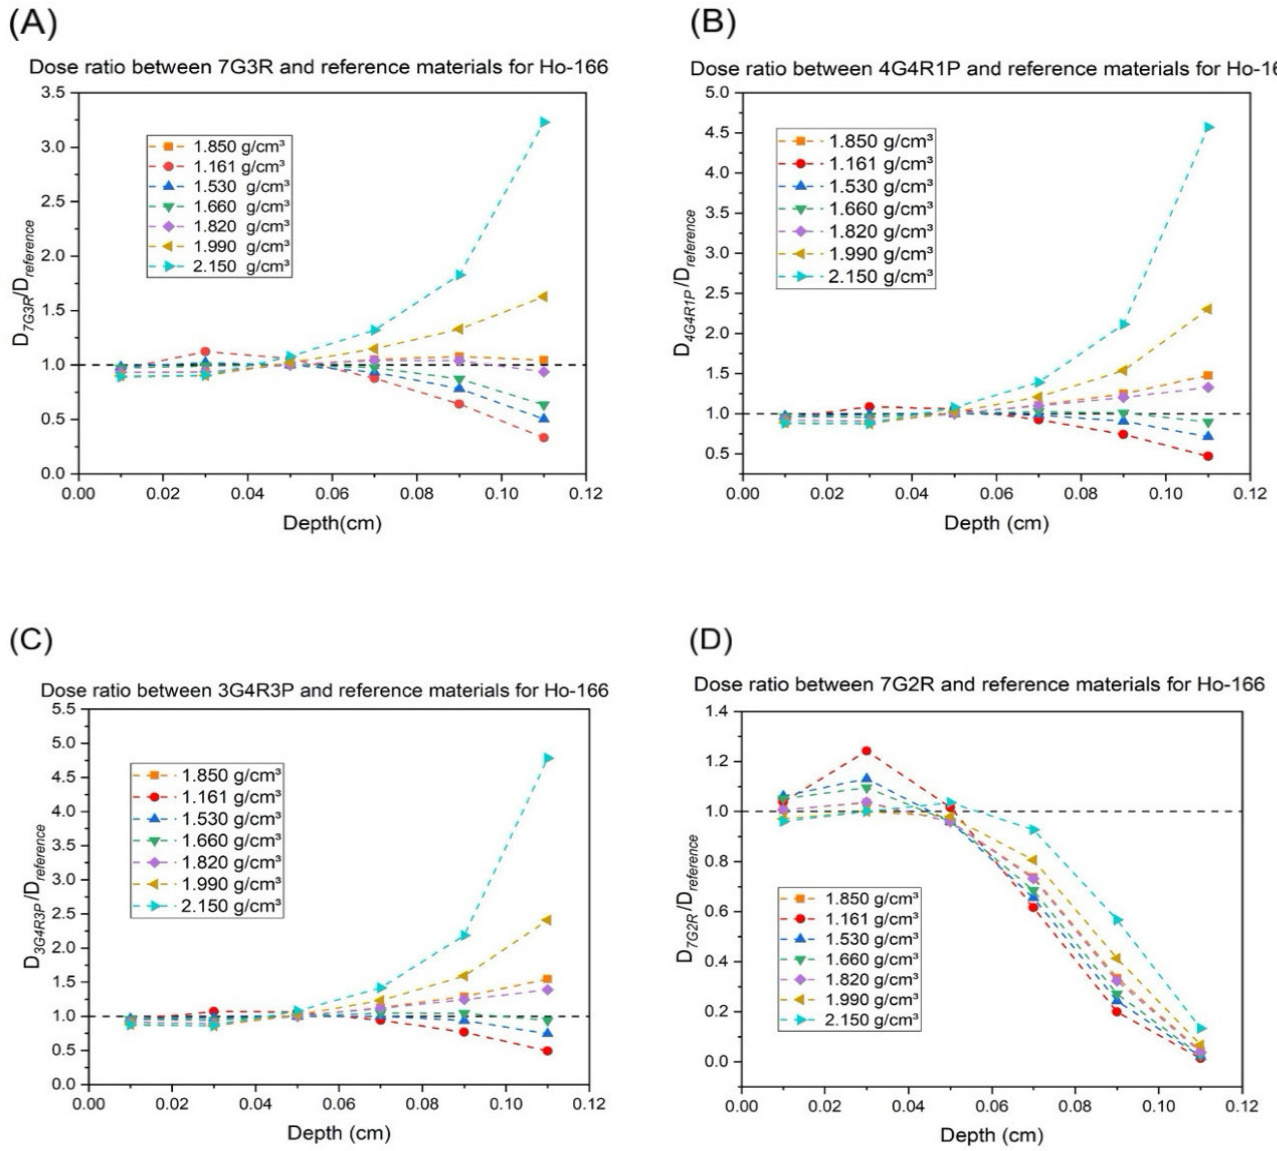

Fig. 7. Dose ratio between the developed formulations and reference materials with different densities for Ho-166.

IV. Conclusion

The present study demonstrated the feasibility of developing low-cost bone-equivalent phantoms using commercially available materials for potential applications in brachytherapy with Ho-166. Gravimetric, morphological, and chemical characterizations showed that variations in the proportions of plaster, epoxy resin, and PLA directly influence the physical properties of the developed formulations. In addition, Monte Carlo simulations demonstrated that these compositional differences affect the radiological behavior and depth-dose distributions of the materials under the simulated irradiation conditions.

The criteria for determining the best overall equivalence were based on two main factors: dosimetric agreement, defined by a dose ratio as close to unity as possible, and the lowest mean relative error compared to the reference materials across the evaluated depth range (0.01 - 0.11 cm). Among the investigated formulations, 7G3R, 4G4R1P, and 3G4R3P exhibited the highest agreement with the dose deposition profiles of the selected CIRS bone-equivalent reference materials. In particular, formulation 7G3R most closely reproduced the radiological behavior of the reference materials with densities of 1.820 and 1.850 g/cm³, while formulations 4G4R1P and 3G4R3P exhibited optimal equivalence with the 1.660 g/cm³ reference. The comparable behavior of the PLA-containing samples suggests that the presence of this polymer does not substantially impact the depth-dose properties of the composites. However, the 7G2R formulation displayed a faster dose fall-off as depth increased, pointing to a reduced radiological agreement under the simulated conditions.

Overall, the proposed methodology provides a simple and low-cost approach for developing bone-equivalent materials, demonstrating primarily manufacturing feasibility and preliminary computational equivalence to reference bone densities for

Ho-166 irradiation. To confirm their potential for dosimetry, calibration, and validation procedures, subsequent stages of this research will incorporate experimental measurements using physical detectors to validate the simulated data. Furthermore, future studies will evaluate the manufacturing reproducibility of their experimental densities across multiple batches and expand the clinical applicability by utilizing other brachytherapy sources.

***Abstract*—Magnetic resonance imaging (MRI) presents geometric distortions intrinsic to the acquisition process, arising mainly from the nonlinearity of spatial gradients and the inhomogeneity of the static magnetic field. These distortions have a relevant clinical impact on applications that require millimetric spatial precision, such as stereotactic radiosurgery and imageguided radiotherapy. Phantoms constitute the main methodological tool for quantifying these deviations, but their reliability depends directly on the manufacturing process employed and on the dimensional validation method adopted. This study aimed to develop and dimensionally compare two phantom models, one geared toward the evaluation of repetitive linear features of decreasing dimensions (Model 1, Comb) and another toward the evaluation of concentric hollow geometries at multiple scales (Model 2, Squares). Both were manufactured by additive manufacturing (3D printing by PETG filament extrusion, polyethylene terephthalate glycol) and by subtractive manufacturing (laser cutting in PMMA, polymethyl methacrylate). Dimensional validation was carried out by two independent methods, a physical caliper and image processing via ImageJ, with overall accuracy quantified by the Relative Root Mean Square Error (rRMSE) and statistically tested by Student's t-test ($\alpha = 0.05$), preceded by a normality check via Shapiro-Wilk. The findings indicate that PETG is preferable for reproducing fine linear patterns, while PMMA remains a viable alternative for robust volumetric structures, reinforcing the physical caliper as the gold standard for high-sensitivity dimensional validation.**

***Index Terms*—magnetic resonance imaging, geometric distortion, dimensional validation, low-cost phantoms**

I. Introduction

Magnetic resonance imaging (MRI) is one of the leading medical imaging modalities for clinical diagnosis. Unlike other techniques, it does not use ionizing radiation, but rather intense magnetic fields associated with radiofrequency (RF) pulses to obtain high-resolution cross-sectional images of soft tissues and anatomical structures, both in 2D and 3D [1].

Physically, the method exploits the magnetic moment of hydrogen protons: under a static field (B_0), the spins align and precess at the Larmor frequency; an RF pulse at the same frequency shifts the magnetization to the transverse plane, and the return to equilibrium (T1 and T2 relaxation) generates the signal detected by the receiver coils. Since different tissues have distinct relaxation times, due to the interactions of protons with the adjacent chemical components of each tissue, the resulting contrast enables anatomical differentiation [2].

Since the first clinical equipment, in the early 1980s, it was observed that the dimensions reconstructed in the image did not correspond exactly to the real dimensions of the objects, with larger divergences at positions farther from the center of the magnet. This is the result of a systematic error caused mainly by the nonlinearity of the gradient field and the inhomogeneity of B_0, added to patient-dependent effects such as magnetic susceptibility and water-fat chemical shift [3]. The problem was already known to the scientific community in the 1980s [4], but its clinical impact only became critical when MRI began to support millimetric-precision applications, such as stereotactic radiosurgery and image-guided radiotherapy, in which distortions of a few millimeters compromise the coverage of the therapeutic target [3]. The choice of acquisition sequence also introduces relevant variability; in patients with hepatocellular carcinoma, the tumor measurement error by MRI varied between 0.75 and 0.87 cm depending on the sequence, resulting

in incorrect classifications according to the criteria in up to 14.3% of cases [5].

Phantoms emerged as the main tool for quantifying these errors, as they possess precisely known geometry and composition. The first three-dimensional phantoms made it possible to map geometric distortion across different equipment manufacturers [3], although more recent studies show that the deviations measured in phantoms do not always reflect the behavior observed in real anatomical images [6]. Today, commercial phantoms are used together with normative criteria, such as the AAPM's TG-284, to validate MRI simulation protocols in radiosurgery [7]. Their use, moreover, is not limited to MRI, as they are employed in practically all medical imaging modalities (CT, PET, SPECT, ultrasound) as a control standard for validation and quality control, with the advantage of dispensing with patient exposure to risk and allowing longitudinal comparisons between equipment [8].

The manufacturing of phantoms has been driven by advanced manufacturing. FDM (fused deposition modeling) 3D printing in polyethylene terephthalate glycol (PETG) offers low cost and good dimensional stability, and relaxometry characterization studies (T1, T2, T2*) have already evaluated this and other thermoplastics as possible tissue mimics in MRI [9, 10]. Polymethyl methacrylate (PMMA), historically machined by laser cutting or CNC (computer numerical control), remains widely used in commercial and research phantoms owing to its good magnetic susceptibility compatibility with water and mineral oils, even though laser cutting introduces thermal edge effects that can compromise dimensional fidelity in small features [11].

The objective of this work was to determine whether additive or subtractive manufacturing techniques present greater dimensional accuracy in MRI calibration. This study reports the methodological development of two phantoms for MRI calibration, comparing additive manufacturing (FDM 3D printing in PETG) and subtractive manufacturing (laser cutting in PMMA), focusing on the comparison between these manufacturing methods and on the proposal of a dimensional validation methodology capable of indicating which process produces the geometrically more faithful phantom.

II. Materials and Methods

A. Geometric Design of the Phantoms

To comprehensively map geometric errors across different size scales and volumetric configurations, two computational phantom models were developed using the Onshape CAD platform:

1) Model 1 (Comb): Designed to evaluate spatial resolution and the fidelity of linear features and repetitive slits, with decreasing nominal dimensions (total length of 64.0 mm).

2) Model 2 (Square Sequence): Composed of a matrix of concentric square cavities, designed to evaluate the stability of robust, orthogonal hollow geometries, in dimensions ranging from 2.0 mm to 20.0 mm.

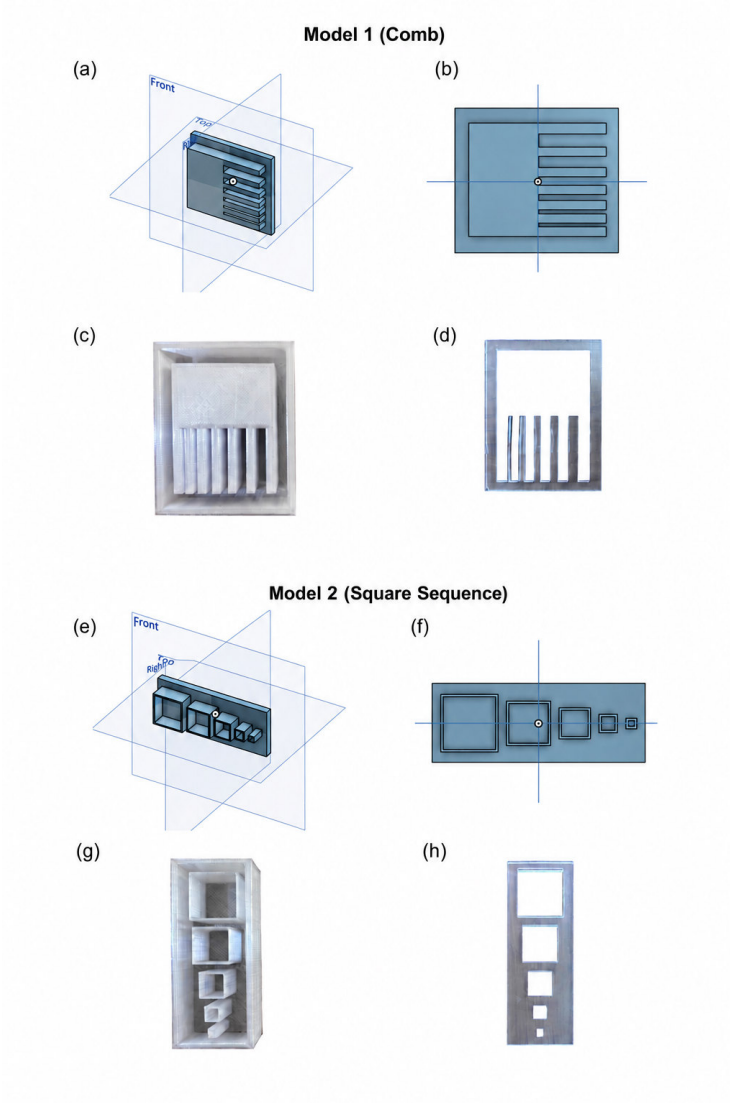

Fig. 1. Physical phantom models developed for metrological evaluation. For Model 1 (Comb), panels (a) and (b) show the three-dimensional and front-view CAD models created in Onshape, respectively; panel (c) shows the FDM 3D-printed PETG phantom, and panel (d) the corresponding laser-cut PMMA phantom. For Model 2 (Square Sequence), panels (e) and (f) present the three-dimensional and front-view CAD models created in Onshape, respectively; panel (g) shows the FDM 3D-printed PETG phantom, and panel (h) the corresponding laser-cut PMMA phantom.

B. Advanced Manufacturing Parameters

1) Subtractive Manufacturing (Laser Cutting – PMMA): The PMMA sheets were processed on an industrial router laser cutter, Prime Cutmaker – CMK 6040 model. The cutting profile was configured with a constant linear speed of 5 mm/s, minimum CO_2 tube power set at 75%, and maximum power at 80%. For the structural bonding of the multilayer acrylic plates, the commercial structural adhesive S-330 Sinteglas was used, prepared strictly at a volumetric ratio of 25 mL of resin base to 1 mL of liquid chemical catalyst.

2) Additive Manufacturing (3D Printing – PETG): The phantoms were fabricated on a high-precision kinematic 3D

printer, Core A1V2 model. Commercial GTmax PETG filament was used, with a nominal diameter of 1.75 mm. The selected extruder nozzle had an outlet diameter of 0.4 mm. The kinematic and thermal slicing parameters were extrusion temperature set at 235 °C, heated bed temperature at 85 °C, standardized layer height of 0.2 mm, print speed of 80 mm/s, and internal infill density set at 50% using a crosshatch rectilinear geometric pattern [10].

C. Metrological Validation Protocol

To mitigate measurement bias and establish statistical error control, dimensional validation was conducted in a binary fashion. For the physical approach, the six measurements collected for each nominal dimension were performed by six different evaluators, all following the same standardized measurement instructions, in order to account for inter-operator variability in the manual measurement process:

1) Physical Approach (Physical Gold Standard): Direct measurements performed with a calibrated caliper (0.01 mm resolution). Six independent measurements were collected (n = 6) for each nominal dimension of interest, minimizing parallax error and operator grip-pressure variability. Despite being adopted as the gold standard, the caliper technique presents inherent limitations that must be acknowledged: its resolution (0.01 mm) approaches the same order of magnitude as the deviations measured in the smallest features (1.5–2.0 mm), its accuracy remains partially dependent on operator technique even under standardized instructions, and it is restricted to two-point linear contact measurements, being unable to capture curved or internal geometric profiles as comprehensively as image-based methods.

2) Digital Approach (Image Processing): Standardized high-resolution photographic capture, under controlled, orthogonal lighting. The images were imported into the open-source software ImageJ [12]. The protocol consisted of spatial calibration in pixels per millimeter (px/mm), based on a known scale, followed by semi-automated digital measurement of the geometric profiles.

D. Statistical Analysis and Error Protocol

The overall cumulative precision of each technical scenario was quantified through the Relative Root Mean Square Error (rRMSE), calculated according to Equation 1:

$$rRMSE = \sqrt{\frac{1}{M} \times \sum \left(\frac{(X_{exp} - X_{theor})}{X_{theor}} \right)^2} \times 100 \qquad (1)$$

Where X_exp represents the mean of the experimental measurements, X_theor represents the theoretical nominal dimension extracted from the CAD, and M indicates the total number of distinct features evaluated in the geometric model. The normality of the residuals and relative errors was tested using the Shapiro-Wilk criterion. Once the parametric distribution was confirmed, Student's t-test for independent samples was applied to assess the existence of statistically significant differences between the materials (PETG vs. PMMA) and between the metrological methods (Caliper vs. ImageJ), adopting a significance level of $\alpha = 0.05$.

III. Results

A. Direct Comparative Analysis

After a series of measurements using both protocols mentioned above, we obtained the difference between the expected values (exact CAD model values) and the mean of the experimentally obtained values. These data are compiled in Tables I and II.

TABLE I

Difference Between Expected and Experimental Value in Model 1 (Comb)

Feature (Model 1)	Measurements relative to CAD (mm)				
	CAD (mm)	*PETG (Cal.)*	*PETG (ImgJ)*	*PMMA (Cal.)*	*PMMA (ImgJ)*
Total Length	64.00	-0.38	+2.51	+0.23	+0.22
Structural Height	51.00	-0.34	+1.88	+0.39	+0.49

Note: Cal. = Physical measurement via Caliper; ImgJ = Digital measurement via ImageJ software.

B. Overall rRMSE Analysis

In addition to the direct comparison of expected values (exact CAD model values), we compared the rRMSE, aiming to compensate for these differences as a function of the size of each part of the phantoms. The consolidated values of the overall rRMSE (%) indicator, broken down by phantom model, polymeric material, and applied metrological methodology, are summarized in Table III.

TABLE III
OVERALL RRMSE VALUES (%) CALCULATED FOR THE DIFFERENT PHANTOMS, MATERIALS, AND MEASUREMENT METHODS

Validation method	Models rRMSE Values (%)			
	Comb PETG	*Comb PMMA*	*Squares PETG*	*Squares PMMA*
Caliper	1.29	8.11	3.81	6.51
ImageJ	3.22	5.96	2.35	8.49

Note: rRMSE represents the square root of the overall cumulative relative mean square error for each geometric set. Lower values indicate greater overall accuracy and manufacturing process replication stability.

C. Overall Statistical Analysis and Dimensional Fidelity

The Shapiro-Wilk test confirmed the adequacy of a parametric model for all groups of relative percentage errors calculated ($p > 0.05$), statistically validating the subsequent use of Student's t-test. The internal variability and the behavior of the deviations with respect to the measurement methods (Caliper and ImageJ) and to the phantom geometries are illustrated in the Box Plot of Figure 2.

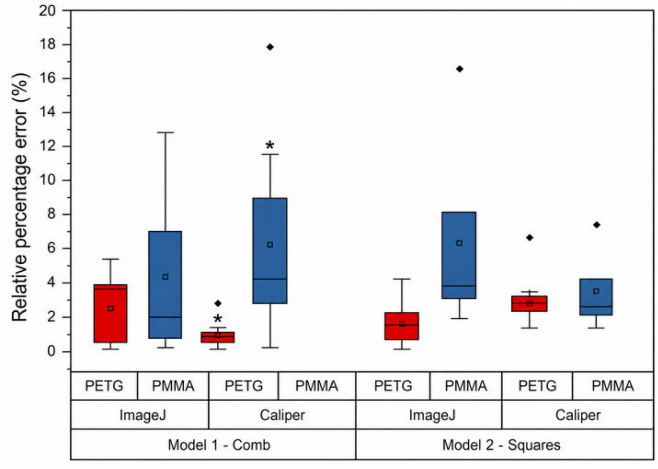

Fig. 2. Distribution of the relative percentage error (%) for PETG and PMMA phantoms in Model 1 (Comb) and Model 2 (Square Sequence), evaluated using digital image analysis (ImageJ) and caliper measurements. Boxplots show the median (horizontal line), interquartile range (box), whiskers extending to 1.5 × IQR, and outliers (individual points). The asterisk (*) denotes a statistically significant difference between PETG and PMMA for the corresponding comparison ($p < 0.05$).

For Model 1 (Comb), the physical approach via caliper demonstrated a robust and statistically significant disparity between materials ($p = 0.0176$), confirming the superiority of the geometric stability of the injected PETG filament over the thermal ablation cutting of PMMA. However, when the same model was evaluated by the digital method in ImageJ, no statistical significance was detected in the difference between materials ($p = 0.285$). For Model 2 (Square Sequence), an absence of statistical significance was observed on both metrological fronts: caliper-based validation resulted in $p = 0.829$, while ImageJ analysis returned $p = 0.120$.

D. Scale Effect on Geometric Deviations

The influence of the nominal feature size on the relative percentage error was further evaluated to investigate the scale effect on geometric deviations. The corresponding results are presented in Figure 3 and 4.

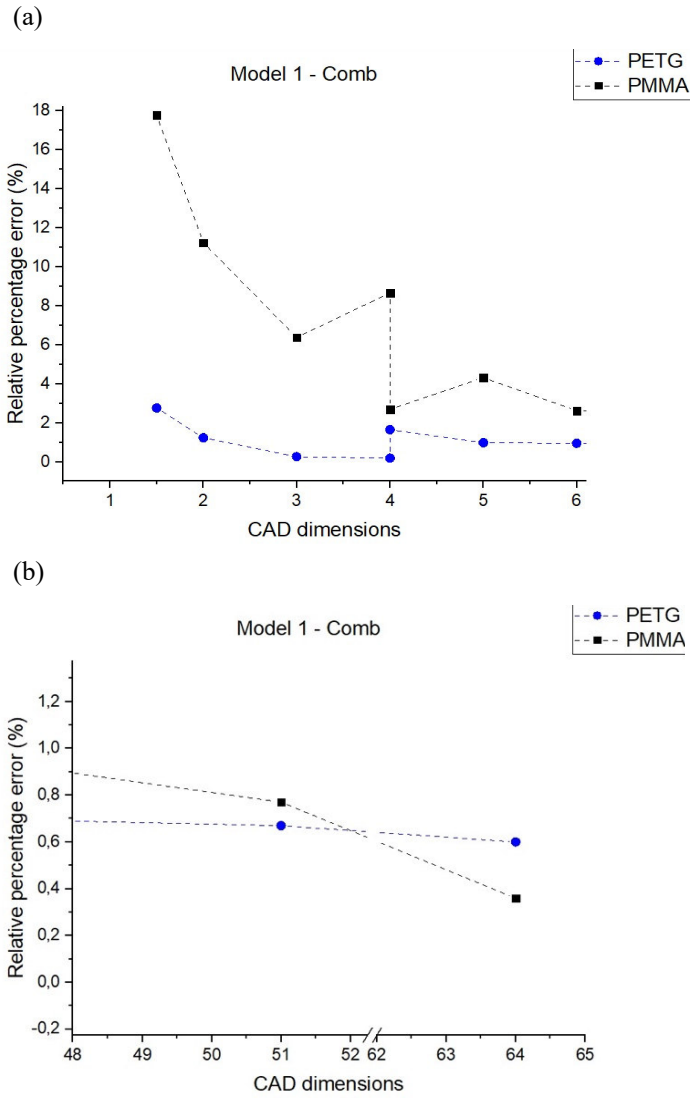

Fig. 3. Distribution curve of relative percentage errors measured using a caliper as a function of the nominal dimensional scale of the designed features: (a) Model 1 (Comb) at low nominal dimensions; (b) Model 1 (Comb) at higher nominal dimensions.

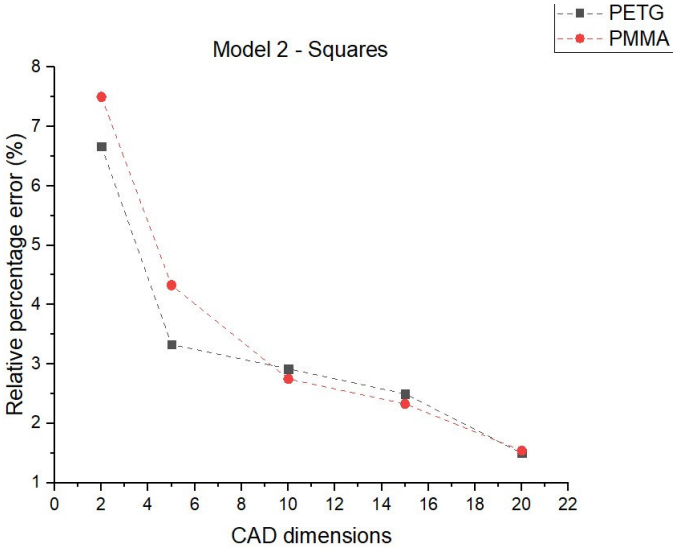

Fig. 4. Distribution curve of relative percentage errors measured using a caliper as a function of the nominal dimensional scale of Model 2 (Squares) across all its dimensions.

The distribution of errors as a function of the designed characteristic size reveals a behavior inversely proportional to the nominal size of the feature. The maximum error percentage peak was invariably concentrated at the smallest nominal dimensions of both phantoms (1.5 mm slits in Model 1, and 2.0 mm edges in Model 2). As the nominal dimension increases toward larger features (such as the 20.0 mm structural base or the 64.0 mm total length), a stable exponential attenuation of the relative percentage error is observed, converging to levels below 1% for both advanced manufacturing methods. Additionally, a singular structural discontinuity behavior (a "step" effect) is noted, located exactly at the 4.0 mm geometric transition point of Model 1.

IV. Discussion

In this work, MRI phantoms were produced using additive (FDM 3D printing) and subtractive (laser cutting) manufacturing techniques. Subsequently, geometric fidelity to the CAD model was analyzed by means of dimensional measurements with a caliper or optical microscopy images in the ImageJ software. The statistical divergence observed between the physical (caliper) and digital (ImageJ) validation approaches in Model 1 (Comb) evidences a metrological attenuation phenomenon arising from digital optical signal processing. Two-dimensional image capture adds an intrinsic background uncertainty, characterized by pixel noise at shadowed edges and by the operator's manual positioning of measurement vectors in ImageJ. This background noise acted as an attenuation filter: it artificially raised the baseline error of the precise PETG parts (from 1.29% to 3.22%), while at the same time masking the severe micro-cutting deviations and physical burrs suffered by the acrylic (PMMA) at the laser cut edges (reducing the apparent error from 8.11% to 5.96%). This finding methodologically validates the use of the physical caliper as the most appropriate technique for high-sensitivity dimensional validation in this study.

On the other hand, the absence of statistical significance observed in Model 2 (Squares), both in the physical scenario ($p = 0.829$) and the digital one ($p = 0.120$), demonstrates that robust, symmetrical hollow volumetric geometries with regular spacing are substantially less susceptible to severe manufacturing distortions. In these structural scenarios, the intrinsic deficiencies of each advanced manufacturing method end up equalizing in terms of overall mean error.

The superior geometric fidelity observed in the fine linear features of Model 1 (Comb) manufactured in PETG by 3D printing (rRMSE of 1.29%), compared with the pronounced deviation of PMMA processed by laser cutting (rRMSE of 8.11%), corroborates the trend described in the literature in other biomedical fields, such as dentistry, in which products can be produced by additive or subtractive methods in digital restorations. Similar dimensional accuracy studies have shown that additive manufacturing methods, such as stereolithography (SLA), frequently achieve significantly smaller mean deviations (RMS) and greater fidelity in complex and marginal details than subtractive processes based on mechanical wear (wax and zirconia milling) or laser ablation. Whereas conventional subtractive manufacturing tends to introduce errors arising from thermal edge effects in micro-cutting features or imperfections induced by drill and mill passes (milling bur passes), additive techniques provide a more controlled and faithful reproduction of geometric profiles relative to the original computational model (CAD). On the other hand, the statistical equivalence observed in the robust, concentric geometries of Model 2 (Squares) between both manufacturing methods in the present study ($p > 0.05$) is also consistent with previous findings in the fixed prosthesis literature, in which no statistically significant differences were detected in the marginal adaptation of robust structural copings when comparing laser sintering (additive) and CAD-CAM milling (subtractive) methods [13, 14, 15].

The macro-mapping of the scale effect validates a classic tendency of the physics of digital polymer manufacturing. The sharp error peak at the smallest nominal dimensions (1.5 mm and 2.0 mm) occurs because small absolute variations in fusion or cutting (on the order of hundredths of a millimeter, inherent to the mechanical resolution of the equipment) carry a greater mathematical weight when normalized by very small design dimensions. When these same absolute variations are diluted across large nominal dimensions (such as 20.0 mm or 64.0 mm), the relative error becomes negligible. This experimentally proves that the final geometric deviation of a phantom does not depend solely and exclusively on the absolute nominal size of the feature but is strongly determined by the volumetric configuration and the geometric neighborhood of the part in the cutting or deposition plane.

V. Conclusion

This work presented the development and dimensional validation of two phantom models intended for future

applications in MRI calibration, manufactured by additive (PETG) and subtractive (PMMA) manufacturing, further comparing two measurement methods, physical caliper and image processing via ImageJ. The results indicate that, for fine linear features, PETG offers greater geometric stability than PMMA, a statistically robust disparity when measured by the physical gold standard but attenuated to the point of not being detected by digital analysis. This reinforces that the chosen validation method is not neutral and can, depending on the processing involved, either artificially raise the error of precise parts or mask real manufacturing defects. For hollow, symmetrical volumetric geometries, on the other hand, dimensional fidelity proved statistically equivalent between the two materials, evidencing that the intrinsic deficiencies of each advanced manufacturing process tend to equalize when the part does not depend on isolated fine features. In both models, the relative error was concentrated at the smallest nominal dimensions and converged to values below 1% for the largest-scale features, indicating that the final geometric deviation of a phantom is determined not only by the absolute size of the feature but also by the volumetric configuration and the geometric neighborhood of the part in the cutting or deposition plane.

Therefore, these results provide an initial answer to the central research question regarding which manufacturing process produces the more dimensionally accurate phantom. Under the conditions evaluated in this study, PETG showed better dimensional accuracy for reproducing fine linear patterns, while PMMA remains a viable alternative for robust volumetric structures, with the additional advantage of lower equipment cost in scenarios where 3D printing is not available. It should be emphasized, however, that this study represents an initial, methodological-development stage, restricted to the dimensional characterization of the phantoms themselves. Thus, the present results allow comparison of the dimensional accuracy of the manufacturing processes but do not yet demonstrate the performance of the phantoms for calibration or geometric distortion control in an actual MRI environment.

Three complementary steps are therefore proposed to consolidate these findings. First, functional validation must be performed by scanning the phantoms on real MRI equipment, across different field-of-view positions and acquisition sequences, in order to quantify the geometric distortion intrinsic to the imaging system itself and not only to the manufacturing process. Second, future work should include multiple phantoms of each model manufactured independently, enabling a proper assessment of inter-piece manufacturing repeatability, in addition to inter-operator agreement in the caliper-based measurements. Third, the inherent resolution limits of the caliper as a gold standard, discussed in Section II.C, should be addressed through complementary high-resolution metrological techniques (e.g. optical or laser scanning) for the smallest evaluated features. Together, these steps would extend the present dimensional validation methodology toward a fully validated protocol for quality control in MRI-guided procedures requiring submillimetric spatial precision.

Abstract*—Wearables are devices such as smartwatches that integrate sensors for the continuous monitoring of physiological parameters, playing an auxiliary role in the early detection of health deviations. This study explores the effectiveness of photoplethysmography (PPG) sensors in heart rate measurement under the IEC 63203-402-3 standard, while addressing the gap in technical information provided by manufacturers. Through a proof of concept of optical mimicry using infrared LEDs, the response of different smartwatch models to simulated signals was tested. The results demonstrate the feasibility of the proposed approach for the evaluated conventional devices and indicate its potential for identifying hardware anomalies, while also revealing limitations in devices incorporating skin-impedance detection. It is concluded that the lack of technical transparency from manufacturers poses significant challenges to the standardization and calibration of these wearables.

***Index Terms*—wearables, smartwatch, photoplethysmography, heart rate, calibration**

I. INTRODUCTION

A smartwatch can measure heart rate through transmission or reflection photoplethysmography (PPG). Transmission PPG is used in finger pulse oximeters to measure oxygen saturation and heart rate through direct transmission of red and infrared light that passes through the finger and reaches a photodiode on the other side. This method, commonly used in hospitals and health centers, has the advantage of reading both beats per minute (BPM) and oxygen saturation.

Reflection PPG uses a photodiode on the same side as the LED transmitter, reaching the blood flow on the surface of the skin and reflecting the signal back to the sensor. This configuration enables PPG measurements in compact wearable devices and is therefore commonly used in smartwatches, including during physical activity. However, reflected PPG signals can be significantly affected by motion artifacts. Heartbeat measurements are obtained through the variation in light attenuation in the receiver. This variation stems from the dilation and contraction of blood vessels, which occur in synchronization with each heartbeat.

Green light is strongly modulated by pulsatile changes in blood volume because hemoglobin exhibits significant absorption in this spectral region. Its relatively shallow penetration depth in biological tissue makes it particularly sensitive to superficial vascular changes, which are relevant for heart-rate monitoring at the wrist (Fig. 1).

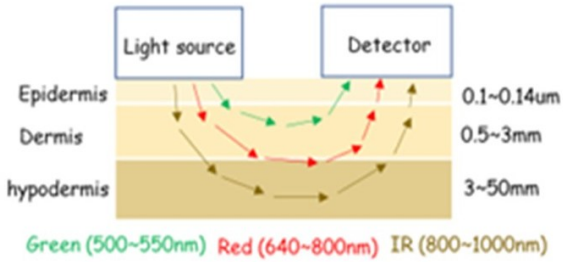

Fig. 1. Light transmission based on wavelength, Source: [3]

Several physiological and environmental factors can affect wrist-worn PPG measurements, including motion artifacts, ambient light, peripheral perfusion, sensor-to-skin contact, and skin optical properties. The influence of skin tone on heart-rate measurement accuracy remains under investigation, with the literature reporting device- and condition-dependent effects [2]. These factors are particularly relevant in clinical or real-world validation, but they are outside the primary scope of the present study. Here, the objective is to isolate the wearable's response to a controlled optical stimulus, reducing physiological and environmental variability in order to investigate the feasibility of a traceable calibration approach at the sensor level.

The IEC 63203-402-3 standard [1] seeks to standardize how heart rate tests are performed and reported, requiring manufacturers to provide detailed information about the

hardware and software of the devices. The goal is for results to be fairly and reproducibly comparable. However, in practice, a lack of transparency is observed, where manufacturers omit critical parameters to maintain confidentiality and prevent competitors from attempting to reproduce their technologies. This information gap reinforces the importance of exploring tests and methodologies to validate the integrity and reliability of wearables.

Recent studies have proposed optical PPG simulators capable of providing repeatable optical signals with controlled characteristics for the characterization and comparison of photoplethysmographic devices [9]. Such approaches demonstrate the potential of artificial optical stimulation for controlled PPG testing. The method investigated in this work follows a related principle but focuses on the practical calibration of commercial wearables and on the synchronization and optical-coupling requirements necessary for the simulated pulsation to be interpreted by proprietary smartwatch algorithms. A direct performance comparison with commercial PPG simulators was not performed in this proof-of-concept study and remains an important topic for future investigation.

Charlton et al. [10] demonstrated that wrist PPG signal quality depends not only on sensor characteristics but also on physiological and measurement conditions, including posture, sensor position, peripheral perfusion, skin optical properties, and LED intensity. These factors reinforce the importance of distinguishing controlled sensor-level calibration from clinical or real-world validation.

II. METHODOLOGY

The experiment was designed as a proof of concept (PoC) to verify the feasibility of mimicking biometric signals via determining the technical requirements necessary for an artificial signal to be processed by the smartwatch's algorithms as a real physiological pulsation.

The light source was controlled via a function generator calibrated in an accredited laboratory, configured with the following parameters:

- Signal Amplitude: 5 V peak-to-peak.
- Sine wave form.
- Pulsation Frequency: 0.5 Hz to 3.5 Hz as established by the IEC 63203-402-3 standard.
- The function generator was externally referenced to a Rubidium Frequency Standard (Model 910R), whose measurement uncertainty is 4×10^{-11}.

Although green light is commonly used in wrist-worn PPG because of its interaction with superficial blood-volume changes, silicon photodiodes are also responsive to near-infrared radiation. The purpose of using an IR LED in the present setup was not to reproduce the wavelength normally employed by the smartwatch, but to determine whether a controlled periodic optical stimulus within the photodetector's spectral response could be interpreted by the device as a pulsatile signal. The successful detection of the IR stimulus by Watches A1–A3 supports this feasibility for the evaluated devices; however, it does not imply wavelength-independent photodiode responsivity.

The test was performed on 5 watches, 3 of the same model (A1, A2, and A3), and two of different models (B and C). Watches A1, A2, and A3 are less advanced and do not have protective barriers against external interference. Watch B, although it has no protection systems, is more modern than the previous ones. Watch C, on the other hand, has an impedance sensor that detects if the watch is in contact with human skin. For this watch, it would be required to develop an electronic system that could simulate human skin impedance and, additionally, improve the synchronization of the pulses generated by the standard function generator with the pulses of the watch under calibration.

A. Experimental Procedure and Repeatability

The five devices were selected based on their availability for this proof-of-concept study, as the acquisition of a broader range of commercial smartwatch models was beyond the resources available for the experimental campaign. Although this convenience-based selection limits the representativeness of the sample, the availability of three units of the same model (A1, A2, and A3) allowed the consistency of the proposed method to be evaluated across nominally equivalent devices. Watches B and C, in turn, provided additional observations involving different hardware characteristics, including the skin-contact detection mechanism identified in Watch C.

At each calibration point, four repeated measurements (n = 4) were performed under the same experimental conditions. Each measurement was recorded only after the smartwatch displayed a stable heart-rate indication. When no stable indication could be obtained at a given calibration point, the result was classified as unavailable (N/A). The mean of the valid measurements was used as the reported heart-rate value, while their dispersion was used to estimate the Type A uncertainty. The optical coupling arrangement was maintained unchanged throughout the repetitions, with the infrared LED positioned inside the optical coupler at a fixed position relative to the smartwatch sensor,

minimizing variations in alignment and exposure to ambient light.

The combined uncertainty was estimated by evaluating Type A and Type B uncertainties. The Type A uncertainty (uA), representing statistical variations, was calculated using (1), where s is the standard deviation and n = 4 is the number of repeated measurements performed at each calibration point.

$$u_A = \frac{s}{\sqrt{n}} \quad (1)$$

The Type B uncertainty (u_B) associated with the smartwatch resolution was estimated assuming a rectangular distribution, as defined in (2). The error of the Rubidium Frequency Standard (Model 910R) is 4×10^{-11}, which is negligible.

$$u_B = \frac{Resolution}{\sqrt{3}} = 0.29\ \text{BPM} \quad (2)$$

Finally, both components were aggregated to determine the combined uncertainty (uc) using the root sum of squares method, as shown in (3).

$$u_C = \sqrt{(uA^2 + uB^2)} \quad (3)$$

Fig. 2. Test setup for 60BPM. Source: Elaborated by the authors.

The experimental setup followed the principle of the PPG simulator test proposed in the IEC 63203-402-3 standard [1], using an infrared (IR) emitting LED as the simulated signal source. To ensure beam integrity and minimize light dispersion, the LED was inserted into an optical coupler designed to accurately direct the photon flux (Fig. 2). This allowed the sensor to be isolated from environmental interference and ensured that the captured intensity variation came exclusively from the controlled source.

III. RESULTS

To ensure methodology compatibility with the synchronization triggers of modern high-sensitivity PPG sensors, such as the MAX30101/MAX30102 [6], [7] or AFE4950 [8], an alignment circuit utilizing an MCP6002 operational amplifier was implemented (Fig. 3).

While the amplifier's finite slew rate causes the output signal to assume a triangular waveform at extreme frequencies above 100 kHz (Fig. 4), the circuit operates without significant waveform distortion within the low-frequency range required for heart-rate calibration.

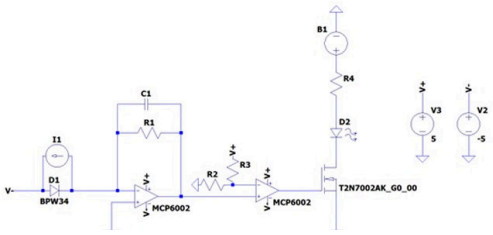

Fig. 3. Simulation of the heartbeat synchronization and mimicry circuit. Source: Elaborated by the authors.

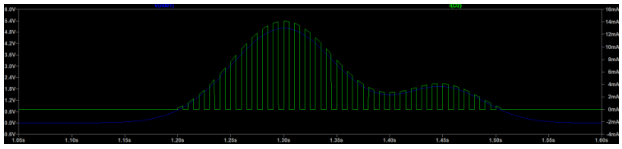

Fig. 4. System response at 100 kHz, showing the distortion of the current signal. Source: Elaborated by the authors.

Table I presents the results obtained in the calibration of the heartbeats measured by watches A1, A2, A3, B, and C. The reported value for each calibration point represents the mean of four repeated measurements, while the associated combined uncertainty was calculated according to Equation (3). According to IEC 63203-402-3 [1], heart-rate accuracy is evaluated using the Mean Absolute Percentage Error or MAPE (4), where HRi is the heart-rate indication provided by the wearable for the i-th measurement, HRref,i is the corresponding reference heart rate derived from the frequency applied by the simulator, and N is the total number of measurements considered in the calculation. Considering the four repeated measurements performed at each of the seven calibration points, a total of 28 measurements were evaluated for each device. The resulting MAPE values were 1.3%, 1.3%, and 1.7% for Watches A1, A2, and A3, respectively. All values were below the 10% acceptance criterion considered from IEC 63203-402-3,

indicating satisfactory performance of the three devices under the controlled conditions evaluated in this proof-of-concept study.

$$MAPE = \frac{100}{N}\sum_{i=1}^{N}\left|\frac{HR_i - HR_{Ref,i}}{HR_{Ref,i}}\right| \quad (4)$$

TABLE I
RESPONSE OF DEVICES TO PULSATION MIMICRY VIA INFRARED EMISSION (RESULTS ARE EXPRESSED AS MEAN ± COMBINED STANDARD UNCERTAINTY)

Expected (bpm)	Dev A1 (bpm)	Dev A2 (bpm)	Dev A3 (bpm)	Dev B (bpm)
30	30,3 ± 0.9	29.8 ± 0.7	31.0 ± 0.8	N/A
60	60,3 ± 0.6	59.8 ± 0.8	59.3 ± 0.7	59.8 ± 0.9
90	89,8 ± 0.7	88.5 ± 0.6	90 ± 1	N/A
120	119,8 ± 0.9	119.8 ± 0.9	118.5 ± 0.4	121.3 ± 0.6
150	151,3 ± 0.6	151.3 ± 0.6	149.8 ± 0.7	N/A
180	180.8 ± 0.6	180.8 ± 0.6	180.5 ± 0.6	N/A
210	209.3 ± 0.7	209.3 ± 0.7	210 ± 1	N/A

Watches A1, A2, and A3 exhibited stable responses across all evaluated calibration points. The measured values remained close to the expected heart-rate values, indicating consistent response to the controlled optical stimulus among the three nominally equivalent devices.

Watch B: No signal was detected at several calibration points. Subsequent technical analysis revealed probable damage to the receiving photodiode, making it impossible to convert the photon flux into electrical voltage, regardless of the external source's intensity. Despite the hardware failure, stable readings were obtained at specific frequency points such as 60BPM and 120BPM.

Watch C: The device prevented data collection due to the presence of a skin impedance sensor. This mechanism acts as a safety lock that requires electrical contact with human skin to activate the optical reading stages, demonstrating that mimicry in devices with this security feature requires the simultaneous simulation of other electrical biometric properties.

IV. DISCUSSION

The experimental results indicate that optical mimicry is feasible for the evaluated devices without impedance-based presence detection. Watches A1, A2, and A3 demonstrated an almost immediate response to the infrared optical pulses, converting the frequencies applied by the standard function generator within the maximum permissible error established by the IEC 63203-402-3 standard. This result supports the feasibility of infrared optical mimicry for the evaluated models, although it should not be interpreted as evidence of wavelength-independent photodetector responsivity.

The calibration process also indicated a possible hardware anomaly in Watch B. The absence of stable readings at several calibration points was consistent with a probable failure in the optical receiving stage, possibly associated with the receiving photodiode. This observation suggests that the proposed setup may also be useful for identifying abnormal sensor behavior during calibration.

Finally, the barrier encountered in Watch C highlights the evolution of security mechanisms. The requirement for galvanic skin impedance detection to activate the PPG stage acts as a logic lock. It is concluded that, for the calibration of devices in this segment, it became necessary to develop a hybrid simulator capable of simultaneously providing the optical stimulus and emulating the electrical impedance of the skin-device interface.

A. Limitations and Metrological Implications

The results should be interpreted within the scope of a proof-of-concept study. The experiments were performed under controlled optical coupling conditions and were intended to evaluate the response of the wearable to a controlled artificial optical stimulus with traceable pulsation frequency rather than to reproduce the full optical and physiological behavior of human tissue. Consequently, factors that affect PPG performance in real-world use, including motion artifacts, skin optical properties, low peripheral perfusion, sensor pressure, and variations in ambient light, were not reproduced in the present setup.

From a metrological perspective, this distinction is important. Calibration using a controlled optical stimulus can evaluate the relationship between an applied pulsation frequency and the heart-rate indication generated by the wearable, while clinical validation evaluates device performance under physiological and environmental variability. Therefore, satisfactory performance under the proposed calibration conditions should not be interpreted as evidence of equivalent accuracy during unrestricted use or under all clinical conditions.

The present study was also limited to five devices and three different models. The results therefore cannot be generalized to all wearable PPG architectures. Further validation should include a larger number of devices and manufacturers, as well as controlled variations in LED wavelength, optical intensity, coupling geometry, waveform shape, ambient-light conditions, and synchronization strategy. Comparison with commercial

PPG or physiological simulators would also provide an important benchmark for assessing the advantages and limitations of the proposed approach.

Furthermore, recent calibration approaches have demonstrated that adaptive sensor parameters, such as optical gain, may be used to mitigate PPG response variability associated with skin pigmentation [11]. This reinforces that the controlled optical calibration proposed here represents only one component of the broader validation required for wearable PPG systems.

V. CONCLUSION

The experiments demonstrated the feasibility of optical signal mimicry as a proof-of-concept approach for heart-rate calibration and integrity verification in the evaluated wearable devices. Watches A1–A3 produced heart-rate indications within the acceptance criterion considered from IEC 63203-402-3 under the controlled experimental conditions. Watch B exhibited anomalous behavior associated with hardware damage, whereas Watch C could not be evaluated using optical stimulation alone because its operation requires skin-contact validation. These results indicate the potential of the proposed method for controlled wearable calibration, but further experimental validation involving a broader range of devices and sensing architectures is required.

The lack of transparency by manufacturers proved to be a significant obstacle, as hardware configurations remain undisclosed. Access to specific sensor information and internal barrier mechanisms is essential to optimize calibration and facilitate objective device benchmarking. Therefore, practical experimentation remains vital to bridge these informational gaps and identify the operational variables of these devices.

VI. FUTURE WORKS

Future work will focus on the calibration of devices such as Watch C, which require skin impedance detection for operation. To address this, we propose an impedance simulation circuit based on wrist tissue parameters described by Bora and Dasgupta [4]. Additionally, we are developing a coupling mechanism to integrate these circuits with the device under test while minimizing external interference. This mechanism will incorporate a translucent silicone interface to function as an attenuating filter. By preventing photodiode saturation and enhancing light scattering, this layer will more accurately simulate the optical response of human tissue.

***Abstract*—Cold head devices are essential for maintaining superconductivity and field homogeneity in modern MRI equipment. This study analyzed the impact of coldhead replacement on the quality control (QC) parameters of a 3.0T MRI, evaluating system stability before and after the component exchange. The results showed that wear of the cold head led to instability in helium pressure, a drop in the signal-to-noise ratio, slice thickness deviations, and an increase in ghosting artifacts. Following the intervention, the magnetic field was stabilized and image quality parameters returned to ideal standards with the recalibration of the center frequency. Thus, it can be concluded that periodic monitoring of QC data validates the effectiveness of predictive maintenance in preventing critical failures, allowing potential failures to be observed through fluctuations in periodic data.**

Keywords—Magnetic resonance, cold head, quality control.

I. INTRODUCTION

In recent decades, the evolution of magnetic resonance imaging scanner has enabled the development of new technologies, highlighted by scanners with more intense magnetic fields based on superconductivity principles. On the other hand, these systems have become more sensitive to small fluctuations in environmental parameters and physical hardware components. Scanners with fields of 3.0 T or higher, for example, utilize ultra-fast gradients (slew rates) that exhibit high susceptibility to external disturbances [1, 2].

The operation of Magnetic Resonance (MR) systems with 3.0 Tesla (3.0 T) magnets imposes rigorous thermodynamic challenges due to the amount of energy stored in the superconducting solenoid. Maintaining the superconductivity of Niobium-Titanium alloys (NbTi) requires the filament temperature to remain strictly below its critical temperature ($T_c = 9.2$ K), being immersed in liquid helium at approximately 4.2 K under normal atmospheric pressure. [3], [4]

In this scenario, the natural evaporation rate of helium is intensified by the heat generated from the activation of magnetic field gradients and radiofrequency (RF) pulses. To prevent this loss, Zero Boil-Off (ZBO) technology is employed, in which the gaseous helium evaporating inside the cryostat is captured and re-condensed into a liquid state via a mechanical cryocooler, returning to the reservoir in a closed loop [3],[4].

The cold head is the component of the cryocooler responsible for providing the thermal exchange required for this liquefaction. Thus, ZBO technology plays a crucial role by eliminating continuous cryogen loss, preventing substantial financial losses and the imminent thermal instability of the magnet [4], [6].

The performance and diagnostic accuracy of high-resolution MRI systems directly depend on the mechanical and thermal stability of the cold head and the cryostat. While cycles, such as the pulse tube, minimize vibrations and microphonics by having no moving parts in the cold head, systems based on mechanical pistons — such as the Gifford-McMahon (GM) — require constant monitoring against micro-frictions that generate thermal instabilities and radiofrequency noise (spike noise). [6],[8]

Furthermore, strict thermal control on the millikelvin scale is essential to prevent micro-drifts in the static magnetic field (B_0) and oscillations in the resonance frequency, factors that degrade field homogeneity and the image signal-to-noise ratio (SNR).[6],[8],[9]

Although modern scanners perform automated calibrations before and during each pulse sequence (such as real-time active shimming and dynamic center frequency adjustment), severe deviations in B_0 homogeneity still generate

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

macroscopic geometric distortion artifacts and chronic failures in the chemical shift fat saturation (fat-sat) technique [8]. Echo-Planar Imaging (EPI) based sequences, such as Diffusion-Weighted Imaging (DWI), suffer severe phase distortions if the internal thermal gradient fluctuates, causing displacement and c artifacts in the phase-encoding direction. [8], [9], [10].

In clinical engineering, the integrity of magnetic resonance imaging (MRI) systems depends on the integrated operation between the cold head, the compressor, and the chiller. Currently, preventive and predictive monitoring of these components relies on telemetry sensors, helium pressure analysis, and vibrational signatures to anticipate mechanical failures [8], [13]. The failure of these cooling systems raises the thermal energy of the cryostat, which can induce a quench, causing the sudden loss of superconductivity along with the violent expansion of liquid helium [13], [14], [15], [16], [17], [18].

Given this scenario and the need for metrological validation, this work aims to experimentally analyze the impact of cold head (helium level and pressure levels) replacement on fundamental image quality parameters, specifically central frequency, slice thickness, SNR, and ghosting factor.

II. Materials and Methods

This study consists of a longitudinal analysis conducted before and after the replacement of the cold head (a system based on Zero Boil-Off technology). Image data were acquired on a 3.0 T magnetic resonance imaging (MRI) scanner (Achieva, Philips Healthcare) using an 8-channel head coil (Model SENSE head coil 8ch) and the Magphan® RT phantom (Model SMR170). The quality control (QC) protocol utilized spin-echo sequences with the following parameters: TR = 500 ms, TE = 20 ms, a slice thickness of 5.0 mm, a 256 × 256 pixel matrix, a FOV of 256 x 256 mm² , and a bandwidth of 364 Hz/pixel. Additionally, the physical operating parameters of the equipment—specifically internal pressure and liquid helium level—were monitored weekly.

Signal-to-noise ratio (SNR), slice thickness, and ghosting artifact metrics were calculated from the phantom images by positioning regions of interest (ROIs), following the guidelines of the established QC protocol. For SNR quantification, a circular ROI was placed at the center of the phantom's homogeneous region to obtain the mean signal intensity ($\bar{S}$). Simultaneously, elliptical ROIs were distributed in the background region (air), outside the object's perimeter, to determine the background noise (σ_{bkg}) (equation 1).

$$SNR = \frac{0.655 \times \bar{S}}{\sigma_{bkg}} \qquad (1)$$

The evaluation of the ghosting parameter (PSG) was performed using the same background elliptical ROIs, positioned in the peripheral directions (top, bottom, right, and left) relative to the phantom. The mean intensities of these regions were compared against the mean intensity of the phantom's central ROI, allowing the calculation of the ghosting factor (Figure 1b, equation 2).

$$PSG = 100 \times \frac{(Left+right)-(Top+Bottom)}{2 \times \bar{S}} \qquad (2)$$

Slice thickness was determined by analyzing the specific ramp profiles of the phantom for this test by full width at half maximum (FWHM), as specified by the phantom manufacturer. Initially, the maximum and minimum pixel intensity values in the x and y directions were mapped to calculate and adjust the optimal window level (WL). Following segmentation by the WL, the boundaries of the ramp structure were defined for the execution of geometric measurements. Finally, the obtained linear dimensions were applied to the mathematical formulations of the QC protocol to determine the effective slice thickness (Figure 1c).

The central frequency was obtained directly from the DICOM image metadata, using the imaging frequency information found in the file header.

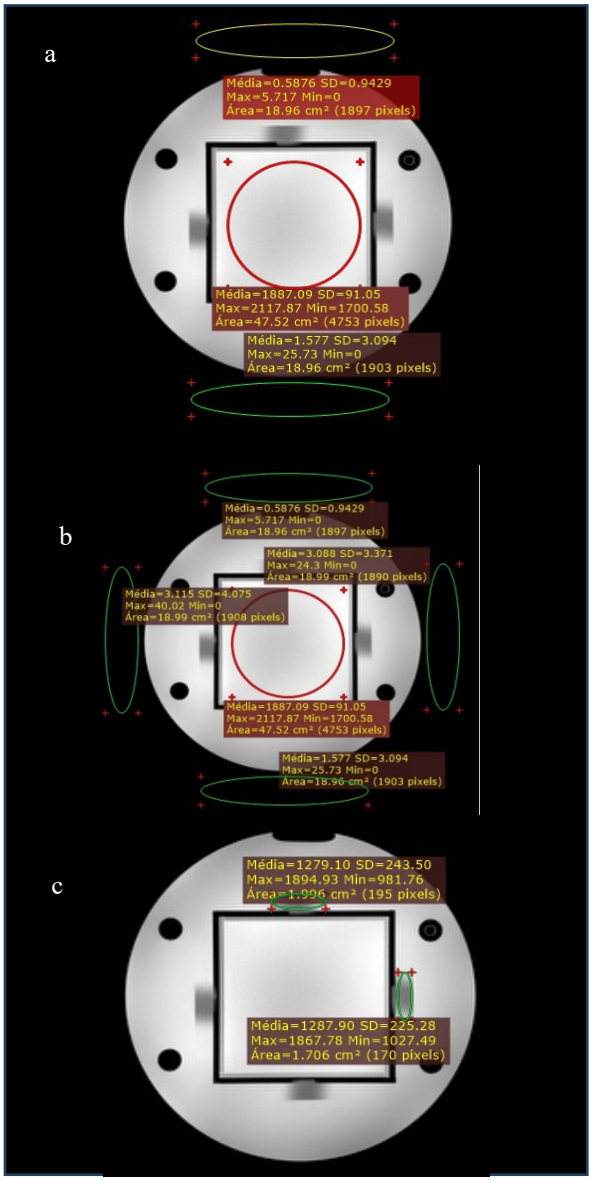

Figure 1(a) signal-to-noise measurements, (b) ghosting measurements, and (c) slice thickness.

The quantitative analysis was performed using RadiAnt software, with subsequent tabulation and data constancy analysis conducted in Microsoft Excel [19].

The measurements were compared before and after the replacement carried out on February 4, 2026.

III. Results and Discussion

To evaluate system constancy in an integrated manner, the image quality control test results were correlated with the historical physical parameters of the equipment. For this purpose, time-trend plots of internal pressure and liquid helium level were generated and detailed, making it possible to verify whether any variations in image quality settings showed a direct correlation with the behavior of the cryogenic system pre-and post-intervention (Figure 2).

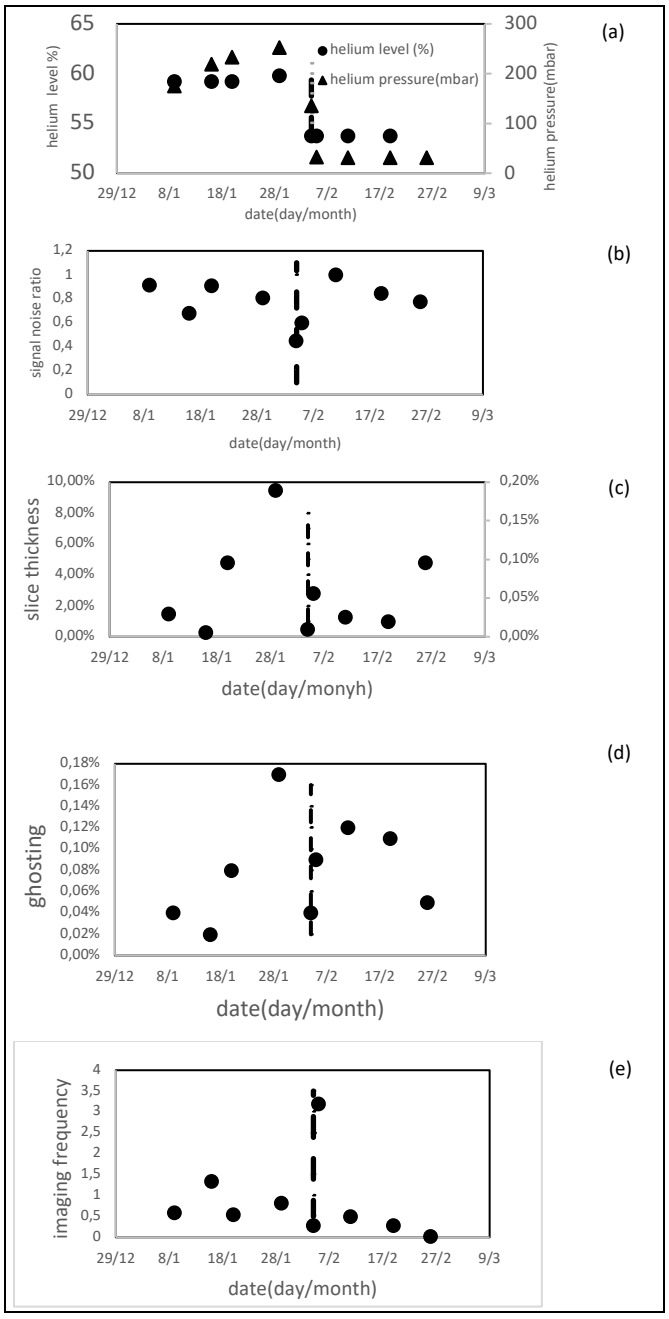

Figure 2:Timeline of 9 measurements pre- and post- intervention (dashed vertical line);(a)Helium level and pressure stability over time;);(b)signal noise ratio;(c)slice thickness;(d) ghosting; imaging frequency

Figure (2a) highlights an instability in the helium pressure, indicating that the old cold head was no longer recondensing the gas adequately. After the component was replaced, the pressure stabilized at lower levels. This thermal stabilization halts fluctuations in the helium evaporation rate and, consequently, stabilizes the magnetic field—a process that, however, requires at least a week to fully stabilize, as observed in the data obtained.[13]. Furthermore, the data obtained are consistent with the manufacturer's recommended limits (30% helium level and 30 mBar helium pressure). [4] [20]

For the parameters shown in Figures 2b to 2d, the tolerance levels recommended by the Normative Instruction IN 97 of the Brazilian Health Regulatory Agency (*Agência Nacional de Vigilância Sanitária - ANVISA*) were applied. [21]

The analysis of the SNR data shown in Figure (2b) can be directly correlated to how thermal and pressure instability affects the homogeneity of the B0 field. It is noted that the SNR had a downward trend and reached a peak just before the replacement, which suggests that a failing coldhead generates mechanical vibrations and thermal fluctuations that will interfere with signal quality.

PSG in MRI is also related to possible mechanical vibrations caused by wear of the cold head and signal phase instabilities. Figure (2d) shows that before the replacement, the value was high, reaching a peak in January. Although there was a short delay before full stabilization was achieved, the general trend after the replacement is a decrease and control of the artifact, returning to low levels by the end of the analyzed time series [13],[18],[19].

Figures (2c) and (2e) show the slice thickness and imaging frequency parameters, respectively. These parameters depend on the stability and calibration of the gradients, as well as the resonance frequency. They are affected by the temperature and pressure of the magnet. It is noted that, most of the time, the slice thickness varied within a low range (usually below 5%), but an isolated peak occurs where the deviation reaches 9.5%, and after the replacement, the slice precision returns to the expected values. It is noted that exactly after the cold head replacement, there are peaks in the Imaging Frequency graph, which is acceptable and described in the literature. Following the replacement, the pressure system stabilizes, and the equipment needs to undergo a center frequency recalibration to adapt to the new stable condition of the magnetic field.

The data showed an end-of-life scenario for a cold head, which presented helium pressure instability that, consequently, likely generated noise, SNR decrease, and artifacts. The replacement intervention allowed the image quality (SNR and slice thickness) to be restored to ideal operating standards

The analysis of the graphs prior to the maintenance and cold head replacement date offers a case study for the development of predictive models in MRI systems. Based on the evaluation of the obtained measurements, it can be verified that despite having high values immediately before the cold head replacement, only the center frequency presented values above the reference parameters of the current national regulations.

Visual inspection of the phantom images on a medical diagnostic display revealed no perceptible differences pre- and post- intervention during quality control tests.

Differences between pre- and post-intervention phases were evaluated using the two-tailed Wilcoxon signed-rank exact test.

Due to the small sample size, the statistical power was limited, preventing the detection of subtle differences between phases (*p-value*>0.75). Nevertheless, a clear trend toward stabilization and a return to normative tolerance parameters was observed, highlighting a meaningful operational impact. Future studies with larger cohorts are recommended to confirm these findings

The cold head replacement was effective in reducing noise in the MRI images of the analyzed scanner, restoring image quality parameters (SNR and slice thickness) to ideal operating limits. Furthermore, the observed trends during the parameter fluctuation period demonstrate the potential of using these historical data to develop predictive maintenance models, preventing unplanned system downtime through periodic quality control (QC) analysis. Although high fluctuations were recorded immediately prior to the component replacement, only the center frequency exhibited values exceeding the reference parameters of the current national regulation.

ACKNOWLEDGMENT

We would like to thank the Financiadora de Estudos e Projetos (FINEP) of Ministério da Ciência, Tecnologia, Inovações e Comunicações (MCTI) and Fundação Instituto de Pesquisa e Estudo de Diagnóstico por Imagem (FIDI) for providing the resonance Imaging scanner. We would also like to thank the technicians who helped us to create protocols for this study.

***Abstract*—Medical beds (MBs) are essential devices for patient care and must comply with regulatory requirements to ensure safety and performance throughout their life cycle. This study evaluated the conformity of MBs submitted to a public procurement process conducted by the São Paulo State Department of Health under Reference Term 330/2025. The evaluation was performed at the Normative Testing Division of the Biomedical Engineering Laboratory of the University of São Paulo and included tests based on ABNT NBR IEC 60601-2-52: 2013 and ABNT NBR IEC 62353: 2019 standards. The evaluation covered documentation, labeling, electrical safety, mechanical construction, mobility, patient entrapment protection, stability, and functional performance requirements. MBs from different manufacturers were initially received for evaluation. One manufacturer was disqualified during the inspection phase due to noncompliance with mattress specifications, and the remaining products proceeded to testing. The results demonstrated that none of the evaluated beds fully complied with the applicable requirements. Nonconformities were identified in many tests. The findings revealed discrepancies between expected regulatory compliance and the actual characteristics of products available on the market, indicating potential risks to patients and healthcare professionals. The study also highlights the importance of integrating safety tests, clinical engineering practices, and post-market surveillance to support continuous product improvement and patient safety.**

***Index Terms*—hospital bed, functionality, security, entrapment, adverse events**

I. Introduction

A medical bed (MB) is a medical device intended for patient rest or sleep, designed to assist in the diagnosis, monitoring, and treatment of diseases, or to compensate for injuries and disabilities [1]. To fulfill these clinical functions, MBs must incorporate a reinforced metal frame and mechanisms that allow the position of the bed to be adjusted, arfticulated side rails as a means of protection against falls and features to facilitate the entry and exit of the patient from the bed. These adjustments may include head, legs and foot elevation, as well as height range or inclination, facilitating both therapy and patient rest and the activities of healthcare professionals.

According to the Brazilian Health Regulatory Agency (ANVISA), MBs are commonly classified as low-risk medical equipment [2]. They are widely used in healthcare facilities such as hospitals, clinics, nursing homes, or in homes when patient requires continuous care or has reduced mobility.

Due to their relevance to life care and support, all health marketed in Brazil must comply with the Brazilian Health Regulatory System (SNVS) by being registered by ANVISA [3]. In addition, electrically operated medical beds and be certified under the Brazilian Conformity Assessment System (SBAC), ensuring that these devices meet both regulatory and technical standards for safety and essential performance.

Additionally, the establishment of the Brazilian Sentinel Hospital Network by ANVISA and the mandatory implementation of Patient Safety Centers (NSP) in healthcare institutions, enabled the systematic monitoring of adverse events occurring during the post-market scenario. These events are reported and monitored by the SNVS through the Surveillance Notification System's module (NOTIVISA). Notifications can be made via the web platform by health professionals and citizens [4].

An analysis of incident reports available in the ANVISA public dashboard revealed 28 incident reports involving hospital beds between 2007 and 2026. Among these notifications, 24 lacked a specified root cause, three were directly associated with patient falls, and one was officially classified as a "drowning" event [5], a critical clinical occurrence that warrants further technical examination of this study.

To ensure product quality and promote good safety practices in hospital environments, the São Paulo State Department of Health (SES-SP) established, through Reference Term (RT) 330/2025, prepared by the General Administrative Coordination (CGA), a public procurement process for the acquisition of MBs. The procurement was conducted through an

electronic auction, adopting evaluation criteria based on the lowest price combined with cost-benefit considerations and conformity evaluation. Compliance was demonstrated through the execution of tests performed according to methodologies aligned with the requirements of the ABNT NBR IEC 60601-2-52: 2013 - Particular requirements for the basic safety and essential performance of medical beds and ABNT NBR IEC 62353: 2019 - Recurrent test and test after repair of medical electrical equipment [1], [6], [7].

In cooperation with SES-SP, this study evaluated the quality and conformity of the MBs defined under RT 330/2025. The evaluation included tests to verify electrical safety, electromechanical construction, essential performance, accessories, labeling, and user instruction manuals. By presenting these findings, this study aims to inform manufacturers about potential gaps between regulatory compliance and real-world clinical use while contributing to improving medical device quality, patient safety, and supporting the objectives of the National Patient Safety Program (PNSP) [4].

II. Methodology and materials

According to the RT, sixteen manufacturers of MBs with weighing scales and twenty manufacturers of MBs without weighing scales competed in the bidding process. The evaluation followed a sequential line: one unit with a weighing scale and one without were tested concurrently. If both MBs fulfilled all requirements, they were accepted, the procurement item was awarded, and the evaluation of subsequent candidates in line was terminated. If the equipment under test failed any item, the testing process was immediately halted, the company was officially notified and the process moved to the next ranked manufacturer. Based on this pricing registry workflow, the laboratory received and evaluated a total of four MBs with weighing scales and four without weighing scales between November 2025 and April 2026. Although additional MBs remained on the waiting list, they were not subjected to experimental testing as the subsequent manufacturers did not meet the mandatory minimum price criteria. It is important to mention that manufacturer's representatives were present throughout the entire evaluation period, and no objections regarding the test procedures, execution, or results were reported.

The tested MBs had the following technical specifications: safe working load of 250 kg; internal bed dimensions of 900x205 mm (width x length); external bed dimensions of 1000x2150 mm; adjustable height without mattress from 420 to 750 mm; viscoelastic mattress with a thickness of 14 cm, steel frame with epoxy paint, articulated side rails with descent damping system, articulated bed in 4 sections (backrest, seat and leg rest with two sections), electric fowler-type movements (backrest, legs, Trendelenburg, reverse and elevation) activated by 4 motors, cardiopulmonary arrest device (electric and mechanical), remote control, minimum IPX4 protection rating against water ingress, antistatic double casters (with hubcap and 150 mm swivel), movement/ brake system activated by a single pedal, steering system or fifth wheel, automatic bivolt power supply with rechargeable battery option, wired remote control and with membrane keyboard control on the side rails for easy cleaning and disinfection (with the possibility of locking the rail control) and equipped with an aluminum or stainless steel IV pole.

To perform the experimental procedures, the infrastructure of the Normative Testing Division (DEN) of the Biomedical Engineering Laboratory (LEB) at the Escola Politécnica of the University of São Paulo (EPUSP) was utilized. The laboratory is equipped with metric scale (1000 mm, DEN ID: ESC-053), caliper (330-114, Mitutoyo, Japan), Weighing Indicator (I35, Precia Molen, France), stopwatch (Superact, DEN ID: CRO-149), balance (ID-U300/4, Filizola, Brazil), inclinator (CR20232, Digimees, Brazil), floor caliper (100460, Digimees, Brazil), electrical safety analyzer (LGI 3000, Entran, Brazil), and an environmental conditions meter (176H , Testo, Germany). All measurement instruments used complied with the specifications established by the ABNT NBR IEC 60601-2-52: 2013 and ABNT NBR IEC 62353: 2019 standards. Furthermore, the measurement instruments were duly calibrated and traceable to recognized metrological standards, ensuring the reliability and accuracy of the tests performed.

To meet the test requirement involving the application of dynamic forces, a mechanical cycling apparatus was developed using a pneumatic cylinder actuator (C95SDB250-XC6, SMC, Brazil) coupled to an air compressor (MSV5.2VL/130, Schulz, Brazil). The system was designed to simulate a patient sitting on the bed and performed 5,000 loading cycles. Before testing, the apparatus was validated using a load cell and weighing indicator to ensure accuracy and repeatability of the applied forces.

Additional materials, as specified by the ABNT NBR IEC 60601-2-52: 2013 standard, included: cone tool to simulate the patient's head, a cylinder tool to simulate the width of the patient's trunk and arm, two inclined planes at 6 degrees, one with vinyl flooring and the other with concrete, a load cushion, two obstacles to simulate a frontal collision with a door frame and another as a floor threshold. After being manufactured, the cone and cylinder tools were calibrated dimensions, mass and roughness. The two inclined planes were validated using an inclination gauge. The two obstacles were validated using a caliper.

A systematic inspection protocol was established for the MBs under test. Upon receipt, an initial checklist was utilized to register the equipment's status. This inspection verified full electromechanical functionality, the presence of standard accessories, and the completeness of the technical documentation (instruction manuals, service manuals, and risk management files). To minimize external variables, all testing was performed under stable and controlled climatic conditions.

MB functionality was evaluated by verifying whether the final test results met the compliance conditions described in the regulatory requirements.

A. Tests for MBs According to ABNT NBR IEC 60601-2-52: 2013 (Including Amendment 1) and ABNT NBR IEC 62353: 2019

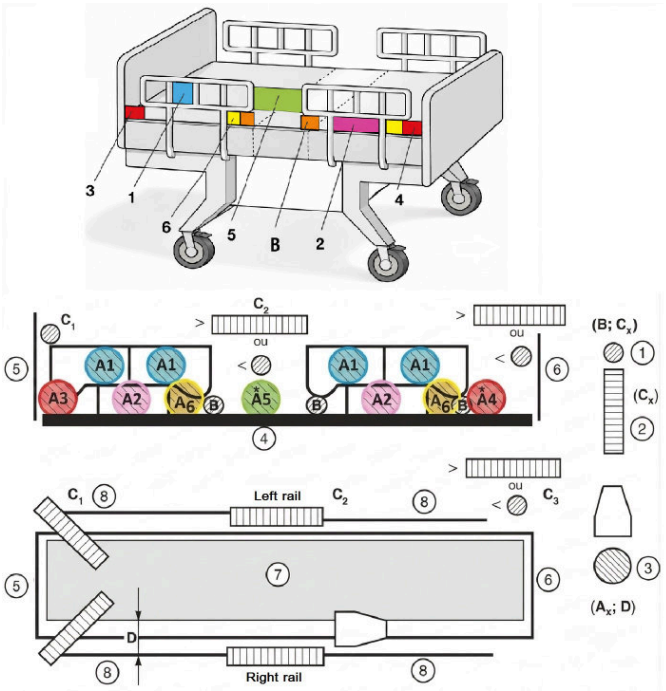

Table I describes the complete relationship between the specific normative clauses and the respective tools employed.

TABLE I
SUMMARY OF MBS TEST PROTOCOLS

Test	Normative Technical Specifications		
	Standard Clause	***Normative Requirement***	***Method***
T1	**201.7.2.2**	Manufacturer identification and labeling	Visual inspection

T15	**201.9.4.2.4.3**	Caster resistance: 10 threshold collisions	Threshold, Caliper balance (250 kg load)
T16	**201.9.8.3.3**	Dynamic loading: 1350 N for 5000 cycles	Mechanical cycling apparatus
T17	**201.9.8.3.2**	Static forces due loading from persons 5000 N for 1 h	Floor caliper balance (250 kg load)
T18	**201.11.8**	Power Supply Interruption	Chronometer
T19	**5.3.2**	Grounding resistance measurement	Electrical Safety Analyzer (ESA)
T20	**5.3.4**	Leakage current limits verification via direct methods	Electrical Safety Analyzer (ESA)

Tests T1 through T4 focus primarily on labeling, control identification, and user instruction compliance. Mechanical integrity, patient entrapment mitigation, and structural stability under extreme vertical, horizontal, and transport loads were addressed from tests T5 to T17, using specialized apparatus such as load cells, calibrated masses, metric scales and standard threshold obstacles. Finally, power supply interruptions (Test T18), grounding resistance measurement (Test T19), and leakage current (test T20) were evaluated to ensure electrical safety.

To evaluate the risk of patient entrapment in non-moving parts (Test T6), the dimensions and critical boundary openings of the beds were checked using the cone and cylinder recommended by the ABNT NBR IEC 60601-2-52: 2013 standard. As illustrated in Figure 1, these evaluations focused on specific areas, such as the spaces within the side rails, between the rails and the head/footboards, and the clearances under the rail profiles.

To evaluate the leakage current (Test T20), an Electrical Safety Analyzer was utilized to perform measurements through both the alternative and direct methods. As illustrated in Figure 2, both methodologies rely on a standardized measuring device (MD) prescribed by the ABNT NBR IEC 62353: 2019.

III. Results

The inspection and functional verification performed upon delivery of the MBs, as documented in the checklist forms, revealed the following findings:

- All beds demonstrated apparent structural integrity of the mattress support platform, articulated movement sections, side rails, headboard and footboard assemblies, castors, brake and locking systems, with no visible signs of damage or defects.
- All beds demonstrated proper operation under both mains and battery power. Functional verification confirmed correct performance of the height adjust-ment, backrest, leg rest, Trendelenburg, reverse Trendelenburg, and CPR functions using both the remote control and patient controls.
- The other parts of the beds, such as the power supply cord or electrical cables, connectors, and IV pole, were in good condition to use.
- A few MBs were delivered with instructions for use and risk management file. In those cases, they were requested to be sent by e-mail to realize the test T4 - 201.7.9.2.

Of the four manufacturers initially selected in the bidding process, one was disqualified during the initial inspection phase because the delivered mattress did not meet the technical specifications defined in the RT, namely the required thickness of 140 mm. Considering this fact, only three manufacturers proceeded to the evaluation tests.

During the initial evaluation, finger trapping zones were identified in two MBs in the area beneath the mattress support platform, associated with the side-rail articulation mechanism (Figure 3). Although this condition is addressed in item 201.9.2.2 of ABNT NBR IEC 60601-2-52: 2013, the requirement was not included in the RT. Therefore, the finding was communicated to the manufacturers as a safety-related observation and was not considered a criterion for disqualification.

According to the RT, it consisted of a total of 20 sets test for each MB, as described in Table I. Table II shows a summary of the conformities and non-conformities regarding the results obtained in the tests of the MBs that performed. However, only 15 tests were performed on one of the MB equipped with a weighing scale (Second-place finishers) failed to meet the requirements of clause 201.9.4.2.4.3 due to a structural failure of its castors while attempting to overcome the threshold and this rendered it impossible to carry out the remaining tests, as required by the bidding process.

IV. Discussion

Patient safety is a globally recognized healthcare priority and a fundamental component of quality of care. Adverse events associated with healthcare delivery remain a major challenge worldwide and have received considerable attention from organizations such as the World Health Organization (WHO).

The tests conducted in this study revealed that none of the evaluated MBs fully complied with the RT´s 20 sets test and applicable regulatory requirements, including documentation, mechanical safety, and electrical safety criteria. These findings demonstrate a gap between expected regulatory compliance and the actual characteristics of products specifically tested in this study, despite their disposable on the market, potentially affecting their safe use in healthcare environments. Given that all measuring instruments were calibrated, ensuring metrological reliability and that the manufacturers observed the tests without raising objections, it was made not to report the values of the results obtained, due to the large volume. Instead, the following comments were made.

Regarding documentation (T4), deficiencies were identified in the instructions for use that could compromise safe operation. Missing information included guidance on bed–mattress compatibility, inspection of critical components, and warnings related to mechanical hazards. In addition, several MBs lacked adequate identification markings (T1) on major components and accessories, omitting essential information such as manufacturer identification, model designation, and part numbers. Such deficiencies hinder traceability, maintenance activities, replacement part procurement, and post-market surveillance.

Some mechanical non-conformities were also observed. Openings within the side-rail structures and gaps between the side rails and the headboard or footboard presented potential entrapment hazards (T6), because they failed to withstand the forces exerted by the conical (250 N) and cylindrical (weight force) test tools when these were inserted into or applied against the relevant areas. Furthermore, the height between the mattress surface and the upper edge of the side rails (T9) was not greater than minimum limit of 220 mm established by the standard. Two of the tested MBs, from different manufacturers, exhibited stability deficiencies by failing to withstand a lateral force of 2200 N in the instability excluding transport test (T13), as well as mobility issues resulting from caster systems unable to traverse floor irregularities (T15). These issues could compromise bed stability and increase the risk of patient falls. Another concern regarding the two tested MBs involved finger-crushing risks associated with the side rail's articulation mechanism.

Electrical safety concerns were also identified. First of all, it is worth noting that the power cords for two of the MBs did not meet the minimum length of 2.5 meters established by the standard (T5). In some MBs, the impedance of the protective earth conductor exceeded the limits of 300 miliohm established by the standard. Additionally, certain models were classified as Class II equipment and employed detachable power supply cords. Although Class II protection is based on double insulation, its application to electrically operated hospital beds deserves careful consideration due to the presence of extensive accessible metallic structures and electromechanical systems. In the event of insulation failure, accessible conductive parts could become energized, potentially exposing patients and healthcare professionals to electric shock hazards. In this context, Class I protection systems may provide an additional safety layer through the use of a protective earth conductor capable of safely conducting fault currents.

The relevance of these findings is reinforced by reports from international surveillance systems. Functional failures, patient entrapment, falls, and operational limitations associated with hospital beds have been recognized worldwide as important patient safety concerns. According to the Food and Drug Administration (FDA), between 1985 and 2009, 803 patient entrapment incidents involving hospital bed rails were reported in the United States, resulting in 480 deaths and 138 nonfatal injuries [9]. Similarly, the Medicines and Healthcare products Regulatory Agency (MHRA) reported 18 deaths and 54 serious injuries associated with hospital beds and bed rails in the United Kingdom between 2018 and 2022 [10]. In Canada, surveillance data identified 125 patient entrapment incidents between 1980 and 2017, including 47 deaths [11]. These reports demonstrate that the risks identified in the present study are not merely theoretical but are associated with documented adverse events in clinical practice.

Despite the relevance of these risks, Brazil still faces challenges in characterizing and analyzing medical device-related adverse events. Although the NOTIVISA system provides a structured framework for adverse event reporting and supports preventive actions at the local and national levels, important limitations remain, including underreporting. Moreover, the system does not provide specific categorization for incidents involving patient falls or entrapment associated with MBs, limiting the ability to identify trends and establish targeted risk-reduction strategies.

A notable example is the single notification classified as a "drowning" event associated with MBs. While this report suggests the potential involvement of an MB in a severe adverse event, the lack of clinical and technical details prevents a proper understanding of the circumstances and identification of root causes. Consequently, opportunities to learn and implement corrective or preventive measures remain limited. Such information gaps may contribute to the under-recognition of risks associated with MBs in the Brazilian post-market surveillance system.

Finally, it should be noted that the present study evaluated only twenty sets of test requirements established in the RT, however the ABNT NBR IEC 60601-2-52: 2013 includes additional tests that were outside the scope of this investigation but remain highly relevant to patient safety and product performance, including evaluation of audible acoustic energy, side-rail locking strength and reliability, protection against excessive temperatures and other hazards, resistance to water ingress, and requirements applicable to machine-

washable medical beds.

V. Conclusions

The tests conducted in this study revealed that none of the particularly evaluated MBs fully met the requirements of the twenty sets test established by the RT in accordance with the ABNT NBR IEC 60601-2-52: 2013 standard, as well as the ABNT NBR IEC 62353: 2019 standard. These findings demonstrate that regulatory certification alone may not be sufficient to ensure that products available on the market consistently meet the expected standards of safety and performance, potentially indicating noncompliance with Good Manufacturing Practices (GMP) despite pre-market registration and certification.

The identified nonconformities indicate the existence of risks that may affect both patients and healthcare professionals during routine clinical use on MBs evaluated.

This study also demonstrates the need for a more integrated approach involving manufacturers, healthcare institutions, clinical engineering services, and regulatory authorities throughout the entire product lifecycle. Effective interaction among these stakeholders is essential to ensure that information obtained during real-world use contributes to continuous product improvement and risk reduction.

Finally, the results reinforce the importance of strengthening the connection between conformity evaluation, post-market surveillance, and clinical practice. Such integration is fundamental for improving the safety, performance, and reliability of medical devices.

I. Abstract

Magnetic nanoparticles (MNPs) were evaluated through complementary magnetic, mechanical, optical, and thermal techniques, including Alternating Current Biosusceptometry (ACB), Magnetomotive Ultrasound (MMUS), Photoacoustic Imaging (PAI), and Magnetic Hyperthermia (MH). The nanoparticles were synthesized by chemical coprecipitation and characterized in terms of their magnetic and morphological properties. A series of nanoparticle concentrations was investigated using tissue-mimicking gelatin/agar phantoms for ACB with two-dimensional spatial scanning, MMUS and PAI and aqueous suspensions for ACB and MH. All investigated modalities detected the MNPs, with the measured responses varying according to nanoparticle concentration and the physical mechanism probed by each technique. MMUS displacement and PAI contrast increased with increasing concentration, demonstrating their ability to provide mechanical and photoacoustic contrast, respectively. In MH, higher nanoparticle concentrations resulted in greater temperature increases, while the specific loss power (SLP) decreased with increasing concentration. ACB measurements enabled the detection and concentration-dependent characterization of the magnetic response before and after the investigated hyperthermia cycles. Overall, the results demonstrate the feasibility of characterizing the same MNP formulation using complementary experimental modalities and highlight its potential for multimodal phantom characterization and magnetic hyperthermia studies.

Keywords: Magnetic Nanoparticles, Alternating Current Biosusceptometry (ACB), Magnetomotive Ultrasound (MMUS), Photoacoustic Imaging (PAI), Magnetic Hyperthermia (MH).

II. Introduction

Magnetic nanoparticles (MNPs) have been widely investigated due to their ability to respond to external magnetic fields and to exhibit properties that can be explored through different physical mechanisms. In particular, magnetite (Fe_3O_4) nanoparticles have attracted attention because their magnetic behavior can be investigated using sensing and imaging techniques, while their interaction with alternating magnetic fields can also result in heat generation. These characteristics make MNPs suitable for comparative studies in which different measurement modalities are used to probe distinct aspects of the same material.

The response of MNPs to external stimuli depends on factors such as composition, particle size, morphology, magnetic properties, and concentration. Consequently, measurements based on magnetic, mechanical, optical, and thermal effects may provide complementary information about the same nanoparticle formulation [2], [5]. Evaluating these responses under controlled experimental conditions is therefore relevant for establishing how nanoparticle concentration influences the measured signals and for identifying the potential and limitations of each characterization approach.

In ACB, MNPs are detected through changes in the magnetic flux produced by their response to an alternating magnetic field. The sensing system employs a gradiometric coil configuration, in which magnetic contributions common to the detection regions tend to be compensated. In the absence of

magnetic material near the sensitive region, this arrangement keeps the system approximately balanced. However, when MNPs are exposed to the excitation field, their magnetization introduces an additional magnetic contribution, disturbing the balance between the coils and resulting in an electrically induced detectable signal. The amplitude and phase of this response are related to the magnetic behavior of the nanoparticles and may vary with their concentration and position relative to the sensing system [1]. In addition, when performed over the phantom, displacement of the sensor enabled two-dimensional spatial scanning, allowing the distribution of MNP-containing inclusions to be mapped and the signal variation across the investigated region to be evaluated.

In addition, Magnetomotive Ultrasound (MMUS) combines magnetic excitation with ultrasound detection to characterize magnetic materials through mechanically induced motion. When MNPs are exposed to an external magnetic field, magnetic forces acting on the particles can produce mechanical displacements in the surrounding medium. These displacements can be detected by ultrasound and used to generate mechanical contrast between regions containing and not containing MNPs. The magnitude of the displacement depends on factors such as the amount of magnetic material and the mechanical properties of the surrounding medium [2].

Photoacoustic Imaging (PAI) provides another complementary contrast mechanism by combining optical excitation with ultrasonic detection. Following the absorption of a short laser pulse, the absorbed optical energy is converted into localized thermal expansion, generating acoustic waves that can be detected by an ultrasound transducer. The resulting photoacoustic signal depends on the optical absorption properties of the investigated material and can therefore provide contrast between regions with different compositions [3]. For MNP-containing samples, PAI can be used to detect the inclusions and evaluate changes in photoacoustic contrast as a function of nanoparticle concentration.

Beyond imaging applications, Magnetic Hyperthermia (MH) explores the thermal response of MNPs under an alternating magnetic field. Energy dissipation by the nanoparticles can result in heat generation through magnetic relaxation mechanisms, including Néel and Brownian relaxation, whose relative contributions depend on nanoparticle and medium properties [4]. The heating efficiency can be quantified by the Specific Loss Power (SLP), which represents the power dissipated per unit mass of magnetic material. In this study, MH measurements were performed using MNP suspensions at different concentrations, allowing the temperature increase and SLP to be evaluated under controlled experimental conditions.

Tissue-mimicking phantoms are experimental models designed to reproduce selected physical properties of biological tissues under controlled laboratory conditions. They provide a standardized environment for evaluating imaging responses while controlling parameters such as geometry, concentration, and spatial distribution of the investigated material. In this study, gelatin/agar phantoms containing MNP inclusions at different concentrations were used for MMUS and PAI measurements, as well as for two-dimensional spatial scanning with ACB, while MNP suspensions in Eppendorf tubes provided a controlled configuration for complementary measurements, particularly magnetic and thermal characterization.

Taken together, ACB, MMUS, PAI, and MH enable the investigation of complementary magnetic, mechanical, photoacoustic, and thermal responses of the same MNP formulation. Therefore, this study aimed to evaluate a magnetite-based MNP formulation at different concentrations using these four techniques, investigating how nanoparticle concentration affects the measured responses and comparing their performance under the respective experimental conditions.

III. Results and Discussion

The synthesized MNPs exhibited well-defined nanoscale structural and magnetic characteristics. In Figure 1(a) the TEM analysis revealed approximately spherical MNPs with a relatively homogeneous size distribution. The particle-size analysis yielded a mean diameter of 6.8 ± 0.25 nm, with most particles distributed approximately between 5 and 8 nm, as shown in the corresponding size-distribution histogram in Figure 1(d). In Figure 1(b) the room-temperature magnetization curve obtained by vibrating sample magnetometry (VSM) exhibited low coercivity and reached magnetization values of approximately 60–65 emu/g. These results are consistent with the magnetic response expected for nanoscale magnetite particles. The MNPs were stabilized using sodium citrate during synthesis, and all concentrations reported in this study correspond to the total mass of MNPs per unit volume of suspension or phantom inclusion.

Figure 1 presents the characterization of the nanoparticles together with the gelatin/agar phantom developed for the experiments, containing $200\,\mu$L inclusions with MNP concentrations of 10, 20, 30, 40, and 50 mg/mL. The use of the same phantom for MMUS and PAI enabled the response of the two imaging modalities to be evaluated using the same concentration series and phantom geometry as shown in Figure 1(c).

For the ACB measurements, the excitation frequency was set to 10 kHz, with a lock-in amplifier gain of 0 dB and a sensitivity of 10 mV. The excitation coil was driven with 13.2 V RMS (approximately 37.6 Vpp) and a current of 56.4 mA. Measurements were performed for MNP concentrations of 10, 20, 30, 40, and 50 mg/mL. For the suspension measurements, the response was corrected by subtracting the signal obtained from a reference sample containing 200 μL of Milli-Q water. The ACB response was characterized in terms of the magnitude (R) and phase (θ) of the detected signal.

Figure 2(a) presents the magnitude (R) and phase (θ) obtained by ACB for MNP suspensions at different concentrations. A progressive decrease in the values of R and θ was observed with increasing MNP concentration. However, this variation represents the displacement of the measured signal relative to the reference condition containing only Milli-Q water. Considering the difference between the reference signal and the signal obtained for each concentration, a progressive

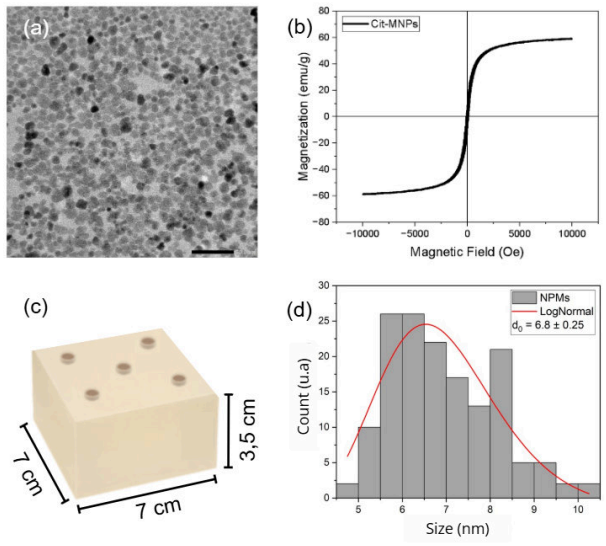

Fig. 1. (a) transmission electron microscopy (TEM) image; (b) room-temperature magnetization curve (emu/g) as a function of the applied magnetic field (Oe); (c) illustration of the gelatin/agar phantom containing inclusions with different MNP concentrations ; (d) histogram of the MNP size distribution.

increase in the response associated with the MNPs was observed. The mean magnitude variation (ΔR) increased from 1.19 mV at 10 mg/mL to 6.23 mV at 50 mg/mL, while the mean phase variation ($\Delta\theta$) increased from 2.38° to 18.77° over the same concentration range.

To quantitatively assess the dependence of the ACB response on MNP concentration, linear regressions were performed between the concentration (C) and both ΔR and $\Delta\theta$. The magnitude variation was described by $\Delta R = (0.1252 \pm 0.0403)C + 0.286$, with $R^2 = 0.9702$, where the uncertainty corresponds to the 95% confidence interval of the slope. Similarly, the phase variation was described by $\Delta\theta = (0.4108 \pm 0.0512)C - 1.948$, with $R^2 = 0.9954$. The high coefficients of determination indicate a strong positive linear relationship between the ACB response and MNP concentration, demonstrating the sensitivity of the technique to the amount of magnetic material present in the samples.

The detection capability of the ACB system was further evaluated from the calibration curve. The limit of detection (LOD) was estimated according to

$$\mathrm{LOD} = \frac{3.3\sigma_{\mathrm{blank}}}{S}, \tag{1}$$

Where σ_{blank} is the standard deviation of the blank response and S is the slope of the calibration curve. The blank response was obtained from $n = 3$ repeated measurements of an Eppendorf tube containing 200 μL of Milli-Q water, measured under the same experimental conditions as the MNP suspensions. For the magnitude response, the standard deviation obtained from the repeated blank measurements was approximately 0.021 mV, and the slope of the ΔR versus concentration calibration curve was 0.1252 mV/(mg/mL). Thus, an estimated LOD of approximately 0.55 mg/mL was obtained.

Figure 2(b) presents the two-dimensional map obtained from the spatial scanning of the biosusceptometer over the phantom, followed by interpolation of the acquired data. The map enabled the spatial visualization of the regions corresponding to the inclusions containing MNPs, with different response levels according to the concentration of magnetic material, thereby facilitating the identification and localization of the inclusions. In the representation shown, the magnitude scale was inverted during data processing, such that lower displayed values correspond to regions with higher experimentally measured magnetic responses. Thus, the dark-blue region, associated with the lowest value on the displayed scale, corresponds to the inclusion with the highest MNP concentration, whereas the other regions exhibit progressively lower responses according to the MNP concentration. This inversion was applied exclusively for graphical representation and does not alter the experimental values obtained during the spatial scan.

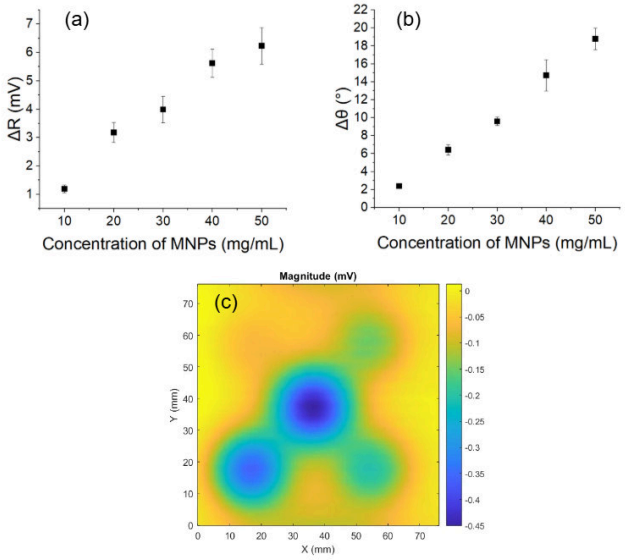

Fig. 2. ACB results: (a) magnitude (R) and (b) phase (θ) variations relative to the reference for different MNP concentrations; (c) interpolated two-dimensional map obtained from the spatial scan performed over the phantom.

In the MMUS experiments, the mechanical displacement of the surrounding medium induced by the magnetic excitation was detected in the regions containing MNPs. Each inclusion was subjected to magnetic field pulses of approximately 0.1 T with a duration of 6 ms, generated by a 130-turn coil with a ferromagnetic core. Ultrasound signal acquisition was performed using a programmable Verasonics ultrasound platform coupled to a linear L14-5/38 transducer, with a center frequency of 9.5 MHz and an acquisition rate of 4 kHz. The transducer was positioned to monitor the displacements produced in the MNP-containing regions during the application of the magnetic pulses. The MMUS response was quantified as the magnetically induced displacement, expressed in μm.

Larger displacements were observed at higher nanoparticle concentrations, consistent with the greater amount of magnetic material within the inclusions. Despite the inherent variability of the phantom, the results demonstrated the ability of MMUS to generate mechanical contrast associated with the presence and concentration of MNPs.

Three repeated acquisitions were performed for each MNP concentration. An example of the acquired B-mode image for the 30 mg/mL inclusion is shown in Figure 3(a), together with the corresponding MMUS displacement map in Figure 3(b).The mean displacement increased from 9.33 ± 1.15 μm at 10 mg/mL to 31.67 ± 3.51 μm at 50 mg/mL. The corresponding mean displacements for 20, 30, and 40 mg/mL were 12.00 ± 2.00, 20.00 ± 0.00, and 23.00 ± 2.65 μm, respectively, as shown in Figure 3(c). The zero standard deviation at 30 mg/mL reflects the displacement quantization of the estimation method rather than perfect repeatability. A linear regression between MNP concentration and mean displacement yielded $D = (0.57 \pm 0.06)C + 2.5$, with $R^2 = 0.969$, indicating a strong positive association between MNP concentration and the magnetically induced displacement under the investigated conditions.

For PAI, the inclusions containing MNPs exhibited enhanced photoacoustic contrast relative to the surrounding gelatin matrix. This behavior is attributed to the increased optical absorption promoted by the MNPs, which enhances the generation of photoacoustic waves detected by the ultrasound transducer [3].

An increase in the maximum temperature was observed with increasing MNP concentration, rising from 26.4 °C to 34.9 °C between the concentrations of 10 and 50 mg/mL. In contrast, the mean Specific Loss Power (SLP) decreased from 5.87 W/g to 4.56 W/g, indicating a reduction in the heating efficiency per unit mass of nanoparticles. This behavior is consistent with previous reports and may be attributed to enhanced dipolar interactions and nanoparticle aggregation in more concentrated suspensions, which restrict the magnetic relaxation mechanisms responsible for heat generation [7].

The same phantoms used in the MMUS experiments were employed for photoacoustic imaging (PAI). Optical excitation was performed using a Nd:YAG laser coupled to an OPO system (AcousticX), operating at 750 nm and 10 Hz. The photoacoustic signals were acquired using an L14-5/38 linear transducer with a sampling frequency of 40 MHz. The images were normalized by the energy of each laser pulse, and the photoacoustic response was quantified using the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR).

For the PAI measurements, a single acquisition was performed for each MNP concentration; therefore, no repeated measurements were available to estimate experimental variability. The results are consequently presented as descriptive values and interpreted primarily as qualitative trends rather than as statistically validated differences between concentrations. For quantitative analysis, a square region of interest (ROI) of 5×5 mm was positioned within each MNP-containing inclusion, and an additional ROI of the same size

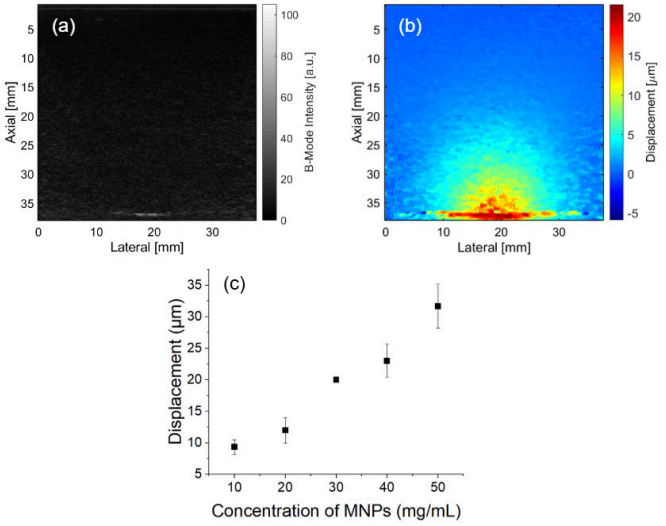

Fig. 3. MMUS results obtained from the phantom containing different MNP concentrations: (a) B-mode image of the 30 mg/mL inclusion; (b) MMUS displacement map for the 30 mg/mL inclusion; (c) displacement amplitude as a function of MNP concentration.

was selected in the surrounding background region. The B-mode image of the phantom is shown in Figure 4(a), while the corresponding photoacoustic image acquired at 750 nm is presented in Figure 4(b). The PAI response was quantified using the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) calculated from the ROI. The measured SNR values were 22.10, 23.31, 24.80, 26.76, and 27.25 dB, while the corresponding CNR values were 11.20, 13.07, 15.90, 19.81, and 21.39 dB for MNP concentrations of 10, 20, 30, 40, and 50 mg/mL, respectively, as shown in Figure 4(c) and Figure 4(d). The increase in these parameters indicates enhanced photoacoustic signal and contrast with increasing MNP concentration, which can be associated with the greater optical absorption provided by the nanoparticles [3]. Although the results indicate a concentration-dependent trend, statistical analysis with a larger number of repetitions would be required to establish the significance and reproducibility of the observed differences.

Overall, the PAI results demonstrate a concentration-dependent increase in both SNR and CNR under the investigated experimental conditions. However, because the present analysis does not include statistical tests between concentrations, the observed differences should be interpreted as a trend rather than as statistically confirmed differences. Additional repeated measurements and statistical analysis would be necessary to assess the significance and reproducibility of the concentration dependence.

MH experiments were performed using 200 μL of MNP suspension exposed to an alternating magnetic field at 222 kHz and 300 A for 10 min using an EasyHeat system (Ambrell). Temperature was monitored using a fiber-optic temperature sensor positioned directly in the suspension, with an initial temperature of approximately 22.6 °C. The maximum

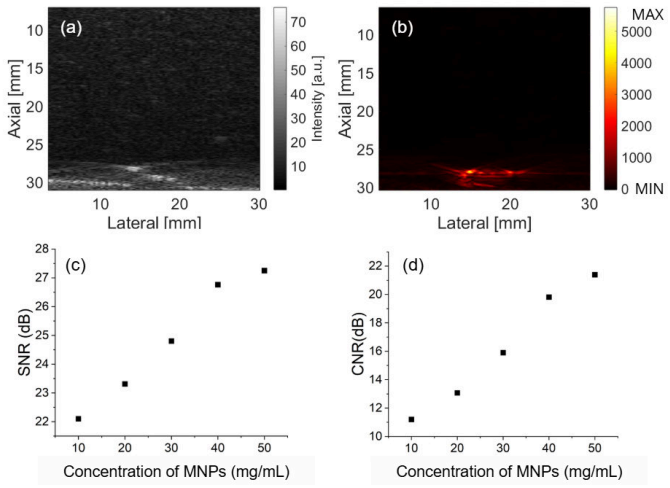

Fig. 4. PAI results: (a) B-mode image of a phantom containing inclusion with MNPs; (b) PA images, acquired at 750 nm; (c) SNR and (d) CNR as a function of MNPs concentration.

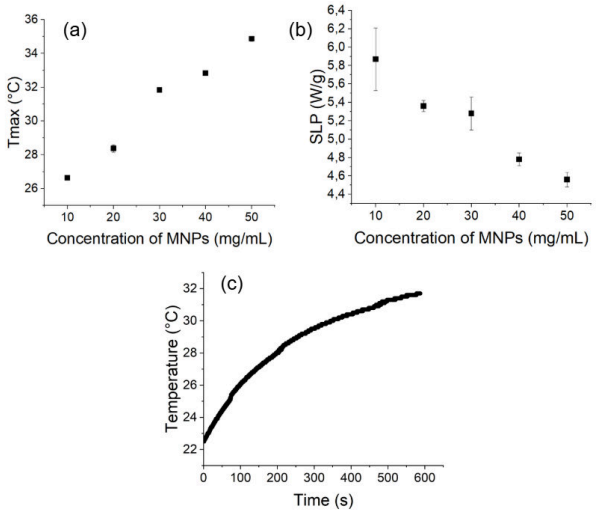

Fig. 5. MH results: (a) maximum temperature variation; (b) specific loss power (SLP); (c) temperature evolution.

temperature increased from 26.4 °C to 34.9 °C for MNP concentrations from 10 to 50 mg/mL, respectively, as shown in Figure 5(a), indicating greater heating with increasing nanoparticle concentration.

The specific loss power (SLP) was calculated according to

$$\mathrm{SLP} = \frac{C_{\mathrm{eff}}}{m_{\mathrm{MNP}}} \left(\frac{dT}{dt} \right) t \to 0, \tag{2}$$

where C_{eff} is the effective heat capacity of the sample (J/K), m_{MNP} is the total mass of Fe_3O_4 nanoparticles in the sample (g), and dT/dt is the initial heating rate (K/s), resulting in SLP values expressed in W/g. No correction for heat losses to the surroundings was applied. The obtained SLP values were 5.87 $\pm$ 0.34, 5.36 $\pm$ 0.06, 5.28 $\pm$ 0.18, 4.78 $\pm$ 0.07, and 4.56 $\pm$ 0.08 W/g for 10, 20, 30, 40, and 50 mg/mL, respectively, as shown in Figure 5(b). Despite the increase in the total amount of magnetic material, SLP decreased by approximately 22% over the investigated concentration range. This behavior may be related to concentration-dependent magnetic interactions and changes in the relaxation mechanisms; however, possible aggregation or structural changes after heating were not directly characterized in this study and therefore cannot be established as the cause.

The temperature profiles showed a progressive increase in the final temperature with MNP concentration, as illustrated in Figure 5(c). After MH, the ACB measurements exhibited changes in both amplitude (ΔR) and phase ($\Delta\theta$), with ΔR values of 0.028, -0.058, 0.154, 0.175, and 0.225 mV and $\Delta\theta$ values of 0.023, -0.367, 0.183, 0.213, and 0.267° for 10–50 mg/mL, respectively. The corresponding changes in ACB amplitude (ΔR) are shown in Figure 6(a), while the changes in phase ($\Delta\theta$) are shown in Figure 6(b). The increase in ΔR at higher concentrations suggests a concentration-dependent change in the magnetic response after heating. However, the non-monotonic behavior at lower concentrations and the absence of post-heating structural characterization prevent a definitive attribution of these changes to nanoparticle aggregation or dipolar interactions. Complementary characterization before and after MH would be required to investigate these effects.

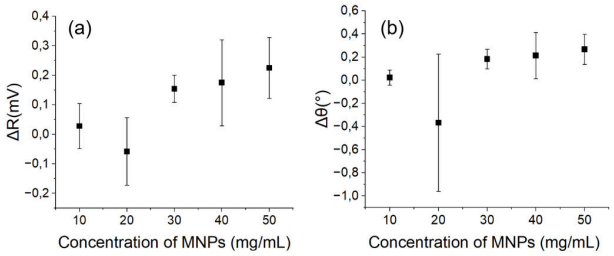

Fig. 6. ACB results after MH: (a) changes in ACB amplitude (ΔR) as a function of MNP concentration; (b) changes in ACB phase ($\Delta\theta$) as a function of MNP concentration.

Although ACB, MMUS, PAI, and MH rely on different physical mechanisms, all techniques exhibited consistent responses to the presence of the MNPs. These results demonstrate that a single nanoparticle formulation can provide complementary magnetic, mechanical, optical, and thermal information. Further studies involving biocompatibility assessment, stability in biological media, post-hyperthermia structural characterization, and integrated multimodal experiments are required before biomedical applications can be established.

IV. Conclusion

The present study investigated the performance of MNPs synthesized by the coprecipitation method in four distinct modalities: ACB, MMUS, PAI, and MH. The results demonstrated that all techniques were capable of detecting the presence of the MNPs, although with different sensitivities and contrast mechanisms.

In ACB, ΔR and $\Delta\theta$ varied linearly with MNP concentration ($R^2 = 0.9702$ and 0.9954; estimated LOD ≈ 0.55 mg/mL), and two-dimensional scanning enabled the localization of the inclusions. Concentration-dependent changes in amplitude and phase were observed after the hyperthermia cycles.

In MMUS, an increasing trend in the induced mechanical displacement was observed with increasing nanoparticle concentration, rising from approximately $9.33\,\mu$m at the lowest concentration to nearly $31.67\,\mu$m at 50 mg/mL. A linear relationship was observed between MNP concentration and mean displacement over the investigated concentration range. In PAI, photoacoustic contrast increased with nanoparticle concentration, highlighting the potential of the MNPs as optical contrast agents in tissue-mimicking environments. In MH, the maximum temperature increased with MNP concentration, exhibiting an approximately 31% increase between 10 and 50 mg/mL. Conversely, SLP decreased by approximately 22%, a behavior attributed to enhanced interparticle interactions and the consequent reduction in magnetic relaxation efficiency at higher concentrations.

Overall, the results demonstrate the feasibility of characterizing a single magnetite-based MNP formulation through complementary magnetic, mechanical, optical, and thermal modalities. Each modality probes distinct physical properties of the same nanoparticle formulation, highlighting their complementary responses across the investigated concentration range.

***Abstract*—Cobalt ferrite nanoparticles have high magnetocrystalline anisotropy, making them attractive candidates for magnetic hyperthermia and theranostics. However, their coercivity and magnetic dipole attraction favor macroscopic aggregation and rapid sedimentation. This work reports the synthesis of citrate-functionalized cobalt ferrite nanoparticles via co-precipitation, evaluating the effect of washing procedures and pH control on colloidal stability. Characterization was conducted using Alternating Current Biosusceptometry (ACB), Dynamic Light Scattering (DLS), Small-Angle X-ray Scattering (SAXS), and Electrophoretic Light Scattering (ELS). The non-optimized protocol showed macroscopic aggregation (hydrodynamic radius $R \approx 1380.5$ nm) and a negligible ACB signal (0.027 mV) due to particle settling. Exhaustive washing to lower ionic strength combined with surface charge adjustment to pH 8.85 yielded an ACB signal of 56.6 mV, stability across 30 days, and a mean zeta potential of -22 ± 1 mV. DLS and SAXS analyses confirmed a bimodal size distribution dominated by primary nanoparticles ($R = 6.9$ nm, 80.6% mass fraction) along with a secondary nanocluster fraction ($R = 52.8$ nm, 19.4% mass fraction) bounded by a maximum inorganic dimension of $D_{\max} \approx 75$ nm. Electrolyte removal and surface charge optimization were essential to obtain stable cobalt ferrite suspensions in aqueous media.**

I. Introduction

Magnetic nanoparticles are widely investigated as platforms for combined diagnostic imaging and localized therapy in nanomedicine. Cobalt ferrite ($CoFe_2O_4$), an inverse spinel oxide, exhibits higher magnetocrystalline anisotropy and Specific Loss Power (SLP) than classical magnetite (Fe_3O_4), which favors magnetic fluid hyperthermia [1]–[3]. Previous reports indicate that small cobalt ferrite nanoparticles ($\approx$ 12 nm) produce high heating rates under alternating magnetic fields [4].

In $CoFe_2O_4$, Fe^{3+} cations occupy tetrahedral and octahedral interstitial sites, whereas Co^{2+} ions reside predominantly in octahedral sites, yielding a strong uncompensated magnetic moment and orbital angular momentum coupling [5]. In bulk form, cobalt ferrite exhibits high coercivity and remanence. When nanoparticles exceed the superparamagnetic limit or lack adequate surface charge, magnetic dipole-dipole attraction causes particle aggregation [6].

In physiological settings, macroscopic aggregates lead to sedimentation, vessel occlusion risks, and rapid clearance by the reticuloendothelial system (RES) in the liver and spleen [7], [8]. Uncontrolled clusters can also modify cellular toxicity profiles through reactive oxygen species generation [9].

Electrostatic stabilization using citrate ions is commonly employed to control aggregation. Citrate binds to surface metal sites via carboxyl groups, leaving uncoordinated carboxylates (COO^-) to generate repulsive forces. Still, electrostatic stabilization remains vulnerable to ionic screening. Residual synthesis salts, such as NaCl, compress the electric double layer (EDL), screening surface charges and enabling dipolar agglomeration [10].

Here, we evaluate the synthesis, purification, and colloidal properties of citrate-functionalized $CoFe_2O_4$ nanoparticles prepared via co-precipitation. We compare a preliminary purification route with an optimized washing protocol, examining the relationship between electrolyte removal, pH, hydrodynamic size, inorganic core structure, zeta potential, and magnetic response in vitro. Characterization was carried out using Alternating Current Biosusceptometry (ACB), Dynamic Light Scattering (DLS), Small-Angle X-ray Scattering (SAXS), and Electrophoretic Light Scattering (ELS).

II. Materials and Methods

A. Chemical Synthesis and Stoichiometry

Cobalt ferrite nanoparticles were synthesized by chemical co-precipitation. Divalent cobalt and trivalent iron hydroxides

were precipitated in an alkaline medium, followed by ferritization at $80\,^{\circ}$C:

$$\mathrm{Co}^{2+}_{(\mathrm{aq})} + 2\mathrm{OH}^{-}_{(\mathrm{aq})} \rightarrow \mathrm{Co(OH)}_{2(\mathrm{s})}, \tag{1}$$

$$2\mathrm{Fe}^{3+}_{(\mathrm{aq})} + 6\mathrm{OH}^{-}_{(\mathrm{aq})} \rightarrow 2\mathrm{Fe(OH)}_{3(\mathrm{s})}. \tag{2}$$

At pH $\approx$ 12 under continuous stirring, the hydroxides condense to form the spinel phase:

$$\mathrm{Co(OH)}_{2(\mathrm{s})} + 2\mathrm{Fe(OH)}_{3(\mathrm{s})} \rightarrow \mathrm{CoFe_2O_{4(s)}} + 4\mathrm{H_2O_{(l)}}. \tag{3}$$

The overall reaction using chloride precursors and sodium hydroxide is:

$$\begin{aligned}\mathrm{CoCl_{2(aq)}} + 2\mathrm{FeCl_{3(aq)}} + 8\mathrm{NaOH_{(aq)}} \rightarrow \\ \mathrm{CoFe_2O_{4(s)}} + 8\mathrm{NaCl_{(aq)}} + 4\mathrm{H_2O_{(l)}}.\end{aligned} \tag{4}$$

A stoichiometric $1:2$ molar ratio ($\mathrm{Co}^{2+}:\mathrm{Fe}^{3+}$) was set to synthesize 1.0 g of $\mathrm{CoFe_2O_4}$ (231.83 g/mol). Precursor salts (0.558 g $\mathrm{CoCl_2}$, 129.84 g/mol; 1.395 g $\mathrm{FeCl_3}$, 162.20 g/mol) were dissolved in 10 mL of deionized water acidified with concentrated HCl to prevent premature Fe^{3+} hydrolysis. This solution was added to 100 mL of 2 mol/L NaOH under magnetic stirring (1000 rpm).

B. Purification, Surface Treatment, and pH Control

Two purification methods were compared:

- **Preliminary Protocol:** Magnetic decantation with a standard ferrite magnet, followed by 3 washing cycles with deionized water without monitoring electrical conductivity or pH.
- **Optimized Protocol:** Magnetic decantation using high-flux NdFeB magnets, followed by surface treatment with dilute nitric acid ($\mathrm{HNO_3}$, 0.01 mol/L) to remove uncoordinated surface metal species. The precipitate was coated with trisodium citrate (0.1 mol/L) at $80\,^{\circ}$C and repeatedly washed with deionized water. Washing continued until supernatant electrical conductivity dropped below $10\,\mu$S/cm, confirming the removal of residual spectator ions (Na^{+}, Cl^{-}). The final suspension was adjusted to pH 8.85.

The target pH of 8.85 was chosen because it lies above the isoelectric point of ferrite (IEP $\approx$ 3.5–4.0) and exceeds the pK_a values of citric acid (p$K_{a1} = 3.13$, p$K_{a2} = 4.76$, p$K_{a3} = 6.40$). At this pH, carboxyl groups are deprotonated into COO^{-}, generating negative surface charge to reduce sedimentation.

C. Alternating Current Biosusceptometry (ACB)

AC magnetic susceptibility was evaluated using an ACB system consisting of a first-order gradiometric pickup coil array coupled to a lock-in amplifier. In the absence of a sample, differential flux is zero.

When a magnetic sample is introduced, the induced magnetic flux variation (Φ_B) produces an electromotive force (emf) according to Faraday's law:

$$\mathrm{emf} = -d\Phi_B/dt. \tag{5}$$

The induced voltage (mV) is proportional to the AC susceptibility and nanoparticle mass within the active sensing volume. ACB measurements were recorded in triplicate at 10-day intervals over 30 days under constant excitation (10 kHz, 2.0 mT).

D. Dynamic Light Scattering and Zeta Potential

Hydrodynamic radius (R_h) and polydispersity (%Pd) were measured by DLS (DYNAMICS, Wyatt Technology). Samples were diluted $1:1000$ in deionized water. The translational diffusion coefficient (D) was converted to R_h using the Stokes-Einstein equation:

$$R_h = \frac{k_B T}{6\pi\eta D}, \tag{6}$$

where k_B is the Boltzmann constant (1.38×10^{-23} J/K), $T = 298.15$ K, and $\eta = 0.89$ mPa $\cdot$ s. Regularization algorithms were applied for multimodal distribution analysis [11].

Surface charge and zeta potential (ζ) of the optimized sample were determined in triplicate by Electrophoretic Light Scattering (ELS) under an applied field of 18.51 V/cm, using the Smoluchowski relation.

E. Small-Angle X-ray Scattering (SAXS)

Small-Angle X-ray Scattering (SAXS) was used to assess inorganic core dimensions and size distribution in liquid dispersion. Scattering profiles $I(q)$ were acquired as a function of the momentum transfer $q = (4\pi/\lambda)\sin\theta$. Indirect Fourier transformation was used to calculate the volume-weighted size distribution $D_v(r)$ as a function of the characteristic real-space dimension r and determine the maximum cluster dimension ($D_{\max}$).

III. Results and Discussion

A. ACB Magnetic Signal and Temporal Stability

ACB measurements showed clear differences between the preparation routes (Table I). The preliminary protocol gave a low induced voltage (0.027 ± 0.005 mV), remaining near the electronic noise floor of the system.

TABLE I
Temporal ACB Induced Voltage Signal Comparison

	Induced Voltage Signal (mV)	
Measurement Interval	**Preliminary Protocol**	**Optimized Protocol**
Day 10	0.030 ± 0.005	55.4 ± 0.8
Day 20	0.030 ± 0.004	56.6 ± 0.8
Day 30	0.020 ± 0.003	56.6 ± 0.7
Overall Mean	$\mathbf{0.027 \pm 0.005}$	$\mathbf{56.2 \pm 0.8}^{*}$

*Significant difference compared to preliminary protocol ($p < 0.001$).

The optimized protocol produced a stable average signal of 56.2 ± 0.8 mV. An unpaired two-tailed Student's t-test indicated a statistically significant difference between protocols

($p < 0.001$). One-way ANOVA across the 30-day window showed no significant signal decay ($p > 0.05$), confirming that the particles remained suspended over time in deionized water.

B. Hydrodynamic Size, Zeta Potential, and DLVO Analysis

DLS data accounted for the differences observed in the ACB response. In the preliminary protocol (Fig. 1), DLS revealed substantial aggregation. Although primary particles ($R = 4.6$ nm) represented 74.5% of the estimated mass, light scattering intensity was dominated (95.3%) by a macro-aggregate population ($R \approx 1380.5$ nm, $\%\text{Pd} = 161.1\%$). Because Rayleigh scattering scales with $I \propto R^6$, large aggregates accounted for nearly all scattered light and settled rapidly, removing magnetic material from the sensing volume of the ACB coils.

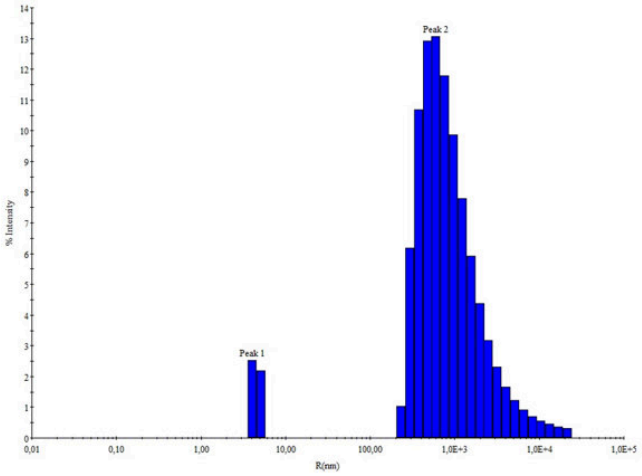

Fig. 1. Hydrodynamic radius intensity distribution for the preliminary non-optimized protocol, showing macroscopic aggregation ($R \approx 1380.5$ nm).

According to DLVO theory, unwashed Na^+ and Cl^- ions increase solution ionic strength and compress the double layer. This reduces electrostatic repulsion, allowing attractive van der Waals and magnetic dipole interactions to cause coagulation [10].

In the optimized protocol, electrolyte removal and pH adjustment suppressed the > 1000 nm aggregate population (Fig. 2). The ACB signal increased by roughly 2080 times (from 0.027 mV to 56.60 mV), with 80.6% of the mass concentrated in primary nanoparticles ($R = 6.9$ nm, hydrodynamic diameter $D_h \approx 13.8$ nm), as summarized in Table II.

TABLE II
COMPARATIVE DLS MULTIMODAL SIZE DISTRIBUTION PARAMETERS

	Preliminary Protocol		Optimized Protocol	
Parameter	**Peak 1**	**Peak 2**	**Peak 1**	**Peak 2**
Radius (R)	4.6 nm	1380.5 nm	6.9 nm	52.8 nm
Polydispersity (%Pd)	11.9%	161.1%	13.8%	43.6%
Intensity (%Int)	4.7%	95.3%	2.9%	97.1%
Mass (%Mass)	74.5%	23.5%	80.6%	19.4%

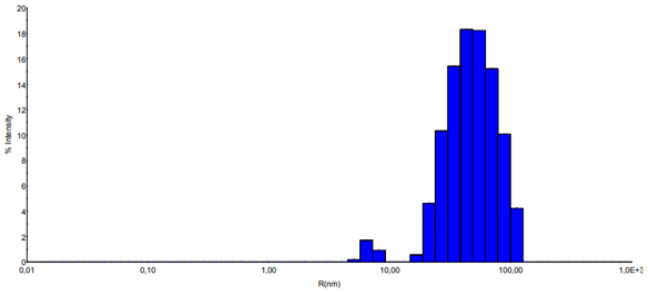

Fig. 2. Hydrodynamic radius intensity distribution for the optimized protocol, showing a bimodal distribution ($R_1 = 6.9$ nm, $R_2 = 52.8$ nm).

Electrophoretic light scattering indicated a mean zeta potential of -22 ± 1 mV (Fig. 3, Table III), confirming negative surface charge from deprotonated carboxylates at pH 8.85.

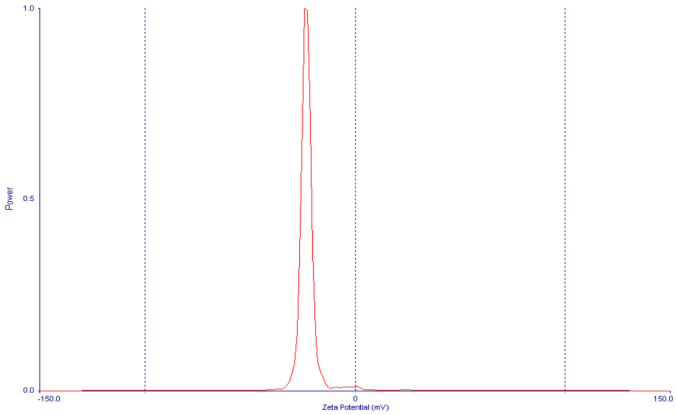

Fig. 3. Zeta potential distribution of the optimized citrate-functionalized $CoFe_2O_4$ suspension.

TABLE III
ELECTROPHORETIC LIGHT SCATTERING ZETA POTENTIAL RUNS

Run	**Zeta Potential (mV)**	**Half Width (mV)**	**Data Retention (%)**
1	-19.76	5.91	44%
2	-22.46	2.80	44%
3	-23.87	2.60	67%
Mean $\pm$ SD	$\mathbf{-22 \pm 1}$	$\mathbf{4 \pm 1}$	**52%**

From a DLVO perspective, a zeta potential of -22 mV provides moderate stability, whereas absolute values above 30 mV are normally required for full electrostatic repulsion. Because cobalt ferrite has strong magnetic anisotropy and permanent dipoles, this moderate charge does not completely eliminate dipole-dipole attractions [6]. As a result, a secondary population of small clusters ($R = 52.8$ nm, 19.4% mass fraction) remained in suspension.

C. Nanostructural Validation via SAXS

SAXS measurements were used to probe inorganic core dimensions in liquid dispersion (Fig. 4). The scattering curve

$I(q)$ decayed smoothly and matched the model fit across the entire q-range, showing no scattering features associated with micron-sized aggregates (Fig. 4a).

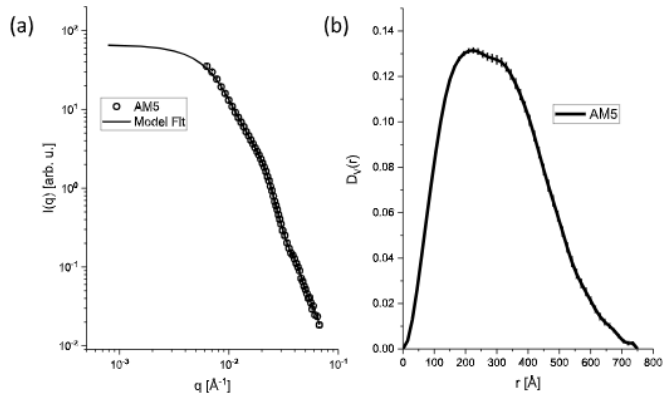

Fig. 4. SAXS data for the optimized $CoFe_2O_4$ suspension: (a) scattering intensity $I(q)$ and model fit, and (b) volume distribution $D_v(r)$ as a function of characteristic real-space dimension r.

The volume-weighted size distribution $D_v(r)$ extracted by indirect Fourier transformation shows a peak centered at $r \approx 230$ Å (23 nm) and reaches a maximum dimension of $D_{\max} \approx 750$ Å (75 nm) (Fig. 4b).

When comparing SAXS and DLS, the physical differences between both techniques must be considered. DLS measures the hydrodynamic radius (R_h), which includes the inorganic core, surface citrate molecules, and the surrounding hydration layer. In contrast, SAXS detects the electron-dense inorganic core. Because scattering scales with particle volume ($I \propto V^2$), the SAXS $D_v(r)$ curve is weighted toward the small cluster population rather than isolated cores ($R_h = 6.9$ nm, $D_h \approx 13.8$ nm).

The maximum inorganic dimension ($D_{\max} \approx 75$ nm) from SAXS is consistent with the cluster population identified by DLS ($R_h = 52.8$ nm, or $D_h \approx 105.6$ nm). The ≈ 30 nm difference between techniques stems from the distinct weighting in SAXS (volume-weighted) versus DLS ($I \propto R^6$), the contribution of the citrate/hydration layer (1–3 nm), and the increased hydrodynamic drag of non-spherical clusters. SAXS and DLS therefore point to the same conclusion: the secondary fraction consists of sub-100 nm clusters rather than macro-aggregates. This prevented gravitational settling and preserved the ACB signal over time.

D. Perspectives and Biological Considerations

The synthesis yielded primary cores ($R = 6.9$ nm) and clusters limited to < 75 nm, but stability in deionized water does not ensure the same behavior in physiological environments. At physiological salt concentrations (≈ 150 mmol/L NaCl), electrolyte screening compresses the electrical double layer, reducing the -22 mV electrostatic barrier [8]. Serum protein adsorption also forms a protein corona, which can trigger agglomeration and accelerate macrophage clearance in the liver and spleen [7], [8].

Future studies should assess colloidal stability under physiological conditions. In particular, DLS, zeta potential, and ACB measurements in PBS and protein-supplemented media (such as FBS or plasma) should be monitored immediately after dispersion and after 24–48 hours. To suppress the 19.4% cluster fraction and prevent salt-induced aggregation, steric coatings like PEGylation or amphiphilic polymers will be required prior to in vitro cytotoxicity, hemocompatibility, and in vivo biodistribution experiments [12].

IV. Conclusion

Controlling electrolyte content and pH improved the colloidal stability of cobalt ferrite nanoparticles synthesized by co-precipitation. Washing the suspension to an electrical conductivity below $10\,\mu$S/cm and setting the pH to 8.85 produced a zeta potential of -22 ± 1 mV and increased the ACB signal to 56.6 mV. DLS and SAXS confirmed a bimodal size distribution dominated by primary nanoparticles ($R = 6.9$ nm, 80.6% mass), alongside a cluster fraction bounded below 75 nm (19.4% mass), demonstrating that citrate electrostatic repulsion alone cannot fully overcome magnetic dipole attractions. Future work will focus on stability tests in PBS and protein media across 24–48 hours, combined with steric polymer coatings (such as PEG) before proceeding to biological evaluation.

***Abstract*— Bacterial resistance and chronic wound infections motivate the development of antimicrobial dressings able to combine structural support and local active delivery. This study produced electrospun polyvinyl alcohol nonwoven mats functionalized with silver nanoparticles and neomycin sulfate, isolated or associated, and evaluated their chemical, morphological and antimicrobial performance against *Staphylococcus aureus* and *Escherichia coli*. A 10 percent PVA solution with 0.5 percent citric acid was electrospun after incorporation of the active agents. The systems were characterized by scanning electron microscopy, energy dispersive spectroscopy, ultraviolet visible spectroscopy and Fourier transform infrared spectroscopy, and antimicrobial activity was tested by agar diffusion. Scanning electron microscopy showed spherical silver nanoparticles with mean diameter of 77.7 nm and continuous fibers with mean diameter close to 314 nm after functionalization. Energy dispersive spectroscopy confirmed silver in the composite, and infrared spectroscopy suggested preservation of the PVA structure with interactions between the polymeric matrix and the incorporated agents. Pure PVA did not inhibit bacterial growth. The combined silver nanoparticle and neomycin system produced the largest inhibition halos for both bacterial strains, increasing inhibition from 16.07 mm to 20.53 mm for *S. aureus* and from 8.97 mm to 15.64 mm for *E. coli* compared with neomycin alone. The results show larger inhibition halos for the combined formulation under the tested conditions and support further investigation of electrospun PVA containing silver nanoparticles and neomycin for antimicrobial wound dressing applications.**

***Keywords*—electrospinning; polyvinyl alcohol; silver nanoparticles; neomycin sulfate; wound dressing; antimicrobial activity**

I. INTRODUCTION

Chronic and infected wounds remain an important public health challenge because delayed tissue repair increases the risk of local infection, systemic complications, prolonged treatment, and higher healthcare costs [1]. The skin acts as the main physical barrier of the organism, and its disruption becomes especially critical in patients with impaired healing, such as individuals with diabetes or other comorbidities, in whom inflammatory response, collagen deposition, angiogenesis, and tissue regeneration may be compromised [1], [2]. Therefore, wound dressings are no longer considered only passive protective barriers; advanced dressings are expected to maintain a moist environment, manage exudate, protect the lesion, and, when possible, deliver therapeutic agents directly to the wound site [2], [3].

This need becomes even more relevant in the context of antimicrobial resistance. The excessive and inappropriate use of antibiotics has accelerated the emergence of resistant bacterial strains, making infections more difficult to treat and increasing the clinical relevance of localized antimicrobial systems [4]. In wound infections, *Staphylococcus aureus* and *Escherichia coli* are frequently used as representative experimental models because they differ in cell-wall organization and antimicrobial susceptibility. Gram-positive bacteria, such as *S. aureus*, have a thick peptidoglycan layer, whereas Gram-negative bacteria, such as *E. coli*, possess an additional outer membrane that may act as a permeability barrier and reduce the effectiveness of antimicrobial compounds [5].

Thus, the development of wound dressings capable of combining structural support with local antimicrobial action represents a promising strategy to address infected wounds while reducing dependence on systemic antibiotic exposure. For this purpose, the dressing matrix must provide adequate porosity, high surface area, close contact with the wound bed, and the possibility of incorporating active agents in a controlled and homogeneous manner. In this scenario, electrospinning has

emerged as a simple and versatile technique for producing polymeric nanofibers from solutions subjected to a high-voltage electric field [6], [7], [8]. During the process, the polymeric solution is stretched into fine fibers that are deposited as a nonwoven mat, producing materials with high surface area, interconnected porosity, and structural similarity to the extracellular matrix [6], [7]. These characteristics are especially attractive for wound dressing applications because they may support fluid exchange, improve contact with the wound bed, and allow the incorporation of bioactive agents, including nanoparticles and antibiotics [3], [9].

Among the polymers used for electrospun wound dressings, polyvinyl alcohol (PVA) is widely investigated due to its hydrophilicity, biocompatibility, low toxicity, low cost and ability to form continuous fibers [9], [10]. Its hydroxyl-rich structure favors water retention and interaction with incorporated compounds, making it suitable for the development of functional wound dressing platforms [9], [10]. However, although PVA-based materials present favorable physicochemical properties for biomedical use, PVA itself does not exhibit intrinsic antibacterial activity. Therefore, the incorporation of antimicrobial agents into the PVA matrix is an important strategy to improve its biological performance [10], [11].

Neomycin sulfate is an aminoglycoside antibiotic commonly associated with topical antimicrobial strategies due to its activity against clinically relevant bacteria and its applicability in localized treatments. In wound-related applications, the local delivery of antibiotics may increase the antimicrobial concentration at the infection site while minimizing systemic exposure and associated adverse effects. However, the widespread and prolonged use of antibiotics has contributed to the emergence of antimicrobial resistance, reducing the effectiveness of conventional therapies and highlighting the need for alternative approaches to control wound infections [4]. In this study, neomycin sulfate was selected as the antibiotic model because it is compatible with topical antimicrobial approaches and allows the evaluation of antibacterial performance when incorporated into an electrospun PVA matrix. Its association with the polymeric dressing also enables comparison between the isolated antibiotic effect and the combined effect with silver nanoparticles.

In this context, silver nanoparticles (AgNPs) have attracted considerable attention because of their broad-spectrum antimicrobial activity and their multiple mechanisms of action. AgNPs may interact with bacterial membranes, proteins, and nucleic acids, promoting membrane disruption, oxidative stress, enzyme inhibition, and impairment of microbial replication [5], [12]. Furthermore, their incorporation into electrospun polymeric fibers can provide localized antimicrobial activity and improve the functionality of wound dressing systems [3], [10]. Previous studies have reported enhanced antibacterial responses when AgNPs are combined with conventional antibiotics, with proposed mechanisms including increased bacterial membrane permeability and simultaneous action on multiple cellular targets [13]. These literature reports provide a mechanistic rationale for evaluating the combined formulation, but they do not establish synergy in the present material.

Based on this rationale, the present study aimed to develop electrospun PVA nonwoven mats containing AgNPs and neomycin sulfate, either alone or in association, and to evaluate their antimicrobial activity against *S. aureus* and *E. coli*. This approach provides a materials-engineering basis for further evaluation of multifunctional nanofibrous wound dressing systems.

II. Materials and Methods

This section describes the experimental strategy used to produce and evaluate electrospun PVA-based nonwoven mats associated with silver nanoparticles (AgNPs) and neomycin sulfate (Neo). The methodology comprised the preparation of the biological model and active compounds, fabrication of the electrospun mats, and evaluation of their physicochemical, morphological and antimicrobial properties.

A. Electrospinning of PVA-based nonwoven mats

The electrospinning solution consisted of 10% (w/v) poly(vinyl alcohol) (PVA) and 0.5% (w/v) citric acid dissolved in distilled water under continuous magnetic stirring at approximately 45 °C until complete dissolution. The solution was then cooled to room temperature before use.

Four electrospinning formulations were prepared: PVA, PVA/AgNPs, PVA/Neo, and PVA/AgNPs/Neo. The control formulation (PVA) consisted only of the polymeric solution. For the PVA/AgNPs formulation, 2.13 mg of silver nanoparticles purchased from Nanostructured & Amorphous Materials, Inc. were added to 1.5 mL of the polymeric solution and stirred at approximately 45 °C until a homogeneous dispersion was obtained. The PVA/Neo formulation was prepared by incorporating 3.75 mg of neomycin sulfate into 1.5 mL of the polymeric solution under the same conditions. For the dual-functionalized formulation (PVA/AgNPs/Neo), 2.13 mg of AgNPs and 3.75 mg of neomycin sulfate were simultaneously added to 1.5 mL of the polymeric solution and mixed until complete homogenization. These values represent the nominal amounts added during formulation; retained loading in the final mats and the release of silver and neomycin were not quantified in this study.

Electrospinning was performed using a syringe fitted with a stainless-steel needle connected to a syringe pump operating at a flow rate of 1 mL h^{-1}. A grounded copper collector covered with aluminum foil was positioned 10 cm from the needle tip, and a voltage of 15 kV was applied between the needle and the collector. All samples were produced under low relative humidity conditions and electrospun for 3 h. Identical processing parameters were employed for all formulations to ensure reproducibility and enable direct comparison of their physicochemical, morphological, and antimicrobial properties.

B. Morphological characterization

Scanning electron microscopy (SEM) was employed to evaluate the morphology of the silver nanoparticles (AgNPs) and the electrospun PVA-based nonwoven mats. Samples were cut into small fragments, mounted on aluminum stubs using conductive carbon tape, and sputter-coated with a thin layer of gold to improve surface conductivity prior to imaging. SEM analyses were performed under high-resolution conditions using an accelerating voltage ranging from 9 to 47.5 kV. Micrographs were acquired at different magnifications to assess fiber morphology, diameter uniformity, and nanoparticle distribution within the polymeric matrix. Fiber and AgNP diameters were measured from the SEM images using ImageJ software and expressed as diameter distributions. The measurements were used descriptively; no independent batch-to-batch inferential analysis was performed for the diameter distributions. In addition, energy-dispersive X-ray spectroscopy (EDS) was performed to confirm the elemental composition and verify the presence and distribution of silver in the PVA/AgNPs and PVA/AgNPs/Neo nonwoven mats.

C. Antimicrobial assay and data analysis

Reference strains of *Escherichia coli* ATCC 25922 (Gram-negative) and *Staphylococcus aureus* ATCC 25923 (Gram-positive) were provided by the Oswaldo Cruz Laboratory (São José dos Campos, Brazil). Before the antimicrobial assays, both strains were cultured in Brain Heart Infusion (BHI) broth and incubated at 37 °C for 24 h. The cultures were subsequently streaked onto BHI agar plates to obtain isolated colonies, and bacterial purity was confirmed by Gram staining. Fresh bacterial suspensions were prepared from isolated colonies and standardized to 0.5×10^6 CFU/mL for the antimicrobial assays.

The antimicrobial activity of the electrospun nonwoven mats (PVA, PVA/AgNPs, PVA/Neo, and PVA/AgNPs/Neo) was evaluated using the agar diffusion method. Circular samples (10 mm in diameter) were placed onto BHI agar plates previously inoculated with the standardized bacterial suspensions. The plates were incubated at 37 °C for 24 h, after which the inhibition zones were photographed and measured using ImageJ software. The agar-diffusion measurements were performed in triplicate, and inhibition zone diameters were expressed as mean ± standard deviation. The triplicates were treated as replicate measurements of this screening assay. Results were analyzed descriptively, and no inferential statistical test or formal interaction/synergy analysis was performed. Therefore, comparisons among formulations are reported as differences in inhibition-zone diameter under the tested conditions.

III. Results and Discussion

The results were organized to connect the structural characterization of the materials with their antimicrobial performance. First, SEM analysis was used to evaluate the morphology and size distribution of the AgNPs and the electrospun fibers. EDS was performed to confirm the elemental composition and the presence of silver in the electrospun nonwoven mats. Finally, the disk diffusion assay was used to compare the antimicrobial activity of the formulations containing individual and combined active agents.

SEM analysis of the commercial AgNPs (Fig. 1) revealed predominantly spherical nanoparticles with a mean diameter of 77.7 nm. Although some degree of aggregation was observed, the particles remained within the nanometer size range, which is desirable for antimicrobial applications. The morphology shown in Fig. 1A is relevant because nanoparticle size and shape may influence dispersion in the polymeric solution, interaction with the electrospun fibers, and antimicrobial performance. This finding agrees with studies reporting that AgNPs present antimicrobial potential associated with their nanoscale dimensions and interaction with bacterial structures [5], [12]. Furthermore, the particle size distribution histogram (Fig. 1B) confirmed the predominance of nanoparticles within the nanometric range, supporting the dimensional analysis obtained from the SEM micrographs.

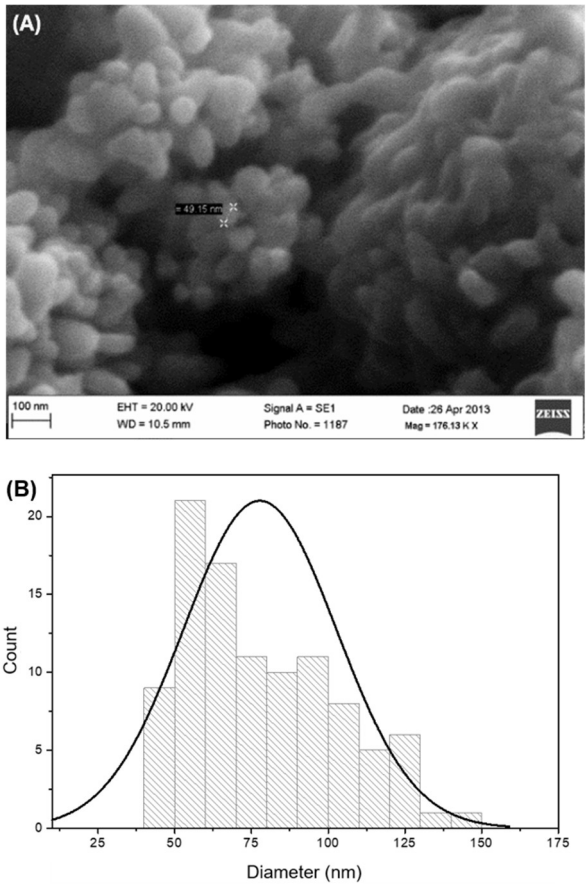

Fig. 1. Morphological characterization of the commercial silver nanoparticles (AgNPs) by scanning electron microscopy (SEM). (A) Representative SEM micrograph showing predominantly spherical nanoparticles. (B) Particle size distribution histogram based on diameter measurements obtained from the SEM images.

After confirming the nanometric dimensions of the AgNPs, SEM was used to evaluate the morphology of the electrospun nonwoven mats before and after incorporation of the

antimicrobial agents. As shown in Fig. 2B, the neat PVA mat exhibited a continuous, homogeneous, and defect-free fibrous network, indicating stable electrospinning under the selected processing conditions. Similarly, the functionalized PVA/AgNPs/Neo mat (Fig. 2C) preserved a homogeneous fibrous architecture, demonstrating that the incorporation of AgNPs and neomycin did not adversely affect fiber formation or the structural integrity of the electrospun matrix. The fibers exhibited a mean diameter of approximately 314 nm (Fig. 2A). In addition, discrete bright regions were observed along the fibers, suggesting the presence of electron-dense particles associated with the polymeric matrix.The preservation of the fibrous morphology is consistent with previous reports showing that electrospinning can produce polymeric nanofiber mats with high surface area, porosity, and structural similarity to the extracellular matrix, which are important characteristics for wound dressing applications [6], [7], [9]. In addition, PVA-based electrospun mats containing AgNPs have been described as suitable platforms for antimicrobial dressings, since the polymeric matrix can support nanoparticle incorporation while maintaining a nanofibrous structure [10]. Therefore, the morphology observed in Fig. 2 suggests that the selected processing conditions were adequate for producing PVA-based nonwoven mats containing antimicrobial agents.

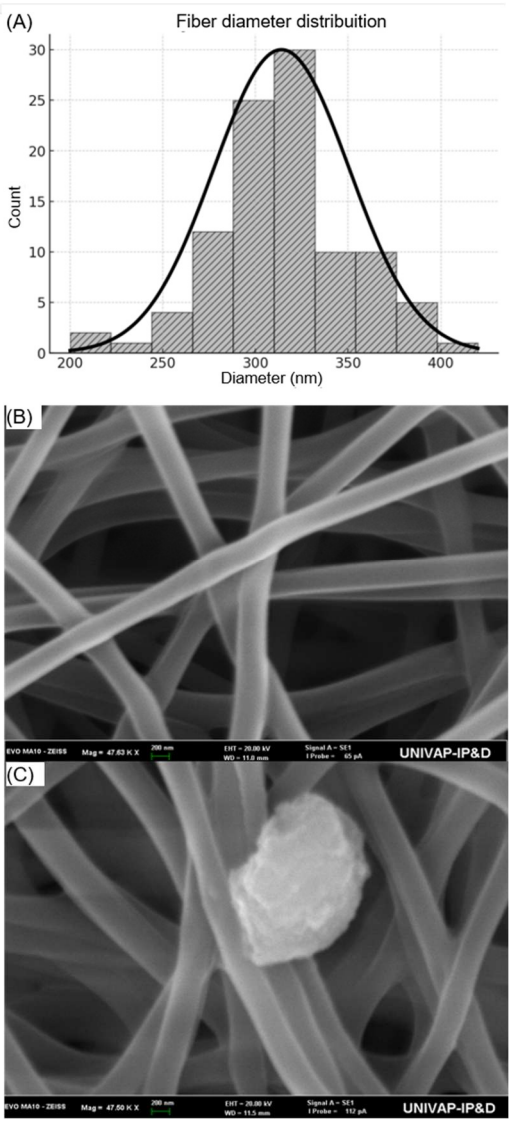

Fig. 2. SEM characterization of the electrospun PVA-based nonwoven mats. (A) Fiber diameter distribution histogram obtained from SEM image analysis. (B) Representative SEM micrograph of the neat PVA nonwoven mat showing a continuous and homogeneous fibrous network. (C) Representative SEM micrograph of the PVA/AgNPs/Neo nonwoven mat showing the incorporation of antimicrobial agents while maintaining the fibrous morphology.

To verify the elemental composition of the functionalized fibers, energy-dispersive X-ray spectroscopy (EDS) was performed. As shown in Fig. 3, the characteristic silver peak confirmed the incorporation of AgNPs into the PVA/AgNPs/Neo nonwoven mat. Gold peaks were also detected due to the gold sputter-coating applied prior to SEM analysis. In contrast, neomycin could not be directly identified because it is predominantly composed of low atomic number elements, such as C, H, O, and N, whose signals overlap with those of the PVA matrix. This limitation is consistent with the analytical nature of SEM/EDS, which is more suitable for identifying elemental composition, especially heavier elements, than for distinguishing organic molecules within polymeric matrices [14]. Therefore, EDS primarily served to confirm the

presence of the metallic component within the electrospun composite.

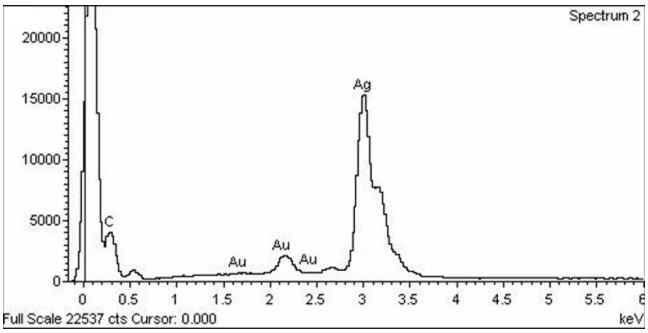

Fig. 3. Energy-dispersive X-ray spectroscopy (EDS) analysis of the PVA nonwoven material incorporated with silver nanoparticles (AgNPs) and antibiotic.

The antimicrobial performance of the electrospun nonwoven mats was evaluated by disk diffusion assay against *Staphylococcus aureus* ATCC 25923 and *Escherichia coli* ATCC 25922. The representative inhibition zones are shown in Fig. 4, while the quantitative results are summarized in Tables I and II. The neat PVA mat exhibited no inhibition halo against either bacterial strain, confirming that the polymeric matrix did not present intrinsic antibacterial activity under the tested conditions. This result is in agreement with previous reports indicating that PVA-based materials, despite their biomedical potential, generally require association with antimicrobial agents to provide antibacterial activity [10], [11]. Because diffusion-zone diameter depends on both antimicrobial action and the mobility of the active compounds through agar, halo size was interpreted as a screening outcome rather than as a direct measure of antimicrobial potency.

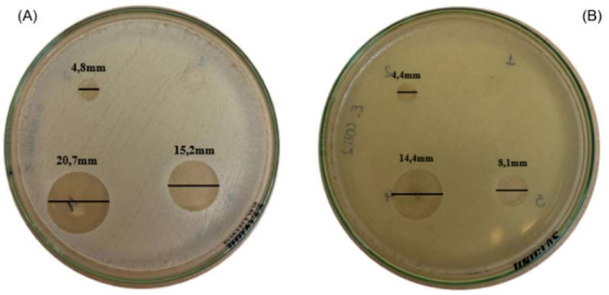

Fig. 4. Antibacterial activity of the electrospun nonwoven mats evaluated by the disk diffusion assay. (A) Staphylococcus aureus ATCC 25923. (B) Escherichia coli ATCC 25922.

For *Staphylococcus aureus*, the results presented in Table I demonstrate that the incorporation of AgNPs into the PVA matrix resulted in a moderate antibacterial response, with an inhibition halo of 5.954 ± 0.99 mm. This effect can be attributed to the antimicrobial properties of AgNPs, which have been associated with bacterial membrane damage, interaction with proteins and nucleic acids, and inhibition of microbial growth [5], [12]. However, the relatively smaller halo observed for PVA/AgNPs may be related to the immobilization of nanoparticles within the polymeric network, which can limit their diffusion through the agar medium compared with freely dispersed antimicrobial agents.

TABLE I
ANTIBACTERIAL ACTIVITY OF ELECTROSPUN NONWOVEN MATS AGAINST *Staphylococcus aureus* ATCC 25923.

Sample	Mean (mm)	SD (mm)
PVA	0.000	0.00
PVA with AgNPs	5.954	0.99
PVA with neomycin	16.068	0.70
PVA with AgNPs and neomycin	20.528	0.24

Source: Authors.

The PVA/Neo formulation exhibited a greater inhibitory effect against *S. aureus*, producing a mean inhibition halo of 16.068 ± 0.70 mm (Table I). This result indicates antibacterial activity of neomycin against the Gram-positive strain under the tested conditions. The largest inhibition halo was observed for the PVA/AgNPs/Neo formulation, which reached 20.528 ± 0.24 mm (Table I and Fig. 4A). Compared with the individual formulations, the combined system increased the inhibition halo by approximately 27.8% compared with PVA/Neo and by more than three-fold compared with PVA/AgNPs. Thus, the combined formulation produced an enhanced halo response under the tested conditions.

For *Escherichia coli*, the results summarized in Table II showed a similar trend, although the inhibition halos were lower than those observed for *S. aureus*. The PVA mat exhibited no antibacterial activity, while the PVA/AgNPs formulation produced a mean inhibition halo of 5.473 ± 1.19 mm. The PVA/Neo formulation showed an increased inhibitory effect, reaching 8.967 ± 0.72 mm (Table II, Fig. 4B). The reduced susceptibility of *E. coli* compared with *S. aureus* may be associated with the presence of an additional outer membrane characteristic of Gram-negative bacteria, which can limit the penetration and action of antimicrobial compounds.

TABLE II
ANTIBACTERIAL ACTIVITY OF ELECTROSPUN NONWOVEN MATS AGAINST *Escherichia coli* ATCC 25922.

Sample	Mean (mm)	SD (mm)
PVA	0.000	0.00
PVA with AgNPs	5.473	1.19
PVA with neomycin	8.967	0.72
PVA with AgNPs and neomycin	15.640	1.03

Source: Authors.

The PVA/AgNPs/Neo formulation exhibited the largest inhibition halo against *E. coli*, with a mean value of 15.640 ± 1.03 mm (Table II and Fig. 4B). Compared with PVA/Neo, the combined formulation resulted in an increase of approximately 74.4% in halo diameter. This enhanced halo response was more

pronounced for *E. coli* than for *S. aureus*. However, the mechanism responsible for the larger halo cannot be distinguished by agar diffusion alone; proposed effects such as bacterial-envelope disruption and facilitated antibiotic access remain literature-based mechanistic interpretations rather than experimentally demonstrated interactions in the present system [13].

Overall, the results from Tables I and II demonstrate that the association of AgNPs and neomycin within the PVA electrospun matrix improved antibacterial activity compared with the individual components. The enhanced response observed for the combined formulation may be associated with complementary antimicrobial mechanisms: AgNPs may affect membrane integrity and cellular functions, while neomycin contributes antibiotic activity against susceptible bacteria [5], [12], [13]. These findings support the potential of PVA/AgNPs/Neo nonwoven mats as antimicrobial materials for wound dressing applications, especially considering that electrospun nanofibrous systems can combine structural support with local delivery of active agents [3], [9], [10].

IV. CONCLUSION

Electrospun PVA-based nonwoven mats associated with AgNPs and neomycin sulfate were successfully produced under the selected processing conditions. SEM analysis showed that the AgNPs presented predominantly spherical morphology with nanometric dimensions, while the electrospun mats maintained a continuous fibrous structure after incorporation of the antimicrobial agents. EDS analysis confirmed the presence of silver in the PVA/AgNPs/Neo formulation, supporting the incorporation of the metallic component into the polymeric matrix.

The antimicrobial assay demonstrated that pure PVA did not inhibit bacterial growth, confirming the absence of intrinsic antibacterial activity of the polymeric matrix. In contrast, the incorporation of AgNPs or neomycin individually resulted in inhibition halos against both *S. aureus* and *E. coli*. The combined PVA/AgNPs/Neo formulation produced the largest inhibition halos for both bacterial strains, reaching 20.528 ± 0.24 mm for *S. aureus* and 15.640 ± 1.03 mm for *E. coli*. These results show that the combined formulation produced larger inhibition halos than either isolated agent under the tested conditions.

Therefore, the developed PVA/AgNPs/Neo nonwoven mat provides a basis for further investigation as an antimicrobial wound dressing material. Further studies involving release kinetics, MIC or viable-count reduction, cytocompatibility, mechanical behavior, swelling, degradation, sterilization, resistant clinical isolates, and wound-simulating conditions are necessary to confirm its safety and applicability as an advanced wound dressing.

***Abstract*—Radiofrequency ablation (RFA) is a minimally invasive technique widely used for the treatment of solid tumors. However, its efficacy is limited in large tumors and in lesions located near blood vessels because of heat dissipation and increased tissue impedance. Graphene oxide (GO)-based nanocomposites functionalized with polyethyleneimine (PEI) and silver nanoparticles (AgNPs) have emerged as promising multifunctional platforms for cancer therapy. In this study, the GO-PEI-Ag nanocomposite was synthesized and evaluated for its cytotoxic effects, alone and in combination with RFA, using Walker 256 tumor cells in vitro. The nanocomposite exhibited a dose-dependent cytotoxicity. However, the combined treatment with RFA did not produce a synergistic reduction in cell viability compared with RFA alone. These findings differ from previous reports involving gold nanoparticle-based systems, in which enhanced RFA efficacy has been associated with the higher electrical and thermal conductivity of gold. Overall, GO-PEI-Ag demonstrated intrinsic antitumor activity and may represent a promising platform for future investigations combining nanotechnology with non-ablative therapeutic approaches.**

I. Introduction

According to GLOBOCAN, about 20 million new cancer cases and 9.7 million cancer-related deaths were reported worldwide in 2022 [1]. This annual incidence is expected to surpass 35 million new cases by 2050, a growth driven by population aging, demographic expansion, and continued exposure to factors associated with carcinogenesis [2].

Among minimally invasive therapeutic modalities, radiofrequency ablation (RFA) has established itself as an effective alternative for treating various solid tumors, particularly in patients ineligible for surgical resection. The technique relies on the application of high-frequency alternating current through an electrode inserted into the tumor lesion, generating tissue heating and coagulative necrosis at temperatures above approximately 60 °C [3].

Nevertheless, its efficacy remains limited in larger tumors ($\geq$ 3 cm) or those located near large blood vessels, owing to

the so-called *heat sink effect*, which dissipates the heat generated during the procedure. Compounding this limitation, the rise in electrical impedance caused by tissue carbonization and necrosis reduces current conduction and restricts the expansion of the ablation zone [4]–[8]. As a result, viable tumor cells may persist after treatment, favoring local recurrence.

Given this scenario, nanomedicines have gained prominence for enabling greater biocompatibility, selectivity, and therapeutic efficacy, even in the face of tumor microenvironment heterogeneity. This potential has driven the development of strategies based on nanoparticle surface engineering aimed at optimizing their interaction with tumor cells [9], [10]. Within this context, graphene oxide (GO) nanoplatforms functionalized with polyethyleneimine (PEI) stand out: GO presents a high surface area and broad potential for chemical functionalization, features that make it a versatile platform for the transport of bioactive molecules and metallic nanoparticles [11]. Functionalization with PEI, in turn, contributes to the colloidal stability of the nanocomposite, promotes electrostatic interaction with the plasma membrane, and enhances its internalization by tumor cells [12]–[14].

The incorporation of silver nanoparticles (AgNPs) into the GO-PEI platform results in a multifunctional nanocomposite with potential for oncological applications. Beyond their well-established antimicrobial activity, associated with silver ion release, generation of reactive oxygen species (ROS), destabilization of the cell membrane, and damage to microbial genetic material [**?**], [15], AgNPs have also been shown to induce oxidative stress, mitochondrial dysfunction, DNA damage, cell cycle arrest, and apoptosis in tumor cells, in addition to enhancing the efficacy of antineoplastic agents [17], [18].

These properties have also motivated their investigation as sensitizing agents in energy-based therapies, including modalities such as photothermal therapy and photodynamic therapy, given their capacity to intensify intracellular oxidative stress and increase the susceptibility of tumor cells to treatment-induced damage [17]–[19].

In light of the above, the combination of the GO-PEI-Ag nanocomposite with radiofrequency represents a strategy with the potential to enhance the cytotoxic effects of thermal therapy, promoting greater cell destruction and, consequently, increasing antitumor efficacy. Thus, the objective of this study was to investigate the potential synergistic effect between GO-PEI-functionalized silver nanoparticles and radiofrequency in a tumor cell model, evaluating their influence on cell viability and the mechanisms associated with the selective antitumor response.

II. Materials and Methods

A. Synthesis of the GO-PEI-Ag Nanocomposite

Silver nanoparticles (AgNPs) were synthesized via chemical reduction in the presence of GO-PEI, yielding a hybrid material with controlled properties and marked biological potential. GO acts as a scaffold, preventing AgNP aggregation, while PEI increases the solubility and functionality of the system, contributing to improved cellular interaction [20].

B. B.In Vitro Experimental Procedures

1) Cell line used:: For the biological evaluation, the Walker 256 tumor cell line (LLC-WRC-256) was used. Cells were cultured in Roswell Park Memorial Institute (RPMI-1640) medium, supplemented with 10% inactivated fetal bovine serum (FBS) and 1% antibiotic solution containing penicillin and streptomycin at a concentration of 100 μg/mL each. Cultures were maintained in an incubator at 37 °C, under a humidified atmosphere with 90% humidity and 5% CO_2. For the biological assays, cells were seeded in culture plates.

2) Cell Viability Assays (Without Radiofrequency): Cell viability was assessed using the Alamar Blue colorimetric assay, with spectrophotometric readings taken in the 560–590 nm range. Cells were treated with ten different concentrations of the nanocomposite: 15.0; 7.5; 5.0; 3.75; 1.87; 0.94; 0.47; 0.23; 0.12; 0.06; and 0.03 μg/mL. Treatments were evaluated after 24 and 48-hour period. All experimental conditions were tested in triplicate, across three independent experiments.

3) Combined Therapy Assays with Radiofrequency (RF): To evaluate the response to combination therapy, cells previously treated with the nanocomposite were subjected to radiofrequency (RF) using the SOFIA® generator, protected under Brazilian patent BR 10 2017 002919 0 and affiliated with the University of Brasília (UnB). Sterile syringe needles served as electrodes, and RF was applied for 3 minutes. The experimental groups consisted of: (1) control; (2) combined treatment with GO-PEI-Ag (1.87 μg/mL) + RF; (3) combined treatment with GO-PEI-Ag (3.75 μg/mL) + RF; and (4) RF alone.

Data distribution was assessed using the Shapiro–Wilk test. For normally distributed data, differences among groups were evaluated by one-way analysis of variance (ANOVA), followed by Tukey's multiple comparisons test. When the normality assumption was not met, the Kruskal–Wallis test was applied, followed by Dunn's post hoc test with Bonferroni adjustment for multiple comparisons. Effect sizes for pairwise comparisons were estimated using Cliff's delta (δ) and reported with 95% confidence intervals (95% CIs). Statistical significance was set at $p < 0.05$ in all cases. Statistical analyses and data visualization were performed using RStudio, version 2025.05.1+513.

III. Results and Discussion

1) Cell Viability Assays (Without Radiofrequency): Cell viability assays revealed reduced viability in the untreated control wells located near those containing the highest concentrations of the GO-PEI-Ag nanocomposite. This spatial pattern suggests interference between adjacent wells, possibly resulting from the formation of microaerosols during pipetting, droplet transport via condensation on the plate lid, and factors inherent to 96-well plate culture, such as the *edge effect*, which promotes evaporation of the medium and alters culture conditions in peripheral wells [21], [22].

To investigate this possible interference, three different experimental plate designs were evaluated (Fig. 2, 3, 4, in which the spatial arrangement of nanocomposite concentrations was

modified. Fig. 1 shows the legend for the nanocomposite concentrations.

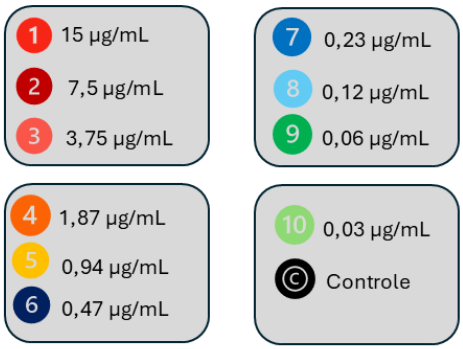

Fig. 1. Concentration legend for the GO-PEI-Ag nanocomposite used in the cell viability assays. Concentrations are represented by a color scale, ranging from warmer, more vibrant tones for higher concentrations to cooler, pastel tones for lower concentrations. Based on the cytotoxicity observed across the experimental designs, concentrations were classified as high (15.0, 7.5, and 3.75 μg/mL), intermediate (1.87 and 0.94 μg/mL), and low (0.47, 0.23, 0.12, 0.06, and 0.03 μg/mL), corresponding respectively to marked, partial, and negligible reductions in cell viability. Numerical labels correspond to: 1 (15.0 μg/mL), 2 (7.5 μg/mL), 3 (3.75 μg/mL), 4 (1.87 μg/mL), 5 (0.94 μg/mL), 6 (0.47 μg/mL), 7 (0.23 μg/mL), 8 (0.12 μg/mL), 9 (0.06 μg/mL), and 10 (0.03 μg/mL); C denotes the untreated control group.

Fig. 2. Plate design No. 1 with a legend of the concentrations used. The nanocomposite concentrations were distributed in alternating rows, with the highest concentrations (15,0–3,75 μg/mL) positioned near the control wells, followed by the intermediate concentrations (1,87–0,47 μg/mL) and the lowest concentrations (0,23–0,06 μg/mL).

Across all experimental designs, the concentrations of 15.0, 7.5, and 3.75 μg/mL resulted in a marked reduction in cell viability, reaching values equal to zero (Fig. 5, Fig. 6, and Fig. 7). However, at concentrations of 1.87 and 0.94 μg/mL, low cell viability was observed in Designs 1 and 2 (Fig. 5 and Fig. 6), whereas in Design 3 (Fig. 7), where these groups were positioned farther from the highest concentrations, high cell viability was observed. Notably, this same pattern was observed in the untreated control wells located near the highest-concentration wells, reinforcing that the reduced viability is not attributable to the nanocomposite's intrinsic cytotoxicity but rather to the spatial arrangement of the wells on the plate.

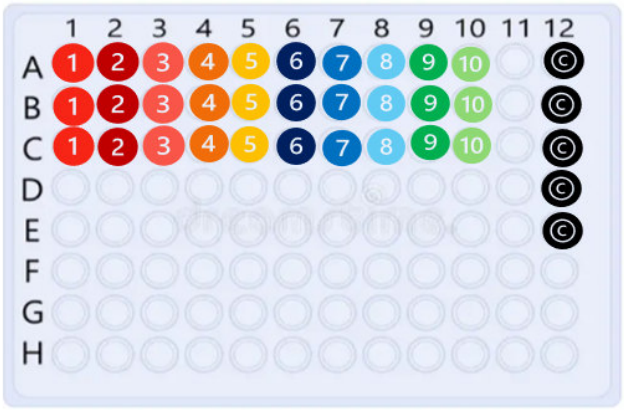

Fig. 3. Plate layout No. 2 with legend for the concentrations used: The concentrations were arranged in sequential rows, starting from the highest concentration to the lowest, with the control placed away from the highest concentrations to reduce their interference with the untreated group.

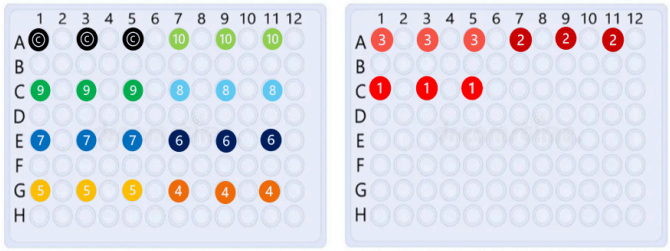

Fig. 4. Plate layout No. 3 with a legend of the concentrations used. The same experimental design was carried out on two culture plates, since the highest concentrations (15.0, 7.5, and 3.75 μg/mL), relative to the other concentrations (1.87–0.06 μg/mL), made it impossible to distribute all experimental concentrations on a single plate. A uniform spacing was maintained between adjacent wells, both laterally and between rows

This behavior is consistent with interference between adjacent wells, likely arising from the dispersion of microaerosols and vapors during pipetting and from droplet transport via condensation on the plate lid. Aerosols originating from wells with higher nanocomposite concentrations carry a proportionally greater cytotoxic load than those from lower-concentration wells; as they disperse across the plate, they preferentially affect the immediately neighboring wells, exposing them to an additional, non-intrinsic source of toxicity beyond their nominal concentration [23]–[25]. This effect is compounded by factors inherent to 96-well plate culture, such as the *edge effect*, which promotes evaporation of the medium and alters culture conditions in peripheral wells [21], [22].

2) Combined Therapy Assays with Radiofrequency (RF): In the experiments combining the GO-PEI-Ag nanocomposite

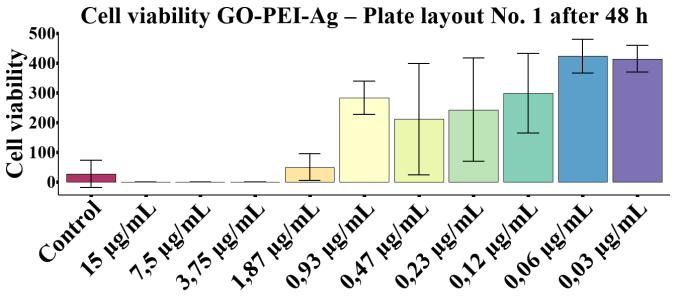

Fig. 5. The cell viability results for plate design No. 1 showed a concentration-dependent cytotoxic effect. The highest concentrations (15, 7.5, and 3.75 μg/mL) resulted in cell viability close to zero. At intermediate concentrations (1.87 to 0.47 μg/mL), a gradual increase in cell viability was observed, whereas the lowest concentrations (0.23 to 0.03 μg/mL) exhibited high cell viability. It is important to note that the untreated control group (C) showed low viability due to interference associated with the plate design, as discussed above. Therefore, given the low viability observed in the control group, the data were not normalized and are presented as absolute fluorescence values, representing cellular activity.

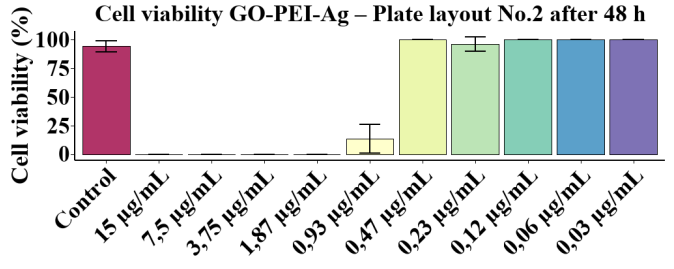

Fig. 6. The results from plate design No. 2 demonstrate that higher concentrations of the nanocomposite maintained high cytotoxicity, with cell viability close to zero. Starting at a concentration of 1.87 μg/mL, a significant increase in cell viability was observed, which remained high at subsequent concentrations, approaching the values observed in the control group, which exhibited maximum viability.Cell viability is expressed relative to the untreated control, which was set as 100%.

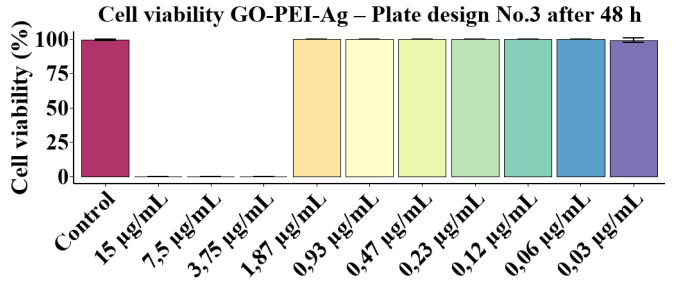

Fig. 7. Viability data based on plate design No. 3 reveal that the highest concentrations of the nanocomposite exhibited high cytotoxicity, with cell viability close to zero, while intermediate and low concentrations maintained high viability, with values similar to those observed in the control group, which exhibited maximum viability.Cell viability is expressed relative to the untreated control, which was set as 100%.

with radiofrequency (RF) ablation, two concentrations were selected: 3.75 and 1.87 μg/mL. The first was chosen for comparison with the study by [25], in which the same assay was performed using a gold-based nanomaterial (GO-PEI-Au) instead of silver. The second, 1.87 μg/mL, was selected as an intermediate dose expected to be sublethal, given the high cell viability observed at this concentration in Design 3 (Fig. 7). This choice was deliberate: the aim of the combined therapy was to potentiate the effect of radiofrequency ablation, rather than to induce tumor cell death through the cytotoxic just the action of the nanomaterial.

The Shapiro-Wilk test indicated that the assumption of normality was not met across the experimental groups at 24 and 48 h. Therefore, differences in cell viability among the experimental groups were assessed using the Kruskal-Wallis test, followed by Dunn's post hoc test with Bonferroni adjustment.

At 24 h, Dunn's post hoc test showed significantly lower viability in the 1.87 μg/mL + RF, 3.75 μg/mL + RF, and RF-only groups compared with the untreated control (adjusted $p < 0.001$ for all comparisons), with very large effect sizes (Cliff's $\delta = 1.000$; 95% CIs: 0.994–1.000). No significant differences, however, were observed among the treatment groups themselves (adjusted $p = 1.000$), with Cliff's δ ranging from -0.247 to 0.235 and all corresponding 95% CIs including zero (Tab. I).

At 48 h, a similar pattern was observed: viability was significantly lower in the 1.87 μg/mL + RF and 3.75 μg/mL + RF groups compared with the untreated control (adjusted $p < 0.001$; Cliff's $\delta = 1.000$; 95% CI: 0.986–1.000), as well as in the RF-only group (adjusted $p = 0.003$; Cliff's $\delta = 0.944$; 95% CI: 0.688–0.991). Again, no significant differences were detected between the treatment groups (adjusted $p = 1.000$), with effect sizes ranging from -0.206 to -0.095 and 95% CIs that included zero (Tab. II).

Taken together, these findings indicate that the addition of the GO-PEI-Ag nanocomposite to RF did not result in a statistically significant increase or decrease in cell viability compared with RF alone at either 24 or 48 h (Fig. 8). No statistically significant differences in cell viability were observed at either time point when combined treatment was compared with RF alone, suggesting that the intrinsic characteristics of the silver nanoparticles may not favor synergistic energy transfer with GO, in contrast to the synergistic effect observed by the research group with the GO-PEI-Au nanocomposite [25].

TABLE I
STATISTICAL ANALYSIS OF CELL VIABILITY TREATED WITH COMBINATION THERAPY AFTER 24 H

Comparison	**Dunn adjusted p**	**Cliff's δ (95% CI)**
Untreated (24 h) vs. 1.87 μg/mL + RF	< 0.001	1.000 (0.994–1.000)
Untreated (24 h) vs. 3.75 μg/mL + RF	< 0.001	1.000 (0.994–1.000)
Untreated (24 h) vs. RF	< 0.001	1.000 (0.994–1.000)
1.87 μg/mL + RF vs. 3.75 μg/mL + RF	1.000	-0.247 (-0.575–0.149)
1.87 μg/mL + RF vs. RF	1.000	-0.037 (-0.382–0.317)
3.75 μg/mL + RF vs. RF	1.000	0.235 (-0.136–0.547)

TABLE II
STATISTICAL ANALYSIS OF CELL VIABILITY TREATED WITH COMBINATION THERAPY AFTER 48 H

Comparison	**Dunn adjusted p**	**Cliff's δ (95% CI)**
Untreated (48 h) vs. 1.87 μg/mL + RF	< 0.001	1.000 (0.986–1.000)
Untreated (48 h) vs. 3.75 μg/mL + RF	< 0.001	1.000 (0.986–1.000)
Untreated (48 h) vs. RF	0.003	0.944 (0.688–0.991)
1.87 μg/mL + RF vs. 3.75 μg/mL + RF	1.000	-0.128 (-0.520–0.309)
1.87 μg/mL + RF vs. RF	1.000	-0.206 (-0.602–0.270)
3.75 μg/mL + RF vs. RF	1.000	-0.095 (-0.532–0.381)

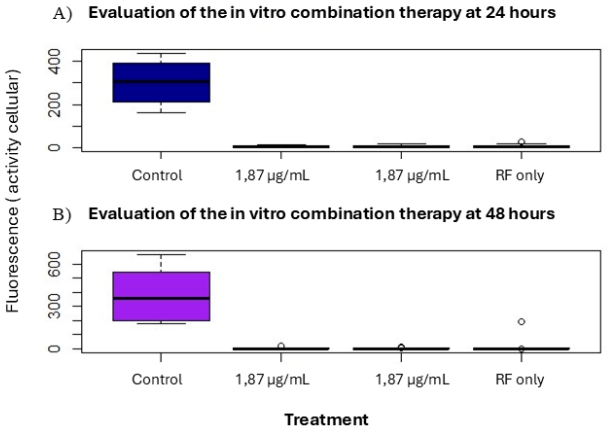

Fig. 8. Cell viability after combination therapy with the GO-PEI-Ag nanocomposite and radiofrequency (RF) ablation at 24 h (A) and 48 h (B). Box plots represent cellular activity measured by fluorescence in the untreated control, GO-PEI-Ag + RF (1.87 and 3.75 μg/mL), and RF-only groups. At both time points, a reduction in cell viability was observed in the treatment groups compared with the untreated control, while no significant differences were detected among the treatment groups.

This lack of an additional effect may suggest that the incorporation of silver nanoparticles into the nanocomposite did not enhance the interaction with RF energy under the conditions evaluated. This finding differs from previous observations by our research group using the GO-PEI-Au nanocomposite, in which the combination with RF produced an enhanced antitumor effect [25].

IV. CONCLUSION

The results demonstrated that GO-PEI-Ag possesses significant intrinsic antitumor activity, inducing a dose-dependent reduction in cell viability, particularly at concentrations of 15, 7.5, and 3.75 μg/mL. However, when evaluated as a potential sensitizing agent for radiofrequency ablation (RFA), the combined treatment with GO-PEI-Ag did not result in a synergistic reduction in cell viability compared to RFA alone, as also reported by Monteiro et al. (2024) [25].

This lower efficacy, when compared to systems based on gold nanoparticles (AuNPs), is likely related to differences in the physicochemical properties of the two nanomaterials. AuNPs can act as conductive dopants, reducing tissue impedance and favoring current conduction and the deposition of radiofrequency energy, which in turn may expand the ablation zone [25]–[27]. The heating observed under RF fields has also been linked to the electrophoretic oscillation of surface charges and the Joule effect, both of which favor greater energy conversion [28]. AgNPs, on the other hand, despite their well-recognized cytotoxic activity, seem to have less impact on local impedance modulation. The combination of this weaker interaction with the RF field and the already high intrinsic cytotoxicity of AgNPs may explain the limited additional benefit brought by radiofrequency, and consequently the lower synergy observed in this study.

Taken together, these findings point to the silver nanocomposite as a candidate for future use either as a standalone antitumor agent or in combination with non-ablative therapeutic strategies that can take advantage of its cytotoxic profile.

V. DECLARATION ON THE USE OF ARTIFICIAL INTELLIGENCE

During the preparation of this manuscript, the generative artificial intelligence tools ChatGPT (OpenAI) and Gemini (Google) were used to support text revision, improve writing quality, organize and connect ideas, and standardize bibliographic references. DeepL was used to assist with the translation of the manuscript and the adaptation of the text to scientific English. None of these tools were used to generate, analyze, interpret, or manipulate scientific data, or to formulate the study's conclusions. All content produced with the assistance of these tools was critically reviewed by the authors, who verified its accuracy, made all necessary revisions, and assume full responsibility for the content and the final version of the manuscript.

ACKNOWLEDGMENTS

The authors would like to thank the advisor, Dr. Ronni Geraldo Amorim, for his guidance and support throughout the development of this work. The authors also thank Dr. Melissa Silva Monteiro for project coordination and leadership; Prof. Dr. Leonardo Giordano Paterno for his support in the production and physicochemical characterization of the nanocomposites; Dr. Sônia Nair Bao for conducting the biological assays at the Microscopy and Microanalysis Laboratory of the University of Brasília (UnB); as well as all participants who contributed to the development of this work.

The authors also acknowledge the funding agencies—the National Council for Scientific and Technological Development (CNPq), the Coordination for the Improvement of Higher Education Personnel (CAPES), the Federal District Research Support Foundation (FAPDF), through the StartBSB Call for Proposals, and the Agency for the Financing of Studies and Projects (FINEP)—for their financial and institutional support, which was essential for the completion of this research.

***Abstract*—The contamination of aquatic environments by healthcare-related pollutants represents a challenge. This study investigated the green synthesis of cerium oxide nanoparticles (CeO_2-NPs) using *Ilex paraguariensis* leaf extract and their performance to adsorb Crystal Violet (CV), a model cationic pollutant. The nanoparticles were characterized by X-ray diffraction, FEG-SEM/EDS, N_2 physisorption, and zeta potential, confirming crystalline mesoporous CeO_2-NPs with a surface area of 85 $\pm$ 1.6 m^2 g^{-1}, pore diameter of 7.8 $\pm$ 1.5 nm, and zeta potential of -10.9 $\pm$ 2.4 mV. Batch adsorption assays at 0.5 g L^{-1} and pH 9 showed concentration-dependent CV removal, reaching 95.6% at 2 mg L^{-1} and decreasing to 51.4% and 36.4% at 5 and 15 mg L^{-1}, respectively, after 180 min. The Sips model provided the best fit (R^2 = 0.999), indicating heterogeneous adsorption and supporting the material's potential as a nanoadsorbent for cationic pollutants, pending validation with healthcare effluents.**

I. Introduction

The management and treatment of wastewater generated by hospitals and clinical laboratories have become an emerging challenge at the interface between biomedical engineering, public health, and environmental sustainability [1]. Unlike municipal wastewater, healthcare effluents contain a complex mixture of persistent contaminants, including pharmaceuticals, antiseptics, and histological dyes (e.g., Crystal Violet, CV), which are frequently resistant to conventional treatment processes due to their complex molecular structures, high chemical stability, low biodegradability, and resistance to microbial degradation [2]. Their continuous release into aquatic environments has been associated with mutagenicity, carcinogenicity, endocrine disruption, and the dissemination of antibiotic-resistant microorganisms, representing a growing risk to both environmental and human health [3].

Among the available treatment technologies, adsorption has attracted considerable attention as an effective approach for removing persistent organic pollutants from aqueous systems due to its operational simplicity, versatility, and potential for pollutant recovery [4]. Cerium oxide nanoparticles (CeO_2-NPs) have been investigated for this application due to their large specific surface area, chemical stability, and favorable surface properties, making them promising candidates for the treatment of wastewater [5]. Furthermore, their surface charge and physicochemical properties make CeO_2-NPs particularly suitable for the adsorptive removal of cationic pollutants, such as CV [6].

However, conventional synthesis routes for CeO_2-NPs commonly employ toxic reducing agents and stabilizers that compromise the environmental sustainability of the process [7].

Fundação de Amparo à pesquisa do Estado do RS (FAPERGS)

Green synthesis has emerged as an alternative approach by replacing hazardous chemicals with renewable plant extracts [8]. Among these, *Ilex paraguariensis* has attracted attention because of its high content of polyphenols and flavonoids, which act as natural reducing and stabilizing agents during nanoparticle formation and enable the production of functional nanomaterials through a simple, low-cost, and environmentally friendly route [9].

Despite growing interest in green-synthesized CeO_2-NPs for aqueous pollutant removal, previous studies have generally investigated adsorption under specific experimental conditions, focusing primarily on individual pollutants and selected kinetic and equilibrium models [10], [11]. Therefore, the present study systematically investigates the adsorption of CV over a broad range of initial concentrations (1–15 mg L^{-1}), combining kinetic modeling based on the pseudo-first-order (PFO), pseudo-second-order (PSO), and intraparticle diffusion (IPD) models with equilibrium analysis using the Langmuir, Freundlich, and Sips isotherms. This comprehensive approach enables a more detailed assessment of concentration-dependent adsorption behavior and provides further insights into the potential of plant-mediated CeO_2-NPs as sustainable nanoadsorbents for removing cationic pollutants [12].

Moreover, developing sustainable technologies for healthcare wastewater treatment directly contributes to Sustainable Development Goals (SDG) 3 (Good Health and Well-being) and SDG 6 (Clean Water and Sanitation) by reducing environmental risks associated with emerging healthcare contaminants [13]. In this sense, the present work aimed to develop and characterize green-synthesized CeO_2-NPs using *Ilex paraguariensis* leaf extract and evaluate their adsorption performance toward CV dye as a model cationic dye, with potential future applications in healthcare wastewater treatment.

II. Materials and Methods

A. Preparation of the Ilex paraguariensis extract

The aqueous extract of *Ilex paraguariensis* leaves was prepared by the infusion method [14]. Fresh leaves of *Ilex paraguariensis* were collected in Rio Grande do Sul, Brazil, thoroughly washed with distilled water to remove surface impurities, and dried at 25 $\pm$ 2 °C. The dried leaves were manually sliced and ground in a Wiley knife mill (TECNAL, model TE-650/1) for three consecutive cycles and subsequently sieved (#250) to standardize the particle size. The aqueous extract was prepared by adding 5 g of the powdered leaves to 50 mL of distilled water maintained at 60 $\pm$ 2 °C under magnetic stirring for 10 min. Subsequently, the suspension was vacuum-filtered to remove the plant residues, and the resulting extract was stored in an amber bottle under refrigeration at 4 $\pm$ 2 °C. The obtained extract, naturally rich in polyphenols and flavonoids, was employed as a renewable reducing and stabilizing agent during the green synthesis of CeO_2-NPs.

B. Biosynthesis of the CeO_2-NPs

CeO_2-NPs were synthesized through a green biosynthesis route employing the aqueous extract of *Ilex paraguariensis* as a natural reducing and stabilizing agent [15]. Initially, a precursor solution was prepared by dissolving 8.628 g of cerium(III) nitrate hexahydrate ($Ce(NO_3)_3{\cdot}6H_2O$, 99%, Sigma–Aldrich) in 100 mL of distilled water. Subsequently, a 50 mL aliquot of the precursor solution was slowly added to the previously prepared 50 mL of *Ilex paraguariensis* extract under magnetic stirring (300 rpm, 25 $\pm$ 2 °C) for 40 min, allowing the phytochemicals present in the extract to promote the reduction of cerium ions, nanoparticle nucleation, and stabilization of the growing particles.

Following the reaction, the suspension was allowed to decant, and the resulting precipitate was collected and dried (60 $\pm$ 2 °C for 12 hours) to remove residual moisture. Finally, the dried material was calcined at 450 $\pm$ 2 °C for 4 hours using a heating rate of (10 °C min^{-1}) to eliminate residual organic compounds from the extract and promote the crystallization of CeO_2-NPs.

C. Characterization of the CeO_2-NPs

The crystalline phases of the green-synthesized CeO_2-NPs were identified by X-ray Diffraction (XRD) using a Bruker D2 Advance diffractometer with Cu Kα radiation (λ = 0.15418 nm), operating over the 2θ range of 20–80° [16]. The morphology and elemental composition were analyzed by Field Emission Gun Scanning Electron Microscopy coupled with Energy-Dispersive X-ray Spectroscopy (FEG-SEM/EDS) using a TESCAN MIRA3 microscope equipped with an Oxford EDX system [17]. N_2 physisorption measurements were performed using an ASAP 2020 (Micromeritics) surface area analyzer at 77 K to determine the specific surface area (S_{BET}), pore volume (V_p), and average pore diameter (D_p), according to the BET method and IUPAC recommendations [18]. Surface charge was evaluated by zeta potential (ZP) measurements using a Zetasizer Nano ZS (Malvern Instruments) at room temperature (25 $\pm$ 2 °C) [19].

D. Adsorption experiments

Batch adsorption experiments were conducted to evaluate CV dye removal using green-synthesized CeO_2-NPs obtained from *Ilex paraguariensis* leaf extract. Aqueous CV solutions were prepared at four nominal initial concentrations (C_0 = 1, 2, 5, and 15 mg L^{-1}) at pH 9, while CeO_2-NPs were added at a dosage of 0.5 g L^{-1}. Under these conditions, the negatively charged surface of the nanoparticles, as characterized in Section III.A, was considered favorable for the electrostatic attraction of the cationic CV molecules [20].

Each suspension was magnetically stirred in the dark at 25 $\pm$ 2 °C, and aliquots were collected at 0, 15, 30, 45, 60, 75, 90, 105, 120, 150, and 180 min. The samples were subsequently centrifuged, and the residual CV concentration (C_t) was determined by UV–Vis spectrophotometry at 590 nm using a calibration curve established for each concentration range

[21]. The removal efficiency (%R) and adsorption capacity at time t (q_t, mg g^{-1}) were calculated according to (1) and (2):

$$\%R = \left(\frac{C_0 - C_t}{C_0}\right) \times 100 \quad (1)$$

$$q_t = \frac{(C_0 - C_t) \times V}{m} \quad (2)$$

where C_0 (mg L^{-1}) is the initial CV concentration, C_t (mg L^{-1}) is the residual concentration at time t, V (L) is the solution volume, and m (g) is the mass of adsorbent used in each assay.

Since all assays were conducted in the dark and in the absence of any catalytic or oxidizing agent, CV was expected to remain chemically stable in aqueous solution under these conditions [22], so a dye-only (adsorbent-free) blank was not deemed necessary to isolate the contribution of adsorption: any decrease in C_t measured throughout the assays could thus be attributed to adsorption onto the CeO_2-NPs rather than to spontaneous degradation of the dye.

The adsorption kinetics of CV onto CeO_2-NPs were evaluated using the nonlinear pseudo-first-order (PFO), pseudo-second-order (PSO), and intraparticle diffusion (IPD) models, expressed by (3), (4), and (5), respectively, for each of the four CV concentrations tested. The equilibrium behavior was described by fitting the Langmuir, Freundlich, and Sips isotherm models, expressed by (6), (7), and (8), respectively, to the q_e versus C_e equilibrium adsorption data, obtained at the end of the 180 min contact period for each of the four initial CV concentrations tested and combined into a single dataset [23].

$$q_t = q_1 \times [1 - \exp(-k_1 \times t)] \quad (3)$$

$$q_t = \frac{k_2 q_2^2 t}{1 + k_2 q_2 t} \quad (4)$$

$$q_t = k_d \times t^{0.5} + C \quad (5)$$

where k_1 (min $^{-1}$) and q_1 (mg g $^{-1}$) are the PFO rate constant and theoretical adsorption capacity; k_2 (g mg $^{-1}$ min $^{-1}$) and q_2 (mg g $^{-1}$) are the PSO rate constant and theoretical capacity; and k_d (mg g $^{-1}$ min $^{-0.5}$) and C (mg g $^{-1}$) are the intraparticle diffusion rate and boundary-layer constants, respectively.

$$q_e = \frac{q_{max} K_L C_e}{1 + K_L C_e} \quad (6)$$

$$q_e = K_F C_e^{1/n} \quad (7)$$

$$q_e = \frac{q_{max} (K_S C_e)^m}{1 + (K_S C_e)^m} \quad (8)$$

where q_{max} (mg g^{-1}) is the maximum adsorption capacity; K_L (L mg^{-1}) is the Langmuir constant; K_F (mg g^{-1})(L mg^{-1})$^{1/n}$ and $1/n$ are the Freundlich capacity constant and heterogeneity factor; and K_S (L mg^{-1}) and m are the Sips constant and heterogeneity exponent, respectively. Model quality was assessed by the coefficient of determination (R^2), following the same statistical treatment described in Section E.

E. Statistical Analysis

Experimental data were organized and processed using OriginPro 2025 (OriginLab Corporation, Northampton, MA, USA) [24]. The software was employed for data visualization, nonlinear curve fitting, and regression analysis of the adsorption kinetic and equilibrium isotherm models. To verify the prediction performance of the isotherm and kinetic models tested, the following error metric functions were used in Statistic® 10.0, expressed by (9), (10), and (11), respectively [25].

$$R^2_{adj} = 1 - \left[\frac{(1 - R^2)(n - p)}{(n - p - 1)}\right] \quad (9)$$

$$SSE = \frac{1}{n}\sum_{i=1}^{n} (q_{exp} - \bar{q}_{pred})^2 \quad (10)$$

$$ARE = \frac{1}{n}\sum_{i=1}^{n} \left[\frac{q_{exp} - \bar{q}pred}{qexp}\right] \quad (11)$$

where q_{exp} and q_{pred} are the experimental and predicted adsorption capacities (mg g^{-1}), respectively; $\bar{q}pred$ is the mean of the predicted values (mg g^{-1}); n is the number of data points; p is the number of model parameters; R^2 is the coefficient of determination (%); $Radj^2$ is the adjusted coefficient of determination (%); SSE is the sum of squared errors; and ARE is the mean relative error (%).

III. Results and Discussion

A. Characterization of the CeO_2-NPs

The XRD diffractogram of the green-synthesized CeO_2-NPs is presented in Fig. 1. The diffractogram exhibited characteristic diffraction peaks at approximately 28.6°, 33.1°, 47.5°, and 56.3°, indexed to the (020), (200), (220), and (311) crystallographic planes, respectively, corresponding to the cerianite phase of CeO_2-NPs (JCPDS/PDF No. 34-0394). These diffraction peaks confirm the formation of crystalline

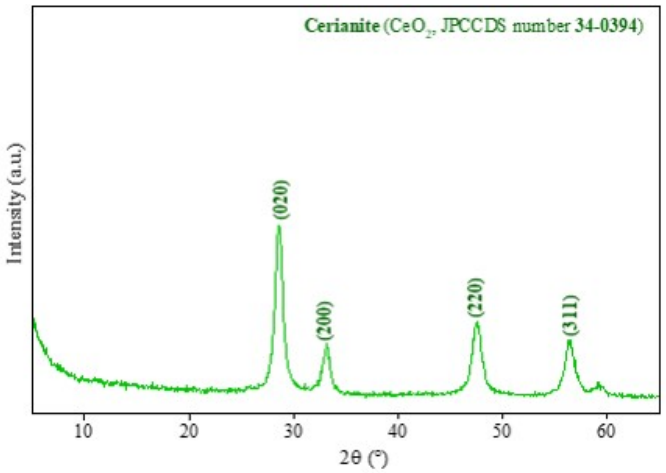

Fig. 1. XRD diffractograms of the CeO_2-NPs from *Ilex paraguariensis* extract.

CeO_2-NPs, in agreement with previous reports on green-synthesized CeO_2-NPs materials [26].

Furthermore, no additional diffraction peaks associated with secondary crystalline phases or precursor-derived impurities were detected, indicating the high phase purity of the synthesized material. The diffraction pattern agrees with previous studies on plant-mediated synthesis of CeO_2-NPs, demonstrating that the biosynthetic route produced crystalline cerium oxide without detectable secondary phases [27].

FEG-SEM micrographs of the green-synthesized CeO_2-NPs are presented in Fig. 2.

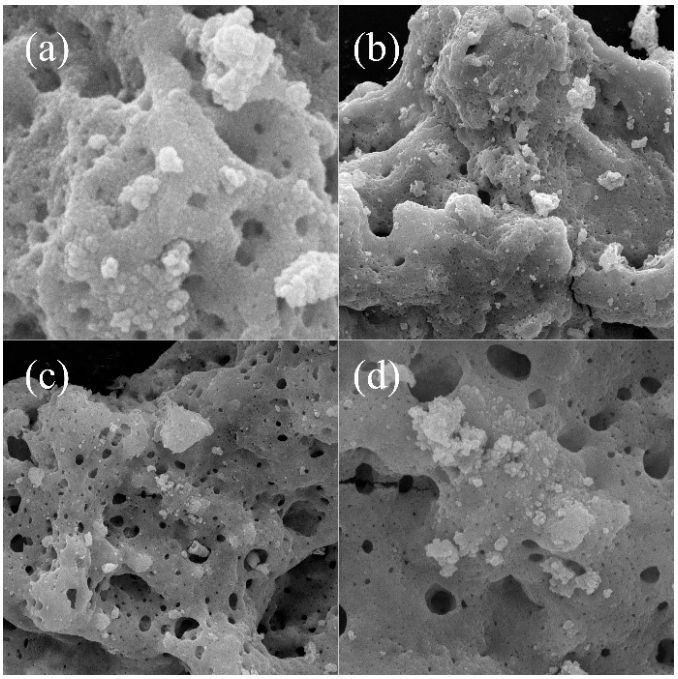

Fig. 2. FEG-SEM micrographs of the green-synthesized CeO_2-NPs obtained using *Ilex paraguariensis* leaf extract at different magnifications: (a) 160 kx, (b) 20 kx, (c) 20 kx, and (d) 80 kx.

Fig. 2a, acquired at 160 kx, reveals agglomerated, quasi-spherical nanoparticles distributed across the material surface. This agglomeration is common in metal oxide nanoparticles and is mainly attributed to their high surface energy and attractive interparticle interactions during synthesis and calcination [28]. Fig.s 2b and 2c, obtained at 20 kx, provide a broader view of the material, revealing a porous architecture composed of interconnected pores distributed throughout the sample. This morphology indicates the formation of an accessible porous network that may facilitate the adsorption of pollutant molecules and improve the contact between the adsorbent surface and the aqueous solution during the adsorption process [29].

At an intermediate magnification (80 kx), Fig. 2d shows the agglomerated CeO_2-NPs deposited on the porous matrix, providing a clearer visualization of the relationship between the nanostructured particles and the porous framework. Similar morphological features have been reported for green-synthesized CeO_2-NPs obtained using plant extracts, in which naturally occurring phytochemicals act as reducing and stabilizing agents during nanoparticle formation, influencing particle nucleation and aggregation [30].

Overall, the FEG-SEM analysis showed that the green synthesis route produced agglomerated CeO_2-NPs with a porous architecture. These morphological characteristics are consistent with previous reports of biosynthesized CeO_2-NPs and are expected to favor interaction between the adsorbent surface and organic pollutants, contributing to the adsorption of dye molecules from aqueous solution [31].

The elemental composition determined by EDS (Fig. 3) confirmed cerium and oxygen as the predominant elements in the synthesized material, corroborating the formation of CeO_2-NPs [32]. The Au signal originated from the conductive coating applied during SEM sample preparation and therefore does not represent the composition of the synthesized nanomaterial. The EDS spectrum revealed cerium as the predominant element (91.9 wt.%), whereas oxygen accounted for 4.5 wt.% of the detected composition. The remaining balance is tentatively attributed to residual carbon from the *Ilex paraguariensis* extract, which was not fully eliminated during calcination at 450 °C, although EDS quantification of light elements should be interpreted with caution.

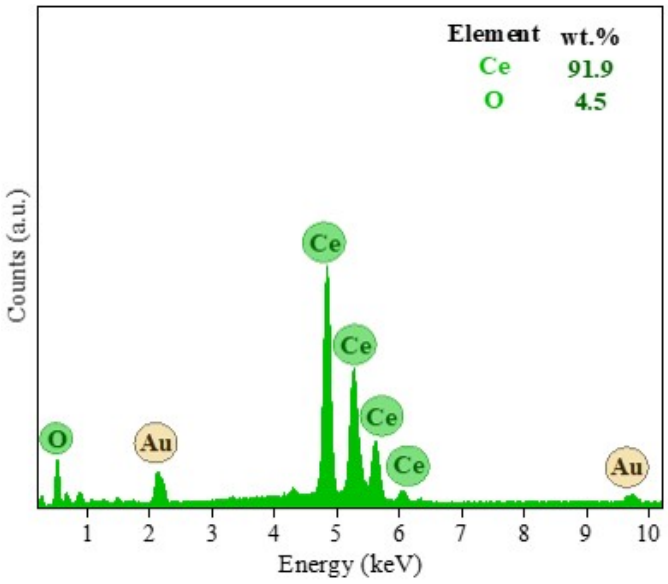

Fig. 3. Elemental analysis of the CeO_2-NPs from *Ilex paraguariensis* extract.

The structural, textural properties, and surface charge of the nanoparticles, quantified via N_2 physisorption and ZP, are consolidated in Table I.

TABLE I
TEXTURAL PROPERTIES AND ZETA POTENTIAL OF THE GREEN CeO_2-NPS

SBET ($m^2\ g^{-1}$)	V_p ($cm^3\ g^{-1}$)	D_p (nm)	ZP (mV)
85 ± 1.6	0.1 ± 0.01	7.8 ± 1.5	-10.9 ± 2.4

According to Table I, the green-synthesized CeO_2-NPs

exhibited a specific surface area of 85 ± 1.6 m^2 g^{-1}, a pore volume of 0.10 ± 0.01 cm^3 g^{-1}, a pore diameter of 7.8 ± 1.5 nm, and a zeta potential of -10.9 ± 2.4 mV. Based on the IUPAC classification, the obtained pore diameter indicates a mesoporous material (2–50 nm) [33]. The combination of a relatively high specific surface area, mesoporosity, and negatively charged surface contributes to the adsorption of the cationic CV dye molecules and supports their interaction with the adsorbent surface during the adsorption process [34]. Although the zeta potential of -10.9 ± 2.4 mV indicates moderate surface charge density, consistent with the agglomeration observed in FEG-SEM micrographs, the electrostatic attraction toward the cationic CV molecules remains operative [35].

B. Adsorption of Crystal Violet

The adsorption profiles of CV onto the green-synthesized CeO_2-NPs (0.5 g L^{-1}, pH 9) showed concentration-dependent removal behavior over the 180 min contact period, as summarized in Fig. 4.

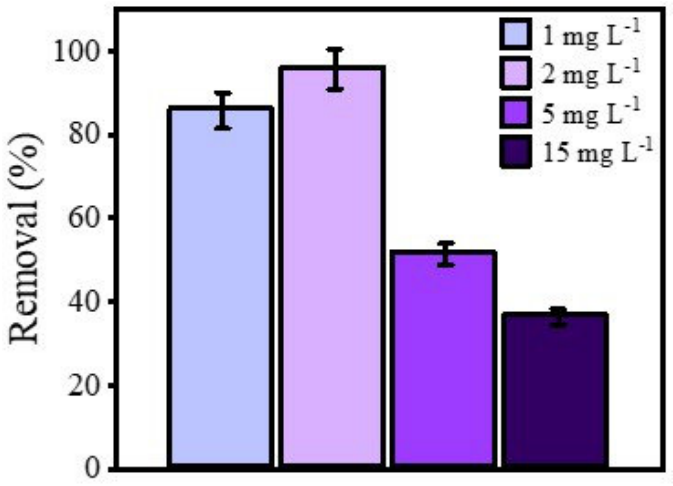

Fig. 4. Adsorption tests of CV under the conditions of CeO_2-NPs = 0.5 g L^{-1}, pH = 9, and T = 25 ± 2 °C, varying the CV concentration.

At the two lowest initial concentrations (1 and 2 mg L^{-1}), removal exceeded 85%, reaching a maximum of 95.6% at C_0 = 2 mg L^{-1}. Increasing the initial CV concentration to 5 and 15 mg L^{-1} decreased the removal efficiency to 51.4% and 36.4%, respectively. This behavior can be attributed to the fixed adsorbent dosage (0.5 g L^{-1}), which provides a limited number of active sites for dye uptake. As the initial CV concentration increases, the ratio of available adsorption sites to dye molecules decreases, resulting in progressive saturation of the adsorbent surface. Similar concentration-dependent decreases in dye removal have been reported for CeO_2-based adsorbents, where increasing pollutant concentration led to lower removal percentages as available surface sites became increasingly occupied [36], [37].

Table II summarizes the kinetic parameters obtained from the PFO, PSO, and IPD models. For the two lowest concentrations (1 and 2 mg L^{-1}), both PFO and PSO described the experimental data equally well ($R^2 \geq 0.99$), with fast rate constants (k_1 = 0.051 to 0.077 min^{-1}), indicating that equilibrium was essentially reached within the experimental time frame. At 5 and 15 mg L^{-1}, the fitted rate constants were markedly lower ($k_1 < 0.006$ min^{-1}), and the extrapolated theoretical capacities (q_1, q_2) considerably exceeded the q_t values actually attained at 180 min, suggesting that equilibrium had not yet been reached under these conditions and that the adsorption process is slower at higher CV loads. The IPD model gave lower R^2 for the low-concentration runs (0.629 to 0.738) with non-zero intercepts ($C \neq 0$), indicating that intraparticle diffusion is not the sole rate-limiting step and that boundary-layer (film) diffusion also contributes to the overall adsorption rate [38].

The equilibrium behavior, described in Table III, showed that the two-parameter Langmuir and Freundlich models provided a comparatively poor description of the data (R^2 = 0.998 and 0.999, respectively), while the three-parameter Sips model, which combines Langmuir- and Freundlich-type behavior, consistently gave the best statistical fit across all CV concentrations (R^2 = 0.999). This result indicates a heterogeneous adsorption process that approaches a finite maximum capacity, in agreement with the mesoporous, negatively charged surface (S_{BET} = 85 ± 1.6 m^2 g^{-1}; D_p = 7.8 ± 1.5 nm; ZP = -10.9 ± 2.4 mV) previously characterized for these nanoparticles, which favors electrostatic interaction with the cationic CV molecule but with site-to-site variability typical of green-synthesized, agglomerated metal-oxide nanoadsorbents [39].

The results in Table III indicate that the Sips model best described the adsorption of CV onto CeO_2-NPs. In this context, it exhibited the highest coefficients of determination (R^2 = 0.999 / R^2_{adj} = 0.999) and the lowest error values, outperforming the Langmuir and Freundlich models. The maximum theoretical adsorption capacity obtained using the Sips model was q_{max} = 0.289 mg g^{-1}.

Regarding the adsorption mechanism, the strong fit to the Sips model reflects the heterogeneous nature of the CeO_2-NP surface. The Sips exponent (m = -3.975) indicates that the process occurs at active sites with different binding energies, with heterogeneous adsorption at low CV concentrations and a tendency toward monolayer saturation at the available sites as the equilibrium concentration increases [40]. Under the experimental conditions employed, the predominant mechanism involves electrostatic attraction between CV molecules, a cationic dye with a positive charge, and the CeO_2-NP surface, which is deprotonated and negatively charged under alkaline conditions, along with possible hydrogen-bonding and Van der Waals interactions [41].

Overall, the results demonstrate that the green-synthesized CeO_2-NPs exhibit promising adsorptive performance toward CV under dark conditions, achieving a maximum removal efficiency of 95.6% at an initial concentration of 2 mg L^{-1}. Adsorption strongly depended on the initial CV concentration, with rapid uptake at lower concentrations and slower adsorption at higher pollutant loads, where the fixed adsorbent dosage limited active-site availability and delayed the

approach to equilibrium. The superior performance of the Sips model indicates a heterogeneous adsorption process, consistent with the mesoporous structure and negatively charged surface of the nanoparticles, which favor interactions with the cationic CV molecules. These findings support the potential of green-synthesized CeO_2-NPs as sustainable nanoadsorbents for cationic dye removal, while further studies involving real healthcare wastewater, competing contaminants, regeneration, reuse, and long-term stability are required to assess their practical applicability in healthcare wastewater treatment.

C. Lessons Learned, Research Gaps and Perspectives

Despite these promising results, several research gaps remain before practical application can be considered. The present study evaluated a single model cationic dye in aqueous solution and did not investigate real healthcare wastewater, competing contaminants, different ionic strengths, adsorbent regeneration and reuse, long-term stability, potential cerium leaching, or process-level sustainability aspects such as synthesis yield, energy consumption during drying and calcination, and reagent/water use. Moreover, although a single additional temperature condition was evaluated, a systematic thermal study was not performed, preventing the determination of thermodynamic parameters such as the Gibbs free energy change (ΔG°), enthalpy change (ΔH°), and entropy change (ΔS°), which could provide further insight into the spontaneity, energetic nature, and temperature dependence of the adsorption process. The absence of direct comparisons with conventional or commercial CeO_2 and other reference adsorbents also limits the quantitative assessment of the material's relative performance.

Future studies should therefore investigate the adsorption process under more realistic conditions, including real or synthetic healthcare wastewater, different pH and ionic strength conditions, competing solutes, and contaminant mixtures. Temperature-dependent adsorption experiments should also be conducted to determine the thermodynamic parameters

and clarify the energetic characteristics and possible changes in the adsorption mechanism with temperature. Furthermore, regeneration cycles, nanoparticle recovery, reuse, long-term stability, and potential cerium release should be evaluated to assess the material's environmental safety and practical feasibility. Comparative studies with commercial CeO_2 and established adsorbents, along with a process-level or life-cycle assessment of the green synthesis route, would also be valuable for benchmarking adsorption performance and sustainability. From a Biomedical Engineering perspective, these investigations may contribute to the future development of sustainable nanoadsorbent-based strategies for treating healthcare-related wastewater.

IV. Conclusion

The present study demonstrated that the green synthesis of CeO_2-NPs using *Ilex paraguariensis* leaf extract is an effective plant-mediated route for obtaining crystalline mesoporous nanomaterials with physicochemical characteristics favorable for adsorption. Structural, morphological, elemental, and surface characterizations confirmed the formation of CeO_2-NPs, with a specific surface area of 85 $\pm$ 1.6 m^2 g^{-1}, a mean pore diameter of 7.8 $\pm$ 1.5 nm, and a negative zeta potential of -10.9 ± 2.4 mV.

Batch dark-adsorption assays demonstrated that CV removal by the green-synthesized CeO_2-NPs (0.5 g L^{-1}, pH 9) was strongly dependent on the initial pollutant concentration, reaching up to 95.6% removal at low CV concentrations (1–2 mg L^{-1}) and decreasing at higher concentrations (5–15 mg L^{-1}), consistent with the increasing demand for available adsorption sites at a fixed adsorbent dose. The kinetic and equilibrium analyses indicated concentration-dependent adsorption behavior, while the Langmuir, Freundlich, and Sips models provided high-quality fits to the equilibrium data, with the Sips model yielding R^2 = 0.999. These findings are consistent with heterogeneous adsorption behavior and highlight the role of the physicochemical characteristics of the CeO_2-NPs in CV uptake.

From a Biomedical Engineering perspective, the results demonstrate the potential of green-synthesized CeO_2-NPs as an adsorbent for the removal of CV, used here as a model cationic pollutant, from aqueous systems relevant to environmental and healthcare-related applications. Importantly, the present results establish adsorption performance under controlled laboratory conditions rather than treatment of real healthcare wastewater. Further studies involving real and complex wastewater matrices, competing contaminants, pH and ionic-strength effects, regeneration and reuse, long-term stability, and possible Ce leaching are necessary to determine the practical applicability of these nanomaterials in healthcare-related wastewater treatment systems.

Acknowledgment

The authors gratefully acknowledge the Franciscan University (UFN) for institutional support and for providing the infrastructure necessary for the development of this study. This research was financially supported by the Fundação de Amparo à Pesquisa do Estado do Rio Grande do Sul (FAPERGS) through the Auxílio Recém-Doutor (ARD – Call 10/2024), Process No. 25/2551-0000968-5. The authors are also grateful to the collaborating universities for providing access to the facilities and instrumentation used for the physicochemical characterization of the materials. Finally, they acknowledge the continued support of public funding programs that foster scientific research and innovation in Brazil.

Conflict of Interest

***Abstract*— The progressive increase in bacterial resistance to conventional antimicrobial agents demands new therapeutic strategies. This study evaluated the antimicrobial activity and associative potential of silver nanoparticles (AgNPs) and Plasma-Activated Water (PAW) against *Staphylococcus aureus* (ATCC 25923). PAW was produced using a cold atmospheric plasma discharge in a gliding arc system. Microbial growth assays by optical density (OD600) demonstrated that PAW alone (activated for 5, 15, and 30 minutes) did not significantly reduce cell growth. The isolated AgNP treatment showed a massive reduction in bacterial proliferation only at concentrations of 12.5% and 25%. However, combining PAW (5 minutes of activation) with a lower, sub-inhibitory AgNP concentration (6.25%) resulted in an equivalent severe reduction in bacterial growth. The results, validated by one-way ANOVA followed by Dunnett's and Tukey's post hoc tests, indicate that this association is highly effective, enabling a 50% reduction in the required nanomaterial dosage for massive bacterial inactivation. Ultimately, this approach effectively reduces the required nanomaterial dosage, representing a promising *in vitro* antibacterial strategy that warrants further investigation regarding cytotoxicity and clinical applicability.**

Keywords—Silver nanoparticles, Plasma-activated water, Antibacterial association, Staphylococcus aureus

I. INTRODUCTION

The progressive increase in bacterial resistance to conventional antimicrobial agents represents one of the most critical challenges for global public health in the 21st century [1, 2]. Opportunistic microorganisms, such as *Staphylococcus aureus* (Gram-positive), stand out due to their high clinical relevance and their capacity to develop resistance to multiple drugs, which complicates the treatment of hospital and chronic infections [1, 3]. In clinical practice, infected cutaneous wounds are particularly concerning, as the presence of resistant pathogens can severely impede the natural healing process and lead to serious complications [4, 5].

In this context, nanotechnology has emerged as a strategic frontier, with silver nanoparticles (AgNPs) being widely investigated due to their broad spectrum of biocidal action [2, 3]. AgNPs synthesized by the bottom-up method allow for rigorous control of physicochemical properties that determine their interaction with the cell wall, destabilization of cytoplasmic membranes, and induction of intracellular oxidative stress [6, 7]. However, the search for strategies that enhance their efficacy at reduced concentrations is fundamental to mitigate potential systemic toxicity and adverse side effects, ensuring safer applications in human healthcare and wound management [8].

Concurrently, atmospheric pressure cold plasma technology has consolidated itself as an innovative tool with promising biomedical and therapeutic applications [9, 10]. The interaction of plasma with water generates Plasma-Activated Water (PAW), a solution rich in reactive oxygen and nitrogen species (RONS), such as hydrogen peroxide (H_2O_2), nitrites (NO_2^-), and nitrates (NO_3^-) [11, 12, 13]. These species promote an oxidative and acidified environment that causes irreversible structural and metabolic damage to bacterial cells, while also regulating inflammatory responses to aid in tissue repair [5, 9, 10].

The rationale of this work lies in investigating the association potential between AgNPs and PAW produced by a gliding arc discharge. The central hypothesis is that the use of PAW as a washing and dispersion medium for nanoparticles can potentiate the bactericidal activity of the system, allowing for a significant reduction in the metabolic viability of clinical pathogens like *S. aureus* even at low concentrations of silver [2, 13]. Therefore, the aim of this study was to evaluate the antimicrobial activity of silver nanoparticles dispersed in Plasma-Activated Water (PAW) produced by a gliding arc discharge against Staphylococcus aureus.

II. METHODOLOGY

A. Synthesis of Silver Nanoparticles (AgNPs)

The silver nanoparticles were synthesized via the bottom-up method [14, 15]. Prior to the procedure, all glassware and magnetic stir bars were washed with aqua regia (a 1:3 ratio of nitric acid to hydrochloric acid) to remove contaminating metals and subsequently rinsed with ultrapure water. In this method, silver nitrate (AgNO3) is reduced by sodium borohydride (NaBH4) to form a colloidal solution. Initially, 30 mL of a 1 mM NaBH4 solution was cooled to approximately 0 °C in an ultrathermostatic bath and maintained under constant magnetic stirring at 1100 rpm for 1 hour. Subsequently, 10 mL of a 2 mM AgNO3 solution was added to the mixture, allowing the reaction to proceed for 7 minutes. The colloidal solution was then removed from the cooling system, stirred at 300 rpm for an additional hour, and left to rest under light for 24 hours. The sample was characterized by UV-Vis spectroscopy and stored in the dark.

B. Production of Plasma-Activated Water (PAW)

The Plasma-Activated Water was produced by exposing 100 mL of distilled water (under magnetic stirring at 400 rpm) to a gliding arc plasma discharge. The system operated at a power of 18.4 W and a frequency of 60 Hz, utilizing a gas mixture flow of 6 L/min of Argon and 4 L/min of compressed

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

air. The distance between the plasma outlet and the sample surface was maintained at 2 mm. The water samples were activated for intervals of 5, 15, and 30 minutes.

C. Bacterial Strains and Antimicrobial Assays

The antimicrobial efficacy against *Staphylococcus aureus* (ATCC 25923) strains was evaluated using microbial growth assays by measuring the optical density at 600 nm (OD600). The bacterial inoculum was standardized at 10^5 CFU/mL. All experiments were conducted in 96-well microplates and incubated for 24 hours at 37 °C. A positive control (C+) consisting exclusively of BHI broth and the bacterial inoculum was included in all assays to establish the baseline for uninhibited bacterial growth.

The experimental design was divided into three stages. For the isolated PAW assessment, the bacterial inoculum was treated with water activated for 5, 15, or 30 minutes. In the isolated AgNPs assessment, the inoculum was exposed to an initial nanoparticle concentration of approximately 1.21×10^{10} AgNPs/mL, which was serially diluted (two-fold) to evaluate the dose-dependent inhibitory effect. For the associative assessment, the lower sub-inhibitory concentrations of AgNPs (3×10^9 and 1.5×10^9 AgNPs/mL) were prepared using PAW activated for 5 minutes as the diluent medium instead of standard water, prior to incubation with the bacterial inoculum.

D. Statistical Analysis

All quantitative data obtained from the OD600 readings were statistically analyzed using GraphPad Prism 8.0.1 software. Data normality was verified prior to analysis using the Shapiro-Wilk test. Subsequently, a one-way Analysis of Variance (ANOVA) was performed, followed by Dunnett's post hoc test (to compare isolated treatments against the control) and Tukey's post hoc test (to compare differences among multiple specific groups in the associative assays), considering $P < 0.05$ as statistically significant.

III. Results and Discussion

The synthesis of silver nanoparticles was confirmed and characterized by UV-Vis spectroscopy. As shown in Fig. 1, the colloidal AgNP solution exhibited a distinct surface plasmon resonance (SPR) absorption band centered at approximately 400 nm, a hallmark optical feature widely reported for structurally stable silver nanoparticles [7, 16]. Ultimately, this spectral behavior is characteristic of the well-controlled bottom-up chemical reduction method using sodium borohydride, corroborating the structural parameters described in previous literature [15].

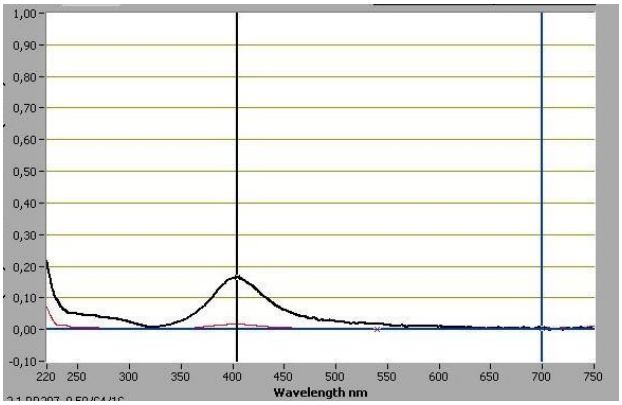

Fig. 1. UV-Vis absorption spectrum of the synthesized AgNPs, displaying a characteristic surface plasmon resonance peak at ~400 nm (n=3).

Furthermore, the physical characterization of the synthesized nanomaterial was complemented by Dynamic Light Scattering (DLS) analysis. As depicted in Fig. 2, the colloidal solution exhibited a Z-average hydrodynamic diameter of 10.99 nm with a Polydispersity Index (PdI) of 0.866. The symmetry and narrow profile of the previously observed SPR peak, combined with this DLS profile, strongly indicate the successful formation of nanoparticles with a homogeneous size distribution and low polydispersity [14, 16]. Achieving a low degree of polydispersity is a crucial parameter in nanomaterial synthesis, as it reflects a uniform colloidal suspension with minimized particle aggregation. This structural homogeneity ensures a high and consistent surface-to-volume ratio, which is vital for maximizing the contact area and optimizing the subsequent antimicrobial interaction with bacterial membranes [14, 16].

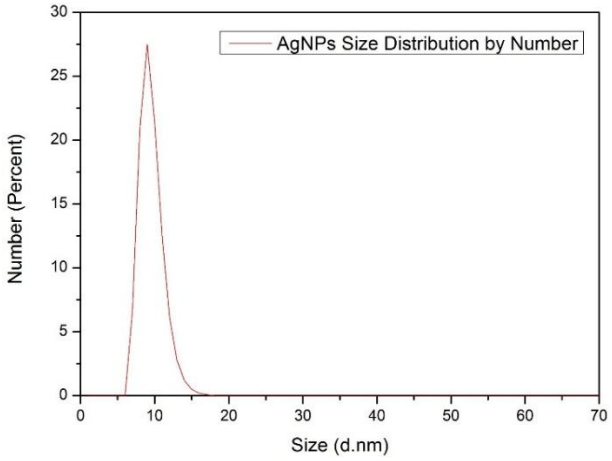

Fig. 2. Dynamic Light Scattering (DLS) analysis of the synthesized AgNPs, showing the hydrodynamic size distribution (n=3).

Regarding the antimicrobial efficacy, the isolated treatment with silver nanoparticles demonstrated a clear dose-dependent inhibitory effect on bacterial growth (Fig. 3). Statistical analysis showed that lower concentrations (3.125% and 6.25%) significantly differed from the positive control (*$p \leq 0.05$), promoting a partial growth reduction of approximately 30%. However, these sub-inhibitory doses did not completely arrest cellular proliferation. Complete inactivation was observed at a concentration of 12.5%, achieving an approximately 96.5% reduction in bacterial growth compared to the control (****$p \leq 0.0001$), a profile that was maintained at the 25% concentration.

This dose-dependent behavior is consistent with the mechanisms described by P. Parvekar et al. (2020), who observed that while AgNPs efficiently disrupt cell membranes and induce intracellular oxidative stress, their isolated biocidal potential relies heavily on the applied concentration. The necessity of a relatively high dose (12.5%) to achieve massive bacterial death corroborates the discussions raised by K. Markowska et al. (2025) and L. O. Camargo et al. (2022). These authors noted that treating resilient pathogens with isolated nanoparticles often requires elevated concentrations, which can be a critical limiting factor in clinical and environmental applications due to potential residual cytotoxicity.

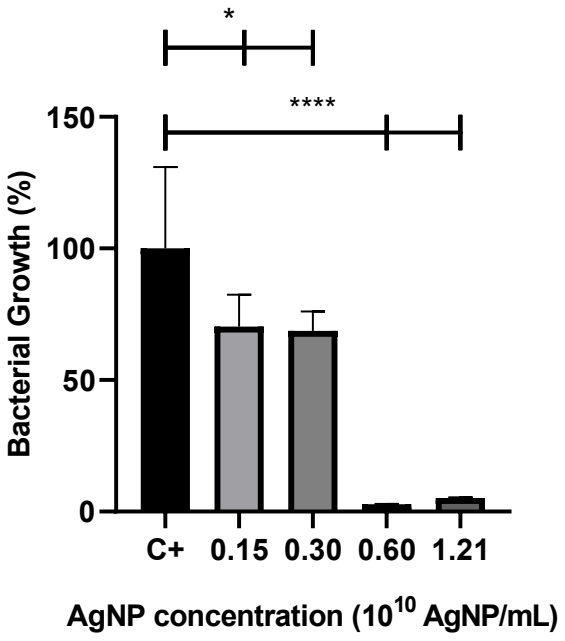

Fig. 3. Analysis of *S. aureus* ATCC 25923 growth following isolated treatment with different concentrations of AgNPs. Data are expressed as a percentage of growth relative to the positive control. *p ≤ 0.05; ****p ≤ 0.0001 (n=3).

The evaluation of the bacterial growth of *S. aureus* ATCC 25923 exposed exclusively to Plasma-Activated Water (PAW) is presented in Fig. 4. The optical density readings indicated that treatments with PAW activated for 5, 15, and 30 minutes did not induce a massive reduction in bacterial growth compared to the positive control (C+). The one-way ANOVA revealed no statistically significant differences among the distinct activation times, nor between them and the control. Consequently, the 5-minute activation time was selected for the subsequent associative assays, as extending the plasma discharge time provided no additional inhibitory benefit.

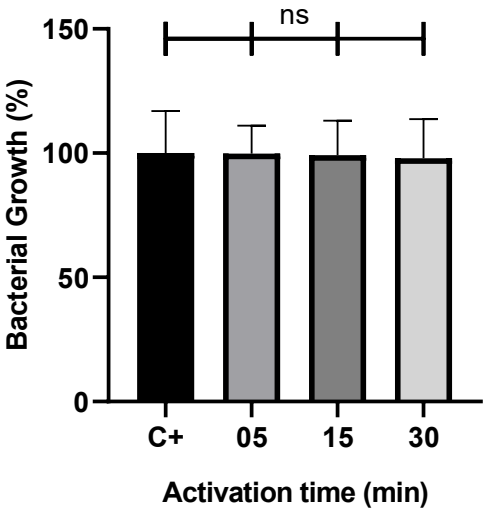

Fig. 4. Analysis of *S. aureus* ATCC 25923 growth following isolated treatment with PAW activated at intervals of 5, 15, and 30 minutes. Data are expressed as a percentage of growth relative to the positive control. ns = not significant, p > 0.05 (n=3).

These results differ from studies such as those by Y. M. Zhao et al. (2022) and A. Mai-Prochnow et al. (2021), which report high isolated biocidal activity of PAW, including the effective inactivation of planktonic cells and the disruption of mature biofilms. However, they strongly align with findings by Z. Xu et al. (2020), that highlighted Gram-positive bacteria, such as *S. aureus*, exhibit higher resistance to reactive oxygen and nitrogen species (RONS) due to their remarkably thick peptidoglycan layer, which acts as a robust physical barrier. Furthermore, it´s been demonstrated that PAW efficacy is highly dependent on the plasma source parameters. In our study, the activation of a relatively large liquid volume (100 mL) at a power of 18.4W likely resulted in a diluted concentration of RONS. Physicochemical measurements of the PAW supported this hypothesis. Immediately after activation, PAW treated for 5 minutes exhibited an acidic pH and a conductivity of approximately 33 µS/cm. Interestingly, monitoring this solution post-activation revealed aprogressive increase throughout the 2-hour evaluation period. In contrast, extending the plasma discharge to 15 and 30 minutes further acidified the initial medium and increased the starting conductivity to 107 µS/cm and 122 µS/cm, respectively. However, the conductivity for these longer activation times remained relatively stable post-activation, returning near their initial values after 2 hours. Despite these distinct chemical dynamics, the RONS concentration generated in this specific volume remained insufficient to independently breach the cellular defense and cause lethal metabolic damage across all evaluated times, validating the choice of the 5-minute activation for the associative assays.

The association potential was evaluated utilizing PAW (activated for 5 minutes) as the dispersion medium for sub-inhibitory concentrations of AgNPs (3.125% and 6.25%) (Fig. 5). According to Dunnett's multiple comparisons test, the combined treatment with the lowest concentration (3.125% AgNP + PAW) did not exhibit a statistically significant difference when compared to the positive control (ns; p = 0.0799).

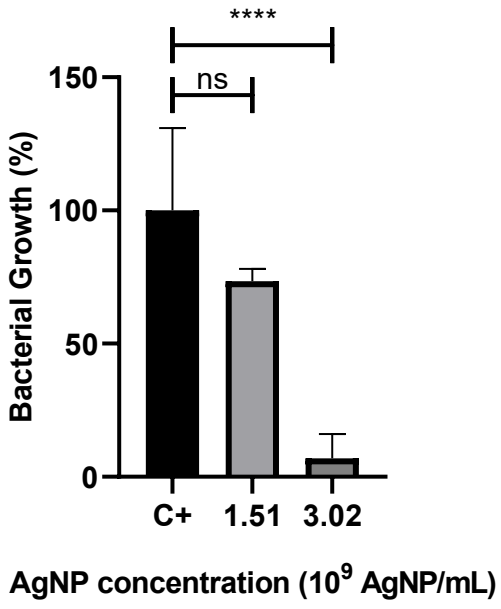

Fig. 5. Analysis of *S. aureus* ATCC 25923 growth following associated treatments (AgNP + PAW) using sub-inhibitory nanoparticle concentrations. Data are expressed as a percentage of growth relative to the positive control. ns = not significant (p > 0.05); ****p ≤ 0.0001. (n = 3).

However, when the 6.25% AgNP concentration (3.02 × 10^9 AgNP/mL) was associated with PAW, a severe drop in bacterial growth was observed, reaching basal viability levels (approximately 93% reduction). According to Tukey's multiple comparisons test, this specific combination presented a highly significant difference not only against the positive control (****; $p < 0.0001$) and the lower combined dose (****; $p < 0.0001$), but also when compared directly to the isolated 6.25% AgNP group (***; $p = 0.0002$) (Fig. 6). This confirms that the associative efficacy is strictly dependent on reaching this specific threshold, effectively reducing the required silver dosage by 50% to achieve massive inactivation.

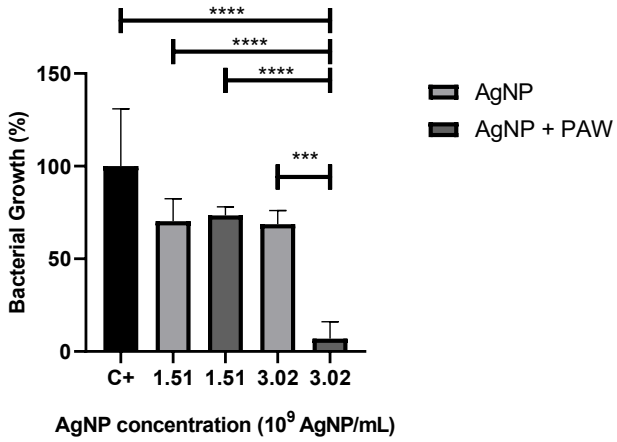

Fig. 6. Statistical comparison of *S. aureus* ATCC 25923 growth inhibition highlighting the associative efficacy between isolated AgNPs and the combined treatment (AgNP + PAW). Data are expressed as a percentage of growth relative to the positive control. ns = not significant ($p > 0.05$); ***$p = 0.0002$; ****$p < 0.0001$. ($n = 3$).

These results strongly support the synergistic mechanisms described in recent literature by B. Nowruzi et al. (2024), S. Wang et al. (2021) and H. R. Lee et al (2021). As proposed by these authors the initial oxidative stress provoked by the PAW, is insufficient to cause cellular death on its own, but compromises the bacterial envelope and begins to deplete endogenous antioxidant defenses, such as staphyloxanthin. This preliminary destabilization explains our findings, as it accelerates the internalization of silver ions. As demonstrated by B. Nowruzi et al. (2024) in combined therapies, this simultaneous attack from RONS and AgNPs overwhelms the bacterial repair pathways, causing irreversible metabolic collapse at significantly lower nanomaterial concentrations. This associative potential is driven by the structural destabilization of the thick Gram-positive cell wall, facilitating a severe and continuous transmembrane influx of silver ions.

Although these in vitro results against a reference strain are highly promising, the exact associative mechanism requires further formal synergy modeling and direct biological validation. Ongoing future studies are focused on the direct chemical quantification of specific RONS, such as hydrogen peroxide, nitrite, and nitrate using targeted colorimetric and reduction assays, to fully elucidate the lethal oxidative pathways. Furthermore, comprehensive nanomaterial characterization and cytotoxicity assessments, will be essential to application biomedical safety and efficacy of this combined approach.

IV. Conclusion

The present study demonstrated the highly effective associative antimicrobial action between silver nanoparticles (AgNPs) synthesized via the bottom-up method and Plasma-Activated Water (PAW) against *Staphylococcus aureus* ATCC 25923. While PAW activated for 5 minutes exhibited no isolated inhibitory effect, and isolated AgNPs required a concentration of 12.5% to achieve a massive reduction in cellular proliferation, their combination allowed for a 50% reduction in the required nanomaterial dosage. Specifically, utilizing PAW as a dispersion medium for a 6.25% AgNP concentration achieved an equivalent basal bacterial viability, an associative efficacy that was statistically validated by Tukey's multiple comparisons test. Ultimately, this *in vitro* combined approach overcomes the limitations of isolated treatments by minimizing the necessary nanomaterial concentration. Future validations involving cytotoxicity assessments and resistant clinical strains are required to fully establish its translational biomedical applicability.
