Fig 2 shows the functionalities available to the professional. These interfaces include patient registration where specific characteristics can be entered, followed by a screen to save the patient's information. After this process, the patient can access the application on their device through a basic registration previously completed by the professional and access their clinical information.

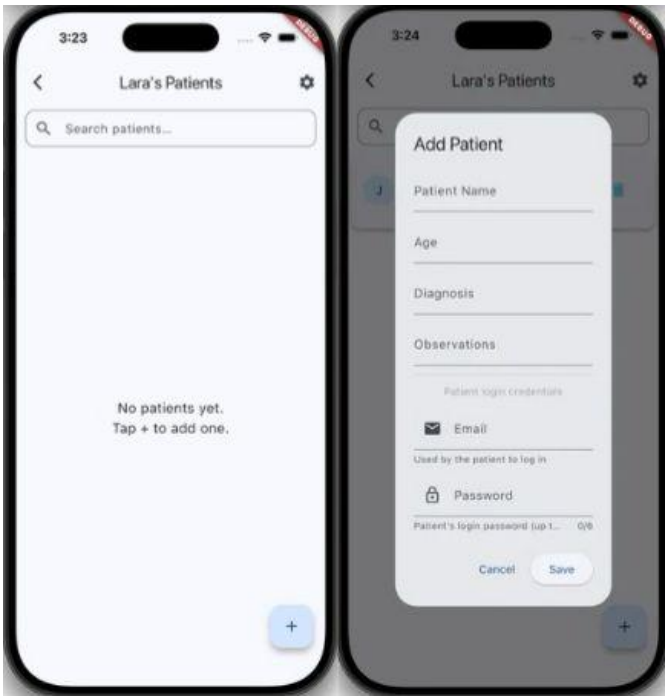

Fig. 2. Functionalities. The left side shows the patient registration area, and the right side corresponds to the screen after clicking the "+" icon to open the patient information and save it.

Fig 3 demonstrates the application from the professional's point of view after logging in, where they can view and leave messages for the patient, adjust the calendar with the treatment days, write important notices, and record videos of the proposed exercises. This monitoring of therapeutic progress and management of rehabilitation activities ensures that each patient is placed within a "folder" with their name and login, allowing the therapist to better organize themselves and prescribe exercises in an individualized way.

Fig 4 illustrates the patient interface. Through them, the user can access the calendar with the days the professional has scheduled treatment, the prescribed exercises, receive notifications, view messages left by the professional, and track their therapeutic progress. Navigation within the application is done using the icons shown in the figures at the bottom of the screens.

The screens were all designed to assist in monitoring physiotherapy and its execution by the patient. The application implementation allowed for cross-platform development with reusable components and standardized visual elements. The integration between the therapist and patient interfaces resulted in an organized and clear application. The interface design and system functionality contributed to a consistent and intuitive navigation experience, preserving the accessibility principles established during the prototyping phase.

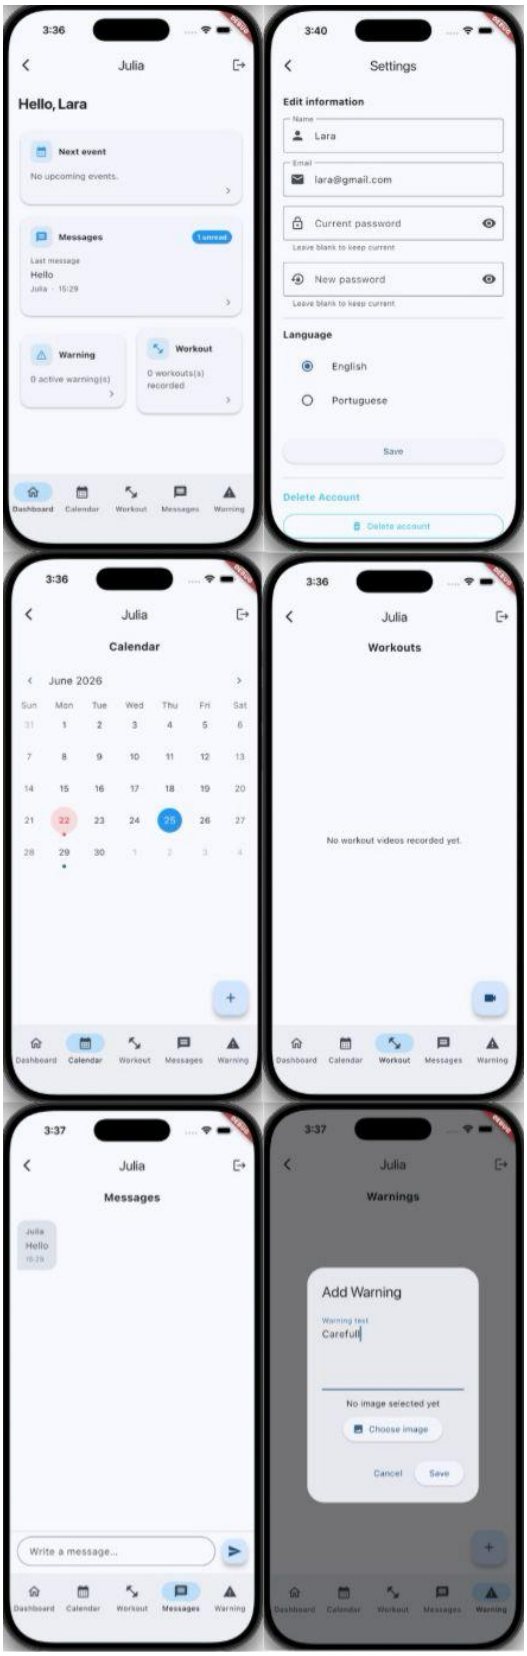

Fig. 3. Application screens. Up left: patient registration; Up right; middle left: main screen; middle left: calendar; middle right: screen for prescribing exercises, which can be done through recorded videos; down left: messages; down right: screen for alerts or important notices.

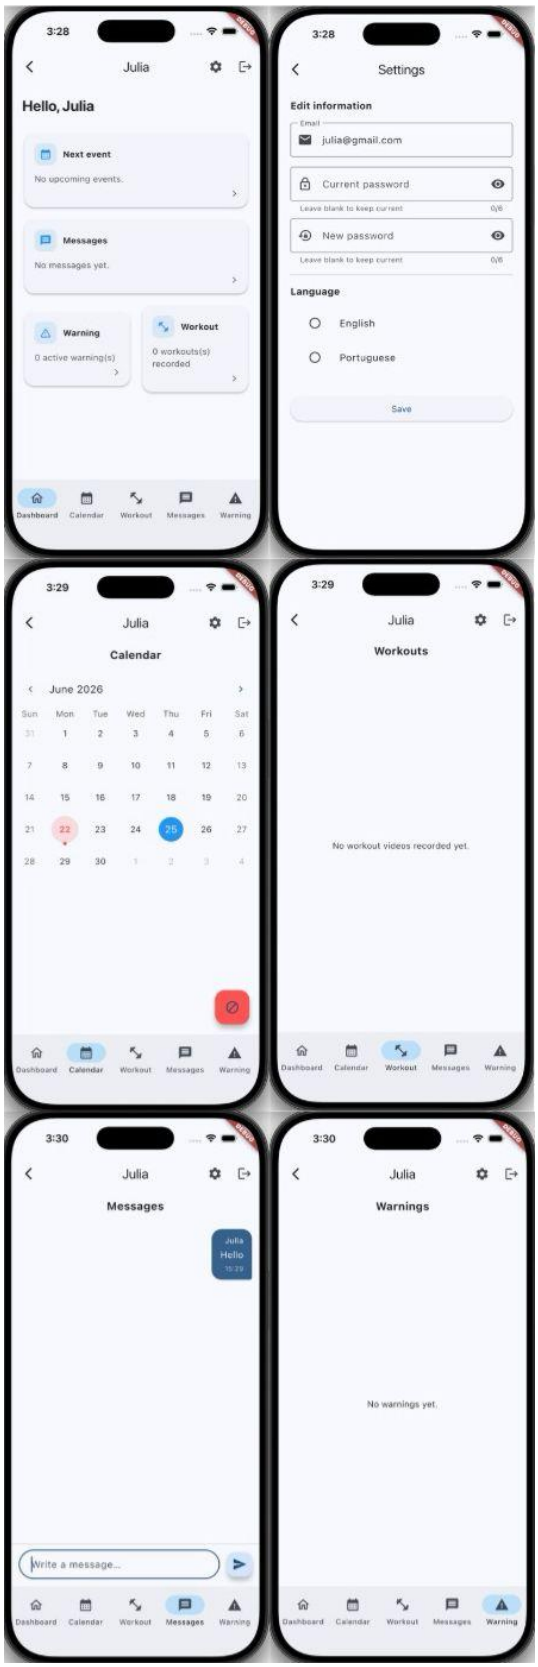

Fig. 4 Patient interface. Up left: a main screen; up down: allows the user to change their password and preferred language); middle left: calendar; middle right: area of prescribed exercises; down left: messages; down right): important notices and reminders.

Overall, the developed system offers features for exercise prescription, clinical monitoring, communication, scheduling, notifications, and physiotherapy follow-up. As can be seen in the images above, two complementary approaches can be observed in a single application with different but mutually beneficial objectives: one interface with the therapist login and another with the patient login, which allows access to information provided by the professional. This organization establishes a simple and effective digital environment focused on supporting the home rehabilitation process.

V. DISCUSSION

The results observed in this study demonstrate the feasibility of developing a telerehabilitation application specifically designed for wheelchair users. The functionalities implemented in the system are in accordance with the recommendations found in the scientific literature on the use of digital technologies in physiotherapy and rehabilitation programs.

The login, exercise prescription and patient monitoring features were developed with the aim of facilitating communication between patient and physiotherapist and increasing treatment adherence, which is in line with the conclusions reported by Chen et al. [8], who highlight the importance of mobile health applications to facilitate remote monitoring. In this way, the inclusion of prescription and real-time patient monitoring resources becomes indispensable, since according to Liu et al. [7], mobile applications can contribute to pain reduction, functional improvement and greater adherence to home rehabilitation programs. In this work, these functionalities were incorporated through interfaces that allow access to prescribed exercises and monitoring of their rehabilitation activities. Another relevant aspect is the communication mechanism between physiotherapists and patients. According to observed studies, continuous interaction and feedback are important factors in maintaining adherence to treatment and encouraging patient involvement in rehabilitation programs [17]. Therefore, the developed application aims to incorporate these principles through messaging and notification features that facilitate therapeutic monitoring.

The app developed also incorporates accessibility principles and digital inclusion strategies, which are mentioned in the articles discussed, as these factors are considered essential for the development of health technologies aimed at people with disabilities [19]. Therefore, these aspects were considered during the planning and implementation phases to ensure simple and clear usability for the public, facilitating access to home rehabilitation resources.

The structure developed in Flutter represents an important technological contribution, as it allows access to rehabilitation from a new perspective, bringing rehabilitation beyond the consulting room and focusing on a specific and select public that is often neglected. In the study by Chen et al. [20], digital rehabilitation solutions integrated with remote monitoring technologies can contribute to improving therapeutic continuity and patient engagement, as well as greater adherence to treatment.

Remote rehabilitation, when compared to previous studies, differs because it involves the specificity of developing an app by a professional in the field and because it is a platform specifically focused on wheelchair users. While many available applications address isolated aspects of rehabilitation [6], the proposed solution combines factors important to the target audience in the same environment.

The inclusion of specific factors for a select audience is also supported by studies that demonstrate effectiveness in the results obtained, as it generates expanded access to physiotherapy services and reduced barriers to treatment [21]. These analyzed findings reinforce the app's potential in rehabilitation contexts.

Despite promising results and technological advancements, some limitations must be considered. The application has not yet undergone usability testing with end users or clinical validation studies. Therefore, it is not yet possible to determine the system's effectiveness in real people, but the results obtained are related to the application's planning and development.

VI. CONCLUSION

In summary, the telerehabilitation application developed to prescribe home exercises for wheelchair users offers functionalities for exercise guidance, communication, scheduling, and monitoring for both the professional and the patient. Therefore, it can be concluded that the application has the potential for technological innovation because it was developed and designed specifically for its target audience.

Although further validation studies and end-user testing are needed to assess its usability, effectiveness, and acceptance in clinical practice, the developed app shows potential to significantly contribute to monitoring the health and quality of life of users. Furthermore, the proposal represents a relevant advancement from a technological and scientific perspective, integrating accessible digital resources that can strengthen health promotion, functional monitoring, and autonomy for this population.

***Abstract*—Accessible cognitive assessment for people with visual impairment requires instruments whose validity and measurement properties are demonstrated for the target population and whose administration does not introduce avoidable visual barriers. This integrative review aimed to identify and critically compare instruments used to assess cognitive abilities in people with visual impairment, with emphasis on population characteristics, language and cultural adaptation, reference measures, psychometric evidence and accessibility. Searches were conducted from August 29, 2025 to June 21, 2026, in BVS, Cochrane Library, CAPES Journals Portal, PubMed, ScienceDirect and Scopus. The search strategy combined "Intelligence Tests" AND "Visual Impairment". Studies published from 2020 to 2025 in English, Portuguese or Spanish were eligible. Reporting was reorganized according to PRISMA 2020, and methodological quality was critically appraised using a COSMIN-based framework adapted to the measurement studies identified. Three studies met the eligibility criteria: a Chinese study of WISC-IV verbal scales in 100 children who were blind; an Italian pilot study of a three-dimensional haptic nonverbal cognitive test in 25 participants with severe low vision or blindness and 25 sighted peers; and a Pakistani study of the Urdu version of the Tromsø Social Intelligence Scale in 215 adolescents with visual impairment. The evidence indicates promising reliability and validity for specific instruments, but the small number of studies, restricted age ranges, cultural and linguistic specificity, and limited representation of Brazilian populations prevent broad recommendations. The main contribution of this review is to demonstrate the scarcity and heterogeneity of current evidence and to identify priorities for future validation studies involving people with visual impairment throughout instrument development.**

Keywords— intelligence assessment, visual impairment, assistive technology

I. INTRODUÇÃO

A deficiência visual é caracterizada pela perda parcial ou total da visão, o que dificulta a realização de atividades diárias sem recursos adaptativos. Segundo a Organização Mundial da Saúde (OMS), ela é classificada em diferentes graus, desde a baixa visão, quando há percepção visual da necessidade de auxílio, até a cegueira total, com ausência completa da visão. Pode ser congênita, por fatores genéticos, por complicações no parto, adquirida ao longo da vida devido a doenças, traumas ou envelhecimento [1].

O estudo da inteligência sempre constituiu um dos grandes interesses da humanidade ao longo do tempo. As primeiras propostas de aferição das funções mentais remontam ao final do século XIX, quando se buscou avaliar a inteligência por meio de diferentes capacidades sensoriais. A primeira contribuição relevante foi de Francis Galton (1822-1911) que concebia a inteligência como um atributo de base hereditária, investigada a partir do estudo de árvores genealógicas. J. McKeenCattell (1860–1944) deu continuidade a essa linha de pesquisa, desenvolvendo medidas preditoras da inteligência, como velocidade de movimento, força muscular, discriminação de peso e sensibilidade à dor. Posteriormente, verificou-se que essas e outras medidas não eram adequadas para mensurar a inteligência. No início do século XX, Alfred Binet (1857-1911) criticou essa abordagem centrada em processos sensório motores e destacou a necessidade de avaliar processos mentais mais complexos, como atenção, memória, compreensão e imaginação, de modo a permitir uma investigação mais abrangente da inteligência [2].

A concepção de inteligência na abordagem psicométrica fundamenta-se na análise fatorial, a qual se baseia nas diferenças individuais reveladas por uma ampla variedade de testes destinados a avaliar capacidades cognitivas. A análise fatorial tem como objetivo identificar subgrupos de testes que avaliam a mesma habilidade cognitiva. Essa abordagem evoluiu ao longo dos anos: inicialmente, elaboravam-se instrumentos de medida sem clareza teórica sobre o que avaliavam; posteriormente, essas formulações tornaram-se mais sofisticadas. Estudos recentes buscam integrar achados da Psicologia e da Neurociência, relacionando aspectos cognitivos e afetivos [3].

A validação dos inúmeros testes psicométricos construídos nas primeiras décadas do século XX em países da Europa e da América do Norte e introduzidos no Brasil ainda nesse período, consolidou-se como instrumento para definir um padrão de inteligência considerado "normal", mediano e comum. Tais parâmetros serviam para determinar quem deveria ou não ser admitido ou permanecer nas escolas. Essas medidas foram desenvolvidas a partir de teorias fundamentadas na eugenia, cujo objetivo era distinguir supostos tipos superiores e inferiores. Esse movimento influenciou diferentes países, promovendo a aferição das capacidades individuais, visando "a seleção das melhores espécies" por meio da "mensuração das imperfeições" [4].

Os testes de inteligência, portanto, foram concebidos dentro do ideário eugenista e carregam equívocos conceituais decorrentes de sua própria origem, centrada na crença de que

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

seria possível avaliar de maneira objetiva o potencial intelectual de um indivíduo [5].

Entre as teorias psicométricas da inteligência, destaca-se a teoria bifatorial de Charles Edward Spearman (1863-1945), fundamental para a conceituação do fator g, determinado pela comparação entre múltiplos itens de uma prova ou entre pontuações de diferentes testes. O fator g explicaria o funcionamento intelectual, sendo responsável pela maior parte da variância observada em testes psicométricos, com forte componente biológico [2].

Em 1912, William Stern (1871-1938) utilizou o conceito de idade mental para formular o Quociente de Inteligência (QI), permitindo quantificar o funcionamento cognitivo em relação ao desenvolvimento e à aprendizagem. O cálculo do QI infantil consiste em dividir a idade mental (IM), definida pela capacidade de aprender e se desenvolver, pela idade cronológica (IC), correspondente ao tempo de vida em dias, meses e anos. Assim, considera-se desenvolvimento normal quando IM e IC são equivalentes [6].

Piaget, biólogo e geneticista francês, defendia que a inteligência não é hereditária nem inata. Para ele, a inteligência se desenvolve articulada à herança biológica, a partir de estruturas sensoriais ou neurológicas que amadurecem conforme a interação do indivíduo com o ambiente. A inteligência relaciona-se ao aspecto cognitivo ao estruturar as interações entre sujeito e objeto. Nesse processo, o sujeito assimila elementos do meio às suas estruturas internas e, simultaneamente, deve acomodá-las, ajustando-as às novas experiências [7].

Teorias posteriores buscaram fragmentar a compreensão da inteligência em grupos específicos [8,9]. Cattell propôs a divisão em dois fatores, inteligência fluida (Gf) (refere-se à execução de tarefas novas e não automáticas, que demandam a formação de relações e a integração de ideias) e inteligência cristalizada (Gc) que corresponde ao conhecimento adquirido ao longo da vida, resultante de experiências e do acúmulo de aprendizagem.

Horn, em colaboração com Cattell, ampliou a concepção de inteligência ao propor um modelo hierárquico, composto por um fator geral e múltiplos fatores específicos, a teoria CHC (Cattell-Horn-Carroll), que constitui a formulação mais atual e abrangente sobre inteligência, sustentado por inúmeras evidências empíricas e por instrumentos específicos destinados à sua mensuração [10].

Existem diversos testes psicométricos recomendados pelo Conselho Federal de Psicologia, destinados à aferição da inteligência por meio do Sistema de Avaliação de Testes Psicológicos (SATEPSI). Atualmente, os mais aplicados e comercializados no mercado estão disponibilizados na Tabela 1.

Os testes de inteligência, assim como outros instrumentos psicológicos, podem ser utilizados para auxiliar no diagnóstico e na identificação das funções cognitivas mais comprometidas, possibilitando o direcionamento de intervenções voltadas ao estímulo das capacidades do indivíduo [11].

Na década de 1950, foi publicada uma análise crítica que reuniu dezenove estudos empíricos, demonstrando que nenhuma intervenção psicológica se mostrava mais eficaz do que o simples passar do tempo [12]. Essa publicação representou um marco relevante, pois fomentou debates e impulsionou um número expressivo de pesquisas voltadas à comprovação da eficácia das psicoterapias [13].

Dessa forma, o objetivo geral deste estudo é compreender os pressupostos teóricos que fundamentam as práticas de aferição da inteligência humana, bem como promover ações que assegurem à população com deficiência visual o direito de utilizar testes de inteligência adaptados às suas necessidades.

II. METODOLOGIA

A. Critérios de Elegibilidade

Foram elegíveis artigos originais publicados entre 2020 e 2025, nos idiomas inglês, português ou espanhol, que investigassem instrumentos de avaliação cognitiva em pessoas com deficiência visual e apresentassem informações sobre validade, confiabilidade, adaptação, desempenho ou acessibilidade do instrumento. Foram consideradas populações com cegueira ou baixa visão, sem restringir previamente a faixa etária, desde que a deficiência visual estivesse explicitamente caracterizada. Foram excluídos registros duplicados, editoriais, artigos incompletos, teses, dissertações, livros e estudos sem relação direta com a avaliação cognitiva de pessoas com deficiência visual. A definição de elegibilidade foi aplicada ao título/resumo e posteriormente confirmada na leitura do texto completo.

B. Fontes de Informação

As fontes de informação foram o Portal Regional da BVS, Cochrane Library, Portal de Periódicos CAPES, PubMed, ScienceDirect e Scopus. A busca foi realizada entre 29 de agosto de 2025 e 21 de junho de 2026. O último acesso/consulta de cada fonte ocorreu em 21 de junho de 2026. A estratégia registrada para todas as fontes foi a combinação dos termos “Intelligence Tests” AND “Visual Impairment”, com adaptações de sintaxe quando necessárias às respectivas plataformas. A APA-PsycNet constava em uma versão anterior da metodologia, mas não apresentou registros no fluxo contabilizado; por isso, não foi considerada uma fonte efetivamente contabilizada nos resultados desta versão.

C. Critérios de inclusão e exclusão

Foram incluídos artigos originais que investigassem instrumentos ou testes destinados à avaliação de algum domínio cognitivo em pessoas com deficiência visual, apresentassem dados sobre propriedades psicométricas, adaptação ou desempenho do instrumento e fossem publicados no intervalo definido. Foram excluídos duplicatas, editoriais, trabalhos incompletos, teses, dissertações, livros e estudos sem relação direta com avaliação cognitiva e deficiência visual.

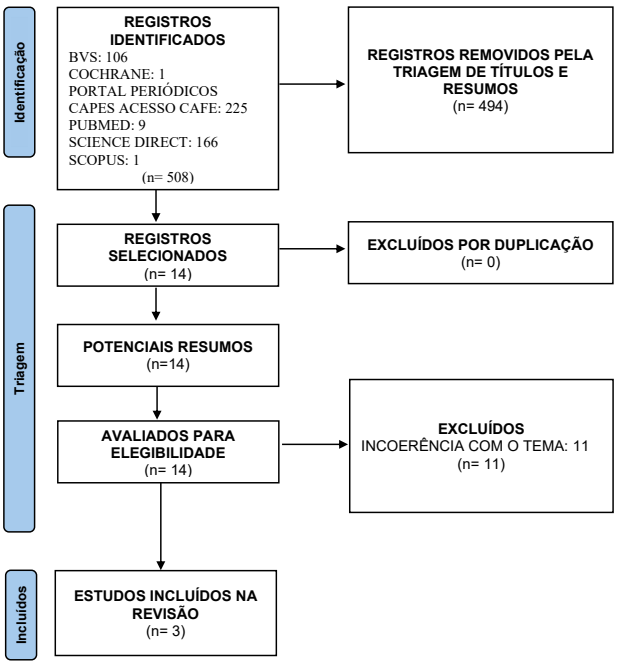
D. Processo de seleção dos estudos

A seleção ocorreu em três etapas: leitura de títulos, leitura de resumos e avaliação do texto completo. O processo de seleção e análise dos artigos seguiu uma metodologia rigorosa, contando com a participação de dois pesquisares independentes para seleção dos estudos. Inicialmente, realizou-se uma triagem com base nos títulos, seguida por uma análise mais aprofundada dos resumos e, posteriormente, a leitura completa dos textos selecionados.

E. Síntese dos resultados

Devido ao pequeno número de estudos e à heterogeneidade dos construtos, populações, idiomas, instrumentos e propriedades psicométricas avaliadas, não foi realizada meta-análise. Os resultados foram sintetizados de forma narrativa e

comparativa, organizados segundo instrumento, construto, população, contexto cultural, acessibilidade e propriedade de medida. Quando disponíveis, foram apresentados coeficientes de confiabilidade, evidências de validade e características da adaptação. A direção da evidência foi interpretada como favorável, promissora ou limitada de acordo com o desenho e os resultados reportados, evitando a generalização dos achados para populações não estudadas.



F. Risco de viés e qualidade metodológica

A qualidade metodológica e o risco de viés foram apreciados por meio de uma estrutura baseada no checklist COSMIN (*COnsensus-based Standards for the selection of health Measurement INstruments*) para propriedades de medida, considerando, conforme aplicável, validade de conteúdo, validade estrutural, consistência interna, confiabilidade, teste de hipóteses/validade de construto e validade transcultural. Foram também considerados aspectos de adequação da população, tamanho amostral, clareza dos procedimentos e completude do relato. Como os instrumentos incluídos abrangem testes de inteligência e uma escala de inteligência social, e não exclusivamente instrumentos de desfechos relatados pelos pacientes, o COSMIN foi empregado como estrutura de apreciação das propriedades de medida, e não como certificação de uso clínico.

III. Resultados e Discussão

A busca contabilizada no fluxo resultou em 508 registros: 106 na BVS, 1 na Cochrane Library, 225 no Portal de Periódicos CAPES, 9 na PubMed, 166 na ScienceDirect e 1 na Scopus. Após a triagem de títulos e resumos, 14 registros permaneceram para avaliação de elegibilidade. Não foram identificadas duplicatas. Na leitura dos textos completos, 11 estudos foram excluídos por incoerência com o tema, resultando em 3 estudos incluídos [6–8]. O fluxograma revisado é apresentado na Figura 1.

Figura 1: Diagrama dos artigos incluídos e excluídos, de acordo com os critérios de inclusão e exclusão estabelecidos no estudo.

Atualização das teorias psicométricas e da avaliação cognitiva

O panorama contemporâneo das teorias psicométricas da inteligência amplia os modelos hierárquicos clássicos ao incorporar abordagens dinâmicas e perspectivas derivadas da neurociência e da ciência de dados. O modelo Cattell-Horn-Carroll (CHC) permanece uma referência importante para a organização de habilidades cognitivas, especialmente ao distinguir capacidades fluidas e cristalizadas. Paralelamente, abordagens como a Teoria do Mutualismo, modelos de redes cognitivas e a Teoria da Resolução de Processos Sobrepostos (POT) discutem a possibilidade de que o fator g represente um fenômeno emergente das interações entre múltiplos processos cognitivos, em vez de uma causa única centralizada. Essas perspectivas são relevantes para a interpretação dos testes porque reforçam a necessidade de definir claramente o construto que cada instrumento pretende medir.

Trabalhos recentes também aproximam psicometria, neurociência e funcionamento de redes cerebrais, discutindo dimensões múltiplas da inteligência e relações entre desempenho cognitivo, conectividade neural e eficiência do processamento. Em paralelo, a psicometria computacional tem explorado aprendizado de máquina e modelos matemáticos para analisar padrões comportamentais complexos, modelar diferenças individuais e ampliar estratégias de avaliação. No entanto, a incorporação de IA à avaliação cognitiva não elimina a necessidade de evidências psicométricas tradicionais; ao contrário, exige avaliação adicional de validade, viés algorítmico, transparência, estabilidade e equidade. Para pessoas com deficiência visual, essa evolução pode ser particularmente relevante quando combinada a leitores de tela, síntese de voz, interfaces hápticas, dispositivos táteis e sistemas adaptativos. Assim, a inovação tecnológica deve ser considerada uma estratégia de acessibilidade e não um substituto da validação do instrumento. A tabela 1 apresenta os testes psicométricos recomendados pelo Conselho Federal de Psicologia, destinados à aferição da inteligência por meio do Sistema de Avaliação de Testes Psicológicos (SATEPSI) disponíveis atualmente.

Tabela 1: Sistema de Avaliação de Testes Psicológicos mais aplicados e comercializados no mercado.

TESTE	*PÚBLICO*	*OBJETIVO*	*CARACTERÍSTICAS*
Son-R	2 ½ a 7 anos e dos 6-40 anos	Avaliação geral das habilidades cognitivas e do desenvolvimento, contribuindo para o diagnóstico diferencial entre síndromes neurológicas e psicológicas.	Instrumento não verbal, que reduz a influência da escolaridade no processo avaliativo. O teste utiliza quatro subtestes para examinar habilidades espaciais, visomotoras e raciocínio abstrato e concreto.
Escala de Maturidade Mental Colúmbia 3 (CMMS-3)	3 anos e 0 meses a 9 anos e 11 meses de idade.	Fornecer uma estimativa da habilidade intelectual ou da capacidade de raciocínio.	Avaliação de crianças que apresentam dificuldades em testes tradicionais de inteligência baseados em linguagem ou desempenho motor.
Escala de Inteligência Wechsler (WISC - IV)	6 anos e 0 meses até16 anos e 11 meses	Auxiliar no diagnóstico de dificuldades de aprendizagem, transtornos do neurodesenvolvimento (como TDAH) e na identificação de ne-	Bateria padronizada e administrada individualmente, composta por múltiplos subtestes organizados em quatro índices: Índice de Compreensão Verbal

		cessidades de intervenção pedagógica ou psicológica.	(ICV); Índice de Organização Perceptual (IOP); Índice de Memória Operacional (IMO); e Índice de Velocidade de Processamento (IVP).
Escala de Inteligência Weschler para Adultos (WAIS – III)	adolescentes e adultos com idades entre 16 e 89 anos.	Avaliar a capacidade intelectual e o funcionamento cognitivo global do indivíduo.	Permite a obtenção de resultados quantitativos referentes a quatro domínios cognitivos: compreensão verbal, memória operacional, organização perceptual e velocidade de processamento.
Escala de Inteligência Wechsler Abreviada (WASI)	Voltados para o atendimento de crianças, adolescentes, adultos e idosos (06 a 89 anos).	Examinar diferentes aspectos cognitivos, incluindo conhecimento verbal, processamento visual, raciocínio espacial e não verbal, bem como inteligência fluida e cristalizada em diversos contextos.	Associação com a WAIS-III e a WISC-III, oferecendo tabelas para estimativa das faixas de QIT. Na adaptação brasileira, também fornece tabelas para estimativa das faixas de QIT na WISC-IV.
Matrizes Progressivas Coloridas de Raven (CPM)	Crianças entre 05 a 11 anos e 11 meses de idade.	Mensurar a inteligência (Fator g) e fornecer informações sobre a capacidade educativa.	Avalia a habilidade de gerar novos insights — predominantemente não verbais — em situações complexas ou familiares, permitindo ao indivíduo ir além das informações disponíveis e identificar elementos que não são imediatamente óbvios.
O Matrizes Progressivas Avançadas de Raven (APM)	Entre 17 e 63 anos e escolaridade mínima de Ensino Superior em andamento.	Avaliar a inteligência e oferecer dados sobre a capacidade educativa de indivíduos com escolaridade mínima de Ensino Superior em andamento.	Avaliação da inteligência geral e pode ser aplicada em contextos clínicos ou em qualquer situação que exija mensuração dessa habilidade (padrão-ouro).

Caracterização dos estudos

Os estudos apresentam populações distintas, Chen *et al.* [6] avaliaram exclusivamente estudantes cegos na China, enquanto Cassar *et al.* [7] incluíram jovens com baixa visão severa ou cegueira e um grupo de pares videntes. Noor *et al.* [8] estudaram adolescentes com deficiência visual matriculados em escolas públicas para pessoas cegas na região de Rawalpindi, no Paquistão. Assim, os resultados não representam de forma homogênea crianças, adultos, idosos, pessoas com diferentes graus de baixa visão ou indivíduos com deficiências adicionais.

A diversidade linguística também é central. O estudo de Chen *et al.* [16] utilizou a versão chinesa da WISC-IV; Cassar *et al.* [17] trabalhou com instrumentos em contexto italiano; e Noor *et al.* [18] realizou tradução e retrotradução para o Urdu, com avaliação por especialistas e teste piloto. No estudo paquistanês, a estrutura fatorial identificada diferiu da estrutura de três fatores da versão original, demonstrando que a adaptação linguística não garante equivalência estrutural entre culturas.

A classificação é uma síntese crítica das informações disponíveis nos estudos e não deve ser interpretada como uma certificação do instrumento. O principal achado metodológico é a concentração das evidências em poucas propriedades: Chen *et al.* [6] apresentaram evidências de consistência interna e estrutura fatorial; Cassar *et al.* [7] concentraram-se em validade de construto em um estudo piloto; e Noor *et al.* [8] apresentaram conjunto mais amplo de evidências, incluindo adaptação linguística, consistência interna, confiabilidade e estrutura fatorial. Os dados referentes a qualidade metodológica dos estudos estão descritos na tabela 2.

Tabela 2: Avaliação de Risco de Viés (COSMIN).

Estudo	Consistência interna	Confiabilidade	Validade estrutural	Validade de construto	Validade transcultural	Amostra/desenho	Síntese COSMIN
Chen *et al.* [6]	Boa	Boa	Boa	Boa	Não estabelecida	Boa para VCI/WMI	Boa, mas restrita a crianças cegas chinesas
Cassar *et al.* [7]	NR	NR	NR	Boa	Não aplicável como estudo de adaptação	Adequada como estudo piloto	Adequada com limitações pelo n=25 no grupo com deficiência visual
Noor *et al.* [8]	Boa	Boa	Boa	Boa	Boa, com adaptação linguística	Boa	Boa para adolescentes com deficiência visual

Os artigos selecionados abordam temas diretamente relacionados à avaliação cognitiva em pessoas com deficiência visual. Os 3 estudos passaram pela avaliação qualitativa, e com a finalidade de abordar detalhadamente os estudos científicos foi elaborada uma tabela descritiva elucidando o objetivo do estudo, teste utilizado, desfecho, amostra e conclusão do estudo (Tabela 3). Os dados foram organizados em ordem de ano de publicação.

Tabela 3: Avaliação descritiva dos estudos selecionados.

Autor	Objetivo	Teste	Desfecho	n	Conclusão
Chen *et al.* [16]	Avaliar as propriedades psicométricas das escalas verbais do WISC-IV em estudantes cegos na China.	WISC-IV e escala cognitiva não verbal.	Alta confiabilidade (0,79–0,97) e validade; correlação moderada com medidas não verbais.	100	O WISC-IV é válido e confiável para avaliação cognitiva de crianças cegas.
Cassar *et al.* [17]	Desenvolver e testar um teste de inteligência não verbal haptico para jovens com deficiência visual.	3-DHMT-CA, Standard Progressive Matrices e WISC-IV	Boa validade convergente e divergente; diferenças entre grupos com e sem deficiência visual.	50	O 3-DHMT-CA é promissor para avaliação cognitiva não verbal, mas precisa de validação em amostras maiores.

Noor *et al.* [18]	Validar a versão em urdu da Tromso Social IntelligenceScale para adolescentes com deficiência visual no Paquistão.	Tromsø Social IntelligenceScale	Alta confiabilidade (α = 0,93), com boa consistência interna, teste-reteste e estrutura fatorial de 4 componentes.	215	A versão em urdu da TSIS é válida e confiável, sendo adequada para avaliar inteligência social em adolescentes com deficiência visual.

A principal contribuição desta revisão é demonstrar que a literatura recente sobre avaliação cognitiva acessível para pessoas com deficiência visual permanece escassa: apenas três estudos atenderam aos critérios estabelecidos. Esse resultado impede recomendações amplas e reforça a necessidade de interpretar cada evidência em função do instrumento, construto, idade, condição visual e contexto cultural. Os estudos incluídos avaliaram diferentes aspectos da cognição, abrangendo compreensão verbal, memória de trabalho, raciocínio não verbal e inteligência social, o que evidencia a heterogeneidade dos instrumentos disponíveis e impede sua consideração como medidas intercambiáveis.

Os resultados do estudo de Chen et al. (2021) [16] avaliaram o uso da quarta edição da Escala de Inteligência Wechsler para Crianças (WISC-IV) quanto à confiabilidade e validade dos escores das escalas verbais, especificamente o Índice de Compreensão Verbal (ICV) e o Índice de Memória de Trabalho (IMT), em crianças cegas na China. As avaliações foram realizadas utilizando a versão chinesa das Escalas de Desenvolvimento Cognitivo Verbal e Não Verbal do WISC-IV. Os achados confirmaram a consistência interna e a validade dos escores para essa população. Foram encontrados coeficientes de confiabilidade por split-half entre 0,79 e 0,97 e coeficientes de consistência interna entre 0,83 e 0,97 para as escalas analisadas. A validade de construto foi apoiada por análise fatorial exploratória e pela correlação moderada e positiva com a escala cognitiva não verbal. Conforme apontado por MacCallum et al. (1999), mesmo em amostras pequenas, com menos de 100 participantes, valores elevados de comunalidade e a presença de poucos fatores podem favorecer a aplicação da análise fatorial exploratória [16].

Esses resultados são relevantes para estudantes cegos na China, mas não permitem concluir que os mesmos parâmetros sejam válidos para crianças brasileiras, pessoas com baixa visão ou outras faixas etárias. A evidência também se refere às escalas verbais e não à totalidade do instrumento. Dessa forma, os resultados devem ser interpretados considerando as características específicas da população investigada e do contexto em que o instrumento foi aplicado. A validade e a confiabilidade observadas em determinada população não podem ser automaticamente generalizadas para indivíduos com diferentes condições visuais, características culturais, linguísticas ou faixas etárias.

No estudo de Cassar et al. (2022) [17], foi realizado um teste piloto de inteligência não verbal para crianças e adolescentes italianos com deficiência visual, incluindo participantes com cegueira ou baixa visão, com idades entre 10 e 16 anos. Participaram 25 indivíduos com deficiência visual, sendo 16 meninos e 9 meninas. O 3-DHMT-CA apresenta uma contribuição tecnológica diretamente relacionada à acessibilidade, por utilizar 22 matrizes tridimensionais táteis que permitem explorar os estímulos por meio da percepção háptica, reduzindo a dependência de informação visual. O participante deve identificar o padrão lógico subjacente aos estímulos táteis tridimensionais, manipulados simultaneamente com ambas as mãos.

A validade convergente do instrumento foi examinada por meio das Standard Progressive Matrices, enquanto a validade divergente foi analisada utilizando os índices verbal e de memória de trabalho da WISC-IV [17]. Entretanto, a amostra de participantes com deficiência visual foi pequena, caracterizando o estudo como piloto, e os próprios autores reconhecem a necessidade de estudos com amostras maiores e de análises qualitativas das estratégias utilizadas durante a resolução dos itens. Segundo Miller et al. (2007) [19], o desempenho em tarefas desse tipo pode estar associado à experiência visual, de modo que participantes capazes de formar imagens mentais da matriz, aqueles com visão normal ou baixa visão menos severa, tendem a obter pontuações superiores. Apesar disso, o estudo destacou estratégias compensatórias relacionadas à memória verbal e de trabalho em jovens com deficiência visual. Dessa forma, profissionais da educação e da reabilitação podem direcionar intervenções para o fortalecimento dessas habilidades, considerando que influenciam outros domínios cognitivos.

Embora o 3-DHMT-CA represente uma alternativa promissora para reduzir a dependência de estímulos visuais, seus resultados ainda não permitem classificá-lo como instrumento estabelecido para uso amplo. A amostra reduzida e as características específicas da população estudada limitam a generalização dos achados para outras populações com deficiência visual. Além disso, a influência da experiência visual e das estratégias cognitivas utilizadas durante a resolução demonstra que o desempenho em testes não verbais e hápticos pode envolver diferentes mecanismos compensatórios, os quais precisam ser considerados na interpretação dos resultados [17], [19].

Já no estudo de Noor et al. (2024) [18], realizado no Paquistão, foi avaliada a validade e confiabilidade da versão em urdu da Escala de Inteligência Social de Tromsø (TSIS), instrumento de autorrelato desenvolvido por Silvera et al. (2001) [20], para adolescentes com deficiência visual. Participaram 215 adolescentes, sendo 108 meninos e 107 meninas, matriculados em escolas públicas para cegos na divisão de Rawalpindi. O estudo foi desenvolvido em duas fases: tradução e validação da escala. A tradução direta e reversa para o urdu foi realizada pelo pesquisador com apoio de cinco especialistas bilíngues inglês–urdu, seguida de avaliação de conteúdo e face e teste piloto.

A versão Urdu da TSIS apresentou α=0,93, além de resultados favoráveis para teste-reteste, split-half e confiabilidade interavaliadores. Os resultados indicaram que o TSIS-U é um instrumento válido e confiável para essa população. Contudo, verificou-se que a estrutura fatorial de quatro fatores apresentou diferenças em relação ao modelo original desenvolvido em contexto ocidental [18], demonstrando que a equivalência transcultural não pode ser presumida. Esse resultado é particularmente relevante para o contexto brasileiro, uma vez que a tradução ou adaptação de um instrumento estrangeiro exige estudos próprios de validade, confiabilidade e estrutura interna na população brasileira.

A comparação entre os três estudos evidencia diferentes concepções de cognição. O estudo de Chen et al. [16] concentra-se principalmente em compreensão verbal e memória de trabalho; o estudo de Cassar et al. [17] aborda o raciocínio não verbal; e o estudo de Noor et al. [18] avalia a inteligência social. Portanto, os três instrumentos não são intercambiáveis. Um escore relacionado à inteligência geral ou a determinados índices cognitivos não pode ser diretamente comparado com uma medida de inteligência social ou com um teste específico de raciocínio não verbal sem considerar o construto avaliado, a população e as condições de aplicação.

A acessibilidade também não deve ser confundida com validade psicométrica. Um instrumento pode apresentar uma forma de apresentação acessível e, ainda assim, não possuir evidências suficientes de validade para determinada população. Da mesma forma, uma boa confiabilidade não demonstra, isoladamente, que o instrumento mede adequadamente o construto pretendido. A escolha de instrumentos para pessoas com deficiência visual deve, portanto, considerar simultaneamente acessibilidade, validade, confiabilidade, normas de interpretação e adequação à população.

As tecnologias digitais representam uma oportunidade para superar algumas dessas limitações. Interfaces compatíveis com leitores de tela, síntese de voz, braille digital, recursos táteis e hápticos, além de sistemas adaptativos, podem permitir diferentes modalidades de apresentação e resposta. A acessibilidade digital deve ser planejada desde o desenvolvimento do instrumento e não apenas adicionada posteriormente [4], [5]. Sistemas computadorizados e algoritmos de inteligência artificial também podem apoiar a adaptação da dificuldade, o registro de respostas e a análise de padrões cognitivos. Entretanto, sua adoção requer estudos de equivalência, avaliação de possíveis vieses algorítmicos, segurança, transparência e validade antes de sua utilização clínica ou profissional.

No Brasil, a aplicabilidade prática possui ainda uma dimensão regulatória. O SATEPSI é o sistema utilizado pelo Conselho Federal de Psicologia para avaliar a qualidade técnico-científica de instrumentos psicológicos e informar as condições de uso profissional [3]. Assim, os achados internacionais desta revisão não devem ser interpretados como recomendação para utilização profissional de instrumentos estrangeiros no país. A decisão sobre uso, administração e interpretação deve respeitar a regulamentação vigente, o manual técnico e as evidências disponíveis para a população e a finalidade pretendidas.

A participação de pessoas com deficiência visual no desenvolvimento e na validação dos instrumentos também merece maior atenção. Além da comparação de escores psicométricos, estudos futuros devem investigar a compreensão das instruções, o conforto, o tempo de aplicação, as barreiras de acesso, as estratégias utilizadas, a preferência por modalidades de resposta e os possíveis efeitos da experiência prévia com tecnologia. Essa abordagem pode contribuir para evitar que um instrumento formalmente acessível permaneça pouco utilizável na prática.

A heterogeneidade observada também impede inferências sobre qualidade de vida, autonomia ou inclusão social, pois esses desfechos não foram avaliados diretamente pelos três estudos incluídos. O benefício potencial da acessibilidade deve, portanto, ser discutido como hipótese ou implicação para pesquisas futuras, e não como resultado demonstrado por esta revisão.

Em síntese, os três estudos apresentam evidências promissoras de confiabilidade, validade e acessibilidade para diferentes instrumentos e populações com deficiência visual, mas a base de evidências permanece limitada e heterogênea. Os resultados de Chen et al. [16], Cassar et al. [17] e Noor et al. [18] devem ser interpretados de acordo com suas respectivas populações, construtos, contextos culturais e características metodológicas. Dessa forma, ainda não é possível recomendar um instrumento único ou estabelecer parâmetros universais para avaliação cognitiva de pessoas com deficiência visual. São necessários estudos com amostras maiores e diversificadas, diferentes faixas etárias e condições visuais, além de processos rigorosos de adaptação transcultural e validação para o contexto brasileiro. A ampliação do uso de tecnologias assistivas, interfaces táteis e hápticas e recursos digitais poderá contribuir para avaliações mais acessíveis, desde que acompanhada de evidências psicométricas e de critérios técnicos e regulatórios adequados.

IV. Conclusão

Esta revisão buscou evidenciar a relevância e a necessidade de instrumentos de avaliação da inteligência adaptados para pessoas com deficiência visual. A ausência de tais instrumentos limita oportunidades e compromete a qualidade de vida dessa população, restringindo o desenvolvimento de suas habilidades e competências. Observa-se ainda que boa parte do campo científico em avaliação psicológica permanece voltado a populações sem dificuldades perceptuais. Nessa perspectiva, a integração com a Tecnologia Assistiva é fundamental, uma vez que seus recursos, dispositivos e sistemas ampliam autonomia e independência, favorecem intervenções mais precisas e promovem a inclusão social, evitando que essas pessoas permaneçam à margem da sociedade.

***Abstract*—Post-stroke Homonymous Hemianopia (HH) is a frequent visual impairment that significantly compromises functional independence. This pilot study investigated the effects of repetitive Transcranial Magnetic Stimulation (rTMS) on cortical responses measured by electroencephalography (EEG) using a Steady-State Visual Evoked Potential (SSVEP)-based visual field assessment. Two patients with chronic post-stroke left underwent four rTMS sessions delivered over the lesioned occipital cortex. EEG responses were recorded before and after the intervention using both a conventional central-fixation SSVEP paradigm and a novel peripheral visual stimulation protocol. Spectral power and variability were analyzed in Theta, Low Beta, and High Beta frequency bands. The peripheral protocol produced more stable recordings with substantially lower signal dispersion than the conventional approach, reducing contamination by electromyographic (EMG) and oculomotor artifacts. Following rTMS, both participants demonstrated increased Low Beta power under the peripheral protocol, suggesting enhanced cortical synchronization and improved responsiveness of preserved visual pathways. Theta-band activity decreased after stimulation, indicating reduced pathological slow-wave activity and possible recovery of perilesional cortical function. In contrast, High Beta responses were heterogeneous, reflecting individual differences in cortical entrainment capacity and neuroplastic potential. Overall, the combination of rTMS with peripheral SSVEP assessment provided more reliable electrophysiological measurements than the conventional paradigm and showed promising sensitivity for monitoring neurophysiological changes after stroke. Although the findings are limited by the small sample size, they support the feasibility of this approach as an objective tool for assessing visual cortical function during rehabilitation. Larger longitudinal studies incorporating computerized visual perimetry are warranted to confirm whether the observed electrophysiological improvements correspond to meaningful functional recovery.**

Keywords—Stroke, SSVEP, rTMS, homonymous hemianopia.

I. INTRODUCTION

The clinical diagnosis of stroke is primarily based on the persistence of symptoms such as impaired consciousness, language disturbances, visual field deficits, extraocular motility abnormalities, visual neglect, motor weakness, and sensory loss following an acute cerebral infarction [1].

A study involving post-stroke patients, with a mean time since stroke ranging from 22 days to 3 months, demonstrated that approximately 915 patients developed some form of visual impairment resulting from either ischemic or hemorrhagic cerebrovascular events. Lesions directly affecting the occipital lobe were the most frequent, accounting for 54% of patients with post-stroke visual impairment. Among the persistent visual deficits, visual field loss (hemianopia) was the most common manifestation [2]. Stroke-related HH is characterized by damage to the occipital cortex or any portion of the retrochiasmal visual pathway extending to the primary visual cortex (V1), impairing visual information processing and resulting in the loss of the same visual hemifield in both eyes [3].

SSVEP is a widely used technique in Brain–Computer Interface (BCI) systems for assessing the response of the visual cortex to periodic visual stimulation. This technique is based on the individual's fixation on a flickering visual stimulus oscillating at a predetermined frequency, which elicits electrical brain responses at the same frequency as the stimulus. These responses are recorded using EEG are predominantly detected over the occipital region, where the visual cortex is located [4].

rTMS is a non-invasive neuromodulation technique that uses magnetic pulses to induce electrical currents in the cerebral cortex, thereby modulating cortical excitability and promoting neuronal plasticity processes [7]. Considering that brain regions affected by stroke frequently exhibit reduced cortical electrical activity, a decrease in the amplitude of signals, is commonly observed when compared with unaffected brain regions [5,6].

In the present study, the SSVEP technique combined with EEG was used as a method to assess the functional condition of the occipital visual cortex. The aim of this investigation was to compare the amplitudes of EEG signals recorded from the hemisphere corresponding to the damaged visual cortex before and after rTMS intervention in post-stroke patients. An increase in signal amplitude may indicate improved cortical activity and responsiveness in the affected occipital region and, consequently, possible changes associated with neuroplasticity processes.

II. Methodology

A. Recruitment and Participants

This study was designed as a pilot, controlled clinical trial with assessor blinding and was conducted at the Espírito Santo Physical Rehabilitation Center (CREFES) in Vila Velha, Brazil. All participants provided written informed consent before enrollment in the study.

Individuals were eligible for inclusion if they had a diagnosis of stroke, were 18 years of age or older, presented with residual hemiparesis or hemiplegia, and had preserved comprehension and communication abilities. Exclusion criteria included a history of epilepsy or seizures, photosensitive epilepsy, severe ocular immobility, previous craniectomy, intracranial metallic implants, or any contraindication to rTMS.

For this pilot analysis, two patients with stroke-related left homonymous visual field loss were recruited. Patient 1, a 46-year-old individual with a large right nucleocapsular hemorrhagic stroke. Patient 2, a 77-year-old individual with an ischemic stroke involving the right middle cerebral artery territory. A total of four rTMS sessions were administered over two consecutive days, with two sessions performed each day, one in the morning and one in the afternoon.

B. rTMS intervention

Each stimulation session lasted approximately 580s, during which 1,000 rTMS pulses were delivered at a frequency of 10 Hz and an intensity corresponding to 60% of the Resting Motor Threshold (RMT). The RMT was determined using the abductor pollicis brevis muscle. The stimulation protocol consisted of 25 trains of stimuli, with 40 pulses per train and inter-train intervals of 20s. Stimulation was delivered over the O2 electrode position corresponding to the lesioned visual cortex, according to the International 10–20 EEG electrode placement system.

The coil was positioned with the handle pointing downward and angled at 45° relative to the sagittal plane, so that the induced electric field remained perpendicular to the underlying cortical gyrus [8]. All sessions were performed using a MagVenture MagPro R30 (Farum, Denmark) equipped with a figure-of-eight coil (Cool-B70).

C. Design and Implementation of the SSVEP Paradigm

The visual field integrity assessment protocol was based on SSVEP. paradigm specifically designed for diagnostic purposes (objective perimetry) was employed. Participants were instructed to maintain visual fixation on a static central target, thereby restricting eye movements and minimizing artifacts generated by saccadic eye movements. Simultaneously, flickering visual stimuli were presented sequentially in four orthogonal peripheral regions at independent stimulation frequencies of 6.0 Hz (Theta), 10.28 Hz (Alpha), 14.4 Hz (Low Beta), and 18.0 Hz (High Beta). Visual stimuli were displayed on a 48 × 27 cm monitor with a resolution of 1280 × 720 pixels. Participants were seated facing the monitor at an approximate viewing distance of 35 cm. This configuration covered 68.4° of the horizontal visual field and 41.6° of the vertical visual field (Fig. 1). Previous studies have demonstrated that peripheral visual stimulation elicits robust cortical responses while significantly reducing discomfort and visual fatigue during prolonged assessments, allowing objective visual field mapping without requiring voluntary eye movements [9]. EEG signals were recorded over the parieto-occipital region using electrodes P7, O1, O2, and P8, EEG signals were acquired using the Emotiv EPOC X system, with a sampling rate of 256 Hz. The signal-processing architecture continuously computed Band Power and Signal-to-Noise Ratio (SNR), comparing these measures with a baseline acquired during the initial 15s calibration period. To improve system sensitivity, the event detection algorithm incorporated a compensatory mathematical correction based on the 1/f power-law spectral distribution (aperiodic noise), an intrinsic characteristic of background electrophysiological activity [10]. Since both spectral power and signal amplitude decrease logarithmically with increasing frequency (a phenomenon further accentuated by the lower density of cones in the peripheral retina) the system adjusted the detection thresholds (SNR thresholds) asymmetrically and inversely proportional to the target stimulation frequency. Consequently, the 18.0 Hz stimulus required a mathematically lower activation criterion than that established for the Theta (6.0 Hz). During the assessment, if the signal failed to exceed the adjusted threshold within the stimulation window, the algorithm recorded a timeout event. The absence of an evoked response provided objective clinical evidence for mapping and topographically identifying potential disruptions or deficits within the contralesional optic radiations associated with the stroke lesion.

Analysis evaluates the impact of rTMS on SSVEP responses in patients with stroke. The analytical focus is the comparison between a conventional SSVEP protocol, in which participants maintain visual fixation on the flickering stimulus, and a peripheral SSVEP protocol, in which participants maintain fixation on the center of the screen while visual stimuli are presented in the peripheral visual field. The peripheral protocol was specifically developed to accommodate the neurophysiological limitations of this patient population.

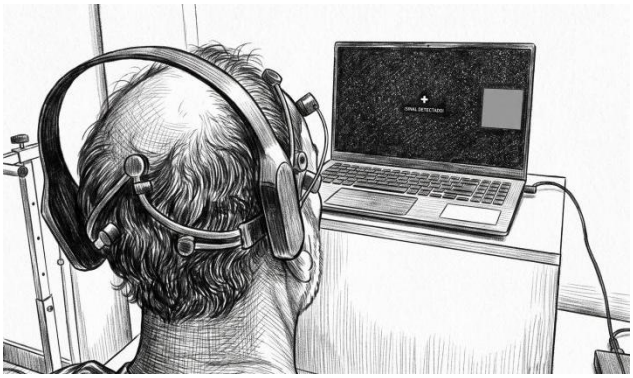

Fig. 1. SSVEP-based EEG signal acquisition system for assessing central and peripheral visual field integrity.

III. Results and Discussion

A. Electromyographic Noise Dispersion Analysis and Mitigation

Use In EEG recordings from patients with neurological impairments, forced visual fixation frequently triggers fatigue and spasticity, contaminating cortical signals with EMG and oculomotor artifacts. To quantify this contamination and assess signal stability, the Coefficient of Variation (CV) was calculated, expressed as the ratio

between the standard deviation (σ) and the mean (μ) of the absolute spectral power:

$$CV = \sigma/\mu \quad (1)$$

The spectral analysis of the baseline session (Pre-TMS) demonstrated that the traditional paradigm is mathematically unsuitable for standardized clinical applications due to its extreme instability. According to the data presented in Table 1, in the Patient 1, for Low Beta band (14.4 Hz), the traditional protocol showed a mean power value of μ = 7.91 associated with an aberrant standard deviation of σ = 64.43, resulting in a CV ≈ 8.14. In biomedical signal processing theory, such a high CV indicates that the recorded activity does not represent a stimulus-evoked response, but rather an anomaly dominated by peripheral noise. In clear contrast, the peripheral protocol demonstrated robustness and ergonomic suitability. For the same patient and frequency band, the baseline recording yielded μ = 0.93 and σ = 0.51, resulting in a CV ≈ 0.54. This substantial reduction in signal dispersion confirms that the peripheral interface minimizes oculomotor strain, providing a cleaner cortical signal suitable for quantifying the actual effects of neuromodulation, which is widely recognized for modulating cortical excitability and promoting neuroplasticity in ischemic tissues [11].

TABLE I. STATISTICAL METRICS OF ABSOLUTE SPECTRAL POWER (PRE- AND POST-TMS) IN BETA BANDS

Band	Protocol	P1/P2	Pre Mean	Pre SD (σ)	Post Mean	Post SD (σ)	p-value	Change (%)
Low Beta	Peripheral vision	P1	0.9320	0.5117	1.1315	0.4855	< 0.001*	+21.41%
		P2	0.3749	0.1612	0.4180	0.1998	0.0241*	+11.49%
	Central vision	P1	7.9132	64.4335	1.1559	0.8882	< 0.001*	−85.39%
		P2	0.3182	0.1282	0.7049	0.4169	< 0.001*	+121.53%
High Beta	Peripheral vision	P1	0.6215	0.2059	1.0530	0.2984	< 0.001*	+69.43%
		P2	0.2578	0.0720	0.2480	0.0892	0.0290*	−3.80%
	Central vision	P1	5.1941	42.8837	0.8935	0.2985	< 0.001*	−82.79%
		P2	0.2899	0.0718	0.4487	0.1537	< 0.001*	+54.77%

[a.] Correspond to specific stimulation frequencies (Low Beta ≈ 14.4 Hz; High Beta ≈ 18.0 Hz). The Wilcoxon signed-rank test was applied to determine the p-value, with a significance level of 5% (α = 0.05).

B. Low-Frequency Spectrum Normalization (Theta Biomarker)

Clinically, a brain affected by ischemia or hemorrhage exhibits a pathological focal increase in Theta spectral activity (4–8 Hz), which is considered a prominent biomarker of tissue damage [12]. The extracted results demonstrated that induced an abrupt and significant reduction in Theta power in Patient 1 (from 5.10 to 2.54, $p < 0.001$). Neurophysiologically, the attenuation of slow-wave activity following neuromodulation reflects the reversal of cortical inhibition and metabolic recovery of perilesional tissue [12]. This phenomenon may have increased the responsiveness of the patient's visual cortex to higher-frequency SSVEP stimuli in subsequent stages.

C. Consistent Facilitation of the Magnocellular Pathway (Low Beta)

The clinical effectiveness of the proposed peripheral vision protocol is illustrated in Fig. 2. At intermediate-to-high stimulation frequencies (Low Beta, 14.4 Hz), a trend toward synergistic facilitation was observed in both patients, in contrast to the unpredictable behavior of the central vision model. Patient 1 exhibited an increase of +21.41%, whereas Patient 2 showed an increase of +11.49% (both $p < 0.05$).

The neuroanatomical explanation for this finding lies in the segregation of the visual pathways. Central vision is predominantly mediated by the parvocellular pathway, which is specialized for high spatial resolution but has limited temporal resolution. In contrast, peripheral vision is predominantly processed by the magnocellular pathway, which exhibits high sensitivity to motion and flickering visual stimuli [13]. The architecture of the proposed system successfully engaged this temporally sensitive pathway, enabling the interface to compensate for the characteristic attenuation imposed by the EEG 1/f law.

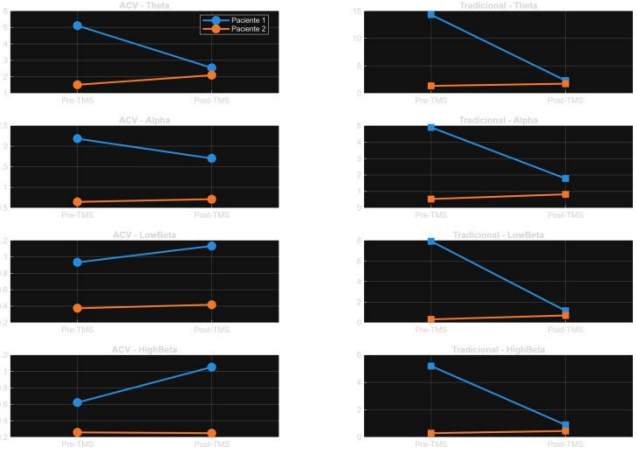

Fig. 2. Individual trajectory dynamics before and after rTMS. A consistent increase in spectral power is observed with the peripheral vision protocol (left), in contrast to the mathematical variability induced by the central vision protocol (right).

D. Neuroplastic Limits and Saturation in the High Beta Band

Despite the overall benefits, the response of the visual cortex in the High Beta band (18.0 Hz) revealed the

neuroplastic limits of each participant, as summarized in Fig. 3. Under the peripheral protocol, Patient 1 exhibited a substantial increase of +69.43% at 18.0 Hz. In contrast, Patient 2 showed a plateau accompanied by a slight decrease of −3.80% ($p = 0.0290$). This contrast provides quantitative evidence that stimulation above 15 Hz may exceed the entrainment capacity of cortical networks with more severe impairment [14].

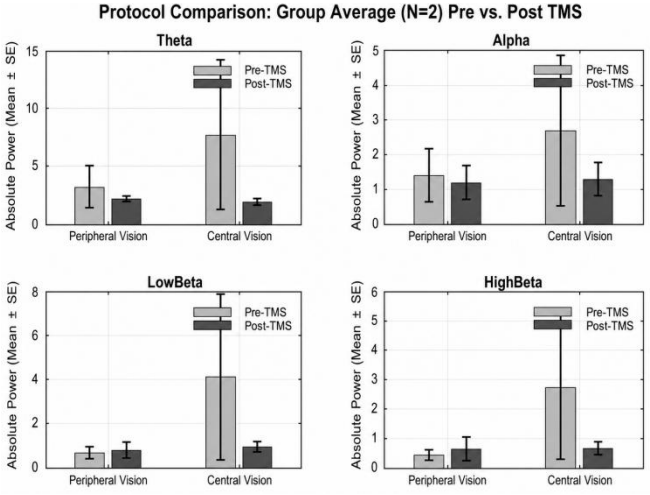

Fig. 3. Group mean power (N = 2) with error bars representing the Standard Error of the Mean. The results demonstrate the reliability of the peripheral vision protocol for pre and post-intervention measurements.

IV. Conclusion

The results of this pilot study demonstrate that the SSVEP-based assessment protocol using peripheral visual stimulation outperformed the conventional central vision paradigm for the electrophysiological evaluation of patients with post-stroke hemianopia. The peripheral protocol produced more stable signals, with lower spectral dispersion and reduced susceptibility to electromyographic and oculomotor artifacts, indicating greater robustness for clinical applications.

The rTMS intervention was accompanied by consistent changes in the analyzed electrophysiological biomarkers. The reduction in Theta-band power suggests a decrease in pathological cortical activity, consistent with the functional recovery of perilesional tissue. Likewise, the increases observed in the Low Beta band indicate improved cortical synchronization to periodic visual stimuli, particularly when using the peripheral vision protocol, demonstrating greater efficiency in engaging the preserved visual pathways.

On the other hand, the heterogeneous response observed in the High Beta band indicates that the effects of neuromodulation depend on individual neurophysiological characteristics. While one participant exhibited a marked increase in spectral power, the other showed a plateau in the response, suggesting that higher stimulation frequencies may reach the synchronization limits of more severely impaired cortical networks.

Overall, these findings indicate that the combination of rTMS and SSVEP-based assessment using peripheral visual stimulation represents a promising approach for the objective monitoring of visual function following stroke. However, due to the small number of participants, the findings should be interpreted as preliminary evidence. Future studies involving larger cohorts, longitudinal follow-up, and different stimulation parameters are required to confirm the reproducibility of these findings and establish the clinical applicability of this protocol for the rehabilitation of post-stroke visual field loss.

The peripheral SSVEP protocol represents a promising methodological contribution to the assessment of occipital visual function. Pre/post-rTMS changes should be interpreted with caution, considering spontaneous variability, fatigue, practice effects, time of day, medication, and electrode contact. The timeout does not constitute objective evidence of damage to the optic radiations.

Furthermore, there is no guarantee that the mathematical increases observed in the peripheral visual field for SSVEP responses following rTMS correspond to actual improvements in visual field function. Confirmation of such functional gains will require evaluation using computerized visual perimetry. It is also noteworthy that Patient 2 reported a burning sensation in the eyes after the rTMS session, as well as pain in the posterior region of the neck. Patient 2 exhibited recovery of upper left limb motor function whose magnitude exceeded the clinical improvement typically expected with conventional physical rehabilitation methods. Although it is not possible to establish a causal relationship based on a single case, this finding strongly suggests that the rTMS intervention may have contributed to the observed motor recovery. These results highlight the need for studies with larger sample sizes and more robust methodological designs to investigate the mechanisms by which occipital cortex stimulation may induce neural plasticity and promote motor recovery following neurological injury.

Acknowledgments

The authors would like to express their sincere gratitude to all co-authors and collaborators whose contributions were essential to the development of this research. Special thanks are extended to CREFES for providing the infrastructure and clinical support necessary for conducting this study. The authors also wish to acknowledge Lucimara Aparecida Pereira for her invaluable assistance, dedication, and support throughout the execution of this research. Finally, the authors are deeply grateful to participants who voluntarily took part in this study.

***Resumo*—A lesão medular cervical pode comprometer a função dos membros superiores e reduzir a independência nas atividades da vida diária. Este estudo apresenta o desenvolvimento preliminar do *Market Rehab*, um ambiente de realidade virtual integrado às luvas hápticas SenseGlove Nova 2 para a realização de tarefas funcionais de alcance, contato, preensão, transporte e liberação de produtos por pessoas com lesão medular cervical. Apresentam-se os resultados de um estudo piloto descritivo com seis voluntários saudáveis para avaliar a viabilidade técnica e a usabilidade do sistema desenvolvido. Neste estudo-piloto, uma execução foi definida como uma tentativa registrada, desde o início até sua conclusão bem-sucedida. Cada participante realizou nove execuções: uma para cada um dos Níveis 1 a 4 e cinco execuções específicas de produto no Nível 5, totalizando 54 execuções entre os seis participantes. Todos os usuários concluíram os cinco níveis de tarefa propostos, apresentando um tempo médio geral de conclusão de 17,07 s, apresentado aqui como um indicador descritivo global. Nas 54 execuções, observou-se uma média de 1,28 tentativa por execução e foram registrados doze erros, dos quais oito ocorreram durante a liberação dos produtos. A pontuação média na *System Usability Scale* foi de 85,8 pontos, o que indica que os usuários avaliaram positivamente a interface, embora tenham relatado distância excessiva de alguns produtos, dificuldade de preensão e percepção do peso da luva. Os resultados confirmam a viabilidade técnica preliminar do sistema, mas indicam a necessidade de otimizar a interação e quantificar o impacto biomecânico da massa distal antes de sua aplicação em pessoas com lesão medular incompleta.**

***Index Terms*—Lesão medular cervical, lesão medular, realidade virtual, luva háptica, SenseGlove, membro superior.**

I. Introdução

A lesão medular (LM) apresenta elevado impacto funcional e social, com estimativas globais indicando aproximadamente 15,4 milhões de pessoas no mundo vivendo com LM em 2021 [1]. Estudos recentes descrevem diferenças relevantes de incidência, etiologia e distribuição demográfica entre regiões [2], [3]. Na América Latina, limitações de acesso, padronização e disponibilidade de serviços especializados ainda afetam a assistência e a reabilitação dessa condição [4].

Nas lesões cervicais, a função dos membros superiores tipicamente reduz significativamente a independência em atividades da vida diária [5]. Portanto, tarefas de alcance, preensão, pinça, transporte e liberação de produtos são componentes funcionais prioritários a serem trabalhados. Embora a lesão comprometa vias motoras e somatossensoriais, processos de plasticidade permanecem relevantes para a recuperação e para o treinamento motor [6].

A reabilitação convencional baseia-se principalmente em exercícios repetitivos, prática intensiva de treinamento funcional e participação ativa [7]. Contudo, sua aplicação pode ser limitada pela redução da motivação do paciente, dificuldade de padronização das tarefas, dependência de observações subjetivas e escassez de medidas objetivas capazes de repre- sentar o desempenho durante atividades funcionais [7], [8].

Nesse contexto, os jogos sérios (JS) surgem como alternativa para complementar processos tradicionais, oferecendo ambientes seguros, controlados e motivadores, alinhados às necessidades terapêuticas [8], além de integrar tecnologias como realidade virtual e feedback háptico, ampliando a imersão e o engajamento [8], [12]. Embora estudos recentes indiquem a viabilidade dessas tecnologias em terapias de LM [13], [18], persistem limitações como elevada heterogeneidade metodológica, amostras reduzidas, escassez de protocolos para membros superiores [4], [6], [9], [10], alem de demanda crescente por intervenções com métricas objetivas de avaliação funcional [15], [16].

As luvas hápticas ampliam essa abordagem ao combinar o rastreamento das mãos com o feedback sensorial [12], havendo apresentado potencial para o treinamento motor de membros superiores em populações neurológicas [12]. Embora esses achados não possam ser diretamente extrapolados para pessoas com LM, os resultados dessas pesquisas indicam que essa integração é promissora. Entre essas tecnologias, as luvas hápticas Nova 2 (SenseGlove, Países Baixos) destacam-se pela compatibilidade com o motor de jogos Unity e com

os óculos Meta Quest 3. Essas integrações permitem recriar tarefas funcionais de alcance, preensão, transporte e liberação de produtos. Para isso, o sistema desenvolvido fornece feedback de resistência passiva em quatro dedos, contato palmar e vibração [19]–[21]. Porém, antes da aplicação clínica, é indispensável validar sua estabilidade, interação, registro de métricas e tolerância ao dispositivo.

Este trabalho tem como objetivo desenvolver e avaliar, por meio de um estudo piloto com voluntários saudáveis, o *Market Rehab*, o qual é um ambiente de Realidade Virtual (RV) criado em Unity, integrado às luvas Nova 2 e aos óculos Meta Quest 3. O estudo não temcomo objetivo demonstrar eficácia terapêutica, mas estabelecer uma base técnica para futura avaliação em pessoas com LM incompleta. Para tal fim, foram analisados: conclusão das tarefas, tempo de execução, número de tentativas, erros de preensão e liberação, bem como a usabilidade do sistema desenvolvido.

II. Metodologia

A. Delineamento do estudo e Características dos Usuários

Neste trabalho foi realizado um estudo piloto descritivo, transversal, não clínico e não terapêutico, destinado à avaliação da viabilidade técnica do sistema proposto. Participaram seis voluntários saudáveis com idades entre 20 e 40 anos, três mulheres e três homens, com idade média de $26{,}33 \pm 5{,}28$ anos, em sessões de 30-40 min.

O critério do inclusão no estudo abrangia voluntários, capazes de compreender as instruções e realizar movimentos voluntários da mão, aceitassem utilizar a luva e o ambiente de RV e assinassem o termo de consentimento livre e esclarecido (TCLE). Foram excluídos voluntários com dor atual no membro superior, lesão recente, alterações cutâneas na área de contato da luva, limitação neurológica ou musculoesquelética relevante, intolerância intensa à RV ou sintomas que impedissem a continuidade da sessão.

B. Sistema e Ambiente de RV

O hardware do sistema é apresentado na Fig. 1, o qual é constituído pelos óculos *Meta Quest 3* (Fig. 1 A) e luvas *SenseGlove Nova 2* (Fig. 1 B) para interação e feedback háptico. O feedback sensorial era aplicado durante as etapas de contato, preensão e liberação dos produtos pelas luvas. Para definir a posição espacial de cada mão, as luvas foram integradas fisicamente aos controles Touch Plus do Meta Quest 3 (Fig. 1 C). O sistema foi configurado para execução em sedestação, visando reduzir deslocamentos excessivos do tronco.

A integração desse hardware foi realizada no motor de jogos Unity 2022.3.62f3, utilizando o Meta XR All-in-One SDK para os óculos e o Nova 2 Unity Plugin v2.6 para as luvas. Nesse mesmo ambiente de RV foi criado o cenário virtual *Market Rehab* (Fig. 2), que reproduz um pequeno mercado contendo plateleiras, um carrinho de compras e produtos alimentícios de diferentes formatos. Na cena, os modelos virtuais das mãos são controlados diretamente pelas luvas hápticas. O sistema executa e registra automaticamente, em

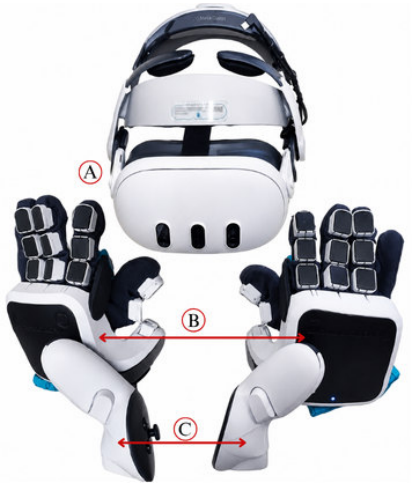

Figura 1. Elementos de hardware do sistema desenvolvido.

Figura 2. Ambiente virtual *Market Rehab* utilizado nas tarefas de manipulação funcional com as luvas hápticas SenseGlove Nova 2.

arquivos CSV, as métricas de desempenho durante a sequência de alcance, preensão, transporte e liberação dos productos.

Dentro do mesmo ambiente de RV foram integrados 5 níveis (Fig.3) baseados em tarefas que foram definidas a partir de movimentos funcionais para a manipulação de produtos, tais como, alcance, contato, preensão, transporte e liberação [5], [9], [10], [12]. Desta forma os componentes de interação associadas a movimentos foram testados e, posteriormente, integrádos em uma atividade contextualizada [13], [14].

Nos quatro primeiros níveis foi utilizada uma execução principal associada ao objetivo do nível. No quinto nível, diferentes produtos foram manipulados individualmente. Por essa razão, as análises por execução identificam o nível e o produto (por exemplo, L04-Leite ou L05-Geleia), enquanto a taxa de conclusão foi calculada para os cinco níveis de tarefa.

C. Procedimento Experimental

Inicialmente, foram registrados os dados dos voluntários do estudo, tais como código anônimo, idade, gênero, mão dominante e experiência prévia com RV. Sintomas de dor, fadiga, tontura e náusea (típicamente inerente ao uso de óculos de RV foram avaliados por meio de uma escala numérica de 0 a 10. Em seguida, com o voluntário em sedestação, as luvas foram colocadas, ativadas e calibradas por meio do *SenseCom*,

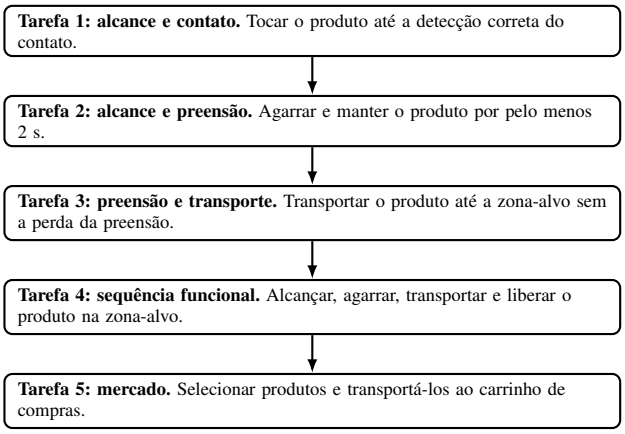

Figura 3. Progressão dos cinco níveis experimentais, do contato inicial à manipulação funcional dos produtos no carrinho de compras.

verificando-se a conexão, o funcionamento do feedback e a coerência entre os movimentos reais e virtuais. Posteriormente, os óculos de RV) foram posicionados e ajustados para garantir o conforto do voluntário.

Antes de cada nível, fori explicado verbalmente a cada voluntário o objetivo e o critério de conclusão do experimento. Não houve etapa livre de familiarização; assim, a primeira execução também foi registrada. Vale resaltar que os usuarios utilizaram a mão de preferência e podiam utilizar ambas as mãos quando necessário.

D. Usabilidade e Análise dos Dados

Após as tarefas, os voluntários responderam ao *System Usability Scale* (SUS), composto por dez itens em escala Likert de cinco pontos [17]. A pontuação foi calculada pelo procedimento convencional e variou de 0 a 100. Para interpretação descritiva da qualidade do sistema desenvolvido, foi adotada a referência de 68 pontos onde uma pontuação entre 68 e 80 é considerada bom; de 80 a 85 é muito bom; e um valor acima de 85 representa um sistema com excelente usabilidade [18]. Também foi disponibilizado um campo aberto para observações gerais do voluntário sobre o sistema.

Devido ao caráter piloto e ao tamanho amostral, foram realizadas análises descritivas considerando: i) tempo por voluntário e execução; ii) erros de preensão e liberação; iv) progressão temporal; v) pontuação SUS.

III. Resultados

A Tabela I sintetiza os principais resultados. O tempo médio de execução do experimento foi de 17,07 s, com intervalo de 9,5–28,7 s, apresentando média de 1,28 tentativas por tarefa e 12 erros ao longo das 54 execuções registradas, ocorridos predominantemente na etapa de liberação.

A. Desempenho nas Tarefas

A progressão temporal de cada voluntário é apresentada na Fig. 4. Os resultados mostram variabilidade interindividual e picos pontuais ao longo do protocolo. O participante P04

Tabela I
Tempo de conclusão, tentativas e erros por nível

Nível	Execuções	Tempo (s)	Mediana (s)	DP (s)	Tentativas	Erros
N01	6	23.68	12.01	34.49	6	0
N02	6	9.00	7.07	3.92	6	0
N03	6	21.54	20.45	15.44	8	1
N04	6	21.99	18.69	15.99	9	3
N05	30	15.49	11.65	10.79	41	8

apresentou um aumento expressivo do tempo para o produto L01-Cereal, enquanto P01 apresentou maiores tempos para L04-Leite e L05-Geleia. Esses picos ocorreram em execuções específicas e não caracterizaram uma redução contínua do desempenho durante toda a sessão.

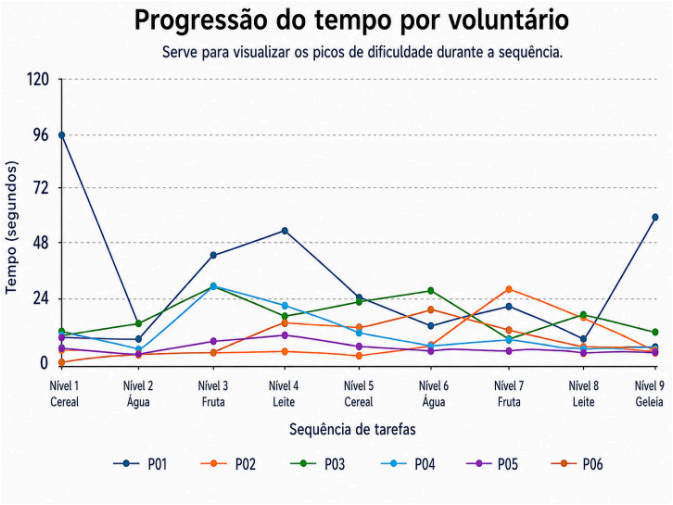

Figura 4. Progressão do tempo de execução ao longo das tarefas para cada voluntário.

A comparação dos tempos médios por voluntário é apresentada na Fig. 5. O voluntário P01 apresentou o maior tempo médio (28,7 s), consistente com o maior número de tentativas e erros registrados, seguido por P04 (22,6 s) e P03 (19,6 s). Em contraste, P05 apresentou o menor tempo médio (9,5 s), seguido por P02 (10,2 s) e P06 (11,8 s).

A distribuição dos erros por execução é apresentada na Tabela II. A maior concentração ocorreu para L05-Geleia, com quatro erros, seguida por L04-Leite, com três ocorrências. Também foram registrados dois erros em L05-Cereal e L05-Fruta, e um erro para L03-Fruta. Não foram observados erros para L01-Cereal, L02-Água, L05-Água e L05-Leite.

A distribuição dos erros entre os voluntários (Fig. 6a) indica que se apresentaram, no conjunto da amostra, quatro erros de preensão e oito de liberação, evidenciando maior ocorrência de dificuldades durante a liberação dos produtos virtuais. Nesse sentido, P01 apresentou oito erros e concentrou a maior parcela das falhas de liberação.

B. Usabilidade

A pontuação média do *System Usability Scale* (SUS) foi de 85,8 pontos, o que representa uma usabilidade excelente

Figura 5. Tempo médio de execução para cada voluntário.

Tabela II
DISTRIBUIÇÃO DOS ERROS POR EXECUÇÃO

Execução	Erros
L05-Geleia	4
L04-Leite	3
L05-Cereal	2
L05-Fruta	2
L03-Fruta	1
L01-Cereal	0
L02-Água	0
L05-Água	0
L05-Leite	0

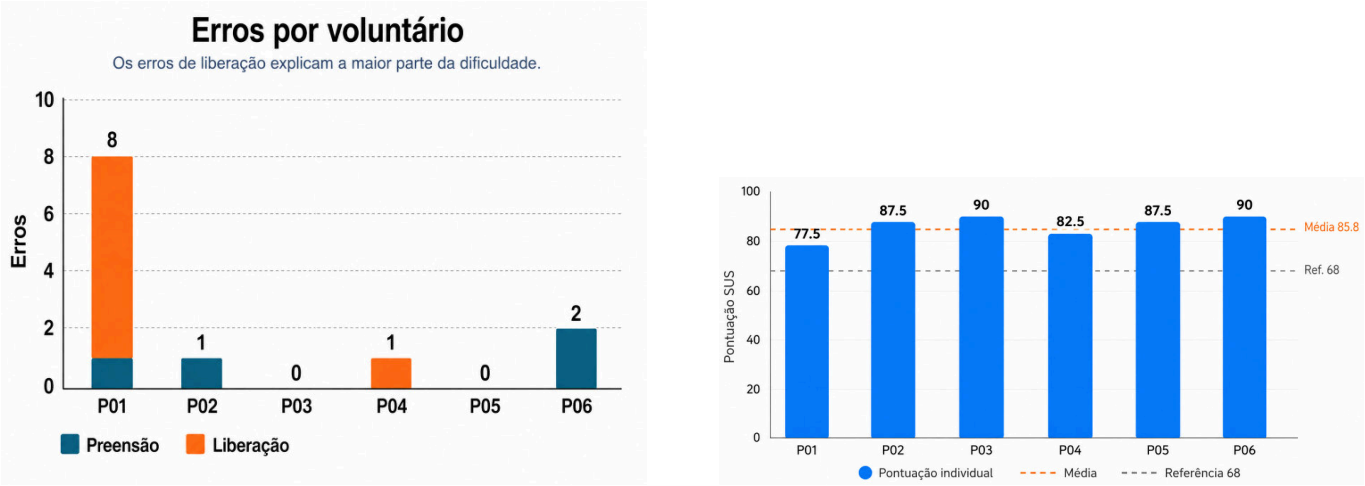
segundo os critérios de avaliação. Todos os voluntários atribuíram pontuações superiores ao valor de referência de 68 pontos, como mostrado na Fig. 6b, sendo que P03 e P06 alcançaram 90 pontos, enquanto P01 apresentou a menor pontuação, com 77,5 pontos.

Nos comentários abertos, os voluntários relataram uma boa aceitação da interface e do ambiente de RV. Entretanto, também indicaram que alguns produtos estavam posicionados a uma distância excessiva ou eram difíceis de agarrar. Ademais, a luva foi percebida como pesada durante a execução das tarefas.

IV. DISCUSSÃO

A. Desempenho e interação no ambiente de RV

Os resultados demonstram a viabilidade técnica preliminar do *Market Rehab* para a execução e o registro de tarefas funcionais em ambiente de RV. Todos os seis voluntários concluíram os cinco níveis propostos, e o sistema registrou de forma estruturada o tempo de execução, o número de tentativas e os erros ocorridos durante a interação. O tempo médio entre os voluntários foi de 17,07 s, com valores médios individuais variando entre 9,5 s e 28,7 s, enquanto foram registradas, em média, 1,28 tentativas por execução. Esses resultados evidenciam variabilidade entre os usuários e mostram que a conclusão das tarefas, isoladamente, não descreve integralmente a interação com o sistema.



Essa diferença pode ser observada, por exemplo, em P01, que concluiu todo o protocolo, mas apresentou o maior tempo médio, maior número de tentativas e oito erros. Em contraste, outros voluntários completaram as mesmas tarefas com menores tempos e menor ocorrência de falhas. Dessa forma, tempo, tentativas e erros fornecem informações complementares para caracterizar o desempenho e permitem identificar dificuldades que não seriam observadas considerando apenas a conclusão dos níveis.

Foram registrados 12 erros totais durante os protocolos, sendo quatro relacionados à preensão e oito à liberação. A maior concentração ocorreu em L05-Geleia, com quatro erros, seguida por L04-Leite, com três ocorrências. Essa distribuição, associada aos relatos de dificuldade para agarrar determinados produtos, sugere que características específicas da interação com cada objeto podem estar relacionadas às dificuldades observadas. No ambiente de RV, essa interação depende da geometria dos produtos, da configuração dos *colliders*, dos limiares utilizados para detectar contato, preensão e liberação e do acoplamento entre a luva e os movimentos dos dedos. Portanto, os erros registrados não devem ser atribuídos exclusivamente ao desempenho motor dos voluntários.

A estrutura progressiva dos cinco níveis permitiu avaliar componentes da interação em diferentes graus de complexidade. Os primeiros níveis envolveram ações mais específicas de contato, preensão e transporte, enquanto os níveis posteriores integraram essas ações em sequências funcionais mais completas. Em especial, o quinto nível contextualizou a atividade em um cenário de mercado, exigindo seleção, transporte e liberação de diferentes produtos no carrinho de compras. Ao mesmo tempo, essa contextualização introduziu maior variabilidade de distância, orientação e geometria dos objetos, fatores que podem contribuir para as diferenças observadas entre as execuções.

Os resultados de L04-Leite e L05-Geleia indicam, portanto, a necessidade de revisar os parâmetros de interação utilizados para esses produtos. Diferentes geometrias podem exigir configurações específicas de *colliders*, zonas de contato e critérios de preensão e liberação. Em versões futuras, além da ocorrência do erro, recomenda-se registrar o estado que originou a falha, como perda de contato, abertura insuficiente da mão, liberação fora da zona-alvo ou reativação involuntária da preensão. Esse detalhamento poderá auxiliar na distinção entre dificuldades relacionadas à configuração do ambiente e aquelas associadas à execução da tarefa pelo usuário.

Os voluntários também relataram distância excessiva de alguns produtos, indicando que a organização espacial inicialmente adotada não foi percebida de forma uniforme por todos os usuários. Esse resultado reforça a necessidade de revisar o posicionamento dos objetos e considerar uma área de alcance individualmente calibrada em versões futuras do sistema. Aspectos como massa adicionada, geometria dos objetos, intensidade do feedback háptico e restrições mecânicas de dispositivos vestíveis também podem interferir na execução

(a) Erros de preensão e liberação por voluntário.

(b) Pontuação individual no SUS.

Figura 6. Distribuição dos erros por voluntário e avaliação da usabilidade do sistema.

de tarefas de destreza e na facilidade percebida de movimento [20].

Essa adaptação torna-se particularmente relevante antes de uma futura avaliação em pessoas com LM, considerando que limitações da função proximal podem comprometer o alcance e o posicionamento da mão durante tarefas funcionais [19]. Entretanto, como o presente estudo incluiu exclusivamente voluntários saudáveis, os resultados obtidos não permitem determinar o impacto dessas variáveis nessa população. Assim, a parametrização individual do alcance deve ser considerada uma etapa futura de desenvolvimento e avaliação, e não uma evidência derivada diretamente deste estudo.

B. Massa Distal e Demanda Biomecânica

A percepção de peso foi um dos principais comentários qualitativos por parte dos voluntários. As luvas Nova 2 apresentam massa nominal aproximada de 350 g por luva [14]. Considerando essa massa, o dispositivo adiciona aproximadamente 3,43 N de carga gravitacional ao membro superior. Embora esse valor, isoladamente, não permita determinar a sobrecarga imposta ao usuário, a localização distal da massa pode aumentar a demanda necessária para sustentar e deslocar a mão durante tarefas de alcance e manipulação. Esse efeito depende da postura adotada, da posição do membro e da capacidade muscular disponível de cada indivíduo.

No presente estudo não foram mensurados momentos articulares, atividade muscular ou fadiga; portanto, não é possível quantificar diretamente o impacto biomecânico da luva. Entretanto, a percepção de peso relatada pelos participantes indica que a massa do dispositivo deve ser considerada em futuras avaliações, particularmente antes de sua utilização em pessoas com LM incompleta.

A comparação com dispositivos destinados especificamente à lesão medular reforça essa preocupação. O módulo manual da RELab tenoexo possui aproximadamente 120 g, enquanto componentes mais pesados são deslocados para o tronco ou para a cadeira de rodas [19]. A massa distal nominal da Nova 2 é cerca de 2,9 vezes maior. Essa comparação não estabelece um limite clínico, uma vez que os dispositivos apresentam objetivos e princípios de funcionamento distintos, mas evidencia a redução e a redistribuição da massa distal como estratégias relevantes de projeto. Revisões da literatura sobre exoesqueletos de mão também identificam o peso, a ergonomia e a distribuição dos componentes como requisitos importantes para dispositivos de reabilitação e assistência [23].

A influência relativa da massa da luva pode tornar-se mais relevante em tarefas que envolvem a manipulação de produtos leves. Nessas condições, parte importante da demanda mecânica necessária para sustentar e deslocar o membro superior pode estar associada ao próprio dispositivo, e não exclusivamente à manipulação do objeto ou à execução da tarefa funcional. Esse aspecto reforça a necessidade de avaliar a massa distal separadamente do objetivo funcional proposto no ambiente virtual.

Além da carga gravitacional, a Nova 2 utiliza freios magnéticos passivos para gerar feedback de força em quatro dedos, com resistência nominal máxima de até 24 N [14]. Essa resistência possui natureza distinta da carga gravitacional associada à massa da luva, pois depende do contato com o objeto e da configuração dos dedos. Além disso, o mecanismo é resistivo e não assistivo. Em usuários com redução da força de flexão ou extensão dos dedos, níveis elevados de resistência podem aumentar o tempo de execução ou limitar a amplitude voluntária do movimento. Portanto, massa distal e feedback resistivo devem ser investigados como fatores biomecânicos distintos.

A relevância clínica da carga adicionada pelo dispositivo depende de sua relação com a capacidade articular residual de cada usuário. O mesmo esforço necessário para sustentar a Nova 2 pode representar uma pequena parcela da capacidade de um adulto saudável e uma parcela consideravelmente maior da capacidade disponível em uma pessoa com fraqueza proximal. Assim, a questão biomecânica central não é apenas

determinar se 350 g representam uma massa elevada, mas avaliar quanto da capacidade muscular disponível é utilizada para sustentar e deslocar o dispositivo durante as tarefas.

A repetição das tarefas também deve ser considerada. Em uma elevação vertical de 0,30 m, por exemplo, a massa nominal da luva corresponde a aproximadamente 1,03 J de trabalho mecânico adicional por elevação. Em protocolos com repetições sucessivas, essa demanda ocorre repetidamente e se associa às contrações isométricas necessárias para estabilizar o ombro e o cotovelo. Nesse tipo de tarefas repetitivas, é necessário avaliar a fadiga e o esforço do membro superior do usuário, os quais normalmente são baseados em eletromiografia (EMG), cinemática, percepção de esforço e medidas de desempenho [22]. Dessa forma, a conclusão dos níveis observada neste estudo piloto não permite inferir tolerância a sessões terapêuticas repetitivas.

Além do trabalho associado ao deslocamento da luva, a demanda fisiológica inclui contrações isométricas para sustentar o membro, estabilização escapular, cocontração e correções posturais. Assim, mesmo quando a mão permanece aparentemente estática no ambiente virtual, a atividade muscular pode continuar e contribuir para a fadiga. Esse aspecto é particularmente relevante em protocolos de reabilitação, nos quais a repetição constitui parte central da intervenção.

A conclusão de uma tarefa também não garante que o movimento tenha sido executado com a estratégia motora desejada. Usuários com função proximal limitada podem aumentar a inclinação ou a rotação do tronco, elevar a cintura escapular, ampliar a abdução do ombro ou apoiar o cotovelo para alcançar um objeto. Essas estratégias podem permitir que o sistema registre a conclusão da tarefa, mas modificam a demanda articular e podem reduzir a especificidade terapêutica da atividade. Por essa razão, a futura avaliação clínica deve considerar não apenas o tempo e a conclusão das tarefas, mas também a qualidade do movimento e a presença de compensações.

Para o presente sistema, uma abordagem semelhante permitiria verificar se o aumento do tempo ou do número de tentativas ocorre por dificuldade de interação, adaptação ao ambiente ou redução progressiva da capacidade de sustentar o dispositivo. Também permitiria comparar o início e o final de um bloco de repetições, identificando alterações que uma análise baseada apenas na média global poderia ocultar.

A transferência do sistema desenvolvido para pessoas com LM incompleta deve ainda considerar a grande heterogeneidade da função residual. Não existe um valor universal, em quilogramas, que defina a carga máxima tolerável para essa população. O nível neurológico, a preservação motora, a assimetria entre os membros, a espasticidade, a dor e a fadiga podem alterar substancialmente a capacidade de sustentar a mão no espaço.

Nesse contexto, a redução de 24% a 53% observada por Lee et al. [21] refere-se à atividade muscular máxima medida por EMG e não pode ser convertida diretamente em uma perda equivalente de torque articular, já que a amplitude do sinal EMG não apresenta uma relação linear universal com a força produzida. Ainda assim, esses resultados demonstram que a redução da capacidade muscular pode ser heterogênea entre músculos do ombro, cotovelo e punho, justificando uma caracterização individual antes da exposição da população-alvo a uma carga distal constante.

Assim, a luva Nova 2 não deve ser classificada de forma absoluta como “leve” ou “pesada” para todas as pessoas com LM. A interpretação mais adequada é que sua massa distal representa uma barreira biomecânica potencial. Essa barreira pode apresentar menor impacto em usuários com função proximal preservada e tornar-se relevante em indivíduos cuja capacidade residual já é amplamente utilizada para sustentar o próprio membro. Portanto, uma futura avaliação deverá determinar quanto da capacidade muscular e articular disponível é exigida para sustentar e deslocar o dispositivo durante as posturas e tarefas reais do *Market Rehab*.

C. Usabilidade, Limitações e Trabalhos Futuros

A elevada pontuação obtida no SUS indica uma percepção global positiva da usabilidade do sistema, particularmente em relação à compreensão e à interação com a interface. As variações observadas nas métricas de desempenho não contradizem essa avaliação, mas fornecem informações complementares sobre a execução das tarefas e as diferenças individuais entre os voluntários. Nesse sentido, a análise conjunta do SUS com medidas como tempo de execução, número de tentativas e erros permitiu uma caracterização mais abrangente da experiência de uso. Enquanto o SUS refletiu a aceitação e a usabilidade percebida do sistema, as métricas objetivas contribuíram para identificar aspectos específicos do desempenho durante a manipulação dos produtos virtuais.

A excelente pontuação SUS de 85,8 e os comentários positivos sobre a interface indicam boa aceitação preliminar. Contudo, usabilidade elevada não elimina limitações biomecânicas. O SUS avalia a percepção global do sistema, enquanto tempo, tentativas, erros e comentários abertos identificam dificuldades específicas. Além disso, os comentários sobre distância, preensão e peso foram exploratórios e não foram obtidos por um instrumento qualitativo estruturado.

A principal limitação deste estudo é a inclusão de apenas seis voluntários sem comprometimento neurológico. Os resultados não demonstram eficácia clínica nem permitem assumir que pessoas com LM incompleta tolerarão a carga distal. A próxima etapa deve seguir uma sequência objetiva:

1) Medir a massa total do conjunto utilizado, incluindo rastreamento, e estimar seu centro de massa;
2) Quantificar momentos externos nas posturas reais das tarefas;
3) Comparar condições sem luva, com luva e com suporte gravitacional do antebraço;
4) Medir a amplitude do sinal de EMG, tempo de sustentação, esforço percebido e fadiga, métricas frequentemente combinadas em avaliações biomecânicas do membro superior [22];

5) Após reposicionar produtos e revisar *colliders* e limiares de preensão/liberação, realizar um estudo piloto estratificado com pessoas com LM incompleta.

No estudo piloto clínico, a força de ombro, cotovelo, punho e dedos deve ser caracterizada previamente. O objetivo central deverá ser determinar qual fração da capacidade muscular disponível é consumida apenas para sustentar a luva e posicionar a mão. Caso a massa se confirme como limitante, devem ser avaliados suporte gravitacional, intervalos de descanso e ajuste individual do feedback resistivo.

A avaliação do movimento também deverá incluir compensações proximais. Um voluntário pode concluir a tarefa por meio de inclinação ou rotação do tronco, elevação escapular, abdução excessiva do ombro ou apoio do cotovelo. Nessa situação, a métrica binária de sucesso permanece positiva, embora a estratégia motora seja diferente daquela pretendida para a terapia. Por esta razão, a futura fase clínica deve registrar a cinemática do tronco e do membro superior ou, minimamente, utilizar uma classificação observacional padronizada das compensações.

Outro passo necessário é definir critérios de progressão e interrupção da terapia. A duração das tarefas e o número de repetições devem ser ajustados conforme esforço percebido, redução sustentada do desempenho, dor ou incapacidade de manter a postura de trabalho. Esse procedimento permitirá diferenciar uma dificuldade de aprendizagem da interface de uma limitação do usuário produzida por fadiga ou carga mecânica. Somente após essa caracterização será possível discutir o uso do sistema na população-alvo.

V. Conclusões

O *Market Rehab* apresentou viabilidade técnica preliminar para a execução e o registro de tarefas de alcance, preensão, transporte e liberação em realidade virtual. Nos seis voluntários saudáveis avaliados, os cinco níveis foram concluídos e o sistema registrou tempo de execução, tentativas e erros. A predominância de erros de liberação, a variabilidade dos tempos e os comentários relacionados à distância dos objetos, à preensão e ao peso da luva identificaram aspectos específicos que devem ser refinados. A pontuação média de 85,8 no SUS indica uma percepção preliminar favorável da usabilidade, devendo ser interpretada considerando o tamanho reduzido e as características da amostra.

Aspectos específicos da interação, tais como a distância excessiva de alguns produtos, a dificuldade de preensão e o peso percebido da luva, definem as prioridades imediatas de aprimoramento do sistema. Em especial, a massa distal deve ser tratada como uma limitação biomecânica potencial antes da transferência do sistema para pessoas com LM incompleta. A continuidade do estudo requer a caracterização mecânica do conjunto, a quantificação da demanda muscular e da fadiga, a comparação com suporte gravitacional e, somente após esses ajustes, a realização de um estudo piloto com a população-alvo. A viabilidade clínica do sistema dependerá da capacidade de executar as tarefas de forma repetitiva, tolerável e sem compensações motoras excessivas, e não apenas de concluí-las.

Agradecimentos

Abstract*— The biomechanical analysis of gait in an aquatic environment presents challenges related to data acquisition and the use of instrumented systems under immersion conditions. This study aimed to evaluate the applicability of a low-cost wearable system for the acquisition and processing of inertial signals during aquatic gait. The system consisted of an ESP32-S3 microcontroller, two MPU-9250 inertial sensors, and a web platform for data acquisition via Wi-Fi. Twenty healthy individuals performed a standardized pool-walking protocol, and the signals were automatically processed to identify steps and extract spatiotemporal parameters. The system enabled continuous acquisition of acceleration signals, automatically identifying algorithm-detected gait events and making it possible to obtain the total number of steps, traversal time, stride length, and cadence. The results demonstrate the applicability of the platform for gait monitoring in an aquatic environment, reinforcing its potential as a low-cost alternative for applications in research, rehabilitation, and Biomedical Engineering.

Keywords*— Wearable sensors; Accelerometry; Hydrotherapy; Aquatic gait.

I. Introduction

Human movement analysis in an aquatic environment has received increasing attention in recent decades, especially in the context of rehabilitation and therapeutic exercise. The physical properties of water, such as buoyancy, viscosity, and hydrodynamic resistance, promote significant changes in movement execution, reducing gravitational load and modifying neuromuscular and biomechanical patterns when compared with the terrestrial environment (TEDESCHI, 2024; ATKINS et al., 2024).

Among the locomotor tasks performed in this context, aquatic gait stands out for its clinical and functional applicability, and it is widely used in rehabilitation and physical conditioning programs. However, despite its relevance, the biomechanical characterization of gait in an aquatic environment still presents important limitations, mainly due to the difficulties associated with instrumentation and data acquisition in this medium (AMIN, 2023).

In recent years, wearable systems based on inertial sensors have become promising tools for human movement analysis, enabling data collection in different contexts with greater portability and less dependence on specialized laboratories. However, the application of these systems in an aquatic environment remains limited because of technical challenges related to device waterproofing, attachment stability, data transmission, and the possible interference of water with signal quality (Marinho et al., 2019; Monoli et al., 2023).

In this context, the development of wearable systems capable of operating reliably in an aquatic environment represents a relevant gap from both a technological and clinical perspective. Although commercial solutions exist for movement analysis in terrestrial settings, their applicability in water is still limited, in addition to their high cost, which reinforces the need for accessible alternatives adapted to this scenario (MacDermid et al., 2017).

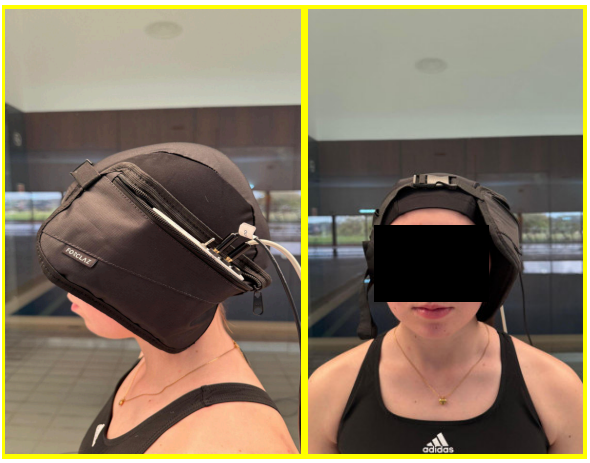
As an alternative, a low-cost wearable system for the acquisition and processing of inertial signals was previously developed. This same system was recently validated for the biomechanical analysis of deep-water running, showing good agreement with a commercial accelerometry system used as the reference method (Souza et al., 2026).

However, its applicability during gait in an aquatic environment had not yet been investigated. Considering that aquatic gait presents biomechanical characteristics distinct from those of deep-water running, it is necessary to verify whether the system maintains its potential for application in this new condition. Thus, the objective of this study was to evaluate the applicability of the same low-cost wearable system for the acquisition and processing of inertial signals during gait in an aquatic environment.

II. Materials and Methods

A. Measurement System

The developed system consists of a compact and portable main module powered by an internal rechargeable battery, eliminating the need for a direct connection to the electrical power supply during data acquisition.



XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

The device integrates two inertial sensors connected to the ESP32-S3 microcontroller through an I²C serial communication interface. The hardware architecture is based on the ESP32-S3 Super Mini development board (Espressif Systems, China), featuring a 32-bit dual-core Xtensa® LX7 processor operating at up to 240 MHz, integrated 2.4 GHz Wi-Fi and Bluetooth® Low Energy (BLE) connectivity, 4 MB of flash memory, and 512 KB of SRAM. Both inertial sensors were sampled by the same microcontroller during each acquisition cycle, ensuring temporal synchronization between the signals acquired from the right and left feet.

The sensing unit is based on the MPU-9250 module, which integrates a triaxial accelerometer and a triaxial gyroscope. The module features 16-bit analog-to-digital converters, enabling the simultaneous acquisition of signals along the X, Y, and Z axes with high resolution and low power consumption.

The embedded system, comprising the microcontroller, battery, and other electronic components, was housed in a custom 3D-printed enclosure. During data collection, the enclosure was placed inside a waterproof pouch and secured to the participant's head, keeping the main module above the water surface while enabling continuous signal acquisition and wireless data transmission throughout the experimental protocol (Figure 1).

Fig. 1. Positioning of the main module of the wearable system inside a waterproof pouch secured to the participant's head during data collection.

The inertial sensors were connected to the main module through cables and remained submerged throughout the experimental protocol. The cable outlets were properly sealed to ensure system integrity and reliable data acquisition in the aquatic environment.

Signal acquisition was performed in real time at a sampling frequency of 50 Hz and an acceleration range of ±2 g. The collected data were wirelessly transmitted in real time via Wi-Fi to a dedicated web-based platform developed as an integral component of the system, where they were stored for subsequent processing and analysis (Perez, 2025; Silva, 2025).

B. Sample

The sample consisted of 20 healthy volunteers (Table 1). Inclusion criteria comprised individuals without functional limitations or clinical conditions that could interfere with walking in an aquatic environment.

Table 1. Demographic and anthropometric characteristics of the study participants.

Variable	Value
Participants	20
Sex	10 males / 10 females
Age (years)	20.2 ± 0.8
Body mass (kg)	59.8 ± 7.4
Height (m)	1.68 ± 0.08

All participants were informed about the objectives and procedures of the study and provided written informed consent prior to data collection. The study was conducted in accordance with the Declaration of Helsinki and was approved by the Ethics Committee of the Faculty of Sport of the University of Porto (CEFADE 27_2025), Portugal, as well as by the Research Ethics Committee of the Federal University of Pernambuco (CAAE: 92738325.0.0000.5208).

C. Familiarization and experimental procedures

Upon arrival, all participants received detailed information regarding the objectives and procedures of the study. They subsequently provided written informed consent and completed an individual demographic questionnaire.

Initially, the participants were instrumented. The inertial sensors were bilaterally attached approximately 2 cm above the right and left lateral malleoli, ensuring consistent anatomical placement and reliable data acquisition. Both inertial sensors were positioned with the same anatomical orientation to ensure consistent alignment of the X-, Y-, and Z-axes across participants. Subsequently, a familiarization session was conducted, during which the participants walked along the experimental pathway at a self-selected comfortable speed, allowing them to adapt to the aquatic environment, the experimental protocol, and the instrumentation.

Data collection was conducted in the swimming pool of the Escola Superior de Saúde Norte da Cruz Vermelha Portuguesa, in Oliveira de Azeméis, Portugal, during the first author's international doctoral mobility program carried out in collaboration with the University of Porto. The pool had an approximate depth of 1.30 m, with the water immersion level standardized to the xiphoid process. The experimental protocol consisted of an 8-m linear walking path, and participants were instructed to walk continuously from one end of the pool to the other. Only the forward

walking segment was included in the analysis; turning movements at the end of the walkway were excluded from signal processing to avoid their influence on gait-event detection and spatiotemporal parameter estimation. No additional manual exclusion of walking segments was performed during data processing. Throughout the trials, the inertial sensors remained in the previously described positions, while the data acquisition system was housed inside a waterproof pouch secured to the upper body near the head, ensuring equipment integrity and maintaining signal quality in the aquatic environment (Figure 2).

Fig. 2. Instrumented participant during data collection in the aquatic environment.

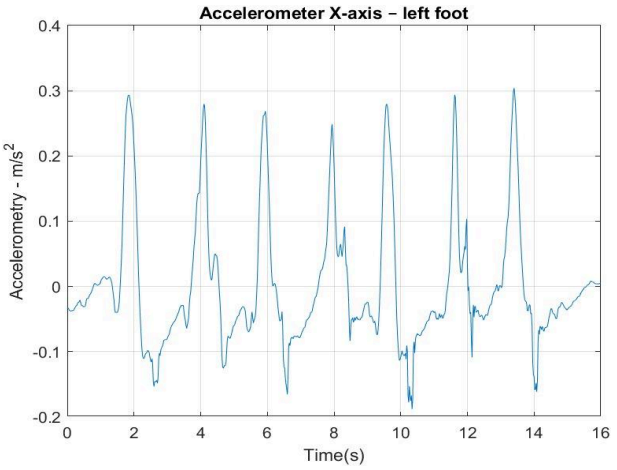
D. Data Processing

The accelerometry data stored on the web-based platform were subsequently processed and analyzed. Initially, the signals were organized according to the acquisition axes (X, Y, and Z), enabling the analysis of movement behavior during walking in the aquatic environment.

Spatiotemporal gait parameters, including the number of steps, cadence, stride length, and walking time, were extracted from the accelerometry signals. These parameters were initially calculated individually for each participant and subsequently analyzed using descriptive statistics, including measures of central tendency and dispersion.

Initially, the accelerometry data were filtered using a moving average filter followed by a low-pass Butterworth filter with a cutoff frequency of 20 Hz. After filtering, gait steps were identified using an adaptive threshold peak detection algorithm. Peaks occurring within less than 0.5 s of each other were classified as false positives, and only one peak was retained.

The beginning and end of the walking trial were identified based on the signal variance calculated using a 50-sample sliding window. The first and last abrupt changes in the variance signal were defined as the start and end of the walking trial, respectively.



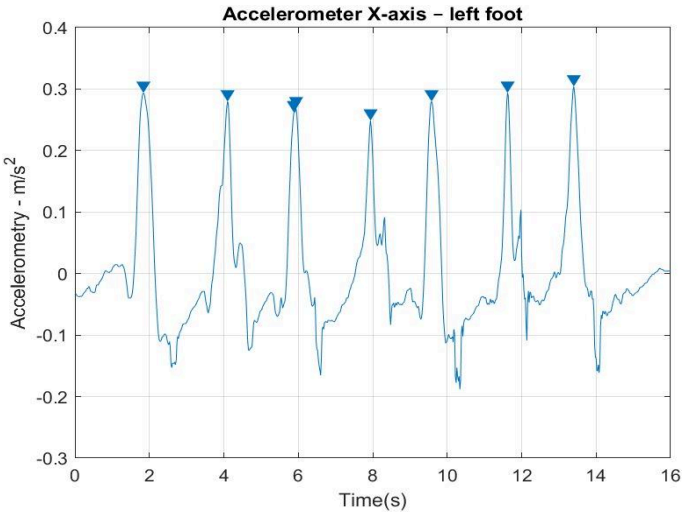
This processing pipeline enabled the automatic determination of the time required to complete the 8-m walking task, as well as the number of steps performed by each foot.

III. RESULTS

A. Signal Acquisition

During data acquisition, periodic and repetitive acceleration signals characteristic of aquatic walking were obtained. An example of these signals is presented in Figure 3.

Fig. 3. Representative X-axis acceleration signal acquired by the accelerometer attached to the left foot during aquatic gait.



The periodic characteristics of the acceleration signals enabled the reliable identification of gait steps using the proposed peak detection algorithm. The detected peaks were consistently associated with the gait cycle throughout the walking trial, allowing automatic step counting for both the right and left feet. These results demonstrate the effectiveness of the proposed processing method for extracting spatiotemporal gait parameters from the acquired accelerometry data.

B. Step Detection

In the next stage of the processing pipeline, acceleration signal peaks were automatically identified using the proposed algorithm, enabling the automatic detection of gait events. A representative example of this procedure is shown in Figure 4.

The algorithm-detected gait events were subsequently used to calculate spatiotemporal gait parameters, including the total number of steps, walking time, stride length, and cadence. Figure 4 illustrates the acceleration signal recorded from the participant's left foot during the walking trial, with the algorithm-detected steps indicated by triangles at the corresponding signal peaks.

Fig. 4. Automatic detection of gait events based on the peaks of the X-axis acceleration signal acquired by the accelerometer attached to one of the feet during aquatic gait.

C. *Spatiotemporal Gait Parameters*

Figure 5 shows the superimposed X-axis accelerometry data for both feet. It can be observed that the patient begins and ends the walk with the right foot, performing a half-step at both the start and the end. The figure also reveals that the acceleration peaks for the left foot are slightly higher than those for the right foot; this difference may be due to slight variations in accelerometer placement or the fact that the left leg is the dominant one. However, the difference is minor and does not affect the data analysis.

Fig. 5. Superimposed X-axis acceleration signals recorded from the right and left feet during aquatic gait.

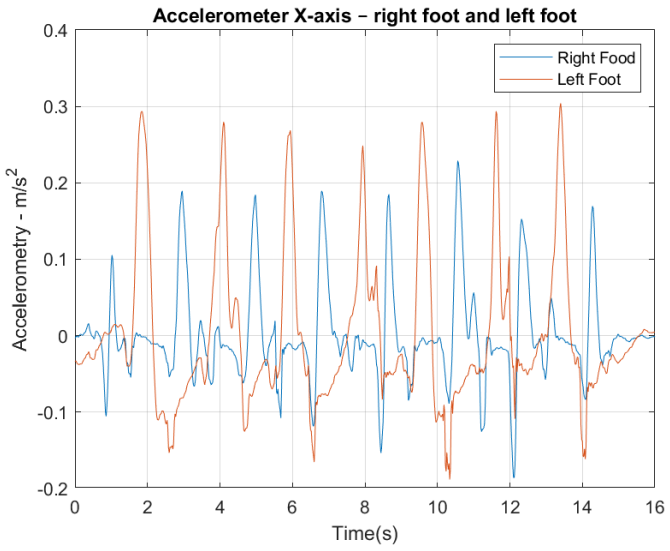


Table 2. Spatiotemporal gait parameters obtained during aquatic gait.

Variable	Mean ± SD
Total number of steps	13.65 ± 3.08
Walking time (s)	16.06 ± 4.73
Stride length (m)	1.19 ± 0.21
Cadence (steps/min)	53.17 ± 12.77

Table 2 presents the spatiotemporal gait parameters automatically extracted from the accelerometry signals acquired by the wearable system. On average, the participants performed 13.65 ± 3.08 steps while completing the 8-m walking trial in 16.06 ± 4.73 s. The mean stride length was 1.19 ± 0.21 m, and the mean cadence was 53.17 ± 12.77 steps/min.

IV. DISCUSSION

The present study extends the application of a low-cost wearable system previously validated for the biomechanical analysis of deep-water running, in which good agreement was observed with a commercial accelerometry system used as the reference method (Souza et al., 2026). Whereas the previous study aimed to establish the concurrent validity of the proposed technological platform, the present work investigated its applicability to aquatic gait, a locomotor task characterized by distinct biomechanical features and widely used in rehabilitation programs. Therefore, the present findings represent a further stage in the development of the system, expanding its potential application to different biomechanical assessment scenarios.

Although the wearable platform was previously validated against a commercial accelerometry system for deep-water running (Souza et al., 2026), the objective of the present study was not to establish the accuracy of gait-event detection during aquatic gait using a concurrent reference system. Instead, this study focused on demonstrating the applicability of the proposed platform for continuous signal acquisition and automated extraction of algorithm-detected gait events and spatiotemporal gait parameters in an aquatic environment. Therefore, the reported gait events should be interpreted as outputs generated by the proposed algorithm rather than as a direct validation of event-detection accuracy.

The use of inertial sensors for monitoring human movement has increased substantially in recent years due to their ability to provide biomechanical measurements using portable, low-cost devices with the potential for application outside specialized laboratory settings. However, the use of these systems in aquatic environments remains relatively limited because of the challenges imposed by water

immersion, including waterproofing of electronic components, sensor fixation stability, data transmission, and appropriate signal processing (Fantozzi et al., 2015; Mangia et al., 2017; Monoli et al., 2023).

The findings of the present study are consistent with those reported by Fantozzi et al. (2015), who demonstrated the feasibility of using inertial measurement units (IMUs) for the kinematic analysis of aquatic gait. Similarly, Mangia et al. (2017) validated inertial sensors for three-dimensional motion analysis in aquatic environments, whereas Lee and Han (2022) showed that low-cost devices, such as smartphones, can also be used for biomechanical assessment. Collectively, these studies, together with the findings of the present work, reinforce the growing trend toward the development of increasingly portable, affordable, and clinically applicable solutions.

Within this context, the system used in the present study is distinguished by integrating inertial sensors, an ESP32-S3 microcontroller, wireless Wi-Fi communication, a rechargeable battery, a 3D-printed enclosure, and a web-based platform for signal acquisition and processing into a single technological platform. This architecture, based on widely available and low-cost components, reduces the dependence on expensive commercial equipment, thereby facilitating the dissemination of biomechanical instrumentation in clinical, academic, and research settings.

In addition to the electronic architecture, the use of wearable sensors in aquatic environments requires overcoming specific challenges imposed by water immersion. Monoli et al. (2023) highlighted that issues related to device waterproofing, sensor placement, data transmission, and the lack of methodological standardization remain important barriers to the widespread adoption of these technologies. In the present study, these challenges were addressed during the system development by keeping only the inertial sensors submerged, while the main unit remained above the water surface inside a waterproof enclosure. This configuration preserved communication between the device and the computational platform without compromising signal acquisition during aquatic gait.

Another relevant aspect concerns signal processing. Monoli et al. (2023) reported considerable heterogeneity among studies regarding sampling frequency, sensor placement, algorithms used for gait event detection, and data processing procedures. This methodological variability hinders direct comparisons between different systems and highlights the need for greater standardization to improve reproducibility and support the consolidation of these technologies. In this regard, the detailed description of the system architecture, sensor placement, and processing pipeline provided in the present study contributes to enhancing the reproducibility of the proposed methodology.

From a biomedical engineering perspective, the main contribution of the present study extends beyond the extraction of spatiotemporal gait parameters. Rather, it lies in the advancement of a previously validated technological platform that has now been successfully applied to a different locomotor task in an aquatic environment. The possibility of using the same hardware architecture across different exercise modalities expands its potential applications and demonstrates the versatility of the proposed system for future adaptations to a variety of functional assessment and aquatic rehabilitation protocols.

The present implementation of the proposed processing algorithm focused on extracting the primary spatiotemporal gait parameters required to demonstrate the applicability of the wearable system during aquatic gait. Additional parameters, such as stride time, step time, symmetry indices, and gait variability, may be incorporated in future developments of the platform, further expanding its applicability for biomechanical and clinical assessments.

Some limitations of the present study should be acknowledged. Although the system was previously validated for the biomechanical analysis of deep-water running using a commercial accelerometry system as the reference method (Souza et al., 2026), the present study focused specifically on its application to aquatic gait. Furthermore, the evaluation was conducted exclusively in apparently healthy individuals, limiting the generalizability of the findings to clinical populations. Future studies should investigate the performance of the proposed system under different walking speeds, water immersion depths, therapeutic protocols, and populations with neuromuscular or musculoskeletal disorders, thereby expanding its clinical applicability.

In summary, the findings demonstrate that the proposed platform represents a promising alternative for biomechanical instrumentation in aquatic environments. The use of low-cost electronic components combined with a portable, modular, and scalable architecture highlights the potential of this technology to expand access to quantitative human movement analysis in clinical, research, and educational settings. Moreover, it contributes to the development of affordable technological solutions for aquatic rehabilitation.

V Conflict of Interest

The authors declare that they have no conflict of interest.

VI. CONCLUSIONS

The developed wearable system was able to continuously acquire accelerometry signals during aquatic gait, enabling the automatic identification of gait events and the extraction of the main spatiotemporal gait parameters. Its architecture, based on low-cost components combined with wireless data transmission and automated signal processing, highlights the potential of the proposed platform for applications in research, biomechanical assessment, and aquatic rehabilitation. In aquatic physical therapy, this technology has the potential to support future objective gait assessment, monitoring of patients' functional progress throughout rehabilitation, and quantification of the effects of different therapeutic protocols, thereby contributing to

evidence-based clinical practice supported by instrumented measurements. Future studies should further validate the proposed system in different populations and clinical protocols, contributing to the consolidation of accessible wearable technologies for human movement analysis in aquatic environments.

***Abstract*—The Six-Minute Walk Test (6MWT) is a standardized protocol for assessing cardiorespiratory functional capacity, but its conventional execution relies on the manual recording of physiological variables, which limits the temporal granularity of the data and hinders the traceability of results. This work presents *SpO2Sense*, a cross-platform mobile application that automates the conduction of the 6MWT by integrating the continuous acquisition of peripheral oxygen saturation (SpO_2) and heart rate (HR) from Bluetooth Low Energy (BLE) pulse oximeters, the structured collection of anamnesis and the Borg Scale, and the estimation of the distance walked from the periodic variation of the received signal strength indicator (RSSI). The application was evaluated at the Pulmonary Physiology Unit of the *Hospital de Clínicas de Porto Alegre* in 34 recordings, using the telemetry system in use at the unit as a reference to adjudicate signal quality. Motion artefact during walking, identified by an explicit rule in which an abrupt shift in the test device is not reproduced by the reference, affected 7 of the 28 adjudicable recordings (25%); loss of the BLE link affected 3 further recordings. Within the contaminated segments the two devices diverged by 91 bpm in HR and 43 percentage points in SpO_2 at the 95th percentile of the paired difference. During rest, by contrast, the median per-patient bias was $+0.19$ bpm for HR and $+0.06$ percentage points for SpO_2, and no artefact originated in the resting phase, indicating that walking itself, rather than the sensor or the link, is the dominant source of failure. For the number of traverses during the walk, no significant difference was found between the automatic RSSI-based estimate and manual counting (Wilcoxon signed-rank, p = 0.140), and a *post-hoc* equivalence analysis against a margin of one traverse (25 m) was compatible with average equivalence (p = 0.00014), although the margin was not pre-specified and average equivalence did not extend to individual agreement. The mobile platform proved technically viable for instrumenting the 6MWT, but this class of low-cost oximeter does not withstand the walking phase, which is precisely the condition the test is designed to impose; mechanical coupling at the measurement site, rather than optical performance, is the limitation that must be addressed first.**

***Index Terms*—six-minute walk test, pulse oximetry, motion artefact, Bluetooth Low Energy, mobile application, Flutter**

I. Introduction

The Six-Minute Walk Test (6MWT) is a reproducible, practical, and low-cost instrument for cardiorespiratory functional assessment, and it is a central component in the follow-up of patients with chronic pulmonary and cardiovascular diseases [1]. Its protocol consists of measuring the greatest distance a patient is able to walk, at their own pace, over six minutes

along a flat corridor, while physiological variables are recorded before, during, and after the effort.

In usual clinical practice, the 6MWT is conducted with the manual recording of peripheral oxygen saturation (SpO_2), heart rate (HR), perceived exertion, and distance walked. For patients with respiratory diseases, this exertion is commonly measured using the Borg scale for pain and dyspnea. This process has intrinsic limitations: the sampling of vital variables is sparse, transient desaturation events may go unnoticed, and manual transcription is susceptible to errors and hinders the subsequent auditing of the data. The growing availability of low-cost pulse oximeters equipped with Bluetooth Low Energy (BLE) opens up the possibility of instrumenting the test with continuous acquisition of SpO_2 and HR data using only a common mobile device [2], [3].

This work describes the design and implementation of a mobile application, named *SpO2Sense*, that automates the conduction of the 6MWT. The application and a low-cost BLE pulse oximeter were tested during routine 6MWT sessions at the Pulmonary Physiology Unit of the *Hospital de Clínicas de Porto Alegre*, with the telemetry system already in use at the unit serving as a reference to adjudicate signal quality. The main contributions are: (i) the integration of continuous SpO_2 and HR acquisition via BLE with the protocol's phase logic; (ii) an algorithm for estimating the distance walked from the periodic variation of the RSSI connection strength signal; and (iii) a characterisation of the dominant failure mode of this class of device during the 6MWT, based on an explicit adjudication rule in which an abrupt shift in the test device is accepted as artefact only when the reference does not reproduce it. The remainder of the article presents related work, the system architecture, the BLE communication layer, the artefact adjudication procedure, and a discussion of limitations and future work.

II. Related Work

The validation of the *wireless* oximetry sensors used in mobile solutions is a critical step to ensure the reliability of the clinical data collected. In this regard, the study conducted by Marshall et al. [4] evaluated the accuracy of commercial and medical-grade portable oximeters during the execution of the Six-Minute Walk Test (6MWT), comparing them with the market gold standard, the Masimo Rad-5. Among the analyzed devices, the Nonin WristOx2 3150 stands out, having demonstrated a performance in the detection of peripheral oxygen saturation (SpO_2) highly comparable to that of the Masimo device, with a mean difference rate within the 3% limit. This work shows that, even when state-of-the-art devices are compared, a difference was observed.

Reported 6MWT instrumentation solutions tend to rely on dedicated hardware or on semi-automatic recording. The adoption of BLE in personal health devices has enabled tele-health applications running on smartphones, lowering the cost barrier for continuous health monitoring while also offering a more user-friendly experience [5]. The development of mobile systems focused primarily on the kinematic computation of the 6MWT for estimating the distance walked was explored in the literature by the study of Salvi et al. [6]. The authors proposed an architecture composed of two applications: a web interface aimed at the physiologist and a mobile application (developed in the Apache Cordova framework) directed at the patient, integrated with a back-end server and wireless pulse oximeters. To estimate the distance walked, they implemented two algorithms based on a smartphone's internal sensors: one using the Global Positioning System (GPS) for outdoor tests, and another based on inertial sensors for indoor tests, whose purpose is to identify the change of direction (turnaround) of the patient in a fixed-distance corridor. In terms of accuracy, the maximum variation reported between the distance estimated by the app and the actual distance for indoor environments was 23 meters, a borderline value, considering that 50 meters is the interval regarded as clinically significant for detecting changes in the status of pulmonary diseases during the 6MWT [7]. Furthermore, the study's validation was conducted predominantly by researchers in a controlled laboratory environment. The system proposed in the present work differs from that approach by combining, in a single mobile application, the continuous acquisition of oximetry, the orchestration of the protocol phases, and the estimation of distance without additional sensors. This provides an algorithmic simplification by reusing the oximeter's own radiofrequency link.

In our study, the Wellue pulse oximeter is assessed against the telemetry system used by the Pulmonary Physiology Unit of the *Hospital de Clínicas de Porto Alegre* (HCPA), which is based on the Nonin PalmSat 2500 model developed in Silva Junior's work [8] and is used here to adjudicate the quality of the signal acquired by the test device.

III. Methodology

A. System Architecture

The application was developed in Flutter, with an interface based on Material 3, enabling cross-platform execution from a single codebase [9]. The project's organization follows a layered pattern inspired by Model-View-ViewModel (MVVM): pure data models, observable state providers (*view-model*), screens and interface components (*view*), and a service layer responsible for accessing the Bluetooth hardware.

Complementary to the MVVM, the system architecture can be described in four functional layers (Figure 1). The first, the sensing layer, is responsible for the acquisition of the physiological data of peripheral oxygen saturation (SpO_2) and HR, expressed in beats per minute (bpm). The second, the communication layer, uses the Bluetooth Low Energy (BLE) protocol to establish the connection between the application and the previously registered oximeters, enabling the reception of SpO_2 and bpm data in real time, with a sampling frequency of 1 Hz. The third layer, the application layer, concentrates the interfaces and functionalities aimed at the health professional, allowing patient registration, the execution and monitoring of the six-minute walk tests (6MWT), and the analysis of the obtained results. Finally, the fourth layer, the database layer,

is responsible for the secure cloud storage of the data collected during the tests, which is linked to the user account created within the application itself. This layered division seeks to modularize the system, making the application of the 6MWT more agile and practical for the health professional.

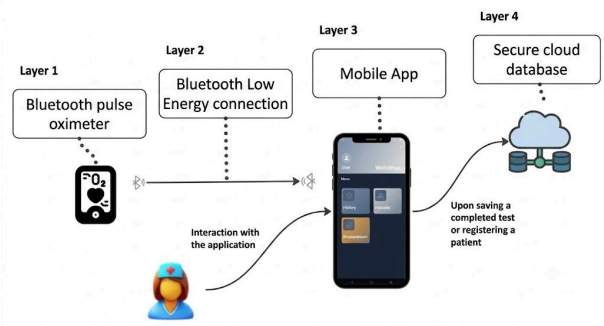

Fig. 1. Mobile app main architecture.

B. Authentication and Persistence

Access to the application is controlled by email-and-password-based authentication, with mandatory email verification. A reactive authentication *gate*, based on a stream of session-state events, decides the initial screen without imperative navigation: unauthenticated users are directed to the login screen, users with an unverified email to the verification screen, and verified users to the main menu. This pattern ensures that email confirmation performed on another device automatically redirects the user.

The data is persisted in a document-oriented cloud database and protected with appropriate authentication-based access rules, using the Firebase system [10]. Patients and exams are stored in a hierarchy in which each professional maintains their own base, without global sharing of records, as illustrated below:

```
users/{uid}/patients/{id}/walkTest/{walkId}
```

Each exam document stores the time series of SpO_2, HR, and radiofrequency signal, the interruption periods, the distance parameters, the anamnesis data, the Borg Scale measurements, and the date and time of each test.

C. Data Acquisition via Bluetooth Low Energy

Bluetooth access is achieved by registering the addresses of the services transmitted by the compatible devices, from which the bytes are collected, a communication enabled by the *FlutterBluePlus* library. Communication with the oximeter is encapsulated in a dedicated service, instantiated once per measurement session, and follows the following flow of events for the interface: discovery of the connected devices transmitting signals, scanning of these signals, and decoding of the oximetry and received signal strength data. Discovery filters the scan results by platform name or by advertised service identifier, identifying these devices by their physical address. The connection adopts a *retry* policy with an increasing linear wait, emitting a disconnection event to the interface in the event of a definitive failure. Once connected, the service starts the periodic monitoring of the signal strength and the service discovery, enabling notifications on the characteristic corresponding to the hardware model. The BLE *payload* is model-specific to each oximeter, with fields positioned at fixed offsets.

D. Distance Estimation from RSSI Variation

Since the 6MWT is performed in a fixed corridor, the distance walked is estimated from the periodic variations of the received signal strength indicator (RSSI), which oscillates as the patient moves away from and closer to the reference point where the device remains stationary. The algorithm smooths the signal by convolution with a uniform window, detects peaks and valleys through derivative analysis, filters extrema by minimum prominence and minimum distance between events, and counts the transitions between extrema as traverses (half of a lap), as illustrated in Figure 2. The interruption periods are removed from the RSSI signal time series before the analysis so as not to distort the count.

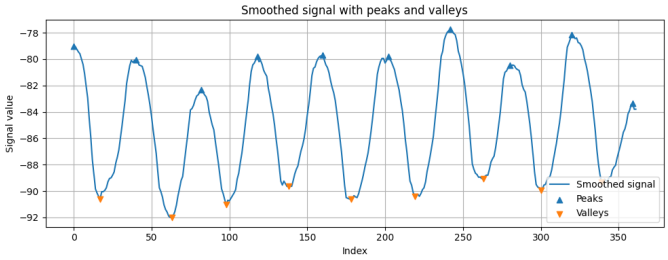

Fig. 2. Figure depicting the `analyse_signal` function used to estimate the number of traverses made by the patient during the 6MWT. Each peak–valley/valley–peak pair is considered half of a lap, which is used to estimate the distance.

E. Test Execution With a Pulse Oximeter

To further evaluate the usage of our mobile app, we conducted tests at the Pulmonary Physiology Unit of the *Hospital de Clínicas de Porto Alegre* (HCPA) with 34 patients who visited the unit to undergo the 6MWT, using the Wellue FS20F fingertip pulse oximeter, which holds a valid registration with the Brazilian Health Regulatory Agency (ANVISA). The study protocol was approved by the Institutional Research Ethics Committee of the Hospital de Clínicas de Porto Alegre and a written informed consent was obtained from all participants before inclusion in the study. The walking test was conducted in a straight indoor corridor 25 meters long, with a complete lap being 50 meters. Although it differs from the 30 meters standard set by the American Thoracic Society (ATS), the 25 meters distance was adopted because it is the measurement currently used at the Pulmonary Physiology Unit. The health professional responsible for the measurement stood in a reference point near the start of the lap, to serve as reference for distance estimation, as seen in Figure 3.

Each recording comprises two consecutive phases. The walking phase corresponds to the first 360 s of acquisition, during which the patient walks the corridor at their own pace. The resting phase follows immediately and lasts up to three minutes, although it frequently ends earlier, when the patient's vital signs return to baseline. Both devices sample at 1 Hz, so the two phases are delimited by sample index rather than by wall-clock time, and all per-phase statistics are normalised by the observed duration of the phase rather than by its nominal length.

During each test session, data on SpO_2, HR, distance covered, and anamnesis, which the application also records, were collected. The entire data collection process was carried out alongside the use of a telemetry system based on Nonin PalmSat2500 developed by Silva Junior et al. [8], currently in use at the Pulmonary Physiology Unit. Both devices were positioned on the same hand of the patient, and the temporal series data collected were synchronized between devices for comparison based on the timestamps. The HCPA system serves as an adjudicator of signal quality rather than as a metrological standard.

F. Cohort and Adjudication of Motion Artefact

Of the 34 recordings collected, 3 were affected by loss of signal in the reference system and 3 by loss of the BLE link, the latter costing 38.8%, 35.7% and 18.3% of the walking-phase samples. Adjudication requires both series to be complete, so the 28 remaining recordings were analysed. Loss of link and motion artefact are treated as distinct mechanisms.

Motion artefact was identified by an explicit rule applied to all 28 recordings, rather than by visual inspection of those suspected of failure. A candidate onset is flagged when the test device shifts by at least 15 bpm in HR, or 4 percentage points in SpO_2, within 3 s. The candidate is retained as artefact only if the reference, over the same window extended by 5 s, does not reproduce the change, its excursion remaining below half the magnitude recorded by the test device; otherwise the event is attributed to a physiological origin. The contaminated segment then runs from the onset until the absolute paired difference falls below 5 bpm, or 2 percentage points, for five consecutive seconds. Segment-level extension is necessary because the artefact presents as a single transition initiating a sustained plateau of divergence, not as a succession of abrupt transitions. A recording is classified as affected when at least one such segment is detected.

Since the traverse-count variable did not satisfy the assumption of normality (Shapiro–Wilk test, detailed in Results), the non-parametric Wilcoxon signed-rank test was adopted throughout this work to compare the reference and test methods. The traverse-count comparison does not depend on the reference oximetry and was therefore performed on the 31 recordings without substantial BLE signal loss, which distorts the RSSI curve directly. It was first assessed whether there was any difference between manual annotation and the estimation through RSSI signal variation. This test was followed by the two one-sided tests (TOST) procedure, implemented with one-sided Wilcoxon signed-rank tests against each extreme of a margin of $\Delta = \pm 1$ traverse (± 25 m). This margin was adopted because it falls below the 30–50 m range considered clinically meaningful in the 6MWT [7]. Finally, a 90% bootstrap confidence interval for the mean paired difference was computed to estimate where this difference lies. As the traverse margin was defined after data collection, the analysis is reported as exploratory. Agreement during the resting phase was summarised as the median across recordings of the mean paired difference within each one, reported with its interquartile range.

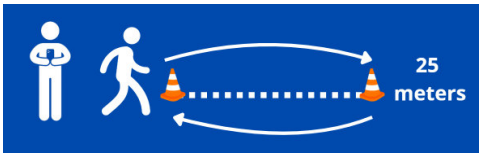

Fig. 3. Diagram showing the distance and how the patient completes the traverses in the test environment. The professional captures the data while stationary at the starting position throughout the entire walk, so that the RSSI variation signal can estimate the distance correctly.

IV. Results

A. App Interfaces and Functionalities

The developed system was designed to integrate oximetry monitoring with the patient's functional assessment (Figure 4). It was structured around three core functionalities: I. Patient and history management, featuring a patient registration module that allows the creation of individual patient profiles, from which the health professional can access the corresponding profile history; II. Monitoring and graphical visualization of the 6MWT, utilizing a real-time graphical interface for SpO_2 and HR levels that covers the entire exertion period (6 minutes) and the rest period (3 minutes), enabling the immediate identification of events such as exercise-induced desaturation with the real-time graphs that display the data updated at a frequency of 1 Hz; III. Gathering and presentation of the collected results, available in a section that summarizes patient performance through HR and SpO_2 variation graphs, walk statistics, anamnesis and metrics for prognostic assessment, including the exact total distance walked and the identification of the SpO_2 nadir, while also providing a downloadable PDF medical report with all this data.

B. Motion Artefact and Device Behaviour

The adjudication rule classified 7 of the 28 adjudicable recordings (25%) as affected by motion artefact during walking. Within the contaminated segments the two devices diverged by 91 bpm in HR and 43 percentage points in SpO_2 at the 95th percentile of the paired difference, reaching 122 bpm and 52 percentage points at their extremes. The divergence was not a matter of noise around a correct value: in the most affected recording the test device reported a constant 55 bpm for 134 consecutive seconds while the reference tracked the effort between 128 and 140 bpm, a pattern consistent with the device falling back to a held estimate once the plethysmographic

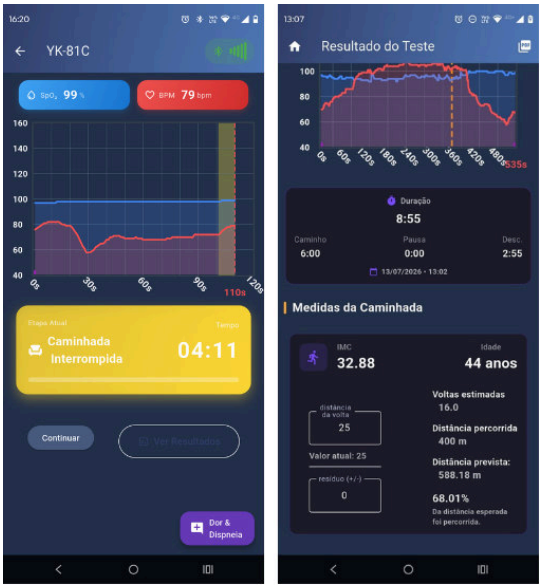

Fig. 4. Real-time graphical interface showing SpO_2 and HR levels during the test with the controls and interface (left). The red traced line shows the current value in time, the blue line represents SpO_2 and the red the HR. The yellow area is the interruption time, when a patient has to sit and rest in the middle of the walk. Results screen displayed after the walk and rest period; PDF medical report containing all the aforementioned data (right). The traced yellow line in the graph represents the start of the resting phase.

signal degrades. Applied to SpO_2 alone, the same rule flagged a further 6 recordings that visual inspection had not identified, in most cases involving only a few dozen samples, which indicates that contamination is distributed along a continuum rather than confined to the recordings classified as failures.

Artefact was confined to the walking phase. Segments persisting into rest occurred in 4 recordings, for 60, 42, 31 and 3 s beyond the end of walking, and in every case the segment had begun during walking, at 97, 271, 75 and 306 s respectively; no artefact originated in the resting phase itself. During rest the two devices were close to indistinguishable, with a median per-patient bias of $+0.19$ bpm for HR (IQR 1.02) and $+0.06$ percentage points for SpO_2 (IQR 1.78), obtained as the median across recordings of the mean paired difference within each one. Loss of the BLE link, a distinct failure mechanism, affected 3 further recordings, costing 38.8%, 35.7% and 18.3% of the walking-phase samples, the last of these concentrated in a single continuous gap of 50 s.

C. Distance estimation through RSSI

In this study, a traverse was defined as a single walk between the two endpoints of the course (A to B or B to A), such that a complete lap corresponds to two traverses. They were counted automatically from the smoothed RSSI signal, whose peaks and valleys – corresponding to the patient's closest and farthest approach to the beacon – were extracted by derivative analysis, and the resulting counts were compared against manual counting in the 31 recordings without substantial BLE signal loss. Normality was assessed with the Shapiro–Wilk test, which rejected normality for the estimated counts ($p = 0.017$), although not for the manual counts ($p = 0.081$). Thus, a non-parametric paired test was therefore adopted.

Manual counting and the software RSSI-based estimate were strongly correlated (Spearman $\rho = 0.97$), and the Bland–Altman analysis showed essentially no bias (median difference = 0.0), with limits of agreement of -2.25 to $+1.25$ traverses (-56.3 to $+31.3$ m) as shown in Figure 5. The paired Wilcoxon signed-rank test ($W = 47.0$, $p = 0.140$) detected no significant difference between methods. This result indicates the absence of a detectable systematic difference and should not be interpreted as evidence of equivalence, since no equivalence margin was pre-specified.

A TOST equivalence analysis was therefore performed: both one-sided Wilcoxon tests rejected their respective null hypotheses against the margin of ± 1 traverse (± 25 m), yielding $p_{\mathrm{TOST}} = 0.00014$, and the 90% bootstrap confidence interval for the mean paired difference was $[-0.06, +0.55]$ traverses ($[-1.6, +13.7]$ m), entirely contained within the margin. The data are therefore compatible with average equivalence between the two counting methods, with the caveat that the margin was not defined *a priori*. This equivalence concerns the central tendency of the paired differences and does not extend to individual agreement. The typical error was modest (mean absolute error of 17.7 m, with 87.1% of recordings within ± 25 m), but the deviations were markedly asymmetric: 14 recordings agreed exactly, 13 overcounted by a single traverse and one by two, while only 3 undercounted, by two or three traverses (-50 to -75 m).

The predominance of single-traverse overcounting is consistent with the algorithm's treatment of the final, incomplete traverse. A patient who is partway along the corridor when the six minutes elapse produces a partial excursion of the RSSI curve, which the extremum-based counter resolves as a whole traverse. The resulting error is bounded at one traverse, always in the direction of overestimation, and would inflate the reported distance by up to 25 m. Rounding the final traverse down, or weighting it by the amplitude of the incomplete excursion, is a straightforward correction that has not yet been implemented.

Taken together, these findings indicate that RSSI-based counting does not differ systematically from manual observation across the cohort, but is not interchangeable with it at the level of the individual test; its defensible role in the current version of the application is therefore that of an assistive, redundant record of the distance walked, rather than a replacement for manual counting.

V. Discussion and Limitations

This pilot work demonstrates the feasibility of instrumenting the 6MWT from a mobile device, raising the temporal granularity of the record to 1 Hz and automating report generation. Beyond the physiological monitoring itself, the app's RSSI-based distance estimation module showed promising agreement with manual traverse counting: the strong Spearman correlation ($\rho = 0.97$), the Bland–Altman median bias of essentially zero, and the *post-hoc* equivalence analysis

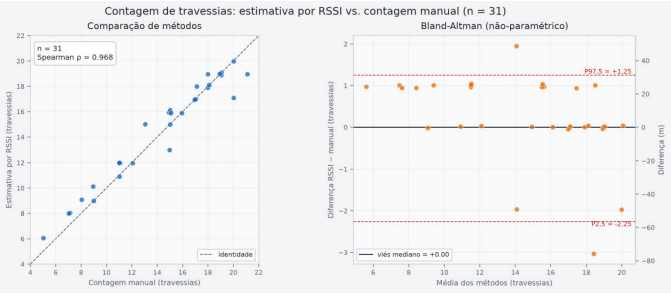

Fig. 5. Method comparison and non-parametric Bland-Altman analysis of manually counted vs. app-estimated traverses ($n = 31$; Spearman $\rho = 0.968$; median bias = 0.00, limits of agreement -2.25 to $+1.25$), showing strong correlation and no systematic bias between methods.

($p_{\mathrm{TOST}} = 0.00014$ against a ± 1 traverse margin) indicate that the two methods do not differ by a clinically meaningful amount on average. Average equivalence, however, is a weaker property than interchangeability at the level of the individual test. The null median bias arises from the cancellation of errors in opposite directions rather than from their absence, and the two directions have different explanations. Overcounting by a single traverse, by far the most frequent deviation, follows from the algorithm resolving the final incomplete traverse as a whole one: the error is bounded at 25 m, always inflates the distance, and is correctable in the counting logic. The three recordings that undercounted by two or three traverses are less readily explained, since they do not coincide with the loss of BLE signal that would suppress the transitions the algorithm relies on, and their cause could not be identified within this cohort. In metric terms, the typical error was modest (mean absolute error of 17.7 m, with 87.1% of tests within ± 25 m), but the lower limit of agreement (-56.3 m) and the largest individual error (-75 m) exceed the 30–50 m range considered clinically meaningful in the 6MWT [7]. Because the large deviations were predominantly undercounts, an error of this magnitude in a single test would underestimate the distance walked and could mask or mimic a clinically relevant change in functional capacity between serial assessments. Until the residual undercounting is understood, the module is best positioned as a redundant record supporting the examiner, and a properly powered study with a pre-specified margin will be required before manual counting can be safely omitted.

The dominant failure mode of the test device during the 6MWT was motion artefact. In 7 of the 28 adjudicable recordings (25%), HR and, in most of them, SpO_2 shifted abruptly during walking without the reference reproducing the change, which rules out a physiological origin. The character of these divergences is as relevant as their magnitude: in the most affected recording the device held a constant 55 bpm for 134 consecutive seconds while the reference recorded between 128 and 140 bpm. A reading of this kind does not present itself as an error: it is stable, plausible in isolation, and indistinguishable from a valid measurement on the screen.

The resting phase indicates where this failure originates. Across the same recordings the median per-patient bias during rest was $+0.19$ bpm for HR and $+0.06$ percentage points for SpO_2, with interquartile ranges close to a single unit, so that the two devices are effectively interchangeable once the patient stops walking. Every artefact segment that extended into rest had begun during walking, and none originated after it; the longest persisted for 60 s beyond the end of the walk before the two series converged again. The same device, on the same finger, in the same patient, therefore performs adequately at rest and fails under walking, which locates the problem in the mechanical conditions of the measurement rather than in the sensor's optical performance or in the BLE link. This also bounds the scope of the finding: it does not indicate that low-cost oximetry is unusable, but that this class of device is not adequate for the 6MWT, whose entire purpose is to impose the condition under which it fails.

Several limitations should be acknowledged. The cohort is small and single-centre, and patient characteristics such as sex, age, BMI, and underlying diagnosis were not analysed as potential sources of variability. The thresholds of the adjudication rule were chosen on physiological grounds rather than calibrated, and no sensitivity analysis over the parameter grid was performed, so the exact count of affected recordings should be read as dependent on them; the rule is nonetheless reported in full, so that the classification can be reproduced or recomputed under different criteria. The RSSI-based distance estimation method was validated in a single, fixed, and unobstructed 25 m corridor with the smartphone held by a stationary operator, and its behaviour under different corridor geometries, device positions, or interference conditions remains untested; a multi-environment study is required before generalisability can be claimed. The equivalence margin adopted for the traverse-count comparison was defined after data collection rather than pre-specified, so that analysis is exploratory and should be confirmed in a study designed around a margin agreed upon in advance. Finally, a plausible contributing factor to the artefact is device mass — approximately 50 g for the Wellue against 20 g for the Nonin-based model — concentrated at the fingertip, where the arm swing of walking imposes the largest accelerations. This points to a concrete design direction rather than to an inherent limit of low-cost oximetry: relocating the batteries and the display into a wrist-worn housing, leaving only a light and firmly coupled optical sensor on the finger, would reduce both the inertial load at the measurement site and the relative movement between sensor and tissue that produces the artefact. Such a modification is well within the reach of low-cost hardware and would be the first thing to test before this class of device is reconsidered for the 6MWT.

VI. Conclusion

This pilot study characterises the dominant failure mode of a low-cost, Bluetooth-connected pulse oximeter when integrated into the 6MWT. Motion artefact during walking rendered one recording in four unusable, producing divergences of 91 bpm at the 95th percentile and, in the worst case, a stable but fictitious reading held for over two minutes — a failure that is invisible to an operator watching the screen. The same devices

agreed closely at rest, and no artefact originated in the resting phase, which locates the problem in the mechanical coupling of the sensor under walking rather than in its optical performance or in the wireless link. The *SpO_2Sense* application itself demonstrated technical feasibility as a platform for instrumenting the 6MWT, successfully combining real-time Bluetooth-based physiological monitoring with automated distance estimation and report generation. The RSSI-based traverse counting module showed agreement with manual counting that was compatible with equivalence at a *post-hoc* margin of one traverse, although individual recordings deviated by up to three traverses; the most frequent of these deviations arises from the final incomplete traverse being resolved as a whole one, which is correctable in the counting logic. This supports its use as an assistive, redundant record of the distance walked rather than a replacement for manual observation, and justifies a properly powered validation study with a pre-specified margin. As a next step, future work will focus on a more thorough validation of the distance estimation algorithm across diverse corridor geometries and clinical settings, alongside refining the counting logic to improve individual-level accuracy. These results support the continued development of the *SpO_2Sense* software platform, while indicating that this class of oximeter is not adequate for the 6MWT in its present form, and that a redesign of the sensor's mechanical coupling — rather than further validation of the current hardware — is the appropriate next step.

Abstract—Sickle cell anemia (SCA) is a major hereditary hemoglobinopathy in Brazil and disproportionately affects the Black population. This study describes a Portuguese-language web prototype that integrates educational content, informed consent, a sociodemographic questionnaire, and an SF-12 scoring workflow. Development was informed by a literature review structured according to PRISMA guidance. The prototype underwent preliminary internal checks of navigation, form flow, responsive display, and score-generation behavior. No deployment with the intended participant cohort, formal usability study, clinical outcome analysis, or independent agreement study of automated scores has yet been completed. Authorization to use the SF-12 and its scoring procedure is currently being requested; participant deployment and operational use of scoring are contingent on confirmation of the applicable conditions. Thus, the contribution is a technological prototype and a proposed validation workflow, not evidence of improved quality of life, adherence, follow-up, or clinical decision-making. Future work will include formal score verification, usability, accessibility, security, and performance testing, followed by prospective evaluation.

Index Terms—sickle cell anemia, quality of life, SF-12, digital health, public health.

I. Introduction

Sickle cell disease designates hereditary hemoglobinopathies associated with hemoglobin S; SCA is its most severe form [1]. A point mutation in the β-globin gene produces hemoglobin S, which polymerizes under low oxygen tension, deforms erythrocytes, and contributes to vaso-occlusion, hemolysis, and painful crises [2]. Systemic complications include acute chest syndrome, stroke, renal disease, retinopathy, and priapism [2, 3]. In Brazil, sickle cell disease is a public-health concern and is addressed through neonatal screening and early diagnosis policies [4].

The disease burden intersects with social determinants and racial inequities in access to care. Recurrent pain, fatigue, hospitalization, and occupational limitations can affect daily functioning and social participation. Systematic assessment of health-related quality of life may therefore help characterize needs, provided that the instrument and digital workflow are appropriately authorized and validated.

The 12-item Short-Form Health Survey (SF-12) summarizes physical and mental health into the Physical Component Summary (PCS) and Mental Component Summary (MCS) [5]. Portuguese-language applicability and Brazilian reference values have been reported [6, 7]. Scoring is not a simple sum and is susceptible to transcription or implementation errors. Digital integration may reduce manual steps, but technical correctness, authorization, usability, and clinical value must be demonstrated separately.

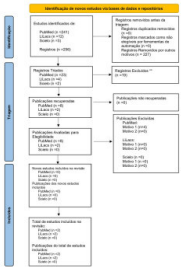

Figure 1: PRISMA flow diagram of the study-selection process. Counts must match the preserved review records.

This work describes the development of a Portuguese-language web prototype that combines educational content, consent, sociodemographic data collection, and a planned SF-12 scoring workflow. The present objective is to document the prototype and the validation protocol still required. No benefit to follow-up, adherence, quality of life, or healthcare decisions is claimed at this stage.

II. Materials and Methods

A. Design and ethical status

This is applied technological-development research informed by a literature review. The protocol for the planned participant stage was approved by the Research Ethics Committee of Universidade Brasil (CAAE 89209325.2.0000.5494; Opinion No. 7,930,601) and has a letter of consent from the São Paulo State Sickle Cell Anemia Association (AAFESP). No participant recruitment or quality-of-life data collection had occurred at the time of this report. Ethics approval does not replace authorization or licensing requirements associated with the SF-12.

B. Literature review

The review was structured using PRISMA guidance and searched PubMed, SciELO, and LILACS for publications from 2019 to 2024, combining terms related to SCA, quality of life, SF-12/SF-36, and digital or mobile applications. Original studies in Portuguese, English, or Spanish involving adults were eligible; reviews and records without accessible full text were excluded. Screening was performed independently and disagreements were resolved by consensus. For full reproducibility, the final review record must preserve each database string, last-search date, deduplication method, counts at every screening stage, reasons for exclusion, and the chosen methodological-quality appraisal.

C. Requirements and architecture

Requirements were organized around four participant-facing functions: educational access, consent, sociodemographic/current-health data collection, and the SF-12 workflow. The prototype was developed at LaTeS using HTML5, CSS3, and JavaScript for the responsive interface, with reported Python/PHP components and a MySQL database.

Figure 2: QR code for the prototype. Public access to the instrument/scoring module should remain restricted while authorization is pending.

The functional sequence is browser interface → application logic → database. The current version does not demonstrate electronic-health-record interoperability or production-scale performance.

Before participant deployment, the production specification must document role-based access, authentication, encryption in transit and at rest, database privileges, audit logs, backup and recovery, retention/deletion rules, incident response, and responsibility for each processing operation. These are deployment requirements and are not reported here as validated functions.

D. SF-12 authorization and scoring workflow

The prototype contains a workflow intended to collect SF-12 responses and calculate PCS and MCS. Authorization to use the instrument and applicable scoring materials is currently being requested. Participant deployment and operational release of scores will occur only after the applicable conditions are confirmed and documented. The Brazilian studies cited above support contextual interpretation but do not themselves establish reproduction or automation rights.

Before deployment, automated outputs must be compared with independently calculated scores derived from an authorized reference procedure. Predefined test vectors, expected values, tolerance criteria, discrepancy logs, and the tested software version must be reported. Required items must be checked before score generation; missing or invalid answers must trigger a correction request rather than a score. The prototype provides no diagnosis or treatment recommendation.

E. Participant flow and data protection

The planned convenience sample comprises 50 adult AAFESP participants of both sexes. The participant first receives the Informed Consent Form (ICF); refusal terminates the research path before questionnaire submission. Consent is followed by the sociodemographic/current-health questionnaire and, subject to authorization, the SF-12 module. Processing of sensitive health data must comply with Law No. 13,709/2018, CONEP Circular Letter No. 1/2021, and National Health Council Resolution No. 466/2012. Compliance requires both governance and verifiable technical safeguards; the production controls listed above must be confirmed before recruitment.

F. Verification and planned evaluation

The current evidence is limited to preliminary internal checks of navigation, consent branching, required-field behavior, responsive display, and score-generation behavior with nonparticipant inputs. These checks are not clinical validation or formal usability assessment. The prospective validation protocol comprises: (1) authorized reference-score comparison; (2) missing/invalid-input tests; (3) reliability and response-time measurement under specified conditions; (4) accessibility checks; (5) security testing; and (6) usability testing with patients and health professionals

Figure 3: Prototype home page.

Figure 4: Educational content section on sickle cell anemia.

using a validated instrument and task-based measures. Outcomes will be reported only after observation.

III. Results and Discussion

A. Review and implemented prototype

The review indicated limited simultaneous treatment of SCA, standardized quality-of-life measurement, and integrated digital follow-up. The available literature reinforces the burden of pain, fatigue, hospitalization, stigma, and mental-health effects, while the identified digital gap motivates technological investigation rather than proving clinical effectiveness.

The responsive prototype is organized into educational and research-flow sections. The educational area addresses definition, symptoms, diagnosis, neonatal screening, comorbidities, treatments, quality of life, and social aspects. The research path presents consent, sociodemographic/current-health questions, and the planned SF-12 workflow (Figs. 3–8). Screenshots demonstrate interface states only; they are not evidence of user acceptance, clinical utility, authorized operational use, or patient outcomes.

B. Automated scoring as a technical hypothesis

Unifying collection and calculation may reduce transcription steps, but this advantage has not yet been quantified. Formal validation requires agreement between automated and independently calculated authorized reference scores. Therefore, the present study does not establish superior accuracy, fewer errors, better engagement, or clinical usefulness. Any novelty statement is limited to the scope and databases searched.

C. Potential relevance to the SUS

A Portuguese-language workflow accessible on common devices could support future quality-of-life data collection in patient associations and outpatient settings. Its relevance to the Brazilian Unified Health System remains a translational hypothesis requiring authorized instrument use, usability/accessibility evaluation, documented security controls, interoperability planning, and prospective measurement of data completeness, professional workload, decision support, and patient outcomes.

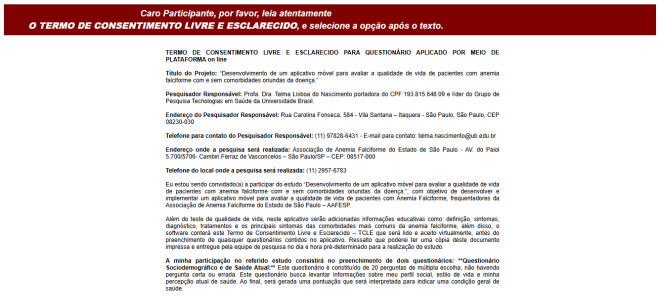

Figure 5: Informed Consent Form interface.

Figure 6: Sociodemographic and current-health questionnaire.

D. Limitations

This study is limited to technological development, a literature review, and preliminary internal checks. No participant deployment, quality-of-life analysis, formal usability study, accessibility audit, performance/load assessment, penetration test, or clinical-workflow evaluation was performed. Agreement with independently calculated authorized scores has not been reported, and SF-12 authorization is in progress. The review report also requires complete search strings, dates, screening counts, and methodological appraisal. Interoperability and long-term scalability were not evaluated. The findings cannot be generalized to clinical effectiveness or patient benefit.

IV. Conclusion

A Portuguese-language web prototype was developed to integrate educational content, informed consent, sociodemographic data collection, and a planned SF-12 workflow for adults with SCA. The study documents the prototype and defines remaining validation steps; it provides neither patient quality-of-life results nor evidence of improved follow-up, adherence, decisions, or outcomes. Authorization for SF-12 use and scoring is being requested, and participant deployment is contingent on resolution of the applicable conditions. Future work includes reproducible score verification, usability and accessibility testing with intended users, security and performance assessment, and prospective multicenter evaluation.

***Abstract*—A multiclass machine-learning framework applied to peripheral blood DNA (deoxyribonucleic acid) methylation profiles previously demonstrated that the pre-tumorigenic RISK (at risk) group exhibits a distinctive epigenetic signature separable from both healthy controls and confirmed breast cancer patients. Within that group, two visually distinct sub-clusters were observed in t-SNE (t-distributed stochastic neighbor embedding) projections, but their biological basis was not addressed. The present study investigates whether chronological age, stratified into three bands (age $<$ 60, 60 $\leq$ age $<$ 70, and age $\geq$ 70), accounts for the substructure observed in the RISK population. Methylation profiles were obtained from 282 at risk women in the GSE58119 cohort (Gene Expression Omnibus series GSE58119), assayed using the Illumina HumanMethylation27 BeadChip, which measures 27,578 CpG (cytosine-phosphate-guanine) sites. They were then re-labelled by age group and re-projected via t-SNE. The visualization reveals that age stratification does not cleanly separate the two clusters: women from all three age bands are present in both clusters, with Cluster 2 containing the majority of every age group. A modest age related trend is nonetheless visible, with the proportion of women assigned to Cluster 1 decreasing slightly with age (40.7% for age $<$ 60, 39.6% for 60 $\leq$ age $<$ 70, and 28.6% for age $\geq$ 70). Statistical testing confirms that this trend is not significant (ANOVA $p = 0.530$; Kruskal–Wallis $p = 0.619$; χ^2 $p = 0.418$; $\eta^2 = 0.001$), even though the two clusters are themselves highly robust (silhouette = 0.663; permutation test $p = 0.001$). These findings indicate that age has only a modest, non-significant influence on the two cluster topology and that other biological or clinical factors must be responsible for the primary separation, motivating further investigation of additional covariates within the pre-malignant state.**

***Index Terms*—DNA (deoxyribonucleic acid) methylation; breast cancer; pre-tumorigenic risk; t-SNE (t-distributed stochastic neighbor embedding); age stratification; epigenetic heterogeneity; CpG (cytosine-phosphate-guanine) islands; machine learning.**

I. Introduction

Breast cancer is one of the foremost contributors to cancer-related mortality among women globally, and its biological complexity continues to pose significant challenges to early detection and risk stratification [1]. While conventional screening modalities such as mammography identify the disease only after tumor formation has occurred, there is growing recognition that epigenetic alterations precede histopathological transformation by several years [2], [3]. Among these, DNA methylation at CpG (cytosine-phosphate-guanine) dinucleotides has attracted considerable attention as a minimally invasive biomarker measurable in peripheral blood [4]. A multiclass classification framework developed to distinguish healthy women, women at elevated risk, and confirmed breast cancer patients from peripheral blood methylation profiles demonstrated strong performance, particularly for the at risk cohort [5]. The AdaBoost (Adaptive Boosting) model achieved 89.5% overall accuracy and an F1-score (F1; harmonic mean of precision and recall) of 0.991 for the RISK class, while Kruskal-Wallis testing confirmed that 90-93% of the top 100 CpG islands discriminated the RISK group from both healthy

CNPq

controls and cancer patients. Dimensionality-reduction analyses using Principal Component Analysis (PCA) and t-SNE further corroborated these findings by revealing a spatially separated cluster for the RISK population. Crucially, the t-SNE projection of the 282 at risk samples disclosed two visually distinct sub-clusters whose biological basis was not investigated. Understanding the source of this intra-group heterogeneity is important because it directly informs whether a single risk assessment model is sufficient or whether separate stratum-specific classifiers are warranted. Age is a well-established modulator of DNA methylation: epigenetic clocks demonstrate that global methylation patterns drift predictably with chronological age [6], and breast cancer incidence is strongly age dependent, peaking in postmenopausal women [7]. While our previous work [5] established the existence of a distinct epigenetic signature in the RISK group and identified a two cluster substructure via t-SNE, the biological drivers of this intra-group heterogeneity remained unexplored. The primary innovation of the present study is the systematic interrogation of this substructure using chronological age as a stratifying variable, coupled with cluster-validation metrics and multi method dimensionality reduction. By demonstrating that age does not account for this topological separation, this work provides a crucial negative finding that redirects future biomarker discovery away from age stratified models and toward the investigation of other latent clinical or biological covariates (e.g., BRCA1/2 status, hormonal history) within the pre-malignant state.

II. RELATED WORK

The relationship between DNA methylation and aging has been extensively characterized. Horvath demonstrated that a weighted combination of 353 CpG sites tracks chronological age across multiple tissue types with high precision [6], and subsequent epigenetic-clock studies revealed that accelerated methylation aging in blood cells is associated with increased cancer incidence [8]. In the context of breast cancer, Hofstatter et al. showed that epigenetic age in normal breast tissue is elevated in luminal cancer patients compared with healthy controls, underscoring a potential link between methylation-age dysregulation and oncogenic predisposition [9]. At the population level, several prospective cohort studies have confirmed that peripheral blood methylation profiles can discriminate women who subsequently develop breast cancer from those who do not, even when samples are drawn years before diagnosis [10], [11]. However, these analyses have generally treated the at risk group as homogeneous rather than stratifying by age. The present work addresses this gap by leveraging age annotated longitudinal data. From a computational perspective, t-SNE has become a standard tool for exploring high-dimensional omics data [12], recent state-of-the-art approaches emphasize the necessity of validating non-linear embeddings with complementary methods like UMAP and PCA, alongside internal clustering metrics (e.g., silhouette, Davies–Bouldin), to ensure that observed topologies reflect genuine biological structure rather than algorithmic artifacts [13], [14]. Furthermore, contemporary breast cancer risk prediction models increasingly integrate epigenetic clocks with traditional risk factors; however, few studies have explicitly tested whether age driven methylation drift is the primary axis of variation in pre-tumorigenic sub-clusters. This study bridges that gap by applying a multi method validation framework to an age annotated at risk cohort.

III. MATERIALS AND METHODS

A. Dataset and cohort description

The dataset employed in this study is the publicly available GSE58119 cohort (Gene Expression Omnibus (GEO) series GSE58119), deposited in the Gene Expression Omnibus (GEO) [15] and processed with the Illumina Infinium HumanMethylation27 BeadChip v1.2, which measures methylation beta values at approximately 27,578 CpG (cytosine-phosphate-guanine) sites in peripheral blood cells. This work uses the same RISK subset of GSE58119 (n = 282) analyzed previously in [5]; the present contribution differs in that we explicitly stratify and analyze the RISK samples by chronological age to interrogate the previously observed two cluster t-SNE topology. The cohort comprises 282 women from a nested case-control design within a prospective breast cancer screening programme. Women who received a clinical breast cancer diagnosis within five years of blood draw were labelled PRE-BRCA (pre-diagnosis breast cancer; n = 148), while those who remained cancer-free were labelled HEALTHY-UNK (healthy, unknown follow-up; n = 134). Both subgroups are here collectively termed the RISK (at risk) population. Participant age at blood draw is recorded in the original GEO submission and serves as the primary covariate of interest.

B. Age stratification

Participants were stratified into three age bands following thresholds commonly used in clinical breast cancer research: (i) age < 60 years, representing predominantly premenopausal and early postmenopausal women; (ii) $60 \leq$ age < 70 years, an intermediate postmenopausal window; and (iii) age ≥ 70 years, representing older postmenopausal women in whom age associated methylation drift is expected to be most pronounced. The resulting age band totals across the RISK group are summarized in Table I.

TABLE I: age stratified sample distribution within the RISK group (n = 282)

Age band	**n**
Age < 60	113
$60 \leq$ Age < 70	134
Age ≥ 70	35
Total	**282**

C. Preprocessing

All preprocessing steps followed the same pipeline described in [5]; no additional normalization, feature selection, or re-weighting was introduced for the present analysis. Beta

methylation values were computed from raw fluorescence intensities as

$$\beta = \frac{TI}{U + TI + \alpha}$$

where TI is the total intensity of the methylated allele, U is the intensity of the unmethylated allele, and $\alpha = 100$ is an offset that stabilizes estimates and prevents division by zero. Missing values were imputed with the per CpG island mean across all samples. The final feature matrix comprised 282 samples x 27,578 CpG sites. No synthetic oversampling was applied at this stage, as the objective is exploratory visualization rather than classification; the key methodological change relative to [5] is the age based re-labelling and stratified interpretation of the embedding.

D. t-SNE configuration

t-SNE was applied to the full 27,578-dimensional methylation matrix using the scikit-learn (Python machine-learning library) implementation (perplexity = 30, learning rate = 200, n_iter = 1,000, random_state = 42). Samples were colored according to their age stratified sub-category label across six categories: PRE-BRCA AGE $<$ 60, PRE-BRCA 60 $\leq$ AGE $<$ 70, PRE-BRCA AGE $\geq$ 70, HEALTHY-UNK AGE $<$ 60, HEALTHY-UNK 60 $\leq$ AGE $<$ 70, and HEALTHY-UNK AGE $\geq$ 70. This annotation scheme enables simultaneous assessment of clinical status and age related positioning within the embedding.

E. Comparison of dimensionality-reduction methods

To confirm that the observed two cluster topology is not an artefact of t-SNE, three additional projections of the same standardized methylation matrix were computed for comparison: Principal Component Analysis (PCA), Uniform Manifold Approximation and Projection (UMAP, $n_neighbors = 15$, $min_dist = 0.1$), and a Linear Discriminant Analysis (LDA) supervised directly by the same k-means reference labels obtained from the t-SNE coordinates (Figure 2). For PCA and UMAP, which are unsupervised, comparing their embeddings against these reference labels constitutes a genuine, label-independent check of whether the bipartition is recoverable by methods that had no access to the cluster assignments. The LDA projection is different because it is explicitly trained to maximize separation between the two k-means classes, strong separation in the LDA axis is expected by construction and does not provide independent evidence of cluster robustness. We therefore report the LDA result only as a sanity check that the two groups are linearly separable in methylation space, not as confirmation of the bipartition's validity.

F. Cluster definition and statistical analysis

To avoid the subjectivity of manually drawn visual boundaries, the two sub-clusters were defined objectively by applying k-means clustering ($k = 2$, random state=42) to the two dimensional t-SNE coordinates. To ensure cluster stability, this partitioning was verified across multiple random seeds (42, 0, 123), yielding consistent assignments ($> 98\%$ agreement). The choice of $k = 2$ was further supported by a silhouette analysis over $k \in [2, 8]$ computed on the standardized methylation matrix, which peaked at $k = 2$ (silhouette = 0.290). Cluster validity was assessed with the silhouette, Davies–Bouldin, and Calinski–Harabasz indices, and the separation was tested for significance with a 1,000-iteration label-permutation test on the silhouette score. The association between chronological age and cluster membership was then evaluated with one-way ANOVA and the Kruskal–Wallis test (age as a continuous variable across clusters), a χ^2 test of independence (age band $\times$ cluster), and the η^2 statistic (fraction of age variance explained by cluster membership).

IV. RESULTS

A. Visual topology of the age stratified t-SNE

The t-SNE projection of the 282 at RISK samples, presented in Fig. 1, confirms the same two cluster topology previously reported for this cohort in [5]: a compact, high-density cluster in the upper-right region of the embedding (approximately TSNE1 (t-SNE dimension 1) in [6, 16], TSNE2 (t-SNE dimension 2) in [4, 10]) and a more dispersed cluster occupying the lower-left quadrant (approximately TSNE1 in [-16, 0], TSNE2 in [-7, 1]). Color-coded by age stratum (a new annotation layer relative to [5]), the visualization reveals that all three age bands are present in both clusters, without any age defined region of the embedding. Younger women (age $<$ 60) are distributed across both clusters, with a slight relative enrichment in Cluster 1 compared with older women (40.7% vs. 28.6% of their respective age groups in Cluster 1). The intermediate band (60 $\leq$ age $<$ 70) shows an almost identical distribution to the youngest band, with 39.6% of its members in Cluster 1. Older women (age $\geq$ 70) are the least likely to appear in Cluster 1, with 71.4% assigned to Cluster 2. Crucially, Cluster 2 contains the majority of women in every age band, including the youngest one. There is therefore no "one age in one cluster, the other age in the opposite cluster" separation; instead, the data show substantial overlap of all age groups across both clusters, with only a modest trend toward a lower Cluster 1 share among older participants. Taken together, these observations indicate that chronological age contributes at most a weak gradient to the spatial organization of the RISK population in the embedding and does not account for the two cluster structure reported in [5].

B. age cluster correspondence

To quantify the degree to which age bands map onto the two clusters, samples were partitioned into the two groups returned by k-means clustering ($k = 2$) of the t-SNE coordinates (Cluster 1: upper-right; Cluster 2: lower-left). The resulting counts and percentages are reported in Table **??** (composition by age band) and Table II (per age band share between clusters). Cluster 1 contains 109 women (38.7% of the RISK group) and Cluster 2 contains 173 women (61.3%). Within each age band, the majority of women fall into Cluster 2 (59.3%, 60.4%, and 71.4% for the three age bands respectively), confirming

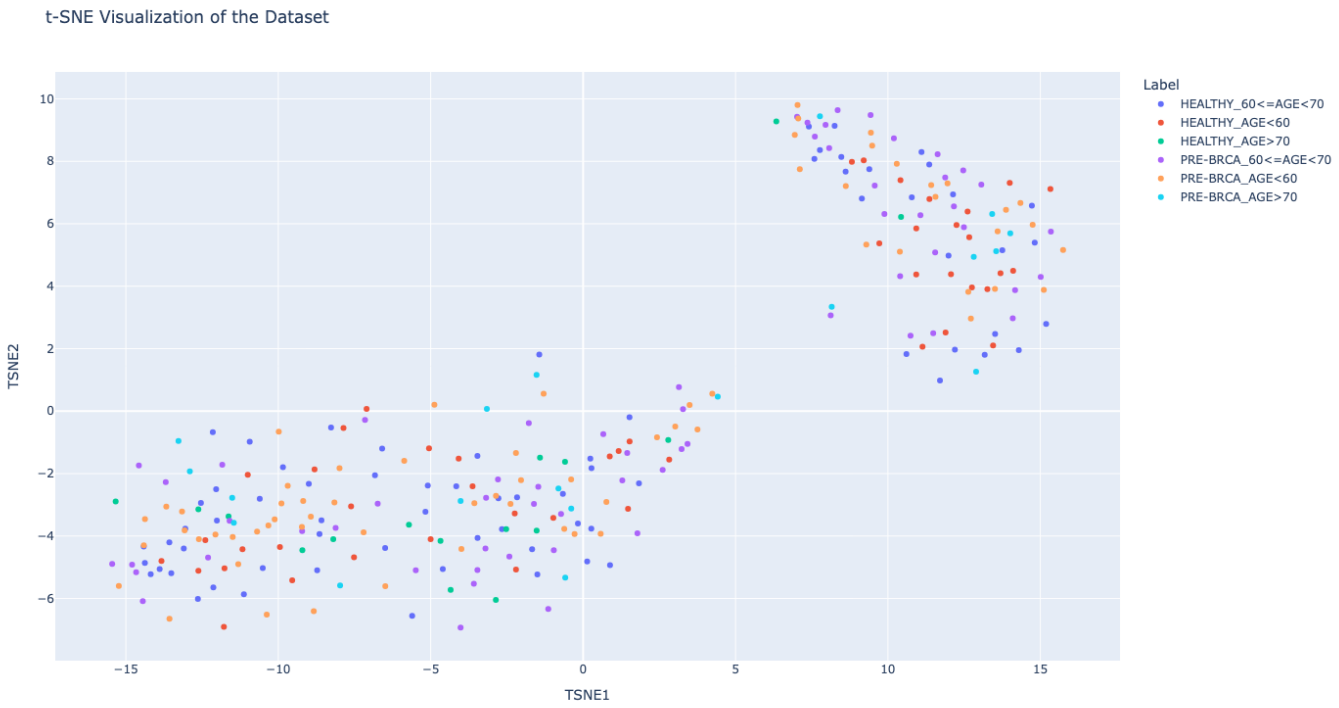

Fig. 1: age stratified t-SNE projection of the RISK sub-cohort (n = 282). Two clusters are visible; all three age bands are present in both clusters, and age provides only modest explanatory coverage of the observed sub-structure.

that neither cluster is dominated by a single age stratum and that the two cluster topology is not driven primarily by age.

The two clusters are themselves well separated and statistically robust: the silhouette score reaches 0.663 in the t-SNE embedding (Davies–Bouldin = 0.453, Calinski–Harabasz = 971.6) and remains positive in the original 27,578-dimensional space (silhouette = 0.246), where the label permutation test rejects the null hypothesis of no structure (permuted silhouette 0.000 ± 0.004, $p = 0.001$). In sharp contrast, no statistical association is found between age and cluster membership: one-way ANOVA ($F = 0.396$, $p = 0.530$) and the Kruskal–Wallis test ($H = 0.247$, $p = 0.619$) detect no difference in age distribution between clusters, the χ^2 test of independence between age band and cluster is non-significant ($\chi^2 = 1.747$, $\mathrm{dof} = 2$, $p = 0.418$), and cluster membership explains essentially none of the variance in age ($\eta^2 = 0.001$). Thus the substructure is highly significant while its alignment with age is not.

TABLE II: Cluster assignment within each age band (% of the age band)

Age band	Cluster 1	Cluster 2	Total
Age $<$ 60	46 (40.7%)	67 (59.3%)	113
60 $\leq$ Age $<$ 70	53 (39.6%)	81 (60.4%)	134
Age $\geq$ 70	10 (28.6%)	25 (71.4%)	35
Total	**109**	**173**	**282**

C. Robustness across dimensionality-reduction methods

The two cluster structure is reproduced by every unsupervised projection examined, confirming that it reflects genuine structure in the methylation data rather than a peculiarity of t-SNE. Figure 2 shows the four embeddings side by side: both t-SNE and UMAP resolve the RISK group into two well separated point clouds, and PCA preserves the same separation along its leading components (PC1 and PC2 capturing 39.8% and 9.2% of the variance, respectively; 51.3% cumulative over three components), all without having been given the cluster labels. The LDA projection also spreads the samples along a dominant discriminant axis, but because LDA was supervised with the same k-means labels being evaluated, this separation is expected by construction and is reported only as a sanity check, not as independent evidence of robustness. As in the t-SNE map, no projection exhibits an age defined region: the six age stratified colour groups are intermixed throughout each embedding.

The quantitative agreement is summarized in Table III, which reports the three internal validation indices computed against the common k-means reference labels. t-SNE yields the cleanest separation (silhouette = 0.663, Davies–Bouldin = 0.453, Calinski–Harabasz = 971.6), closely followed by UMAP (0.650, 0.463, 811.0); PCA preserves a moderately strong separation in only two linear dimensions (0.495, 0.806, 333.7), and the same partition remains detectable even in the original 27,578-dimensional space (0.246, 1.588, 103.1). The

Fig. 2: Comparison of four dimensionality-reduction methods (t-SNE, PCA, UMAP, and LDA) applied to the same 282-sample RISK methylation matrix, coloured by the six age stratified sub-categories. The two cluster topology is reproduced by every method, and no embedding shows an age defined region.

consistency of these indices across linear (PCA) and non-linear (t-SNE, UMAP) unsupervised techniques demonstrates that the bipartition is a robust, method-independent property of the RISK cohort; the supervised LDA result is consistent with this conclusion but, being circular by construction, is not counted as independent supporting evidence.

TABLE III: Internal cluster validation indices for each embedding, computed against the common k-means reference labels

Method	Silhouette	Davies–Bouldin	Calinski–Harabasz
Original space	0.246	1.588	103.1
t-SNE	0.663	0.453	971.6
PCA (2D)	0.495	0.806	333.7
UMAP	0.650	0.463	811.0

V. DISCUSSION

A. Summary of findings

The primary finding of this study is that chronological age does not cleanly separate the two cluster substructure of the RISK population in the t-SNE space. All three age bands are present in both clusters, and Cluster 2 contains the majority of women in every age band. A modest age related trend is observed, with the proportion of women assigned to Cluster 1 decreasing slightly from 40.7% (age < 60) to 39.6% ($60 \leq$ age < 70) and 28.6% (age ≥ 70); however, this trend does not reach statistical significance under ANOVA, Kruskal–Wallis, or χ^2 testing ($p = 0.530$, 0.619, and 0.418 respectively), and cluster membership accounts for only $\eta^2 = 0.001$ of the variance in age. The clusters themselves, by contrast, are statistically robust (permutation test $p = 0.001$). This result has both conceptual and practical implications for breast cancer risk stratification.

B. Biological interpretation

From a conceptual standpoint, the modest age related trend in cluster assignment is consistent with the well established phenomenon of epigenetic drift, in which methylation at specific CpG sites changes as a function of accumulated cellular divisions and lifelong environmental exposures [16]. Postmenopausal women exhibit distinct methylation signatures relative to premenopausal counterparts, reflecting hormonal shifts that modulate DNA methyltransferase (DNMT) activity and methyl-group availability [17]. The slightly lower share of older women in Cluster 1 is compatible with this background biology. However, the substantial overlap of all age groups across both clusters indicates that the dominant axis of variation between Cluster 1 and Cluster 2 is not chronological age. One candidate explanatory variable is already present in our own metadata and was used to construct the six-category colour scheme in Fig. 1: case/control status, i.e., whether a participant was subsequently diagnosed (PRE-BRCA, $n = 148$) or remained cancer-free (HEALTHY-UNK, $n = 134$).

Unlike BRCA1/2 mutation carrier status, parity, body mass index (BMI), and use of hormonal therapies which genuinely could not be evaluated here due to metadata limitations case/control status requires no additional data collection, and testing its association with the two cluster partition (e.g., via the same χ^2 and permutation-based framework applied to age in Section III-E) is a necessary analysis that we have not yet completed and that should be reported before this work is considered finished. A finding that the two sub-clusters align with future diagnosis status, rather than with age, would substantially change the interpretation and significance of this study: it would suggest the t-SNE bipartition itself carries prognostic information, rather than being an unexplained structural curiosity. We flag this explicitly as the most important open question raised by the present analysis, ahead of the other candidate covariates listed below. Future work should systematically test each of these variables as potential explanatory factors for the primary two cluster separation.

C. Implications for risk modeling

From a practical standpoint, the limited age dependence of the cluster assignment has direct implications for biomarker discovery and the design of future screening models. Because the two t-SNE sub-clusters are not aligned with age strata, a single pooled classifier is unlikely to be substantially confounded by chronological age alone. However, it may also fail to capture the as-yet-unidentified covariate that drives the actual cluster separation. Consequently, future breast cancer risk-stratification models should not rely solely on age adjusted classifiers. Instead, biomarker discovery pipelines must incorporate multi omic or detailed clinical covariate data to isolate the true biological signal driving this epigenetic heterogeneity, thereby enabling more precise, personalized screening intervals for women in the pre-malignant state.

The intermediate age band ($60 \leq \text{age} < 70$) is the largest in this cohort and shows a distribution between the two clusters that is essentially indistinguishable from that of the youngest band, possibly reflecting the biological transitional nature of this period: late perimenopausal or early postmenopausal, with high inter-individual variability in hormonal and epigenetic trajectories. This observation reinforces the conclusion that age, on its own, is insufficient to define risk relevant epigenetic subgroups within the at risk population.

D. Limitations and future work

A limitation of the present analysis is its post-hoc, observational nature. A more specific limitation is that, while we used PRE-BRCA/HEALTHY-UNK status to colour Fig. 1, we did not statistically test whether this case/control label rather than age explains the two cluster partition, even though this label was already available and required no additional data collection; this test should be carried out and reported as a direct extension of Section III-E before any claim about the explanatory irrelevance of clinical covariates can be considered complete. Furthermore, while t-SNE is highly effective for visualizing local neighborhood structures, it is an exploratory tool whose output can be sensitive to hyperparameters such as perplexity, learning rate, random seed, and distance metrics. Although we mitigated this by confirming topological stability across UMAP and PCA (with LDA included only as a non-independent sanity check, see Section III-D), the subjective interpretation of 2D projections remains a constraint. Additionally, the age stratification was applied to a t-SNE computed on the full RISK group without a priori selection of age informative CpG sites. We also did not assess whether batch or array-processing effects (e.g., chip or scan-date structure), a recognized source of artefactual clustering on Illumina BeadChip platforms, could contribute to the observed bipartition. Future work will address these limitations by: (i) testing the association between the two cluster partition and case/control (PRE-BRCA vs. HEALTHY-UNK) status; (ii) applying age regressed methylation matrices to confirm that the two cluster structure persists after mathematically removing age associated variation; (iii) checking the partition against available batch/array metadata; and (iv) systematically evaluating the impact of specific clinical covariates available in extended metadata, such as BRCA1/2 mutation status, body mass index (BMI), parity, hormone replacement therapy, and time to diagnosis, to identify the true drivers of this epigenetic substructure.

VI. CONCLUSIONS

Building directly on [5] and using the same GSE58119 RISK cohort and preprocessing pipeline, this work demonstrates that the two sub-clusters observed in the t-SNE projection of this pre-tumorigenic breast cancer risk population are not cleanly separated by chronological age. Women from all three age bands are distributed across both clusters, with Cluster 2 containing the majority of every age group. Only a modest age related trend is observed, with the proportion of women assigned to Cluster 1 decreasing slightly with age (40.7%, 39.6%, and 28.6% for the three age bands). Age therefore has a modest, non-significant influence on cluster assignment and does not explain the two cluster structure. Rather than definitively excluding age's role in epigenetic heterogeneity, these findings suggest that other biological or clinical factors are likely the primary drivers of this separation. These findings carry direct implications for the design of risk-stratification models based on peripheral blood DNA methylation: while age adjusted classifiers may offer minor refinements, they are insufficient on their own, as age does not align with the dominant axis of variation between the two clusters. Future studies should systematically test candidate covariates (e.g., BRCA1/2 status, parity, BMI, hormonal therapy), apply age regressed methylation matrices, and investigate whether the two sub-clusters encode different time-to-diagnosis intervals within the PRE-BRCA stratum, which could enable finer grained epigenetic risk scoring for women at high hereditary risk of breast cancer.

ACKNOWLEDGMENT

The authors are grateful for the Department of Science and Technology of Brazil's Ministry of Health (DECIT/MS; Departamento de Ciência e Tecnologia do Ministério da Saúde), and to the Brazilian research agencies CNPq (Conselho Nacional de Desenvolvimento Científico e Tecnológico) and Facepe (Fundação de Amparo à Ciência e Tecnologia do Estado de Pernambuco), for the partial financial support of this research.

***Abstract*—Alzheimer's disease, a progressive neurodegenerative disorder affecting millions globally, presents significant challenges in diagnosis, particularly in its early stages. It is estimated that 35.6 million people suffer from the disease, with 1.2 million cases in Brazil alone [1]. Characterized by the accumulation of amyloid-beta plaques [2], the disease is often discovered in advanced stages due to the difficulty of its diagnosis, which directly impacts the possibilities for effective treatment. This paper investigates the potential of Convolutional Neural Networks (CNNs) as an auxiliary tool in the diagnosis of Alzheimer's disease, aiming to improve detection accuracy and earliness. By training and comparing different CNN architectures using a database of magnetic resonance imaging (MRI) scans from patients, the study seeks to identify the hyperparameters that maximize metrics such as recall, precision, and F1-score in classifying the different stages of the disease. The results demonstrate the effectiveness of applying CNNs to Alzheimer's diagnosis, highlighting the high recall achieved in identifying advanced stages. Additionally, the research contributes to the understanding of the impact of hyperparameters on CNN performance for this specific task, paving the way for the development of more precise and efficient diagnostic support tools.**

***Index Terms*—Alzheimer's, Convolutional Neural Networks, Diagnosis, Machine Learning, MRI.**

I. Introduction

The use of artificial intelligence (AI) has become increasingly present in daily life, with diverse applications that permeate multiple aspects of human existence. In healthcare, AI has driven a true revolution, making it possible to conduct preliminary diagnoses almost instantaneously. As these technologies evolve and become more accessible, the expectation is that the quality of life of populations will be significantly impacted.

Alzheimer's disease, a progressive neurodegenerative condition, represents a considerable challenge for global public health. According to Alves [1], an estimated 35.6 million people suffer from the disease, with 1.2 million in Brazil alone. Characterized by the progressive loss of cognitive functions, the disease begins with mild memory changes and gradually evolves to more severe conditions, compromising the quality of life of patients and their families [3]. Although there is still no cure for the disease, early identification is crucial for effective treatment and for allowing the patient to actively participate in their health care.

This work investigates the potential of Convolutional Neural Networks (CNNs), a powerful machine learning method, in developing tools for the rapid and accurate diagnosis of Alzheimer's disease. Using a dataset of magnetic resonance imaging (MRI) scans [4], we constructed and compared different CNN architectures to identify the hyperparameters that yield optimal performance in classifying the different stages of the disease.

The specific objectives of this study are:

- Perform a literature review on the use of computational techniques in the diagnosis of Alzheimer's disease.
- Develop and test multiple CNNs to identify potential cases of the disease from MRI images.
- Identify the hyperparameters that lead to the best CNN performance in the task of classifying Alzheimer's stages.

We believe that the results of this research will contribute significantly to the development of early diagnosis support tools for Alzheimer's disease, opening pathways for more effective interventions and improving patients' quality of life.

II. Theoretical Background

This section presents the theoretical concepts that underpin this work. First, we address Alzheimer's disease, its characteristics, and the challenges related to its diagnosis. Next, we

explore the paradigm of machine learning (ML), focusing on artificial neural networks and highlighting their application in disease diagnosis—specifically in Alzheimer's detection.

A. Alzheimer's Disease

Alzheimer's disease (ICD-10 G30) is a chronic and progressive neurodegenerative disease that causes cognitive decline, impacting work capacity, social relationships, and quality of life [2]. The most common initial symptom is short-term memory loss, followed by difficulties in learning, communication, and reasoning, which affect daily activities and interpersonal relationships.

Accounting for about 60% to 70% of dementia cases, Alzheimer's still does not have its causes fully elucidated [5]. The disease was first described in 1906 by the German psychiatrist Alois Alzheimer, and its progression, although variable, leads to a gradual loss of bodily function control, culminating in death. Life expectancy following diagnosis is generally between 3 and 9 years [6].

Alzheimer's is the most frequent form of dementia in elderly patients and is characterized by the accumulation of beta-amyloid plaques, mainly in the prefrontal and mesial-temporal areas of the brain [2]. The formation of amyloid plaques damages brain tissue, contributing to the progression of the disease.

Diagnosis is complex and requires a multidisciplinary evaluation involving careful analysis of clinical data, imaging exams, and neuropsychological tests. Frota et al. [7] describe the following core criteria for diagnosis:

- Progressive decline of cognitive abilities.
- Insidious onset (months or years).
- Exclusion of other causes of dementia through neuroimaging exams, such as computed tomography (CT) or magnetic resonance imaging (MRI).

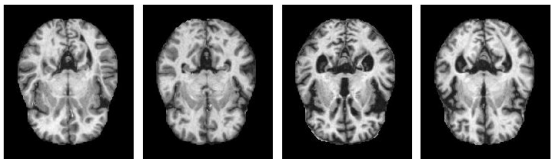

Fig. 1. Different stages of Alzheimer's disease, ordered by progression. Source: [4].

B. Machine Learning

Machine Learning (ML) is a branch of artificial intelligence (AI) aimed at developing computational systems capable of learning from data without being explicitly programmed [9]. The goal of ML is to create algorithms that, given a set of training data, identify patterns, make predictions, and make decisions autonomously.

C. Artificial Neural Networks

Artificial Neural Networks (ANNs), or simply neural networks, are computational models inspired by the operation of the human brain. ANNs consist of interconnected units called artificial neurons, which process and transmit information similarly to biological neurons [16].

Neurons are organized in layers: the input layer receives the input data, the output layer provides the network's result, and the hidden layers between the input and output perform information processing. Neural networks with multiple hidden layers are called deep neural networks.

1) Multilayer Perceptron: The Multilayer Perceptron (MLP) is one of the most widely used neural network architectures, consisting of an input layer, one or more hidden layers, and an output layer.

2) Bias Insertion in Neural Networks: Bias is a parameter that can be added to neurons, increasing the network's flexibility and its ability to learn complex patterns within data [18], [19].

3) Activation Functions: Activation functions are applied to the output of each neuron to introduce non-linearity into the network, enabling the modeling of complex relationships in the data. The choice of activation function depends on the problem and the characteristics of the data. Common activation functions include Rectified Linear Unit (ReLU), Hyperbolic Tangent, Logistic (Sigmoid), and Softmax [20].

4) Loss Functions: Loss functions are used to quantify the error between the neural network's output and the target output. The objective of network training is to minimize the loss function. Examples of loss functions for classification problems include Cross-Entropy and Hinge Loss [18].

5) Backpropagation: The backpropagation algorithm is essential for training neural networks. It calculates the gradient of the loss function with respect to the network weights, allowing weights to be updated in the direction that minimizes error. Figure 2 illustrates the backpropagation process.

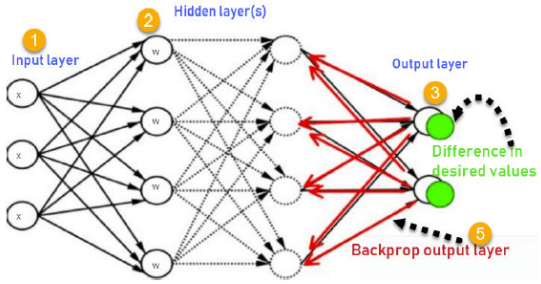

Fig. 2. Diagram of backpropagation. Source: [21].

6) Dropout: Dropout is a regularization technique designed to prevent overfitting in neural networks. During training, dropout randomly deactivates a percentage of neurons, forcing the network to learn more robust representations that are less dependent on specific individual neurons [24], [25].

7) Convolutional Neural Networks (CNNs): Convolutional Neural Networks (CNNs) are a specific type of neural network widely used in image processing. CNNs excel at automatically extracting relevant features from images without requiring manual feature engineering. The defining operations of CNNs are convolution, pooling, and flattening, as illustrated in Figure 3.

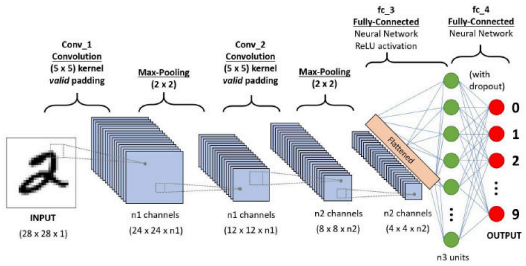

Fig. 3. Diagram of CNN operations. Source: [27].

a) Convolution: Convolution is the fundamental operation of CNNs. It applies a filter (kernel) to the input image to extract specific features, such as edges, textures, and patterns.

b) Pooling: Pooling reduces the dimensionality of feature maps generated by convolution, making the network more robust to shifts in feature positions within the image. The most common type of pooling is max pooling, which selects the maximum value within an image region [26].

c) Flattening: Flattening transforms the multidimensional matrix resulting from pooling into a one-dimensional vector, which is then used as input to a fully connected neural network.

III. Related Work

The application of Convolutional Neural Networks (CNNs) to diagnose neurodegenerative conditions such as Alzheimer's has been extensively researched over the past decade. Recent studies, such as that by *Islam and Zhang* [8], applied deep convolutional networks to structural magnetic resonance imaging (SMRI) data to classify different stages of Alzheimer's disease. The model uses convolutions with 7x7 operators over SMRI data and features four layers of 56, 28, 14, and 7 neurons, in addition to the output layer. The activation function used was *Softmax*. The achieved precisions were 99% for non-demented individuals, 75% for very mild cases, 62% for mild, and 33% for moderate cases, demonstrating that precision decreases as Alzheimer's severity increases. The architecture of this model can be seen in Figure 4.

Another significant study was conducted by *Ding et al.* [30], who utilized the *Inception V3* architecture to predict Alzheimer's progression across three stages: cognitively normal (CN), mild cognitive impairment (MCI), and Alzheimer's disease (AD). Evaluation metrics such as precision and recall (or sensitivity) demonstrated superiority over traditional methods and even outpaced evaluations performed by radiologists. Radiologists outperformed the model only in the intermediate MCI stage, whereas the model outperformed human experts in AD and CN cases. The complete model architecture is shown in Figure 5.

Zhang et al. [25] also applied a deep learning approach, utilizing two data modalities: MRI and PET (Positron Emission Tomography) images. They proposed two models with nearly identical configurations applied separately to the two modalities. Pearson's correlation coefficient was used to check

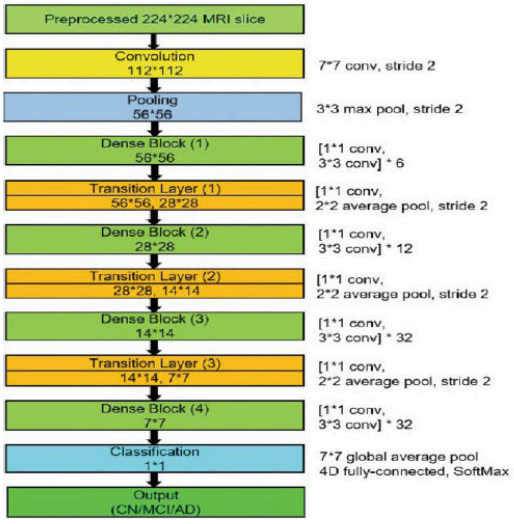

Fig. 4. Architecture proposed by *Islam and Zhang* [8].

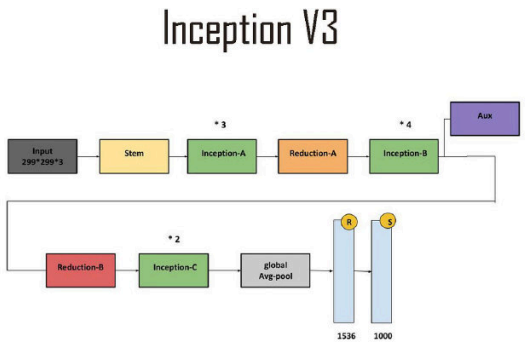

Fig. 5. *Inception V3* Architecture [30].

agreement between the two models, achieving an AUC of 0.98 for the CN vs. AD comparison, but only 0.88 for the intermediate MCI stage. The architecture used in their study is illustrated in Figure 6.

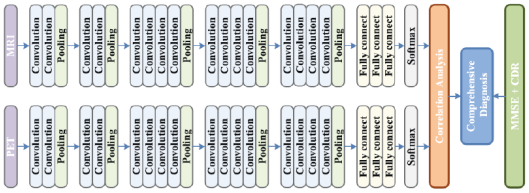

Fig. 6. Architecture proposed by *Zhang et al.* [25].

Table I summarizes the results of these works.

IV. Methodology

The study was conducted to diagnose Alzheimer's Disease using CNNs applied to brain MRI scans. The methodological process followed a series of essential steps, ranging from data acquisition to model training and evaluation.

TABLE I
SUMMARY OF RESULTS FROM RELATED WORKS

Authors	Accuracy	Class	Recall	Precision	F1-Score	AUC
(ISLAM; ZHANG, 2018)		ND	0.99	0.99	0.99	
		VMD	0.50	0.75	0.60	
		MD	0.71	0.62	0.67	
		MoD	0.50	0.33	0.40	
(DING et al., 2019)		CN	0.59	0.60	0.59	0.84
		MCI	0.54	0.55	0.55	0.52
		AD	0.81	0.76	0.78	0.98
(ZHANG et al., 2019) AD/CN	98.47%	AD	0.96			0.98
(ZHANG et al., 2019) MCI/CN	85.74%	MCI	0.90			0.88
(ZHANG et al., 2019) AD/MCI	88.20%	AD	0.97			0.88

A. Data Acquisition and Preprocessing

The data used in this study were retrieved from a repository available on Kaggle (a data science learning platform), consisting of brain MRI images of patients at different stages of Alzheimer's Disease. These images were categorized into four classes: Non Demented (ND), Very Mild Demented (VMD), Mild Demented (MD), and Moderate Demented (MoD).

A major challenge in medical image classification is class imbalance, which can lead to poor model generalization, particularly for underrepresented classes. In this work, we used the SMOTE implementation from the `imbalanced-learn` library with the parameters `strategy="not majority"` and `random_state=0`.

Prior to applying SMOTE, the dataset contained 6,394 MRIs; after oversampling, it expanded to 12,796 MRIs. The original distribution alongside the post-oversampling distribution is presented in Table II.

TABLE II
CLASS DISTRIBUTION BEFORE AND AFTER OVERSAMPLING

Class	Original (Tr./Te.)	Oversampling (Tr./Te.)
1 (ND)	2407/792	2414/785
2 (VMD)	1662/577	2384/815
3 (MD)	681/214	2385/814
4 (MoD)	47/16	2414/785

Each image underwent intensity normalization to ensure all images shared the same intensity scale, which is essential for the model to learn consistent patterns.

B. Convolutional Neural Network Architecture

Different CNN architectures were evaluated to identify the optimal configuration. All models shared the following core components:

- Input layer: resized images of 128x128 pixels.
- 1st Convolutional Layer: 8 filters of 9x9, with ReLU activation.
- 2nd Convolutional Layer: 16 filters of 5x5, with ReLU activation.
- Hidden layers (minimum of 1): ReLU activation.
- Output Layer: 4 neurons (one for each class), with Softmax activation.

All models were trained using categorical cross-entropy loss and the Adam optimizer with an initial learning rate of 0.001.

C. Model Training

All models were trained on 75% of the data and evaluated on the remaining 25%. For each, was used the same partition of training and test without cross-validation. Training was performed over 20 epochs with a batch size of 32.

D. Performance Evaluation

Metrics used to evaluate model performance included accuracy, precision, recall, and F1-score. Additionally, ROC curve plots were generated for visual analysis.

E. Hyperparameter Tuning

To optimize model performance, various hyperparameter combinations were tested, including the number of layers, neurons per layer, dropout rates, and bias inclusion. A total of 24 distinct hyperparameter configurations were evaluated.

Tested dropout rates were 0% and 20%, while the number of layers varied between 1, 3, and 10. The number of neurons per layer was set to 40 and 100. Regarding bias, models were trained both without bias and with zero-initialized bias. The loss function across all models was cross-entropy.

V. EXPERIMENTS AND RESULTS

A. Performance Evaluation

Model performance was evaluated based on accuracy, precision, recall, F1-Score, and Area Under the ROC Curve (AUC).

Minimum viable model thresholds were established in reference to [8]. A model was considered viable if it achieved a recall and AUC of 0.5 or higher for Non Demented, Very Mild Demented, and Mild Demented, and 0.99 or higher for Moderate Demented. A total of 20 models met these criteria.

To compare models, intervals with one standard deviation around the mean were analyzed across all metrics. Sixteen models fell within this interval, and none scored above it. Five of these models achieved maximum performance across all metrics for the MoD class. For these five, accuracy served as the tie-breaker; the configuration providing the highest test accuracy consisted of 3 layers with 100 neurons per layer (without dropout or bias), scoring above 0.89 across all metrics as detailed in Table III.

TABLE III
PERFORMANCE OF THE BEST MODEL ACROSS DIFFERENT DEMENTIA CLASSES

Accuracy	Class	Precision	Recall	F1-Score
95.4%	Non Demented (ND)	0.94	0.91	0.92
	Very Mild Demented (VMD)	0.89	0.94	0.91
	Mild Demented (MD)	0.98	0.95	0.97
	Moderate Demented (MoD)	1	1	1

The results demonstrate that the top-performing model delivered exceptional performance, particularly in classifying the MoD class, achieving perfect scores across all metrics. A recall and precision of 1 indicates that the model never confuses this class with others. High recall is especially critical in medical diagnostics, where false negatives can lead to severe clinical outcomes.

The high sensitivity (recall) in the MoD class indicates that the model accurately identifies patients in advanced stages of the disease. For all the models, the performance improves with the severity of the class. This observation highlights the need for refinement to enhance early detection.

B. Evaluation of Models with Different Hyperparameters

Analysis of models trained under various hyperparameter configurations revealed that:

- Networks with 10 layers generally yielded poorer results, exhibiting the highest variance in performance (standard deviation up to 0.35). Average accuracy was 76.4%, while maximum accuracy reached 87.9%.
- Applying dropout at a rate of 20% increased variance in the results. Models without dropout achieved an average accuracy that was 10% higher.
- Incorporating bias did not significantly affect performance, indicating that bias parameters can be omitted for this specific problem without sacrificing performance.

C. Analysis of ROC Curves and AUC

To further assess model performance, ROC curves were generated for each class, and Area Under the Curve (AUC) values were calculated. Figure 7 displays the plot for the top-performing model.

The model with 3 layers and 100 neurons per layer achieved exceptional performance, reaching an AUC of 1.0 for the MoD class and AUCs above 0.95 across all other classes. This demonstrates high discriminative capability across all stages, particularly in more advanced disease progression.

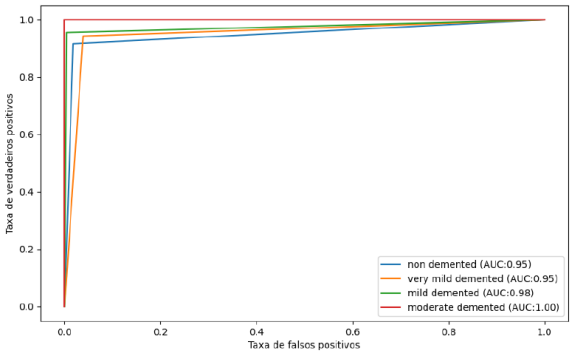

Fig. 7. ROC Curves for the model with 3 layers of 100 neurons

D. Importance of Recall and F1-Score

In medical diagnostics, such as in Alzheimer's Disease, recall is a critical metric because failing to properly diagnose a condition can carry serious consequences. Our models were evaluated with a primary focus on recall to ensure accurate identification of true positives in every class. All evaluated models achieved recall values above 0.99 for the *Moderate Demented* class, indicating a minimal false negative rate.

Furthermore, the F1-score was used to balance precision and recall, especially in scenarios where precision was lower due to class distribution skewness. As shown in Table IV, all models achieved F1-scores above 0.9 for most classes, reflecting a solid balance between capturing true positives and minimizing false positives.

TABLE IV
MODEL PERFORMANCE ON THE TEST SET

Model Config.	Acc. (%)	Prec.	Sensit.	F1.
Viable				
3 Layers, 100 Neurons	95.4	≥ 0.94	≥ 0.91	≥ 0.91
1 Layer, 40 Neurons, Bias	91.02	≥ 0.84	≥ 0.82	≥ 0.83
Other Configurations	91.02 - 95.4	≥ 0.97	≥ 0.96	≥ 0.90
Non-Viable				
10 Layers, 40 Neurons, Dropout (w/ and w/o bias)	54.5 - 59.5	≥ 0.36	≥ 0.07	≥ 0.12
Other Configurations	≥ 70	≥ 0.97	≥ 0.96	≥ 0.9

E. Comparison with Previous Studies

Our proposed model—utilizing Softmax activation and three layers of 100 neurons—presented better results than existing approaches in all metrics, including on severe disease classes. Even though the datasets were different, this performance indicates that the chosen architecture and hyperparameters are well suited for Alzheimer's stage classification.

It is worth noting that performance on milder stages was lower than on advanced stages (the opposite behavior of [8]), showing room for improvement in early detection. Techniques such as hyperparameter fine-tuning, data augmentation, and more complex architectures—such as 3D Convolutional Neural Networks (3D CNNs) [31] or incorporating multiple data sources [32]—may help enhance performance during early Alzheimer's stages.

F. Experimental Conclusions

The top-performing model consist of 1 to 3 layers with 100 neurons per layer, trained without dropout. Figure 7 displays the ROC curve for the best configuration (3 layers, 100 neurons, Softmax).

These results are promising, indicating that CNNs can serve as effective diagnostic aids for Alzheimer's Disease. However, current limitations in identifying initial stages remain. Future work should investigate data augmentation, complex network architectures, and multi-modal integration to boost early detection capabilities.

G. Limitations and Future Directions

A key limitation is the reliance solely on MRI data, which may restrict insights into early disease onset. In future work, we plan to explore multimodal frameworks combining MRI with PET scans and genetic markers to increase diagnostic accuracy.

The strong unbalecement on the dataset presents a challenge for the confiability in its performance. A revalidation of the architeture with more diverse datasets is necessary.

Another promising direction is integrating attention mechanisms into CNNs, combining CNNs with Recurrent Neural Networks (RNNs), or leveraging Vision Transformers to capture temporal and fine-grained spatial patterns. Transfer learning techniques using pre-trained medical imaging models could also improve performance on underrepresented classes.

Finally, ensemble learning techniques combining multiple model architectures could enhance predictive robustness, particularly for the earliest stages of Alzheimer's Disease.

VI. Conclusion and Future Work

While our results are promising, several areas remain for improvement. Future research can explore advanced architectures, such as attention mechanisms or transformer-based networks, to enhance feature discrimination between subtle Alzheimer's stages.

Additionally, automated hyperparameter tuning via grid search or Bayesian optimization could yield further performance improvements. Evaluating the model on larger, more diverse datasets will also help validate generalization across varying patient populations and imaging modalities.

This study demonstrates that Convolutional Neural Networks (CNNs) are a powerful tool for assisting in Alzheimer's diagnosis, particularly during advanced stages. The proposed model achieved an overall accuracy of 95.4%, with notable performance on the MoD class, reaching a recall of 1. These outcomes show high reliability in identifying advanced patients, which is critical in clinical settings to prevent false negatives and ensure timely care. Challenges in early detection likely stem from subtle structural changes in early dementia that overlap with normal brain aging patterns.

***Abstract*—Accurate chronic wound triage is critical in clinical settings, yet the adoption of deep learning in this domain is often limited by the opaque nature of AI models and the absence of deployable engineering workflows. This paper presents an end-to-end Artificial Intelligence-assisted Clinical Decision Support System (AI-CDSS) that integrates Convolutional Neural Networks (CNNs) with Large Language Models (LLMs) for interpretable wound triage. Operating solely on visual data to maximize point-of-care usability, the vision component employs a VGG16 backbone optimized through transfer learning and selective fine-tuning to classify images into six categories. The fine-tuned model achieved a global accuracy of 74.79%, with class-wise analysis showing that fine-tuning increased venous ulcer recall from 87.09% to 91.94% at the cost of a corresponding decline in pressure ulcer recall to 23.53%, a trade-off addressed through a permanent, always-visible safety disclosure rather than a dynamic confidence threshold. The classifier is embedded in a scalable, asynchronous microservices architecture. The system employs a generative LLM as a Narrative Interpretability layer, translating probabilistic outputs and patient metadata into structured clinical pre-reports that explicitly surface model uncertainties to support clinician decision-making.**

***Index Terms*—Digital Healthcare, Narrative Interpretability, Clinical Decision Support System, Chronic Wound Triage, Convolutional Neural Networks, Large Language Models.**

I. Introduction

Accurate and timely assessment of chronic wounds, including diabetic foot, pressure, venous, and surgical ulcers, remains a persistent challenge in clinical practice due to their high prevalence and economic burden [1], [2]. Wound evaluation relies heavily on visual inspection, which is time-consuming and subject to inter-observer variability. Delays or misclassification may lead to suboptimal interventions and increased burden on patients and healthcare systems [3].

The expansion of telemedicine has increased demand for scalable digital workflows that support triage and documentation while preserving traceability and interpretability [4], [5]. CNNs have achieved competitive performance in medical image classification and are increasingly explored for wound classification [6]–[8].

Moving from a standalone classifier to a clinically usable solution requires more than predictive performance. A digital healthcare system must support asynchronous processing, uncertainty communication, and clinician-centered outputs [9]. LLMs have been explored for natural-language summarization and report drafting in healthcare, but their use in decision support must be framed with explicit safeguards and separation from clinical judgment [10]–[12].

This work proposes an end-to-end AI-CDSS Proof of Concept (PoC) for digital health. To maximize point-of-care usability, a vision-only approach is adopted with a VGG16 backbone [13] trained via Transfer Learning and selective Fine-Tuning to classify wound images into six categories. The classifier is integrated into a modular, asynchronous microservices architecture (Figure 1) connected to a generative LLM [14] acting as a Narrative Interpretability layer, producing structured clinical pre-reports that explicitly state model uncertainties.

The primary contribution is the design, implementation, and evaluation of this platform, with methodological emphasis on a two-stage training strategy: Transfer Learning with pre-trained ImageNet weights, followed by targeted Fine-Tuning of deep convolutional blocks [13]. The class-wise trade-offs introduced by fine-tuning are empirically evaluated, and the end-to-end architecture is shown to compensate for algorithmic limitations through the generative interpretability layer.

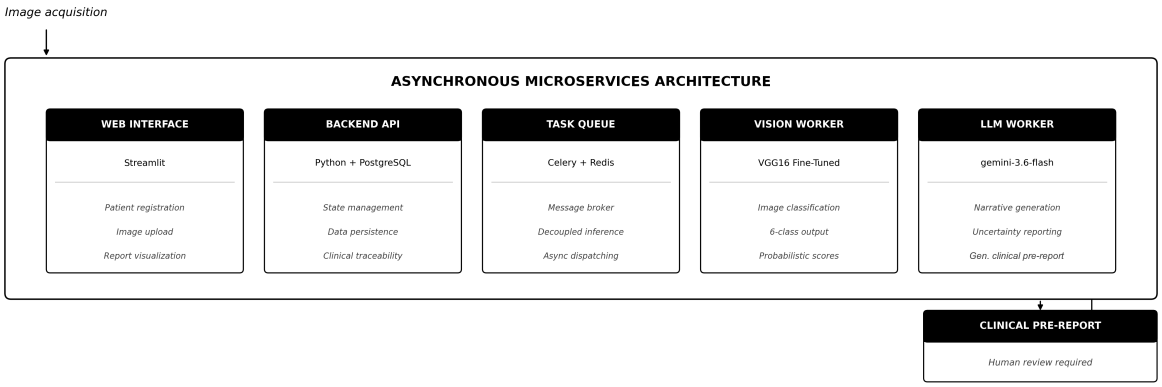

Fig. 1. Overview of the proposed AI-CDSS workflow, from visual data ingestion to LLM-generated pre-reports.

II. Background and Related Work

A. CNNs for Ulcer Image Classification

CNNs have become the standard approach for medical image classification due to their ability to learn hierarchical visual representations from data [6]. In wound care, CNNs have been applied to classify chronic wounds from photographs captured under heterogeneous conditions typical of real-world clinical and telemedicine settings [7], [8], [15].

Anisuzzaman et al. [8] and Patel et al. [15] showed that fusing image data with body location coordinates improves classification accuracy for chronic wounds. Although effective, manually mapping spatial coordinates for each lesion introduces operational friction in fast-paced point-of-care workflows. This work diverges by adopting a vision-only approach, relying on targeted model optimization to compensate for the absence of spatial metadata. Per-class metrics including recall, precision, and F1-score are used to identify clinically relevant failure modes [16], and uncertainty communication is treated as a system design requirement [17].

B. Transfer Learning and Fine-Tuning

Transfer learning reduces data requirements by adapting representations learned from large-scale natural image datasets to the target medical domain [18], [19]. VGG16 remains a common baseline due to its straightforward architecture, facilitating reproducible comparisons in resource-constrained settings [13]. Fine-tuning introduces a trade-off between domain specialization and overfitting; class-wise analysis is recommended to assess whether performance gains are generalizable or reflect redistribution across classes [20], [21].

C. CDSS and LLMs in Health Applications

CDSS are grouped into knowledge-based and AI-based systems [5], [11]. In both cases, effective adoption depends on how outputs are communicated and how uncertainty is managed [9]. LLMs have been explored as a Narrative Interpretability layer downstream of predictive models, translating structured evidence into clinician-facing narratives that reduce reporting burden while preserving traceability [12]. Concerns about hallucination and over-reliance motivate designs that constrain LLMs to reporting tasks with mandatory human-in-the-loop review [10], [22].

III. Methodology

A. Dataset and Preprocessing

This study used the public dataset "Multi-modal wound classification using images and locations" [8], [15], collected at the AZH Wound and Vascular Center. Spatial metadata was excluded to implement a vision-only workflow suitable for mobile point-of-care use [8]. The dataset is publicly available and anonymized, complying with ethical standards for secondary data analysis.

Images were captured with an iPad Pro and a Canon digital camera, presenting real-world variability in scale, illumination, and background. The six-class taxonomy and the exact per-class distribution are described in Table I. The dataset was partitioned into 696 training images and 234 test images following the original split [8]. The class distribution is imbalanced: the most represented class (V, 185 training images) outnumbers the least represented pathological class (P, 100 training images) by a factor of 1.85, which we revisit in Section IV as a contributing factor to the class-wise recall gap observed after fine-tuning. Data augmentation including rotations ($\pm 20°$), width and height shifts (20%), shear distortions (20%), zoom variations (20%), and horizontal flipping was applied to mitigate overfitting and improve feature generalization [18], [20].

TABLE I
Image classes and per-class sample counts.

Class	Meaning	Train	Test
D	Diabetic Foot Ulcer	139	46
P	Pressure Ulcer	100	34
S	Surgical Wound	122	42
V	Venous Leg Ulcer	185	62
N	Normal Skin	75	25
BG	Background	75	25
Total		**696**	**234**

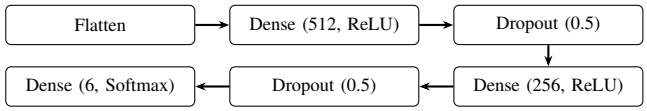

Fig. 2. Custom classification head appended to the VGG16 backbone after `block5_pool`.

B. Model Architecture and Two-Stage Training

VGG16 [13] was selected as the CNN backbone for its established performance and role as a reproducible baseline in medical imaging [6]. The original ImageNet classification head was replaced by a custom head appended after the last max-pooling layer (`block5_pool`), as illustrated in Figure 2.

Training proceeded in two stages. In the first stage (Transfer Learning), the convolutional base was frozen and the custom head was trained using the Adam optimizer with learning rate $lr = 1 \times 10^{-4}$, categorical cross-entropy loss, and Early Stopping with patience of 10 epochs. In the second stage (Fine-Tuning), the highest-level convolutional block (`block5`) was unfrozen and the network was retrained with a reduced learning rate ($lr = 1 \times 10^{-5}$) and stricter Early Stopping (patience of 5 epochs), allowing the filters to specialize in wound-specific visual textures while avoiding catastrophic forgetting of the pre-trained weights.

In both stages, Early Stopping and checkpoint selection monitored loss and accuracy computed on the 234-image test partition, since the original protocol did not carve out a separate internal validation split from the training data. We flag this explicitly as a methodological limitation: because the same partition used for model selection is also used for the final reported metrics, the selected checkpoint's test accuracy is likely optimistic relative to a protocol with an independent validation split. A corrected protocol, holding out a stratified subset of the 696 training images for validation while leaving the test set untouched until final evaluation, is planned as a follow-up; we do not expect it to change the qualitative class-wise trends discussed in Section IV, though it may lower the reported point accuracy.

C. AI-CDSS System Architecture

The platform is orchestrated via Docker Compose across four containerized services sharing a common bridge network. The `backend` directory is not a standalone service; it is a shared Python module mounted as a volume into both the `streamlit` and `worker` containers, providing common access to the classification model, database operations, and LLM integration. A shared `bucket` volume provides persistent file storage for uploaded images and generated PDF reports. Table II describes each service.

The relational schema (Figure 3) maintains strict links between patient records, image assets, and AI-generated outputs. Every pre-report is therefore auditable and tied to the specific model checkpoint used during inference. Once the Celery worker computes the classification probabilities, the distribution is packaged with patient metadata and passed to a structured prompting pipeline. The generative component is Google's `gemini-3.6-flash` [23], invoked through the `google-genai` SDK with default generation parameters (no explicit temperature or top-p override). The prompt template supplies the predicted class, the full probability vector, and the model's historical precision, recall, and F1-score for that class, and instructs the LLM to produce a report of no more than 300 words. The LLM produces a clinical draft that states model uncertainties explicitly, presents secondary differential diagnoses, and is formatted as a preliminary summary explicitly labeled for clinician verification prior to any clinical use [10].

TABLE II
DOCKER COMPOSE SERVICES OF THE AI-CDSS ARCHITECTURE.

Service	Image / Stack	Role
`streamlit`	Streamlit	Web interface for patient registration, image upload, and report visualization.
`worker`	Celery	Asynchronous worker that loads the fine-tuned VGG16 model, executes image classification, invokes the LLM to produce the clinical pre-report.
`postgres`	PostgreSQL	Relational persistence of patient records, image metadata, classification results, and generated pre-reports.
`redis`	Redis	In-memory message broker connecting the web interface to the asynchronous worker.

Because the deployed system persists real patient identifiers, clinical history, and images, unlike the pre-anonymized public dataset used for model training, it falls under Brazil's General Data Protection Law (LGPD) [24]. The present proof of concept does not yet implement encryption at rest, authentication, or an anonymization pipeline for stored records; hardening the platform to LGPD requirements, including encrypted storage, role-based access control, audit logging, and a data-retention policy, is a prerequisite for any use beyond controlled evaluation and is prioritized as future engineering work.

The complete source code is publicly available.[1]

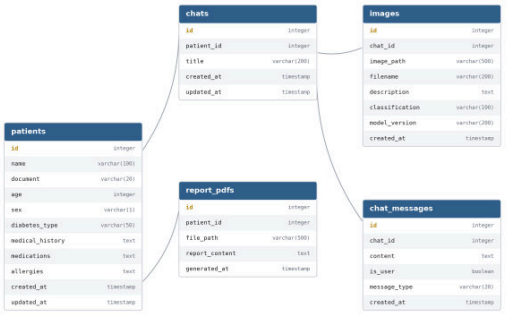

Fig. 3. Entity-relationship diagram of the AI-CDSS, illustrating the relational structure for clinical data persistence and auditability.

IV. Results and Discussion

A. Incremental Model Performance

The vision engine was developed across three phases. Table III summarizes the performance gains at each stage.

Phase 1 (Epoch 50): Transfer Learning established a baseline at 72.22% accuracy. The learning curves in Figure 4 show stable convergence but a persistent gap between training and validation loss, indicating the classification head had not reached a stable plateau. The confusion matrix in Figure 5 shows high accuracy for non-pathological classes (BG and N), but a significant overlap between Pressure (P) and Venous (V) ulcers, suggesting the frozen convolutional base was insufficient to capture the fine-grained textural differences between these etiologies.

Phase 2 (Epoch 94): Extending training with a weight restoration protocol improved accuracy to 74.79%, as shown in Figure 6. The confusion matrix in Figure 7 reflects improved recall for Diabetic (D) and Surgical (S) classes, but class P recall remained at 29.41%, confirming that the P/V confusion is a structural limitation of the frozen feature extractor and justifying the subsequent fine-tuning stage.

Phase 3 (Fine-Tuning): Unfreezing `block5` matched the extended transfer-learning accuracy (74.79%) while substantially redistributing recall across classes. The F1-score comparison in Figure 8 shows a substantial gain for class V, whose recall reached 91.94%. The final confusion matrix in Figure 9 confirms that venous ulcer triage reached high reliability. Class P recall decreased to 23.53%, a consequence of the model specializing in the dominant class distribution. Global accuracy alone therefore does not capture the effect of fine-tuning; the class-wise trade-off, gaining venous sensitivity at the cost of pressure-ulcer sensitivity, is the actual outcome of this stage and is treated accordingly throughout this section. Notably, class P recall declines monotonically across all three phases (38.24% at Epoch 50, computed from Figure 5; 29.41% at Epoch 94; 23.53% after fine-tuning), indicating that the sensitivity loss reflects progressive specialization toward the dominant class distribution rather than an isolated effect of the fine-tuning stage.

TABLE III
Performance Gains Across Training Stages.

Stage	Epoch	Accuracy	Recall (V)
Initial Baseline	50	72.22%	87.09%
Extended TL	94	74.79%	87.09%
Fine-Tuning	13 (+94)	74.79%	91.94%

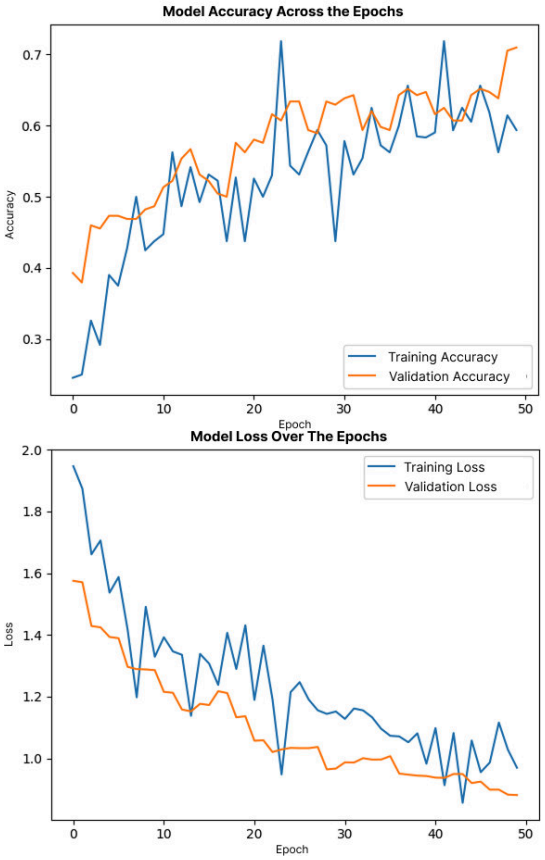

Fig. 4. Learning curves, Epochs 1–50. The gap between training and validation loss indicates room for further optimization.

We treat this reduction in class P recall as a patient-safety limitation, since pressure injuries are themselves a patient-safety indicator subject to prevention protocols and adverse-event reporting in Brazilian clinical services [3], not merely as an optimization trade-off. The current single-split protocol cannot reliably calibrate a per-prediction confidence threshold (Section IV-B), so the Narrative Interpretability layer instead embeds a static, always-visible disclosure of the model's documented class P sensitivity (recall of 23.53%) into every generated pre-report. Clinicians are alerted to this weakness regardless of the classifier's output for a given image, favoring a transparent, permanently visible safety disclosure over an uncalibrated dynamic trigger [17]. This disclosure complements, but does not substitute, validated structured risk-assessment instruments such as the Braden and Norton scales, and it does not replace institutional pressure-injury prevention protocols:

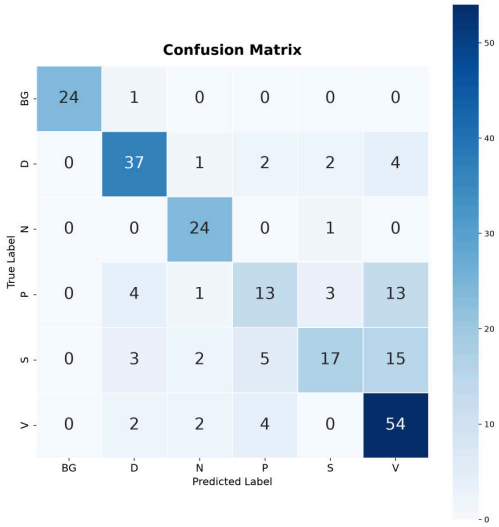

Fig. 5. Confusion matrix at Epoch 50. High accuracy for non-pathological classes, with notable overlap between P and V ulcers.

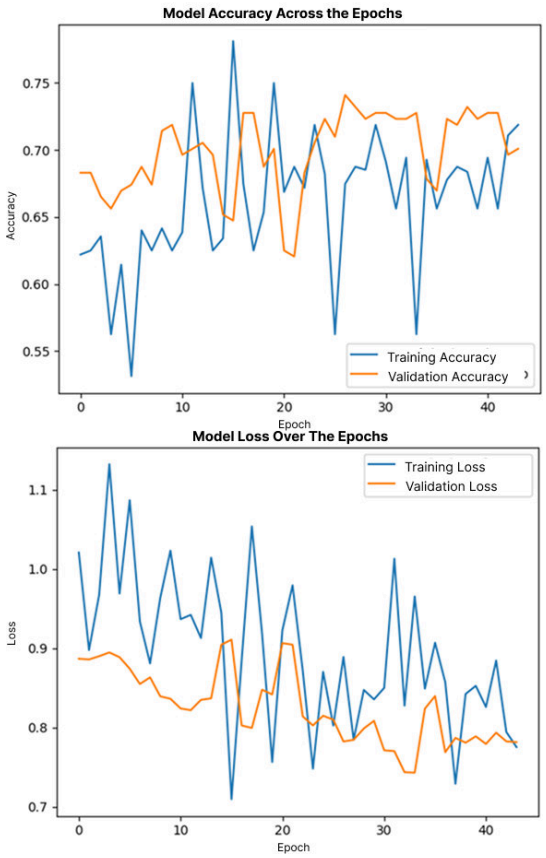

Fig. 6. Learning curves for the continuation phase (44 additional epochs, cumulative total of 94). Stable convergence achieved through automated weight restoration.

the classifier output is meant to prompt attention, while risk stratification and preventive care decisions remain governed by established clinical scales.

The global accuracy of 74.79% achieved by the fine-tuned model corresponds to a 95% Wilson confidence interval of [68.9%, 79.9%] ($n = 234$), reflecting the estimation uncertainty inherent to a test set of this size. This result is consistent with the literature under comparable constraints, though direct comparison is limited by differing preprocessing and data splits. Anisuzzaman et al. [8] reported 75.64% accuracy using whole images alone and 82.48% when fusing image and body-location data. Patel et al. [15], using a region-of-interest (ROI) cropping step and a 70/15/15 split, reported 85.41% accuracy without location data and 87.50% when adding location, a result driven in large part by ROI cropping rather than multi-modality alone. Relative to the whole-image, single-modality figure from Anisuzzaman et al., our result is comparable; the gap to the multimodal figures (7.7 to 12.7 percentage points) reflects both the cost of excluding spatial metadata and, in Patel et al.'s case, the absence of ROI cropping, which we did not adopt to preserve a simple, single-stage pipeline for point-of-care deployment. In this work, spatial metadata was intentionally excluded to keep the workflow viable at the point of care. The venous ulcer recall of 91.94% reflects the clinical priority assigned to that class, and the permanent, metrics-based safety disclosure for pressure ulcers addresses the sensitivity limitations that a global accuracy figure alone would not reveal.

B. Model Calibration

Clinical deployment requires calibrated confidence, not only point accuracy: predicted probabilities should reflect the true likelihood of correctness. We assessed calibration with the Expected Calibration Error (ECE) [25], using 10 equal-width confidence bins over an independent re-evaluation of the released model checkpoint on the 234-image test partition. This re-evaluation reproduced the 74.79% headline accuracy (175/234) reported in Table III, confirming that inference on the released checkpoint is deterministic given a fixed, non-shuffled test partition. Because Early Stopping and checkpoint selection are themselves single-run decisions (Section III), the reported point accuracy still carries the run-to-run variance of the training process, not of inference; repeating training across multiple random seeds and reporting mean $\pm$ standard deviation, rather than a single point estimate, is planned as future work.

The resulting ECE was 0.052, with a mean predicted confidence of 69.6% against an observed accuracy of 74.8%: the model is, on average, mildly underconfident rather than overconfident (Figure 10). Because the current protocol lacks a validation split independent from the test set (Section III), this ECE is reported as a diagnostic computed on the same data used for evaluation; we do not apply post-hoc temperature scaling here, since fitting a temperature parameter on the test set itself would reintroduce the same leakage. Recalibration on a proper held-out calibration split, obtained once the validation protocol described in Section III is corrected, is proposed as future work.

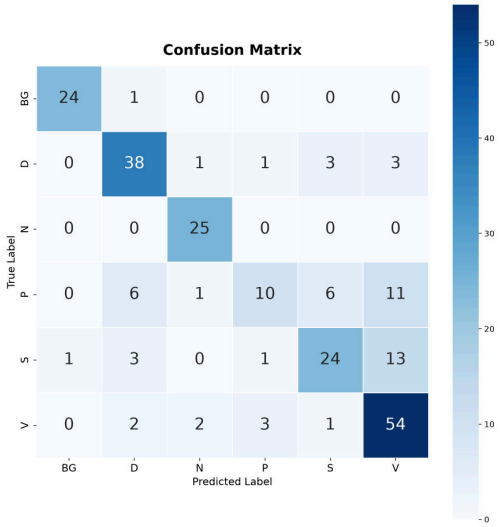

Fig. 7. Confusion matrix at Epoch 94 (74.79% accuracy). Class P recall remains at 29.41%.

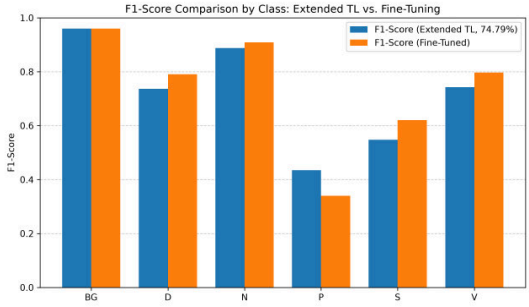

Fig. 8. Class-wise F1-score comparison: Extended Transfer Learning versus Fine-Tuned model. Both stages reach 74.79% global accuracy; the gain from fine-tuning is a redistribution of recall toward class V, not a change in the aggregate figure.

C. Operational Validation

Figures 11 and 12 illustrate the operational interface using a synthetic patient record created solely for demonstration; no real patient data is shown. Figure 11 shows the patient registration interface, which allows structured clinical data entry alongside high-resolution image upload at the point of care.

Figure 12 shows the decision support interface. The system presents the CNN's classification output translated by the LLM into a narrative clinical pre-report directly in the chat: the primary predicted class and confidence, a differential discussion of the leading secondary candidate classes drawn from the full probability vector, and the model's documented class-wise limitations, including the reduced sensitivity for pressure ulcers, which are always appended to the report regardless of the current prediction. The AI is positioned as a documentation assistant, not a diagnostic authority; the pre-report is a preliminary, AI-generated draft intended for manual clinician review and is not a substitute for clinical judgment.

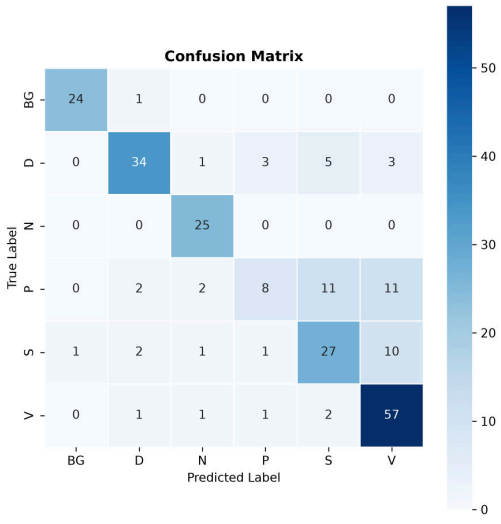

Fig. 9. Final fine-tuned confusion matrix. Venous (V) class recall reaches 91.94%.

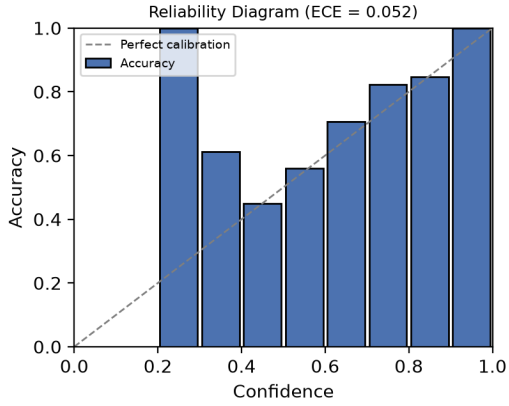

Fig. 10. Reliability diagram for the re-evaluated fine-tuned model (ECE = 0.052). Bars show observed accuracy per confidence bin; the dashed line marks perfect calibration.

V. Conclusion

This paper presented a scalable and interpretable digital healthcare workflow for chronic wound triage, designed for the resource-constrained, point-of-care settings common in Brazilian public health services, where anatomical location metadata and specialized equipment are often unavailable. The proposed AI-CDSS integrates a VGG16 vision engine, an asynchronous microservices architecture, and a generative LLM interpretability layer. It delivers practical value under the constraints of a limited and imbalanced medical dataset and treats uncertainty communication as a first-class design requirement, not an afterthought.

The two-stage training strategy yielded a peak accuracy of 74.79% (95% CI [68.9%, 79.9%]) and a venous ulcer recall of 91.94% after fine-tuning, as detailed in the class-wise analysis. The analysis also exposed the trade-offs introduced by domain specialization: global accuracy metrics can

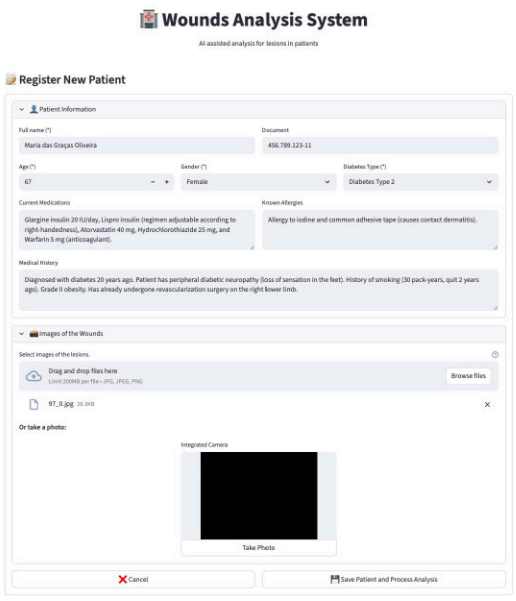

Fig. 11. Patient registration form with structured clinical data entry and image upload.

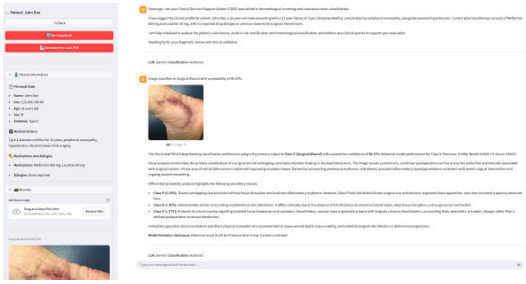

Fig. 12. Decision support interface: CNN probabilities translated into a narrative clinical pre-report by the LLM, including the always-visible pressure-ulcer sensitivity disclosure.

obscure class-specific performance drops, and the resulting drop in pressure ulcer recall is itself a patient-safety limitation, not merely an algorithmic one. The Narrative Interpretability layer addresses this architecturally, embedding a permanent, metrics-based safety disclosure of the classifier's known class-wise weaknesses into every generated report, so that model limitations are communicated instead of concealed.

From an engineering perspective, the containerized microservices architecture operationalizes the CNN predictions through an asynchronous pipeline that decouples inference from the clinical interface. The LLM is constrained to reporting tasks, and every generated pre-report is explicitly labeled as a preliminary, AI-generated draft that must be independently verified by a qualified clinician before any use in patient care. This preserves clinical accountability while reducing documentation burden.

The study has the following limitations: (i) the vision-only approach restricts resolution of etiologies that depend on anatomical context; (ii) the dataset size and imbalance limit the statistical generalization of the model, particularly for underrepresented classes such as pressure ulcers; (iii) Early Stopping and checkpoint selection relied on the test partition itself rather than an independent validation split, likely biasing the reported point accuracy optimistically (Section III); (iv) the LLM-generated pre-reports have not undergone formal medical evaluation for hallucination risks or semantic safety; (v) the deployed prototype does not yet implement the encryption, access control, and anonymization safeguards required for LGPD-compliant production use (Section III). Future work will address these through a corrected train/validation/test protocol with multi-seed repetition, class-imbalance handling (class weighting, focal loss, or resampling), calibration on a proper held-out split, lightweight backbones (e.g., MobileNet, EfficientNet-Lite) for point-of-care deployment on low-resource hardware, a small clinician-based evaluation of pre-report fidelity and safety, dataset expansion, integration of selective anatomical metadata, and LGPD-oriented hardening of the production system.

***Resumo*—As doenças cardiovasculares figuram entre as principais causas de mortalidade no mundo, o que torna fundamental o desenvolvimento de ferramentas capazes de auxiliar na identificação precoce de alterações cardíacas. Este trabalho apresenta o desenvolvimento de um aplicativo móvel para classificação automática de imagens de eletrocardiogramas (ECG) utilizando redes neurais convolucionais (CNNs). O sistema foi desenvolvido com o objetivo de fornecer suporte à tomada de decisão em cenários de emergência, permitindo a execução local do modelo em dispositivos móveis. Para o treinamento da rede foi utilizada uma base de imagens de ECG composta por quatro classes: normal, arritmia cardíaca, histórico de infarto do miocárdio e infarto agudo do miocárdio. Técnicas de pré-processamento, aumento artificial de dados e balanceamento de classes foram empregadas para melhorar a capacidade de generalização do modelo. A arquitetura foi implementada utilizando TensorFlow e posteriormente convertida para TensorFlow Lite, permitindo sua execução local no dispositivo móvel. No conjunto de validação utilizado, foram obtidas taxas de acerto de 98,3% para infarto agudo do miocárdio e superiores a 86% para as demais classes. Os resultados demonstram a viabilidade técnica da integração do modelo à aplicação móvel, embora ainda sejam necessárias avaliações com dados independentes e em condições reais de captura antes de considerar sua utilização em contexto clínico.**

***Index Terms*—eletrocardiograma, redes neurais convolucionais, aprendizado profundo, aplicativo móvel, classificação de eletrocardiogramas**

I. Introdução

As doenças cardiovasculares permanecem entre as principais causas de mortalidade no mundo, respondendo por milhões de óbitos anualmente. Dentre essas doenças, o Infarto Agudo do Miocárdio (IAM) destaca-se pela necessidade de diagnóstico rápido e início precoce do tratamento, fatores diretamente relacionados à redução da mortalidade e das sequelas associadas à condição. Diretrizes do Ministério da Saúde ressaltam que a realização precoce do eletrocardiograma e a identificação de alterações compatíveis com IAM são etapas fundamentais para a tomada de decisão clínica e o encaminhamento adequado do paciente [1].

O eletrocardiograma (ECG) é o exame inicial e mais comum para avaliar a atividade elétrica cardíaca e identificar alterações associadas a diferentes patologias. O sinal de ECG é composto por ondas e segmentos que representam eventos específicos do ciclo cardíaco, permitindo a identificação de anormalidades por meio da análise de sua morfologia. A onda P está associada à despolarização dos átrios; o complexo QRS representa a despolarização ventricular; e a onda T corresponde à repolarização dos ventrículos. Além dessas estruturas, intervalos como PR, QT e RR fornecem informações importantes sobre a condução elétrica e a regularidade do

ritmo cardíaco [2].

A Figura 1 apresenta os principais componentes de um traçado eletrocardiográfico normal. A análise conjunta dessas ondas e segmentos permite identificar alterações associadas a diferentes condições clínicas, fornecendo informações importantes para o diagnóstico médico.

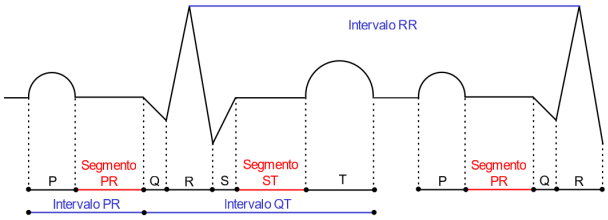

Figura 1: Principais ondas, segmentos e intervalos presentes em um eletrocardiograma normal.

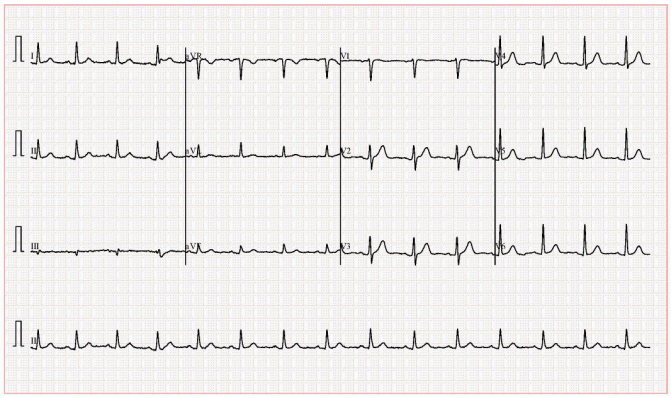
Alterações em regiões específicas do ECG podem indicar diferentes patologias cardíacas. No caso do IAM, é comum observar alterações no segmento ST, como elevação ou depressão, indicativas de comprometimento do músculo cardíaco [3], [4]. Arritmias cardíacas podem ser identificadas por irregularidades no ritmo e na morfologia das ondas, enquanto pacientes com histórico de infarto podem apresentar alterações persistentes no traçado mesmo na ausência de um evento agudo.

Apesar de sua ampla utilização, a interpretação de exames de ECG depende de conhecimento especializado e de experiência clínica. Nos últimos anos, técnicas de aprendizado profundo têm apresentado resultados promissores na análise automatizada de sinais biomédicos. Em particular, redes neurais convolucionais (CNNs) demonstraram elevada capacidade de extrair automaticamente características relevantes a partir de imagens médicas, alcançando desempenho comparável ao de especialistas em diferentes tarefas de classificação [5], [6].

Paralelamente, o crescimento das tecnologias móveis e das soluções de *mobile health* tem possibilitado a incorporação de técnicas de inteligência artificial em ferramentas voltadas ao suporte clínico. Essas soluções permitem realizar análises diretamente no local de atendimento, reduzindo a dependência de infraestrutura externa e ampliando o acesso a recursos computacionais em ambientes com conectividade limitada.

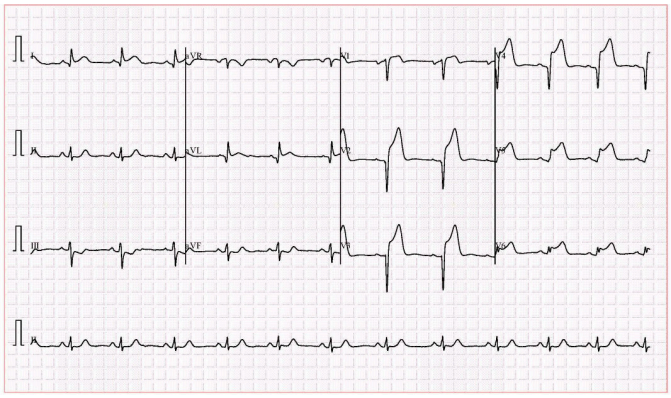
Diversos trabalhos têm explorado técnicas de aprendizado profundo para a classificação automática de eletrocardiogramas. Entre eles, destaca-se o trabalho de Khan et al. [7], que utilizou a base de imagens de ECG disponibilizada em [8] para classificar exames em quatro categorias: normal, arritmia cardíaca, histórico de infarto e infarto agudo do miocárdio. Os autores empregaram uma arquitetura baseada em SSD MobileNet V2, obtendo uma acurácia média próxima de 98% na classificação das imagens. O estudo demonstrou o potencial das redes neurais profundas para identificação automática de alterações cardíacas a partir de imagens de ECG.

Outra referência importante é o trabalho de Hannun et al. [5], que utilizou redes neurais profundas para classificação de arritmias cardíacas a partir de sinais de ECG ambulatoriais, alcançando desempenho comparável ao de cardiologistas especialistas. De forma semelhante, Ribeiro et al. [6] desenvolveram um sistema baseado em aprendizado profundo para diagnóstico automático de eletrocardiogramas de 12 derivações, obtendo resultados expressivos em diferentes categorias de doenças cardíacas.



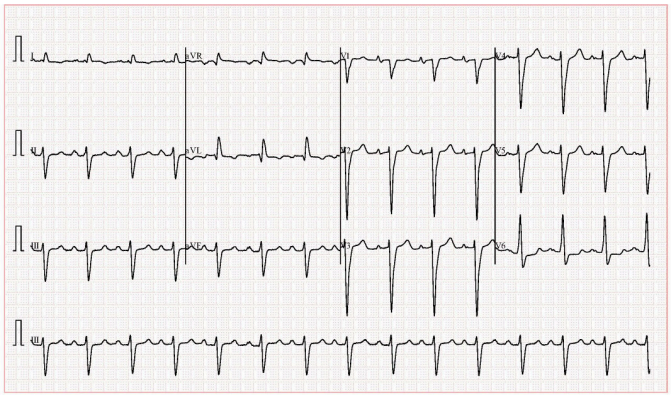
Diante desse contexto, este trabalho propõe o desenvolvimento e a avaliação técnica de uma aplicação móvel para classificação automática de imagens de ECG utilizando uma rede neural convolucional. O modelo é executado localmente no dispositivo por meio do TensorFlow Lite, permitindo seu funcionamento sem dependência de conexão com a Internet. Além das classes relacionadas aos exames cardíacos, foi incorporada uma classe denominada *Not ECG*, destinada à identificação de imagens que não correspondem a eletrocardiogramas. O estudo concentra-se na viabilidade técnica da integração entre o modelo de classificação e a aplicação móvel, não abrangendo, nesta etapa, sua validação para utilização clínica.

II. Materiais e Métodos

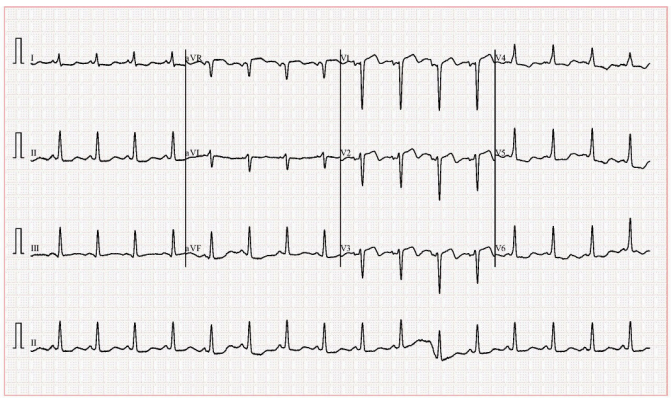


A. Base de Dados

A base de dados utilizada foi obtida a partir do conjunto de imagens de ECG disponibilizado por Khan et al. [8]. O conjunto original é composto por cinco categorias: ECG normal, arritmia cardíaca, histórico de infarto do miocárdio, infarto agudo do miocárdio e casos relacionados à COVID-19. As Figuras 2a, 2b, 2c e 2d apresentam exemplos das classes utilizadas neste trabalho. Os exames correspondem a ECGs de 12 derivações, contendo informações provenientes das derivações dos membros e precordiais. Embora as alterações associadas às diferentes patologias se manifestem em derivações específicas, o modelo proposto utiliza a imagem completa do exame como entrada, extraindo características globais do traçado. As categorias apresentadas representam, respectivamente, exames normais, casos de infarto agudo do miocárdio, arritmias cardíacas e pacientes com histórico de infarto.



Como o objetivo deste trabalho está voltado à classificação das principais categorias cardíacas presentes na base e à integração do modelo a uma aplicação móvel, a classe referente à COVID-19 não foi utilizada. Em contrapartida, foi adicionada uma quinta categoria denominada *Não é ECG*, composta por imagens que não representam eletrocardiogramas válidos. Essas imagens foram obtidas a partir do conjunto Imagenette [9], utilizado para compor exemplos negativos durante o treinamento. A inclusão dessa classe tem como objetivo aumentar a robustez da aplicação em situações reais, evitando que o sistema tente classificar fotografias de objetos, documentos ou superfícies como exames cardíacos. Para compor essa categoria, foram utilizadas aproximadamente 1500 imagens, selecionadas aleatoriamente a partir de um conjunto de cerca de 14000 imagens.



(a) Exemplo de ECG normal.

(b) Exemplo de infarto agudo do miocárdio.

(c) Exemplo de arritmia cardíaca.

(d) Exemplo de histórico de infarto do miocárdio.

Figura 2: Exemplos de diferentes traçados de eletrocardiogramas analisados.

Após as etapas de balanceamento e aumento de dados, o conjunto final utilizado no treinamento passou a contar com aproximadamente 7309 imagens distribuídas entre as cinco classes consideradas neste trabalho, conforme apresentado na Tabela I.

Tabela I: Distribuição de imagens por classe após as etapas de balanceamento e aumento de dados

Classe	Original	Final
Normal	500	1500
Infarto Agudo do Miocárdio	74	1480
Histórico de Infarto	154	1386
Arritmia Cardíaca	481	1443
Não é ECG	1500	1500
Total		7309

B. Aumento de Dados e Balanceamento

A distribuição original das classes apresentava forte desbalanceamento, especialmente no caso de infarto agudo do miocárdio. Para reduzir esse problema, foi implementada uma estratégia de aumento adaptativo de dados, na qual cada classe recebeu um número diferente de transformações sintéticas, de acordo com sua representatividade.

As imagens da classe normal foram ampliadas aproximadamente três vezes, enquanto as de infarto agudo receberam até vinte variações artificiais por amostra. As classes de histórico de infarto e arritmia também receberam fatores de aumento específicos. Essa estratégia permitiu obter uma distribuição mais equilibrada entre as categorias sem descartar informações relevantes das classes majoritárias.

Além do aumento de dados, foi realizada uma etapa de curadoria manual do conjunto de imagens. Exames que apresentavam borrões severos, ruídos excessivos ou artefatos que comprometiam a visualização das ondas cardíacas foram removidos do treinamento, o que contribuiu para melhorar a qualidade das características aprendidas pela rede neural.

C. Arquitetura da Rede Neural

Para a etapa de classificação foi desenvolvida uma rede neural convolucional profunda composta por cinco blocos convolucionais sequenciais. Os blocos utilizam camadas convolucionais com função de ativação ReLU e camadas de normalização (*Batch Normalization*). Nos quatro primeiros blocos são empregadas operações de *Max Pooling* e *Dropout*, enquanto o último bloco é seguido por uma camada *Global Average Pooling*.

A quantidade de filtros aumenta progressivamente ao longo da arquitetura, variando de 32 a 512, permitindo a extração hierárquica de características cada vez mais complexas a partir das imagens de ECG. Após a etapa de extração de características, a arquitetura utiliza uma camada Global Average Pooling, seguida de duas camadas densas, ambas regularizadas por penalização L2. Essa técnica adiciona um termo de penalização à função de perda durante o treinamento, desestimulando a atribuição de pesos excessivamente elevados aos neurônios da rede. Como resultado, reduz-se o risco de sobreajuste (*overfitting*) e melhora-se a capacidade de

generalização do modelo para dados não vistos anteriormente. A camada de saída utiliza a função Softmax para classificar as cinco categorias clínicas consideradas neste estudo. A arquitetura da rede neural convolucional descrita é ilustrada na Figura 3.

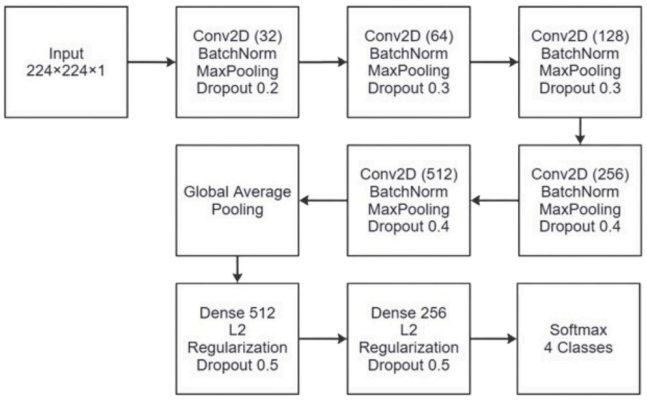


Figura 3: Arquitetura da rede neural convolucional utilizada para a classificação de eletrocardiogramas.

D. Treinamento

Após o carregamento e o pré-processamento das imagens, foi aplicado aumento de dados (*data augmentation*) de forma adaptativa às classes de ECG, com o objetivo de reduzir o desbalanceamento entre as categorias. Foram utilizadas transformações aleatórias envolvendo rotação, perspectiva, escala, brilho, contraste, adição de ruído e deslocamento horizontal. A classe *Not ECG* não foi submetida ao processo de aumento de dados.

Após a geração das imagens aumentadas, o conjunto resultante foi dividido de forma estratificada em 80% para treinamento e 20% para validação. Dessa forma, o procedimento utilizado nesta etapa do trabalho não realizou a separação dos conjuntos antes do aumento de dados. Essa característica constitui uma limitação do experimento, uma vez que versões derivadas de uma mesma imagem original podem estar presentes nos conjuntos de treinamento e validação, podendo produzir estimativas otimistas do desempenho do modelo.

As transformações de aumento de dados incluíram rotações aleatórias entre $-10°$ e $+10°$, pequenas alterações de perspectiva e escala, variações de brilho e contraste, adição de ruído gaussiano e deslocamentos horizontais. As transformações foram aplicadas de maneira probabilística, permitindo a geração de diferentes variações de uma mesma imagem.

O treinamento foi realizado utilizando o otimizador Adam, com taxa de aprendizado inicial de $0{,}0001$, *weight decay* de $0{,}0001$ e tamanho de lote (*batch size*) igual a 16. Foi estabelecido um limite máximo de 80 épocas, utilizando como função de perda a entropia cruzada categórica esparsa (*sparse categorical cross-entropy*).

Para controlar o treinamento, foi utilizado *Early Stopping* com monitoramento da perda de validação e paciência de 15 épocas, restaurando os pesos correspondentes ao melhor resultado observado. Também foi empregado *ReduceLROnPlateau*, reduzindo a taxa de aprendizado pela metade após sete épocas sem melhoria na perda de validação, até o limite mínimo de 10^{-7}.

O modelo foi desenvolvido em Python utilizando a biblioteca TensorFlow [10], responsável pela definição da arquitetura da rede neural, treinamento e avaliação do modelo. Os experimentos foram executados em um computador equipado com um processador AMD Ryzen 5 5600G (3,90 GHz), 16 GB de memória RAM e uma placa gráfica NVIDIA GeForce RTX 4060 Ti. O processamento em GPU foi utilizado para acelerar as etapas de treinamento da CNN.

E. Aplicativo Móvel

Após o treinamento, o modelo foi convertido para o formato TensorFlow Lite, permitindo sua execução em dispositivos móveis com menor consumo de recursos computacionais. A aplicação foi desenvolvida com React Native e TypeScript, o que permitiu a criação de uma solução multiplataforma. Dessa forma, o aplicativo pode ser executado em dispositivos Android e iOS a partir de uma única base de código. A interface permite a captura de imagens por meio da câmera do dispositivo ou a seleção de imagens previamente armazenados na galeria.

O processamento é realizado integralmente no dispositivo, sem necessidade de comunicação com servidores externos. Após a análise, o aplicativo apresenta a classe predita e as probabilidades associadas a cada categoria. Além do módulo de classificação de ECG, o aplicativo incorpora funcionalidades relacionadas ao protocolo de administração de tenecteplase, auxiliando profissionais de saúde no atendimento a pacientes com IAM.

F. Ferramentas de Desenvolvimento

Durante o desenvolvimento, o modelo Claude Sonnet 4.6 foi utilizado exclusivamente como ferramenta de apoio à programação, auxiliando na implementação e depuração do código, sem participação no processo de classificação ou avaliação dos ECGs.

III. Resultados e Discussão

A Figura 4 apresenta a matriz de confusão obtida durante a validação do modelo. Os resultados demonstram a viabilidade técnica da execução local do modelo em uma aplicação móvel, embora ainda sejam necessárias avaliações adicionais em dados independentes e em condições reais de captura.

Tabela II: Acurácia por classe obtida pelo modelo

Classe	Acurácia
Normal	90,6%
Infarto Agudo do Miocárdio	98,3%
Histórico de Infarto	91,2%
Arritmia Cardíaca	86,5%
Não é ECG	100,0%

A Tabela II apresenta os resultados obtidos para cada classe. A classe *Not ECG* apresentou 100% de acerto no

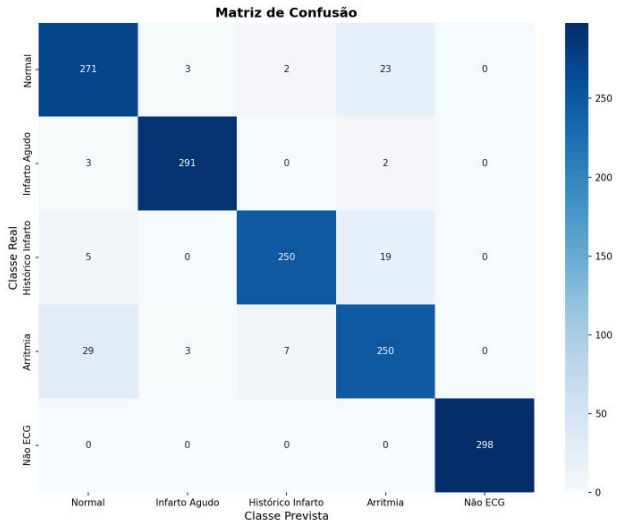

Figura 4: Matriz de confusão obtida durante a validação do modelo.

conjunto de validação utilizado. Entretanto, esse resultado deve ser interpretado considerando que as imagens negativas utilizadas foram provenientes de uma base de imagens genéricas, apresentando diferenças visuais consideráveis em relação aos ECGs. Dessa forma, o resultado demonstra a capacidade de separação entre as categorias avaliadas, mas não permite concluir que o modelo seja robusto diante de entradas inválidas mais próximas das condições reais de uso, como ECGs desfocados, parcialmente enquadrados, fotografados com baixa iluminação ou outros documentos médicos visualmente semelhantes.

A classe de infarto agudo do miocárdio apresentou 98,3% de acerto no conjunto de validação utilizado. Embora alterações morfológicas, como modificações no segmento ST, sejam características clinicamente associadas ao infarto agudo do miocárdio, não é possível afirmar que essas regiões tenham sido determinantes para as classificações realizadas pela CNN. O modelo processa a imagem completa do ECG e, neste estudo, não foram aplicadas técnicas de explicabilidade capazes de identificar quais regiões da imagem contribuíram para sua decisão.

A classe de arritmias cardíacas apresentou a menor taxa de acerto (86,5%). Esse comportamento pode ser explicado pela elevada heterogeneidade dessa categoria, que abrange diferentes tipos de alterações do ritmo cardíaco, como fibrilação atrial, extrassístoles, bloqueios de ramo e taquicardias. Como essas condições apresentam morfologias distintas entre si, a variabilidade intraclasse torna o processo de aprendizado mais complexo quando comparado às demais categorias, que possuem padrões visuais mais homogêneos.

A Figura 5 apresenta a interface da aplicação desenvolvida. A integração do modelo convertido para TensorFlow Lite permitiu realizar toda a inferência localmente, eliminando a dependência de servidores externos e reduzindo os requisitos de conectividade.

Apesar dos resultados obtidos, uma limitação importante do modelo está relacionada à forma como os exames são processados. A CNN recebe como entrada a imagem completa do eletrocardiograma redimensionada para 224×224 pixels em escala de cinza, tratando o exame como um padrão visual único. Dessa forma, o modelo não segmenta nem analisa individualmente as 12 derivações, extraindo características globais presentes em todo o traçado. Essa abordagem permite realizar a classificação a partir de características globais da imagem, porém não permite determinar quais derivações contribuíram para a decisão do modelo nem inferir a localização anatômica do infarto.

Os resultados deste trabalho apresentaram taxas de acerto de 90,6% para ECGs normais, 98,3% para infarto agudo do miocárdio, 91,2% para histórico de infarto, 86,5% para arritmias cardíacas e 100% para a categoria *Não é ECG*. Embora os resultados possam ser contrastados com os reportados por Khan et al. [7], uma comparação direta deve ser realizada com cautela, devido às diferenças na arquitetura utilizada, no protocolo experimental, no processamento dos dados e à inclusão da categoria adicional *Not ECG*.

Em relação ao trabalho de Khan et al., o presente estudo utiliza a mesma base principal de imagens de ECG, mas possui como foco a integração do modelo de classificação a uma aplicação móvel com inferência local. Além disso, foi incorporada a classe *Not ECG*, destinada à identificação de imagens que não correspondem a eletrocardiogramas. Assim, o principal diferencial deste trabalho está na integração do modelo ao ambiente móvel e na inclusão dessa categoria adicional, e não na proposição de uma nova arquitetura de CNN.

Nesta etapa, a aplicação foi avaliada apenas com imagens padronizadas provenientes da base utilizada no experimento. Não foram realizados testes em condições reais de captura pela câmera do dispositivo. Portanto, os resultados apresentados não contemplam possíveis variações de iluminação, perspectiva, foco, resolução, enquadramento ou diferenças entre câmeras de dispositivos móveis.

IV. Conclusão

Este trabalho apresentou o desenvolvimento e a integração de uma rede neural convolucional a uma aplicação móvel para classificação de imagens de eletrocardiogramas. A conversão do modelo para TensorFlow Lite possibilitou a realização da inferência diretamente no dispositivo móvel, sem necessidade de conexão com serviços externos. Além das quatro categorias relacionadas aos ECGs, foi incorporada a classe *Not ECG*, destinada à identificação de imagens que não correspondem a eletrocardiogramas.

Nos dados utilizados para validação, foram observados diferentes desempenhos entre as classes, incluindo 98,3% de acerto para infarto agudo do miocárdio e 100% para a classe *Not ECG*. Entretanto, esses resultados devem ser interpretados considerando as limitações metodológicas do estudo, especialmente a realização da divisão entre treinamento e validação

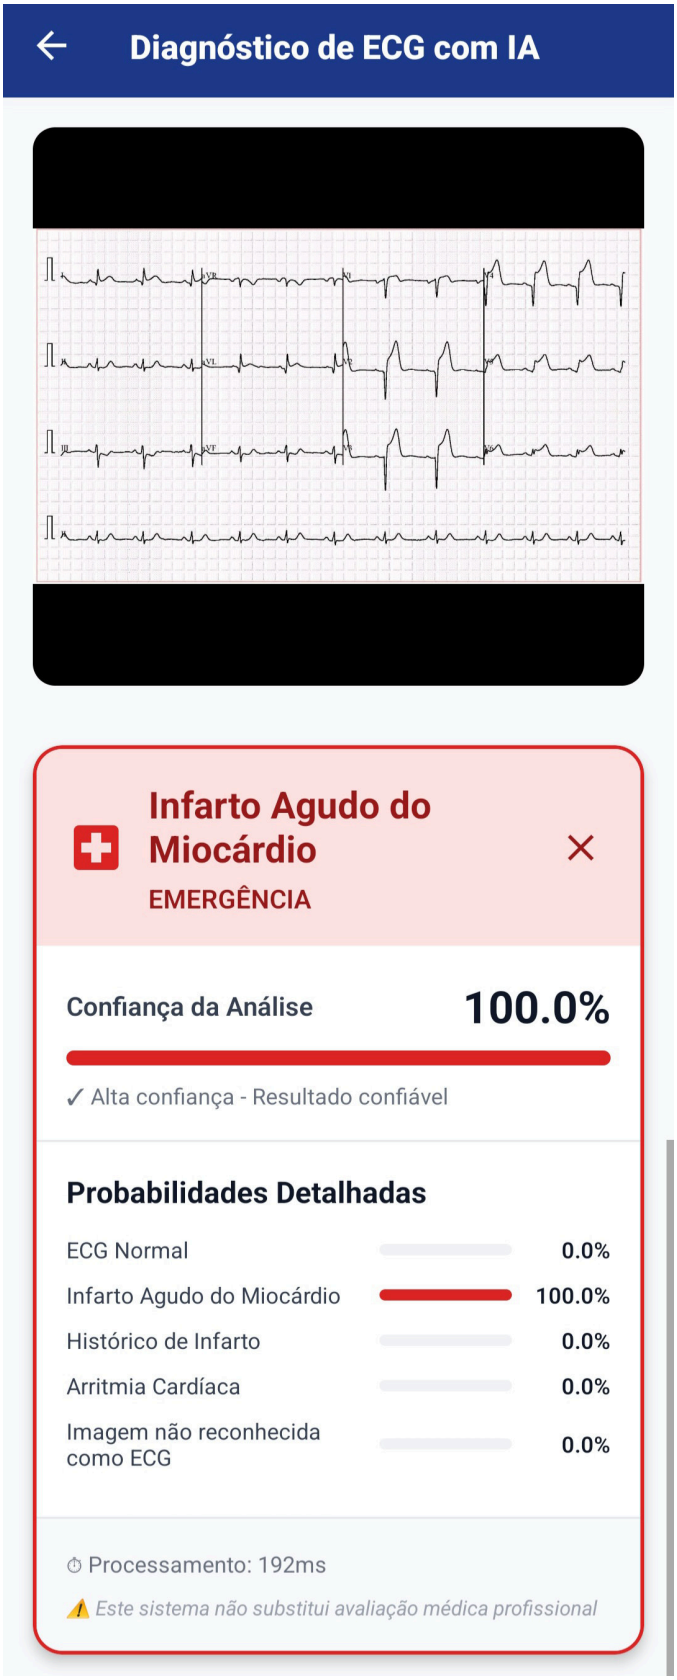

Figura 5: Interface do aplicativo desenvolvido para classificação de ECG.

após o processo de aumento de dados, o que pode resultar na presença de imagens derivadas de uma mesma amostra original em ambos os conjuntos e produzir estimativas otimistas de desempenho.

Além disso, a aplicação foi avaliada somente com imagens padronizadas, não tendo sido realizados testes em condições reais de captura ou validação clínica. Dessa forma, os resultados obtidos demonstram principalmente a viabilidade técnica da execução local do modelo e de sua integração à aplicação móvel, não sendo suficientes para estabelecer sua utilização como ferramenta de diagnóstico ou apoio à decisão clínica.

Como trabalhos futuros, pretende-se realizar a separação dos conjuntos antes da aplicação do aumento de dados, além de utilizar conjuntos independentes para teste. Também deverão ser investigadas métricas adicionais e o comportamento do sistema em diferentes dispositivos e condições de captura, incluindo variações de iluminação, perspectiva, resolução, enquadramento e qualidade das imagens. Adicionalmente, pretende-se investigar estratégias para a análise individual das derivações do ECG, possibilitando avaliar quais derivações apresentam alterações e sua relação com diferentes territórios cardíacos.

Agradecimentos

Este trabalho foi financiado em parte pela Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), Código de Financiamento 001. Os autores também agradecem o apoio do Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), da Fundação Araucária, da Secretaria de Estado de Ciência, Tecnologia e Ensino Superior do Paraná (SETI), da Secretaria de Estado da Saúde do Paraná (SESA) e da Universidade Tecnológica Federal do Paraná (UTFPR).

***Resumo*— O câncer de mama é a neoplasia de maior incidência e taxa de mortalidade entre as mulheres mundialmente. O diagnóstico precoce desempenha um papel determinante para a elevação dos índices de cura, os quais podem alcançar até 95% quando a lesão é identificada em estágios iniciais. Este trabalho propõe e avalia um sistema de auxílio ao diagnóstico médico (CAD) baseado em Aprendizado de Máquina para a detecção precoce do câncer de mama a partir de atributos extraídos de imagens de ultrassonografia mamária em modo-B (base Lenet_ultrassonografia.arff, contendo 879 instâncias e 501 atributos numéricos). Avaliou-se o impacto da redução de dimensionalidade comparando o Algoritmo Genético (AG) e a Otimização por Enxame de Partículas (PSO). Em seguida, testou-se um conjunto diversificado de classificadores supervisionados, incluindo Bayes Net, Naive Bayes, Support Vector Machine (SMO/SVM com kernels linear e polinomiais) e algoritmos de Árvores de Decisão (J48, Random Tree e Random Forest variando de 100 a 500 árvores). Para mitigar o desbalanceamento das classes, aplicou-se a técnica SMOTE sobre o conjunto de treinamento. Os experimentos foram executados sob validação cruzada 10-fold com 5 repetições (50 execuções). A combinação do Algoritmo Genético (255 atributos selecionados) com o classificador Random Forest de 200 árvores destacou-se como a arquitetura mais equilibrada entre as avaliadas, obtendo Acurácia de 87,90% ± 1,60%, Índice Kappa de 0,722 ± 0,077, Sensibilidade de 87,4% ± 4,65%, Especificidade de 87,4% ± 5,26% e Área sob a Curva ROC (AUC) de 0,970 ± 0,016. Na etapa de validação em conjunto de teste independente, o modelo alcançou uma sensibilidade de 91,6% (79 acertos em 81 lesões malignas) e especificidade de 87,4%. Conclui-se que a abordagem proposta oferece elevada acurácia diagnóstica aliada a um baixo custo computacional, sugerindo evidências preliminares para sua viabilidade técnica como um modelo de suporte a decisão em ambientes de triagem oncológica.**

Palavras-chave— Câncer de mama, Ultrassonografia modo-B, Aprendizado de Máquina, Seleção de atributos, Algoritmo Genético, Particle Swarm Optimization, Random Forest, Engenharia Biomédica.

I. INTRODUÇÃO

O câncer de mama representa uma das neoplasias malignas de maior relevância para a saúde pública global, figurando como a principal causa de mortalidade por câncer na população feminina mundial [1]. Segundo estimativas da Organização Mundial da Saúde (OMS), projeta-se que a doença seja responsável por aproximadamente 715 mil óbitos ao ano no marco de 2025 [2]. Do ponto de vista anátomo-patológico, a condição caracteriza-se pela proliferação celular descontrolada e atípica do tecido epitelial mamário, com elevado potencial de invasão local e disseminação metastática para sítios distantes através das vias linfática e hematogênica.

A despeito desse cenário epidemiológico alarmante, a literatura clínica evidencia de forma consensual que o diagnóstico precoce constitui o fator de maior impacto no prognóstico da paciente. Quando a lesão tumoral é identificada e caracterizada em suas fases iniciais (Estágios I e II), as taxas de cura e sobrevida em cinco anos chegam a atingir 95% [2]. Mesmo em tumores do tipo invasivo, mais susceptíveis a complicações metastáticas, o diagnóstico tempestivo possibilita intervenções terapêuticas cirúrgicas e farmacológicas menos invasivas, mais eficazes e com menor taxa de morbidade [2].

No âmbito dos exames de imagem médica, embora a mamografia digital permaneça como a modalidade de rastreio

populacional padrão-ouro, ela apresenta limitações bem documentadas, especialmente na avaliação de mamas densas — cenário no qual a sobreposição de tecidos reduz significativamente a sensibilidade do exame — além da desvantagem inerente da exposição à radiação ionizante [1]. Em contrapartida, a ultrassonografia mamária em modo-B firma-se como uma modalidade diagnóstica não invasiva, altamente acessível, isenta de radiação e apresenta alta eficácia na diferenciação entre lesões císticas e sólidas, servindo como método complementar valioso na prática biomédica e radiológica [1].

Entretanto, a interpretação de exames ultrassonográficos é intrinsecamente dependente da experiência do operador e sujeita à variabilidade inter e intra-observador, dada a complexidade na análise de contornos, ecoestrutura, atenuação acústica e margens tumorais [1]. Nesse contexto, o desenvolvimento de sistemas de Diagnóstico Auxiliado por Computador (CAD - Computer-Aided Diagnosis) baseados em inteligência artificial e aprendizado de máquina surge como uma solução promissora para fornecer uma segunda opinião objetiva, quantitativa e reprodutível aos profissionais de saúde [1].

Objetivando otimizar a eficácia diagnóstica e a eficiência de triagem, este estudo investiga a aplicação de métodos de aprendizado de máquina aplicados a dados de ultrassonografia mamária de modo-B. O foco central compreende a avaliação comparativa de estratégias metaheurísticas de seleção de atributos — Algoritmo Genético (AG) e Otimização por Enxame de Partículas (PSO) — visando reduzir o espaço de atributos e superar o 'mal da dimensionalidade'. Em seguida, analisa-se a capacidade preditiva de diversos algoritmos de classificação em um protocolo experimental rigoroso, definindo uma arquitetura computacional capaz de combinar alta sensibilidade diagnóstica e reduzida complexidade operacional.

II. FUNDAMENTAÇÃO TEÓRICA

A. Ultrassonografia Mamária em Modo-B e Extração de Atributos

A ultrassonografia mamária baseia-se na emissão de ondas mecânicas de alta frequência (tipicamente entre 7 e 15 MHz) geradas por transdutores piezoelétricos. As ondas sonoras propagam-se nos tecidos biológicos e sofrem fenômenos de reflexão, refração e atenuação ao encontrarem interfaces com diferentes impedâncias acústicas [1]. Os ecos refletidos são captados pelo próprio transdutor, convertidos em sinais elétricos e processados por algoritmos de reconstrução para formar a imagem em modo-B (Brightness mode), na qual a amplitude do eco é mapeada em níveis de cinza.

No contexto deste trabalho, os dados originais derivam do repositório público e padronizado BUS-BRA [1], coletado a partir de exames ultrassonográficos de 1.064 pacientes, totalizando 1.875 imagens com confirmação diagnóstica por biópsia e classificação segundo o sistema BI-RADS (Breast Imaging Reporting and Data System) [1]. A caracterização quantitativa das lesões (extração de atributos) abrange descritores de textura (matriz de coocorrência de níveis de cinza - GLCM), parâmetros morfométricos da margem tumoral (circularidade, rugosidade, compacidade) e estatísticas de intensidade e atenuação acústica [1]. Cabe ressaltar que a base derivada utilizada neste estudo (Lenet_ultrassonografia.arff, contendo 879 instâncias) é um recorte amostral cuidadosamente pré-processado, no qual cada instância (linha de atributos) corresponde de forma unívoca a um achado focal/paciente distinto. Essa seleção mitigou a presença de múltiplas imagens de um mesmo indivíduo, prevenindo o vazamento de informações em nível de paciente (*patient-level leakage*) durante as etapas posteriores de particionamento e validação cruzada.

B. Redução de Dimensionalidade e Algoritmos de Seleção

datasets de imagens biomédicas frequentemente apresentam alta dimensionalidade. O dataset considerado (Lenet_ultrassonografia.arff) possui 501 atributos numéricos derivados da extração de características. A presença de um número elevado de atributos em relação ao tamanho da amostra induz o fenômeno conhecido como 'mal da dimensionalidade', elevando o risco de sobreajuste (overfitting), degradando o desempenho dos classificadores e aumentando o tempo de processamento computacional.

Para contornar essa limitação, investigou-se a aplicação de duas metaheurísticas de otimização estocástica:

1) Algoritmo Genético (AG): Inspirado nos mecanismos da evolução natural e seleção darwiniana, o AG codifica subconjuntos de atributos como cromossomos binários. Através de operadores de seleção, cruzamento (crossover) e mutação, a população evolui ao longo de gerações para maximizar uma função de aptidão (fitness) baseada na capacidade discriminatória dos atributos [17]. Configurou-se o AG com 50 gerações e 100 iterações.

2) Otimização por Enxame de Partículas (PSO - Particle Swarm Optimization): Baseado no comportamento social de agrupamento de aves e peixes, o PSO ajusta iterativamente a posição e velocidade de partículas candidato no espaço de busca d-dimensional. Cada partícula atualiza sua trajetória considerando sua melhor posição individual histórica (p_{best}) e a melhor posição global compartilhada pelo enxame (g_{best}) [17]. O algoritmo foi executado com 50 gerações e 100 iterações.

C. Tratamento de Desbalanceamento com SMOTE

O desbalanceamento de classes é um desafio recorrente na área biomédica, em que a proporção de casos patológicos costuma ser inferior à de casos benignos ou controles. A base estudada apresenta 272 amostras da classe C1

(maligna/casos) e 607 amostras da classe C2 (benigna/controles). Classificadores treinados sob conjuntos desbalanceados tendem a apresentar um viés em favor da classe majoritária, resultando em uma taxa frequentemente elevada de falsos negativos para a doença maligna.

Para solucionar essa assimetria, utilizou-se o filtro SMOTE (Synthetic Minority Over-sampling Technique) [5]. O SMOTE cria instâncias sintéticas da classe minoritária através de interpolação no espaço de atributos. Para cada amostra x_i da classe minoritária, identifica-se seus k vizinhos mais próximos da mesma classe; seleciona-se aleatoriamente um vizinho x_{zi} e gera-se um novo ponto sintético x_{novo} conforme a relação:

$$x_novo = x_i + \lambda \cdot (x_zi - x_i), \quad \lambda \in [0, 1] \qquad (1)$$

D. Modelos de Aprendizado de Máquina

Com o intuito de obter uma análise abrangente e robusta, selecionou-se uma gama diversificada de famílias de classificadores de aprendizado supervisionado:

• Random Forest (RF): Modelo ensemble baseado na construção de múltiplas árvores de decisão não correlacionadas, utilizando reamostragem bootstrap (bagging) e seleção aleatória de atributos por nó. Avaliaram-se configurações com 100, 200, 300, 400 e 500 árvores [6].

• Árvores de Decisão (J48 e Random Tree): O algoritmo J48 representa a implementação no ambiente Weka do clássico C4.5, que utiliza a razão de ganho de informação para realizar divisões recursivas. A Random Tree constrói árvores individuais considerando subconjuntos aleatórios de atributos a cada nó.

• Classificadores Bayesianos (Naive Bayes e BayesNet): O Naive Bayes assume independência condicional absoluta entre os atributos dada a classe. A BayesNet (Redes Bayesianas) flexibiliza essa suposição, mapeando as relações de dependência estocástica através de grafos acíclicos direcionados (DAGs).

• Máquinas de Vetores de Suporte (SVM/SMO): Implementadas via algoritmo Sequential Minimal Optimization (SMO), buscam determinar o hiperplano de separação de margem máxima no espaço de atributos. Foram testados kernels linear, polinomial de grau 2 e polinomial de grau 3, fixando o parâmetro de penalização C = 0,01.

III. METODOLOGIA

A. Descrição do Dataset e Pipeline Experimental

O fluxo metodológico desenvolvido está sumarizado na estratégia de processamento da base Lenet_ultrassonografia.arff, composta por 879 instâncias e 501 atributos numéricos contínuos, acompanhados pelo rótulo da classe categórica (C1 = 272 amostras malignas; C2 = 607 amostras benignas). A metodologia seguiu cinco etapas fundamentais:

1. Carregamento e conversão da base de dados original no formato ARFF;

2. Particionamento inicial e estratificado do dataset em conjuntos de Treinamento (70%) e Teste (30%) utilizando o filtro Resample sem reposição de instâncias. Esta etapa isola o conjunto de teste de qualquer intervenção subsequente de otimização;

3. Execução dos algoritmos de seleção de atributos (AG e PSO) estritamente sobre o conjunto de Treinamento para determinação do subconjunto ótimo de características;

4. Aplicação do filtro de atributos gerado na etapa anterior ao conjunto de Teste independente, garantindo que ele possua a mesma dimensionalidade do Treinamento sem influenciar a seleção;

5. Balanceamento exclusivo do conjunto de Treinamento reduzido via SMOTE;

6. Treinamento, validação cruzada 10-fold com 5 repetições e avaliação final dos classificadores no conjunto de teste independente nos ambientes Weka e Jamovi.

B. Seleção de Atributos e Configuração Experimental

Os dois algoritmos de seleção foram executados sob as mesmas condições iniciais de parada para garantir isonomia na comparação: 50 gerações e 100 iterações. Conduzida exclusivamente sobre os 70% dos dados de treinamento, a busca por Algoritmo Genético (AG) convergiu selecionando um subconjunto promissor de 255 atributos (redução de ~49,1% da dimensão original). Por sua vez, a Otimização por Enxame de Partículas (PSO) demonstrou maior agressividade de compressão, selecionando 104 atributos (redução de ~79,2%).

Após a convergência, os atributos eliminados no Treinamento também foram removidos do conjunto de Teste. Os dados finais foram convertidos para o formato CSV e submetidos ao software Jamovi para condução das análises estatísticas descritivas das métricas operacionais. .

C. Protocolo de Treinamento e Validação Cruzada

Para favorecer a generalização do modelo e mitigar o risco de memorização estática dos dados (overfitting), adotou-se o módulo Experimenter do software Weka. O conjunto de treinamento (70% da base original) passou por balanceamento via SMOTE e foi avaliado por validação cruzada K-Fold com K=10, repetida por 5 execuções independentes com sementes de aleatoriedade distintas (totalizando 50 ciclos de treino/validação por classificador). Ressalta-se que a total independência metodológica do conjunto de teste (30%) foi preservada, uma vez que não teve participação nas etapas de seleção de atributos ou geração de

instâncias sintéticas, resultando em métricas de avaliação realistas e não otimistas.

D. Métricas de Avaliação do Desempenho

A eficácia diagnóstica dos modelos foi quantificada a partir das métricas consagradas na literatura biomédica, calculadas a partir dos valores da matriz de confusão: Verdadeiros Positivos (TP), Verdadeiros Negativos (TN), Falsos Positivos (FP) e Falsos Negativos (FN).

• Acurácia (Acc): Razão entre as predições corretas e o total de amostras:

$$Acc = (TP + TN) / (TP + TN + FP + FN) \qquad (2)$$

• Coeficiente Kappa de Cohen (kappa): Medida de concordância inter-observadores ajustada para a concordância esperada pelo acaso (P_e):

$$\kappa = (P_o - P_e) / (1 - P_e) \qquad (3)$$

em que P_o representa a acurácia observada do classificador.

• Sensibilidade (S_n): Proporção de casos malignos diagnosticados corretamente:

$$S_n = TP / (TP + FN) \qquad (4)$$

• Especificidade (S_p): Proporção de lesões benignas identificadas corretamente:

$$S_p = TN / (TN + FP) \qquad (5)$$

• Área sob a Curva ROC (AUC): Desempenho global da capacidade de discriminação probabilística da taxa de verdadeiros positivos em função dos falsos positivos.

IV. RESULTADOS E DISCUSSÃO

A. Análise do Desempenho dos Classificadores sob Algoritmo Genético

Os resultados obtidos durante os 50 ciclos de validação cruzada no conjunto de treinamento utilizando a base reduzida pelo Algoritmo Genético (255 atributos) estão consolidados na Tabela I, contendo as médias e desvios-padrão (\mu \pm \sigma) das métricas estipuladas.

TABELA I
DESEMPENHO DOS CLASSIFICADORES COM SELEÇÃO POR ALGORITMO GENÉTICO (MÉDIA ± DESVIO-PADRÃO)

Classificador	Acurácia (%)	Kappa (κ)	Sensib. (S_n)	Especif. (S_p)	AUC-ROC
RF 100	87,86 ± 1,60	0,720 ± 0,072	0,873 ± 0,045	0,873 ± 0,052	0,970 ± 0,017
RF 200	87,90 ± 1,60	0,722 ± 0,077	0,874 ± 0,046	0,874 ± 0,053	0,970 ± 0,016
RF 300	87,90 ± 1,68	0,722 ± 0,074	0,875 ± 0,049	0,875 ± 0,044	0,970 ± 0,015
RF 400	87,87 ± 1,60	0,721 ± 0,073	0,877 ± 0,048	0,877 ± 0,048	0,970 ± 0,016
RF 500	87,87 ± 1,55	0,721 ± 0,072	0,876 ± 0,041	0,876 ± 0,048	0,970 ± 0,016
BayesNet	71,80 ± 4,37	0,404 ± 0,097	0,595 ± 0,058	0,740 ± 0,076	0,792 ± 0,041
Naive Bayes	67,30 ± 4,29	0,347 ± 0,086	0,546 ± 0,057	0,731 ± 0,046	0,731 ± 0,035
SMO (SVM)	79,80 ± 1,50	0,551 ± 0,033	0,824 ± 0,039	0,674 ± 0,155	0,799 ± 0,061
J48	82,70 ± 1,50	0,614 ± 0,077	0,832 ± 0,048	0,822 ± 0,042	0,861 ± 0,040
RandomTree	82,50 ± 4,01	0,610 ± 0,080	0,827 ± 0,051	0,824 ± 0,055	0,825 ± 0,040

A análise da Tabela I revela que a família de classificadores baseada em conjuntos de árvores (Random Forest) alcançou os desempenhos mais elevados e estáveis. As variações de Random Forest com 100 a 500 árvores obtiveram acurácias superiores a 87,8% e valor de área sob a curva ROC (AUC) consistente de 0,970, demonstrando elevada capacidade discriminatória.

Dentre as configurações de Random Forest, os modelos com 200 e 300 árvores obtiveram os índices Kappa mais elevados (0,722 ± 0,077), caracterizando uma concordância substancial segundo os critérios de Landis e Koch. Por outro lado, os classificadores probabilisticos demonstraram desempenho inferior: o Naive Bayes obteve a menor acurácia (67,30%) e a menor sensibilidade (54,60%), consequência direta da violação da premissa de independência estocástica entre os atributos extraídos das imagens ultrassonográficas.

B. Comparação com a Seleção por Enxame de Partículas (PSO)

Em relação à abordagem de Otimização por Enxame de Partículas (PSO), observa-se comportamento preditivo análogo no que tange à superioridade das florestas randômicas. O algoritmo Random Forest com 200 árvores manteve a liderança técnica no conjunto de validação sob a base do PSO. Em contrapartida, o modelo SVM com kernel linear apresentou o pior desempenho global sob o filtro PSO, sugerindo que a redução agressiva para 104 atributos elimina

relações não lineares essenciais para o hiperplano de separação linear.

Embora o PSO promova uma compressão de atributos mais severa (104 atributos contra 255 do AG), a seleção por Algoritmo Genético proporcionou maior estabilidade estatística e leve vantagem nos valores absolutos de sensibilidade no conjunto de validação. Ademais, do ponto de vista operacional, o AG demandou menor número total de iterações para atingir a convergência ideal em comparação ao enxame de partículas.

C. Critério de Seleção do Modelo Ótimo e Custo Computacional

A definição do modelo ideal deve considerar o compromisso entre acurácia diagnóstica e viabilidade de implementação computacional. Ao comparar o Random Forest de 200 árvores com o de 300 árvores sob a seleção por AG, constata-se que ambos os modelos apresentam desempenhos virtualmente idênticos (Acurácia de 87,90% e Kappa de 0,722).

Contudo, do ponto de vista da Engenharia Biomédica e da aplicação clínica em tempo real, o modelo com 200 árvores exige um custo computacional significativamente menor no processo de inferência e alocação de memória RAM. Por conseguinte, elegeu-se a combinação Algoritmo Genético + Random Forest (200 árvores) como a arquitetura mais adequada para este estudo.

D. Avaliação no Conjunto de Teste Independente e Matriz de Confusão

Após a consolidação da arquitetura ótima (AG + Random Forest 200 árvores), o modelo treinado foi submetido à avaliação no conjunto de teste independente (30% dos dados, englobando aproximadamente 263 instâncias não vistas durante a etapa de otimização). Os resultados do teste final foram extraídos via aba Classify do ambiente Weka e estão apresentados na matriz de confusão da Fig. 1.

FIG. 1. MATRIZ DE CONFUSÃO E DESEMPENHO NO CONJUNTO DE TESTE INDEPENDENTE (AG + RANDOM FOREST 200 ÁRVORES)

Classe Real \ Predita	**Previsto: MALIGNO (C1)**	**Previsto: BENIGNO (C2)**
Real: MALIGNO (C1)	**VERDADEIRO POSITIVO 91,6% (79 casos)**	FALSO NEGATIVO 8,4% (02 casos)
Real: BENIGNO (C2)	FALSO POSITIVO 12,6% (20 casos)	**VERDADEIRO NEGATIVO 87,4% (162 casos)**

A análise da matriz de confusão demonstra resultados promissores do modelo de suporte CAD em dados não vistos. No grupo de tumores malignos (Classe C1), o sistema identificou corretamente 79 de 81 casos, alcançando uma Sensibilidade de 91,6% e limitando a taxa de Falsos Negativos a apenas 8,4% (2 casos). Em rastreio oncológico, minimizar os falsos negativos é o requisito sanitário mais crítico, haja vista que a omissão de um tumor maligno atrasa o tratamento e compromete drasticamente a sobrevida da paciente.

Paralelamente, para a classe de lesões benignas (Classe C2), o modelo obteve uma Especificidade de 87,4% (162 acertos em 182 lesões benignas), com 12,6% de Falsos Positivos (20 casos). Esse nível de especificidade é relevante, indicando que , em um cenário de aplicação real, um modelo de suporte CAD com tais métricas poderia auxiliar secundariamente na redução de indicações para biópsias invasivas desnecessárias e mitigar a ansiedade associada a diagnósticos falso-positivos.

V. CONCLUSÃO

Este estudo apresentou evidências preliminares da viabilidade técnica da integração de algoritmos de Aprendizado de Máquina e seleção de atributos metaheurística no processamento de imagens de ultrassonografia mamária em modo-B para o apoio ao rastreio precoce do câncer de mama.

As análises estatísticas comparativas evidenciaram que a abordagem combinada utilizando o Algoritmo Genético (seleção de 255 atributos) e o classificador Random Forest configurado com 200 árvores alcançou o melhor equilíbrio operacional. A solução atingiu acurácia de 87,90%, índice Kappa de 0,722 e área sob a curva ROC de 0,970 na validação cruzada, culminando em uma elevada sensibilidade diagnóstica de 91,6% e especificidade de 87,4% no conjunto de teste independente.

Destaque-se que a escolha criteriosa do modelo de 200 árvores (em detrimento de arquiteturas mais complexas como 300 a 500 árvores) viabilizou uma redução expressiva do gasto computacional e da latência de processamento sem qualquer prejuízo às métricas de acurácia, aspecto relevante para futuras investigações voltadas à implementação em equipamentos ultrassonográficos portáteis de ponto de atendimento (Point-of-Care).

Apesar dos resultados promissores, reconhece-se como potencial limitação deste estudo a utilização de um único conjunto de dados, o que pode restringir a capacidade de generalização do modelo proposto quando avaliado frente a imagens adquiridas em diferentes instituições de saúde ou com equipamentos de ultrassom distintos. Para mitigar essa limitação, em trabalhos futuros, pretende-se expandir a validação do modelo proposto através da inclusão de bases de dados multicêntricas com diferentes marcas de transdutores, bem como explorar técnicas de fusão multimodal unindo atributos ultrassonográficos, mamográficos e variáveis

clínicas da paciente para o desenvolvimento de um sistema CAD de suporte à decisão em tempo real integrável ao Sistema Único de Saúde (SUS).

***Abstract*—Electronic Health Records (EHRs) require secure and interoperable mechanisms for health information exchange. This study presents a systematic literature review of blockchain-based EHR architectures published between 2021 and 2026. Twenty studies were included, comprising fifteen primary studies and five secondary studies. The analysis of the primary studies revealed a predominance of permissioned blockchain platforms, particularly Hyperledger Fabric, combined with smart contracts, access control mechanisms, interoperability services, and hybrid storage models in which clinical data remain stored in off-chain repositories. Based on the recurring architectural patterns identified across the literature, a conceptual reference architecture was synthesized to summarize the functional components most frequently adopted in blockchain-based EHR systems. The findings indicate a convergence toward common architectural design patterns and provide a consolidated reference for future research on secure and interoperable healthcare information systems.**

***Index Terms*—Blockchain, Electronic Health Records, HL7 FHIR, Interoperability, Smart Contracts.**

I. Introduction

Electronic Health Records (EHRs) have become essential for healthcare delivery, supporting the storage, management, and exchange of clinical information across healthcare organizations. Despite advances in health information technologies, challenges related to interoperability, privacy, security, and data governance continue to limit efficient information sharing among heterogeneous systems [1]–[3].

Blockchain has emerged as a promising technology for addressing some of these challenges by providing decentralized trust, data integrity, auditability, and secure access management. Combined with smart contracts, blockchain enables the automation of consent management, authorization policies, and transaction auditing. Consequently, blockchain-based solutions have been proposed for Electronic Health Records, Personal Health Records, Health Information Exchange, and Internet of Medical Things (IoMT) applications [4]–[9], [14].

This work was supported by the Programa Pesquisando Desde o Primeiro Dia (PDPD) through an undergraduate research scholarship granted by the Pró-Reitoria de Pesquisa of the Federal University of ABC (Propes/UFABC), Brazil.

Recent studies increasingly combine blockchain platforms with complementary technologies such as interoperability standards, distributed storage, cloud services, and cryptographic mechanisms. Although these solutions pursue similar objectives, they differ regarding blockchain platforms, storage strategies, interoperability mechanisms, and security models, making it difficult to identify the architectural characteristics that consistently define blockchain-based EHR systems [7]–[13], [15], [16].

Previous reviews have examined blockchain adoption in healthcare from perspectives such as privacy, security, and health information management [1]–[3]. However, there remains limited understanding of the architectural patterns that recur across blockchain-based EHR solutions.

To address this gap, this study presents a systematic literature review of blockchain-based EHR architectures published between 2021 and 2026. Twenty studies were included, comprising fifteen primary studies and five secondary studies. The architectural synthesis was derived exclusively from the primary studies, while secondary studies were used to contextualize technological trends and research challenges. Based on the comparative analysis, a conceptual reference architecture was synthesized to summarize the functional components most frequently reported in blockchain-based EHR systems. The main contributions of this work are: (i) a systematic comparison of blockchain-based EHR architectures; (ii) the identification of recurring architectural patterns; and (iii) the synthesis of a conceptual reference architecture derived from evidence extracted from the primary studies.

II. Materials and Methods

This systematic literature review was conducted to identify and analyze blockchain-based architectures for Electronic Health Records (EHRs). The review followed the main principles of the PRISMA 2020 guidelines for study identification, screening, eligibility assessment, and qualitative synthesis. The review was conducted through four sequential activities: literature search, study selection, eligibility assessment, and data extraction.

The review included both primary and secondary studies. Primary studies proposed architectures, frameworks, or technical solutions for blockchain-based EHR systems, whereas secondary studies consisted of literature reviews that provided contextual information regarding the evolution of the field. To avoid duplication of evidence, only the primary studies were considered in the identification of recurring architectural patterns and in the synthesis of the conceptual reference architecture, while secondary studies were used exclusively to contextualize the findings and support the discussion.

A. Search Strategy

The literature search was performed in four scientific databases: PubMed, Scopus, Web of Science, and IEEE Xplore. These databases were selected because they index studies in healthcare, biomedical informatics, and computer science, covering the principal publication venues related to blockchain applications in healthcare.

The search strategy combined terms associated with blockchain, Electronic Health Records, interoperability, and information security. Boolean operators (AND and OR) were used to construct database-specific queries. The search expression was defined as:

> (”blockchain” OR ”blockchain-based” OR ”distributed ledger”) AND (”electronic health record” OR ”EHR” OR ”personal health record” OR ”PHR”) AND (”interoperability” OR ”data sharing” OR ”health information exchange”) AND (”security” OR ”privacy” OR ”access control” OR ”encryption”) AND (”framework” OR ”architecture” OR ”model” OR ”system” OR ”guideline” OR ”standard”)

Only studies published between 2021 and 2026 were considered.

B. Study Selection and Data Extraction

All retrieved records were exported to Zotero for reference management and duplicate removal. After eliminating duplicate records, titles and abstracts were screened to identify potentially relevant studies. The screening process excluded publications that were unrelated to blockchain-based EHR systems, outside the defined publication period, unavailable as full-text articles, or classified as editorials, letters, or conference abstracts without complete manuscripts.

The remaining studies underwent full-text assessment to verify their relevance to the objectives of this review. Articles that did not present a clear methodological description or did not specifically address blockchain applications for Electronic Health Records were excluded. Studies were classified as primary or secondary during the full-text assessment. Primary studies described original blockchain-based EHR architectures, frameworks, or implementation strategies, whereas secondary studies synthesized previous research findings. This classification was used throughout the review process to distinguish evidence sources and avoid incorporating secondary evidence into the architectural synthesis. The screening and data extraction processes were conducted by the first reviewer and subsequently verified by a second reviewer. Any discrepancies were resolved through discussion.

For each included study, information regarding blockchain platform, network type, interoperability mechanisms, security strategies, storage architecture, and other architectural characteristics was extracted and organized in a structured data extraction form. For the primary studies, the presence or absence of architectural components was recorded to support a comparative analysis of their occurrence across the literature. The frequency of each component was calculated as the number and percentage of primary studies in which the component was identified. These frequencies were subsequently used to characterize the recurrence of architectural elements across the reviewed literature and to support the synthesis of the conceptual reference architecture.

C. Quality Assessment

Because the review included studies with different objectives and methodological designs, a simplified quality assessment was performed for the primary studies. The assessment considered three criteria: (i) clarity of the architectural description, (ii) description of implementation or validation procedures, and (iii) discussion of limitations or practical applicability. The assessment was used to characterize the evidence base and support the interpretation of the findings, but it was not employed as an exclusion criterion.

The results of the quality assessment are presented in the Results section and were considered when interpreting the strength of the available evidence.

III. Results

A. Characteristics of the Selected Studies

The literature search identified 631 records across PubMed, Scopus, Web of Science, and IEEE Xplore. After duplicate removal, 436 unique records remained for title and abstract screening. Following the application of the predefined eligibility criteria, 135 articles underwent full-text assessment, of which 20 satisfied all inclusion criteria and were included in the qualitative synthesis. The study selection process is illustrated in Fig. 1.

The final sample included both primary and secondary studies addressing blockchain applications for Electronic Health Records (EHRs). Primary studies proposed new architectures, frameworks, and secure data-sharing mechanisms, whereas secondary studies synthesized the current state of research and discussed technological trends, research challenges, and future directions. Table I summarizes the general characteristics of the selected literature.

Among the 15 primary studies, 13 proposed new architectures or frameworks, whereas two focused on the evaluation of previously developed solutions. The remaining five studies corresponded to secondary literature reviews.

The temporal distribution of the selected publications shows an increase in research activity after 2022. Earlier work primarily investigated the feasibility of applying blockchain to improve the security and integrity of Electronic Health

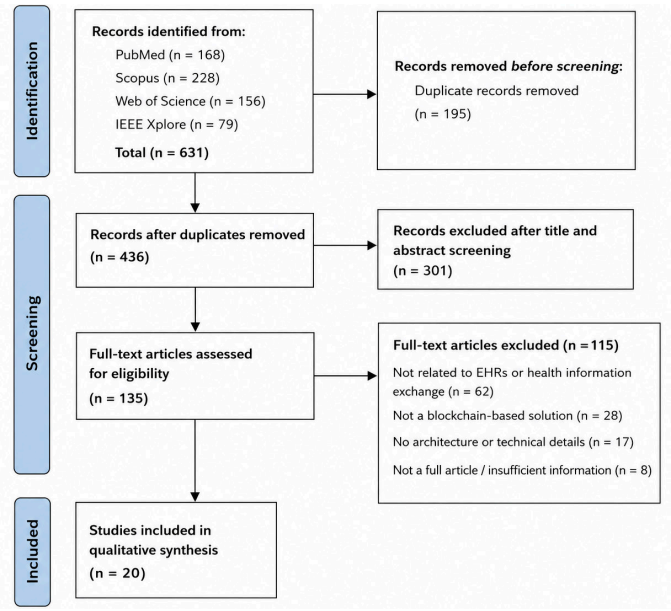

Fig. 1. PRISMA 2020 flow diagram illustrating the study identification, screening, eligibility assessment, and inclusion process adopted in this review.

TABLE I
GENERAL CHARACTERISTICS OF THE SELECTED STUDIES.

Characteristic	Category	n	%
2*Study type	Primary studies	15	75.0
	Secondary studies	5	25.0
3*Publication period	2021–2022	6	30.0
	2023–2024	8	40.0
	2025–2026	6	30.0
3*Research focus	Architecture proposal	13	65.0
	Framework evaluation	2	10.0
	Literature review	5	25.0

Records, whereas more recent publications proposed complete software architectures integrating permissioned blockchain platforms with complementary technologies such as smart contracts, cloud computing, distributed storage, Internet of Medical Things (IoMT), and interoperability standards including HL7 FHIR [7]–[11], [13], [18], [19].

Despite differences in application domains and implementation strategies, most selected studies focused on secure, interoperable, and auditable health information exchange while preserving patient privacy and data integrity. Rather than relying exclusively on blockchain, the majority of proposed solutions adopted hybrid architectures combining distributed ledgers with off-chain storage, cryptographic mechanisms, standardized communication protocols, and fine-grained access control policies [6]–[13].

To avoid duplication of evidence, only the 15 primary studies were included in the quantitative synthesis of architectural components and in the derivation of the reference architecture. The five secondary studies were used exclusively to contextualize research trends, reported challenges, and future directions discussed in the literature.

A summary of the quality assessment (Table II) performed for the primary studies is presented in Section II, providing an overview of the methodological characteristics of the evidence base used for the architectural synthesis.

TABLE II
SUMMARY OF THE QUALITY ASSESSMENT OF THE 15 PRIMARY STUDIES.

Criterion	Yes	No	% Yes
Architectural description	15	0	100
Implementation/validation	8	7	53.3
Limitations discussed	6	9	40

B. Quality Assessment

The quality assessment was performed for the 15 primary studies according to the criteria described in the Materials and Methods section. Table II summarizes the results obtained for each evaluation criterion.

All primary studies provided sufficient architectural descriptions to support data extraction and comparative analysis. However, fewer studies reported implementation details, experimental validation, or performance evaluation. Likewise, the discussion of limitations and practical applicability was not consistently addressed across the reviewed literature.

Overall, the assessment indicates that the current evidence base is largely composed of architectural proposals and proof-of-concept implementations. Consequently, the architectural patterns synthesized in this review should be interpreted as recurring design characteristics reported in the literature rather than as evidence of validated large-scale healthcare deployments.

C. Blockchain Platforms and Network Architectures

The comparative analysis of the selected studies revealed a predominance of permissioned blockchain platforms for Electronic Health Record (EHR) systems, with Hyperledger Fabric being the most frequently adopted technology. Ethereum appeared less frequently, while a smaller number of studies proposed custom permissioned or cross-platform blockchain solutions.

Table III summarizes the blockchain platforms identified in the reviewed literature. Hyperledger Fabric was identified in 9 of the 15 primary studies (60%), making it the most frequently adopted blockchain platform. Ethereum appeared in two studies (13.3%), whereas three studies (20%) proposed custom permissioned implementations. Only one study addressed interoperability across heterogeneous blockchain networks.

Hyperledger Fabric was the most frequently adopted blockchain platform among the reviewed studies. Most implementations employed permissioned networks that support authenticated participation, configurable access policies, and institutional governance suitable for healthcare environments [7]–[11].

Among the primary studies included in this review, no implementation relied exclusively on a public permissionless

TABLE III
BLOCKCHAIN PLATFORMS IDENTIFIED AMONG THE PRIMARY STUDIES.

Blockchain Platform	n	%	Main Characteristics
Hyperledger Fabric	9	60	Permissioned blockchain supporting institutional governance, smart contracts, and secure health information exchange.
Ethereum	2	13.3	Public blockchain mainly employed for smart contract implementation and decentralized authorization.
Custom Permissioned Blockchain	3	20	Institution-specific blockchain implementations designed for secure EHR sharing.
Platform-independent / Cross-platform	1	6.7	Architectures supporting interoperability among heterogeneous blockchain networks.

blockchain for EHR management. Instead, the proposed solutions adopted permissioned or consortium blockchain networks involving hospitals, laboratories, healthcare providers, and other trusted institutions operating under predefined governance policies [7]–[12].

Earlier publications primarily focused on demonstrating the feasibility of blockchain for secure Electronic Health Record management. More recent work proposed increasingly comprehensive solutions integrating smart contracts, distributed storage, cloud services, Internet of Medical Things (IoMT), interoperability standards, and advanced access control mechanisms [7]–[11], [13]–[16].

Despite differences in implementation strategies, most proposed solutions adopted a similar storage model. Blockchain was primarily employed to maintain transaction metadata, cryptographic hashes, audit logs, and access permissions, whereas complete Electronic Health Records remained stored in external repositories such as hospital databases, cloud infrastructures, or distributed storage systems [8], [9], [11], [12], [15], [16], [20]. This hybrid storage strategy was identified in the majority of the primary studies and represents one of the most recurrent architectural characteristics observed in the reviewed literature.

D. Security and Access Control Mechanisms

Security mechanisms were consistently addressed across the reviewed studies. Although different blockchain platforms and software architectures were proposed, most solutions combined cryptographic techniques, smart contracts, identity management, and fine-grained access control policies to ensure the confidentiality, integrity, and traceability of Electronic Health Records (EHRs) [6]–[13], [15], [16], [20]. Table IV summarizes the principal security mechanisms identified in the reviewed literature. Smart contracts were the most frequently reported component, supporting authorization, patient consent management, audit automation, and transaction validation. Role-Based Access Control (RBAC) and Attribute-Based Access Control (ABAC) were also widely adopted to regulate access according to user roles or contextual attributes.

Smart contracts were the most frequently reported mechanism for implementing security policies in blockchain-based EHR systems. They were employed to automate patient consent, verify access permissions, register audit events, and regulate data sharing among healthcare organizations [4], [5], [7], [9], [13].

Access control was another recurring component among the reviewed implementations. Initial studies predominantly adopted Role-Based Access Control (RBAC), whereas more recent solutions incorporated Attribute-Based Access Control (ABAC), contextual authorization, and patient-centric permission models capable of adapting access decisions according to different clinical scenarios [6], [8], [10], [11], [15], [16].

Nearly all reviewed architectures recorded access events, permission updates, and data-sharing operations on the blockchain ledger, taking advantage of its immutable transaction history. However, complete Electronic Health Records were rarely stored on-chain. Instead, cryptographic hashes, metadata, transaction identifiers, and audit records were maintained on the blockchain, while clinical information remained stored in external repositories such as hospital databases, cloud infrastructures, or distributed storage systems [7]–[12], [15], [16], [20].

Across the reviewed studies, secure EHR management was consistently implemented through the combination of permissioned blockchain networks, smart contracts, cryptographic mechanisms, access control policies, and off-chain data repositories. This combination of technologies represents the predominant security model identified in the reviewed literature.

E. Interoperability and Data Storage Strategies

The reviewed studies consistently combined blockchain with interoperability standards and external storage solutions to support secure Electronic Health Record (EHR) exchange across heterogeneous healthcare systems. Rather than relying exclusively on distributed ledger technology, the proposed solutions integrated standardized communication protocols, application programming interfaces (APIs), and complementary storage infrastructures to enable interoperability among healthcare organizations [7]–[13]. Table V summarizes the principal interoperability mechanisms and data storage strategies identified in the reviewed literature. HL7 FHIR and RESTful APIs were the most frequently adopted communication technologies, while off-chain repositories represented the predominant strategy for storing complete Electronic Health Records.

Nearly all reviewed implementations adopted hybrid storage architectures in which complete Electronic Health Records remained stored in external repositories, whereas blockchain maintained cryptographic hashes, transaction metadata, access

TABLE IV
CORE SECURITY COMPONENTS IDENTIFIED IN BLOCKCHAIN-BASED EHR ARCHITECTURES.

Security Mechanism	Primary Purpose	Typical Implementation
Smart Contracts	Automate authorization, consent management, audit procedures, and transaction validation	Execution of access policies, patient consent management, and automated auditing within permissioned blockchain networks.
Role-Based Access Control (RBAC)	Restrict data access according to predefined user roles	Authorization based on professional roles such as physicians, nurses, patients, and administrators.
Attribute-Based Access Control (ABAC)	Provide context-aware authorization based on user and resource attributes	Dynamic authorization considering contextual attributes such as organization, department, emergency status, or user permissions.
Identity Management	Authenticate and identify participants in permissioned blockchain networks	Digital identities, certificates, and membership services used to authenticate trusted healthcare organizations and users.
Audit Logging	Maintain an immutable history of data access and system events	Recording of transactions, permission updates, and access history on the blockchain ledger for traceability and accountability.
Cryptographic Mechanisms	Protect confidentiality, integrity, and secure data exchange	Hash functions, digital signatures, encryption, and proxy re-encryption applied to protect sensitive clinical information.
Patient Consent Management	Allow patients to control authorization for sharing Electronic Health Records	Consent policies implemented through smart contracts, enabling patients to grant or revoke access permissions.

TABLE V
CORE INTEROPERABILITY COMPONENTS IDENTIFIED IN BLOCKCHAIN-BASED EHR ARCHITECTURES.

Component	Primary Purpose	Typical Implementation
HL7 FHIR	Standardized representation and exchange of clinical information	Interoperable exchange of Electronic Health Records between heterogeneous healthcare information systems.
RESTful APIs	Communication among blockchain services and healthcare applications	Integration of blockchain platforms with hospital information systems, cloud services, and external repositories.
Off-chain Storage	Storage of complete Electronic Health Records	Hospital databases, cloud repositories, and distributed storage maintaining clinical data outside the blockchain.
InterPlanetary File System (IPFS)	Distributed storage of large medical files	Secure storage of diagnostic images, clinical documents, and other large healthcare datasets.
Cloud Computing	Scalable storage and computational infrastructure	Cloud-based repositories supporting secure data storage, processing, and system scalability.
Cross-platform Interoperability	Exchange of data across heterogeneous blockchain networks	Communication among healthcare organizations operating different blockchain platforms.
IoMT Integration	Continuous acquisition of patient-generated health data	Secure integration of connected medical devices with blockchain-enabled healthcare systems.

permissions, and audit records [7]–[12], [15], [16], [20]. More recent publications increasingly incorporated interoperability standards such as HL7 FHIR together with RESTful APIs to facilitate communication among hospitals, laboratories, cloud services, and healthcare information systems [7]–[10], [12], [13]. Several studies also integrated complementary technologies including cloud computing, distributed storage platforms such as IPFS, and Internet of Medical Things (IoMT) devices to support scalable storage, secure data exchange, and continuous acquisition of patient-generated health information [8], [13], [14], [16].

Across the reviewed literature, blockchain was consistently integrated with interoperability standards, external storage repositories, cloud services, and healthcare communication interfaces. These components formed the predominant interoperability model identified among the reviewed blockchain-based EHR architectures.

F. Architectural Synthesis

The comparative analysis identified a consistent set of architectural design patterns across the reviewed studies. Although the selected works differed in their implementation details, blockchain platforms, and application scenarios, most solutions shared a common set of functional components supporting secure and interoperable Electronic Health Record (EHR) systems [6]–[13], [15], [16], [20].

Table VI summarizes the architectural components most frequently identified in the reviewed literature. Together, these components represent the architectural elements identified across the 15 primary studies included in this review and provide the empirical basis for the synthesis of the conceptual reference architecture.

Based on the recurring architectural design patterns identified across the selected studies, a conceptual reference architecture was synthesized to summarize the functional layers consistently adopted by blockchain-based EHR systems. Rather than representing a specific implementation, Fig. 2 presents a conceptual model that integrates the common design principles observed throughout the reviewed literature.

Unlike the individual architectures proposed in the reviewed studies, the reference architecture presented here does not represent a new implementation. Instead, it synthesizes the recurring architectural components identified across multiple

TABLE VI
ARCHITECTURAL COMPONENTS IDENTIFIED IN THE PRIMARY STUDIES (N = 15).

Architectural Component	n	%	Architectural Role
Off-chain storage	15	100	Stores complete Electronic Health Records outside the blockchain while preserving scalability and performance.
Smart contracts	14	93.3	Automate authorization, patient consent management, and enforcement of access policies.
Permissioned blockchain	13	86.7	Provides the trusted distributed infrastructure responsible for transaction validation, integrity, and auditability.
Cryptographic mechanisms	13	86.7	Ensure confidentiality, integrity, authentication, and secure information exchange.
Access control (RBAC/ABAC)	11	73.3	Restricts access to clinical information according to predefined security policies.
Audit logging	11	73.3	Maintains immutable records of transactions and data access events.
RESTful APIs	8	53.3	Enable communication between blockchain services and healthcare applications.
Identity management	7	46.7	Authenticates organizations and users participating in permissioned networks.
Patient consent management	7	46.7	Allows patients to control authorization for Electronic Health Record sharing.
Advanced cryptographic schemes	7	46.7	Provide enhanced privacy through mechanisms such as proxy re-encryption and zero-knowledge approaches.
HL7 FHIR	4	26.7	Supports standardized exchange of clinical information among heterogeneous healthcare systems.
IPFS	3	20	Supports distributed storage of large medical files and documents.
IoMT integration	2	13.3	Enables secure acquisition and sharing of patient-generated health data.
Edge computing	1	6.7	Provides distributed processing capabilities closer to data sources.

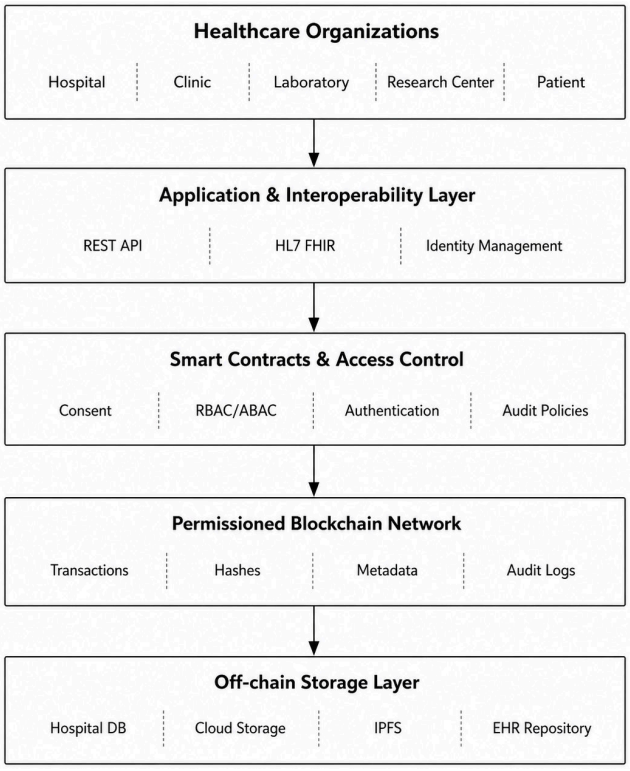

Fig. 2. Conceptual reference architecture synthesized from the reviewed studies. The architecture summarizes the functional layers consistently identified in blockchain-based Electronic Health Record systems, including healthcare organizations, interoperability services, smart contracts and access control, permissioned blockchain infrastructure, and off-chain storage repositories.

independent studies into a single conceptual model, providing a consolidated view of the design principles currently adopted

in blockchain-based EHR systems.

As illustrated in Fig. 2, healthcare organizations—including hospitals, clinics, laboratories, research centers, and patient applications—interact through an application layer responsible for interoperability and identity management. Communication among heterogeneous healthcare systems is supported by standardized interfaces, particularly RESTful APIs and HL7 FHIR services, enabling secure information exchange across institutional boundaries.

Security policies are implemented through a dedicated functional layer comprising smart contracts, consent management, authentication mechanisms, role-based and attribute-based access control, and audit policies. Together, these components regulate secure data sharing among authorized participants.

The permissioned blockchain network functions as the trust layer of the proposed reference architecture. Rather than storing complete Electronic Health Records, it maintains transaction metadata, cryptographic hashes, audit logs, and access records, ensuring integrity, traceability, and non-repudiation while minimizing storage requirements.

Complete Electronic Health Records remain stored in off-chain repositories, including hospital databases, cloud platforms, IPFS nodes, and dedicated EHR repositories. This hybrid storage model was consistently identified across the reviewed studies and summarizes the storage strategy adopted by most blockchain-based healthcare architectures.

To facilitate the interpretation of the traceability analysis, the primary studies included in the architectural synthesis were assigned identifiers (P1–P15), as shown in Table VII. These identifiers are subsequently used in Table VIII to indicate the studies supporting each architectural layer of the conceptual reference architecture.

To improve transparency in the derivation of the conceptual reference architecture, Table VIII presents the relationship between each architectural layer and the primary studies that reported at least one of its constituent components. Because each layer may comprise multiple architectural elements, the supporting studies do not necessarily report all components listed within a given layer. Only primary studies were considered in this mapping to avoid duplication of evidence from secondary reviews. The inclusion of an architectural layer in the reference model required evidence from one or more primary studies reporting the corresponding architectural components.

IV. Discussion

The comparative analysis of the primary studies revealed a convergence toward common architectural principles for blockchain-based Electronic Health Record (EHR) systems. Rather than operating as standalone solutions, blockchain platforms are increasingly integrated with interoperability services, distributed storage mechanisms, and security frameworks to support health information exchange [15]–[17].

Among the recurring patterns identified, permissioned blockchain platforms, particularly Hyperledger Fabric, were the most frequently reported technologies. Smart contracts, access control mechanisms, and audit capabilities were also consistently incorporated into the reviewed architectures, reflecting the need for governance, traceability, and controlled data sharing in healthcare environments [4], [5], [7], [9], [13].

The widespread adoption of hybrid storage architectures further indicates that blockchain is commonly employed as a coordination and verification layer, while complete Electronic Health Records remain stored in off-chain repositories. Similarly, interoperability emerged as a central architectural requirement, with HL7 FHIR and RESTful APIs representing the principal mechanisms for communication among heterogeneous healthcare systems [8], [9], [11], [12], [15], [16], [20].

Despite these recurring patterns, the available evidence remains largely based on architectural proposals, prototypes, and proof-of-concept implementations. The quality assessment indicated that relatively few studies reported implementation validation or performance evaluation, limiting conclusions regarding large-scale deployment and real-world effectiveness. Governance, regulatory compliance, interoperability across independent institutions, and long-term operational performance remain important research challenges [15]–[17].

The conceptual reference architecture synthesized in this review was derived from the recurring components identified across the primary studies and should be interpreted as a representation of patterns reported in the literature rather than as a validated implementation model. Furthermore, the review was restricted to studies published between 2021 and 2026 and to four scientific databases, which may have limited the inclusion of additional relevant studies.

V. Conclusion

This study presented a systematic literature review of blockchain-based architectures for Electronic Health Records (EHRs) published between 2021 and 2026. The analysis of the primary studies identified recurring architectural patterns, including the widespread adoption of permissioned blockchain platforms, smart contracts, interoperability services, and hybrid storage architectures.

Based on these findings, a conceptual reference architecture was synthesized to consolidate the principal functional components reported in the literature. Rather than representing a validated implementation, the proposed architecture summarizes the architectural patterns most frequently observed across blockchain-based EHR systems.

The main contributions of this review are the systematic comparison of blockchain-based EHR architectures, the identification of recurring architectural elements, and the synthesis of a conceptual reference architecture derived from evidence extracted from primary studies.

Although blockchain-based EHR research shows increasing architectural convergence, further empirical validation remains necessary, particularly regarding large-scale deployment, interoperability across healthcare institutions, governance, regulatory compliance, and real-world performance. The findings provide a consolidated reference for future research on secure and interoperable healthcare information systems.

***Resumo*—A Vigilância Epidemiológica do Sistema Único de Saúde (SUS) tem incorporado cada vez mais sistemas inteligentes para prevenção de surtos, porém a lacuna de transformação do monitoramento dos dados em canais de comunicação de forma direta e ágil com a população sob risco ainda persiste. Embora o Brasil utilize plataformas como o Infodengue, fundamentadas em modelagem preditivo-estatística, suas saídas permanecem centralizadas em painéis de análise para especialistas e restritas aos parâmetros climáticos como "gatilhos"epidemiológicos, não sendo a realidade de algumas cidades brasileiras. A arquitetura AlertaSUS, proposta neste artigo, expande esse escopo ao descentralizar o fluxo decisório por meio de alertas hiperlocais direcionados a microrregiões específicas, parametrizadas por modelos de *nowcasting* e *forecasting* (Infodengue), como também pela Lei Geral de Proteção de Dados (LGPD). A conformidade jurídica e a segurança dos dados são estruturadas sobre um protocolo de acoplamento cego (*blind join*) em polígonos de risco, indexados via Geohash, inviabilizando tentativas de reidentificação ou engenharia reversa de perfis clínicos individuais no território.**

***Index Terms*—SUS, epidemiologia, alertas, geohash.**

I. Introdução

No Brasil existem ferramentas de monitoramento epidemiológico, como o Infodengue da Fundação Oswaldo Cruz e da Faculdade Getúlio Vargas, que oferecem suporte analítico em âmbito municipal. Contudo, surtos recentes de dengue evidenciaram assimetrias espaciais e dinâmicas de transmissão que divergem dos padrões históricos, o que demanda flexibilização metodológica nos modelos vigentes, como integrar preditores adicionais não climáticos, para mitigar falhas de previsão em microescala. Ademais, o fluxo de comunicação do Infodengue envia alertas para especialistas previamente cadastrados e as informações da plataforma requer análise gráfica de dados. Outro fator analisado é que o alerta gerado pelo Infodengue mapeia o risco de forma agregada para o município, limitando o envio de alertas específicos para divisões intraurbanas menores, pois dentro do município existem áreas com infestação positiva para o vetor e outras não. Posto isso, o AlertaSUS surge em caráter complementar ao Infodengue, que é fundamental na orientação e emissão de alertas para as secretarias estaduais e municipais.

Além das diferenças espaciais observadas na dinâmica de transmissão, a relevância dos fatores epidemiológicos varia conforme a escala geográfica. Os maiores pesos de entropia foram associados ao sorotipo, ao *El Niño* e ao Índice de Gini no Brasil; o *El Niño*, Índice de Gini e turismo na Região Sul; o *El Niño*, sorotipo e precipitação no Ceará; e o *El Niño*, sorotipo e turismo em Fortaleza. Esses resultados sugerem que gatilhos epidemiológicos definidos em escala nacional ou estadual não devem ser necessariamente generalizados para escalas municipais ou intraurbanas. Essa heterogeneidade constitui uma das motivações para a adoção de gatilhos configuráveis regionalmente no AlertaSUS.

Este trabalho investiga a viabilidade técnica de uma arquitetura de comunicação hiperlocal, operando sob demanda e em múltiplos níveis de granularidade geográfica (bairro, rua, residênci), integrando dados dinâmicos de transmissão biológica e eventos epidemiológicos à estrutura do AlertaSUS. O modelo foi instanciado para o monitoramento de arboviroses, em complementaridade ao Infodengue, com ampliação dos tipos de alertas (manuais e automáticos) para indicadores exógenos (como fluxo populacional e sorotipos), sob validação final de um especialista. Ao estabelecer esse fluxo bidirecional, mitiga-se o *gap* de comunicação com o cidadão por meio de

mensagens diretas e estruturadas sob a segurança e privacidade dos dados. As plataformas de vigilância existentes são eficazes para monitorar a dinâmica de doenças, mas não oferecem disseminação proativa e centrada no cidadão, ao mesmo tempo em que atendem aos requisitos de privacidade derivados da LGPD. Essa lacuna motivou a arquitetura proposta, que integra mecanismos de preservação da privacidade, indexação espacial hiperlocal (uma integração de Geohash) e comunicação voltada ao cidadão, em uma estrutura unificada, projetada para complementar as infraestruturas de vigilância existentes.

II. Referencial Teórico

Sistemas de alerta epidemiológico com componente geoespacial existem em outros contextos internacionais. O *HealthMap* (*H*arvard) agrega dados abertos e mídias sociais para detecção de surtos globais, porém sem hiperlocalidade. O *Early Warning and Response System*(EWARS) da Organização Mundial da Saúde (OMS) opera em contextos de crise humanitária, sem comunicação direta ao cidadão. Nenhum desses sistemas combina (i) hiperlocalidade (ii) comunicação proativa ao cidadão, o que configura o diferencial arquitetural do AlertaSUS.

Infodengue é um sistema de alerta precoce por meio de monitoramento de transmissão de arbovírus (dengue, *chikungunya* e *zika*) e opera em todos os municípios. Visa antecipar alterações nos padrões de notificação de arbovírus, para que os profissionais de vigilância sejam informados rapidamente sobre os riscos de epidemias [1]. O sistema produz estimativas dos casos corrigindo atrasos de notificação e com diferentes fontes de informação. O sistema coleta dados, integra bases de dados, realiza a modelagem estatística (ciclo reprodutivo do vetor e clima) e gera alertas semanais. O sistema contempla casos notificados de dengue, dados climáticos, séries temporais e localização geográfica. O Infodengue considera fatores ambientais que influenciam o ciclo do mosquito como: temperatura média, umidade relativa e pressão atmosférica. Já as variáveis de transmissão, considera o Número Reprodutivo Efetivo (Rt), que representa quantas pessoas, em média, são infectadas por um caso existente, sendo considerada as seguintes classificações: tendência de redução da transmissão (Rt < 1); transmissão estável (Rt = 1) e crescimento da epidemia (Rt > 1) [2]. Utiliza a classificação de alertas em quatro níveis: verde (baixa transmissão), amarelo (condições favoráveis à transmissão), laranja (transmissão sustentada), vermelho (alta incidência / epidemia) [1]. Posto isso, com a integração dos sistemas, o Infodengue representa um importante aliado ao AlertaSUS.

Entre 2015 e 2024, o Brasil registrou surtos de dengue de forma atípica, que limitaram a aplicabilidade do Infodengue como único sistema de alerta: (i) o surto de 2015 no Ceará, precedido por seca severa e não por chuvas elevadas; (ii) o recorde de 2024 no Brasil, com menor precipitação anual histórica (1.480 mm); (iii) a introdução simultânea de quatro sorotipos em 2024 no Brasil, gerando reinfecções em massa independentemente das condições climáticas. Nesses cenários, fatores como o sorotipo circulante e o fluxo de pessoas, variáveis ausentes no Infodengue, foram determinantes para a explosão de casos, reforçando a necessidade de um sistema complementar com variáveis epidemiológicos locais configuráveis.

No AlertaSUS, os alertas criados pelos epidemiologistas, possibilitam uma flexibilização para análise de outros fatores (não somente climáticos). O sistema hiperlocal permite o envio de alertas direcionados, a partir de filtros por residência, rua ou bairro, pois cerca de 75% dos focos do vetor estão dentro das residências [3]. O controle e o monitoramento nesses focos são realizados pelos Agentes de Combate à Endemias (ACE), profissionais do SUS, por meio de inspeções, sendo oportuno utilizar o alerta com hiperlocalidade para áreas com focos positivados.

As epidemias de dengue têm várias causas, incluindo o aumento da temperatura e da chuva, saneamento inadequado, existência de criadouros domésticos, resistência do vetor aos inseticidas e a presença de quatro sorotipos circulando simultaneamente em países endêmicos, o que favorece a reinfecção [4]. Essas causas têm contribuído para uma maior incidência de dengue ao longo dos anos [5]. A partir da evolução dos casos prováveis de dengue no Brasil, mostra que praticamente nenhuma área está protegida contra a dengue [6]. Alterações climáticas e meteorológicas (temperatura, precipitação, umidade e *El Niño*) são fatores críticos que afetam a reprodução, a sobrevivência e a distribuição geográfica do vetor, influenciando na transmissão de patógenos *Aedes* [4]. Desta forma, a aplicação de modelos preditivos, a exemplo do Infodengue, viabiliza o monitoramento sistemático das variáveis climáticas.

Um fator primordial que transcende a modelagem computacional preditiva é a privacidade e segurança dos dados. A viabilidade operacional da arquitetura está condicionada à preservação da identidade dos usuários cadastrados, alinhada com a LGPD [7]. O risco de ataques de reidentificação geográfica é mitigado no AlertaSUS pela exclusão de chaves relacionais associadas à identificação civil dos usuários, pois a correlação entre os dados clínicos anonimizados de origem e o canal de notificação ocorre em um plano de segregação lógica pelo parâmetro denotado como $ID_{Espacial}$, que funciona como uma função de agregação poligonal indexada via estrutura de *Geohash*. O emparelhamento seguro de dados ocorre como uma operação de interseção conjuntista cega ou junção cega (*Blind Join*), expressa na Equação 1:

$$\mathcal{J}_{\text{cega}} = \{u \in \mathcal{U}_{msg} \mid \exists\, c \in \mathcal{C}_{epi} : f_{space}(u) = f_{space}(c) \wedge \mathcal{R}(c) > \gamma\} \tag{1}$$

A Equação 1 define a operação de junção cega, cujo objetivo é identificar o conjunto de usuários aptos a receber alertas sem a necessidade de compartilhamento de informações pessoais entre os domínios envolvidos. A operação baseia-se na correspondência do identificador espacial anonimizado e na verificação do nível de risco epidemiológico local. Na Equação 1:

- $\mathcal{J}_{\text{cega}}$ representa o conjunto resultante da operação de junção cega entre os usuários cadastrados e as notificações epidemiológicas;
- $\mathcal{U}_{msg}$ representa o conjunto de usuários cadastrados na plataforma, que autorizaram previamente o recebimento de alertas por meio do protocolo de consentimento explícito (*opt-in*);
- $\mathcal{C}_{epi}$ representa o conjunto de notificações epidemiológicas anonimizadas provenientes dos sistemas oficiais de vigilância;
- u corresponde a um usuário pertencente ao conjunto $\mathcal{U}_{msg}$;
- c representa uma notificação epidemiológica pertencente ao conjunto $\mathcal{C}_{epi}$;
- $f_{space}(\cdot)$ corresponde à função de mapeamento espacial responsável por transformar tanto os usuários quanto as notificações em um mesmo identificador geográfico anonimizado (por exemplo, um Geohash);
- $\mathcal{R}(c)$ representa a função de avaliação do risco epidemiológico associado à notificação; expressa a função de risco local ponderada em relação ao limiar epidemiológico crítico γ;
- γ representa o limiar mínimo de risco estabelecido para que um alerta seja disparado.

O conjunto $\mathcal{J}_{\text{cega}}$ é formado por todos os usuários u cadastrados para receber mensagens, para os quais existe pelo menos uma notificação epidemiológica c pertencente à mesma região espacial anonimizada e cujo risco epidemiológico seja superior ao limiar crítico γ. Desse modo, o fluxo de dados direcionado ao *gateway* de mensageria preserva o estado clínico individual, mitigando a superfície de exposição de dados sensíveis em conformidade com as diretrizes da LGPD.

III. Metodologia

Na pesquisa foi realizado um levantamento do número de casos de dengue e os fatores epidemiológicos por ano (*El Niño*, temperatura média, umidade relativa do ar, precipitação pluviométrica média, saneamento básico, Índice de Gini, sorotipos, densidade demográfica, taxa de incidência e fluxo de turista), no período de 2000 até 2025, por meio do acesso aos seguintes sistemas:

(a) Casos prováveis de dengue: Portal de Dados Abertos do SUS [6];
(b) Variáveis climáticas: Inmet [8];
(c) Saneamento básico: Sistema Nacional de Informações sobre Saneamento (SNIS) [9];
(d) Condições socioeconômicas: Instituto Brasileiro de Geografia e Estatística (IBGE) e o Instituto de Pesquisa Econômica Aplicada (IPEA) [10];
(e) *El Niño*: utilizada a métrica *Index* ONI (*Oceanic Niño Index*), fornecida pela Administração Oceanográfica e Atmosférica Nacional dos EUA - NOAA), que mede a anomalia da temperatura da superfície do mar na região do Pacífico Equatorial [11];
(f) Sorotipos: histórico do comportamento e surgimento dos sorotipos no Brasil, baseado nos dados de vigilância genômica e isolamento viral da Fiocruz e do Ministério da Saúde [12];
(g) Densidade demográfica: a evolução estimada ano a ano é baseada nos Censos de 2000, 2010, 2022 e nas projeções intercensitárias oficiais do IBGE [13];
(h) Índice de Turismo (internacional e inter-regionais): Anuário Estatístico de Turismo, gerado pelo Ministério do Turismo (MTur) [14];

As metodologias empregadas no Infodengue são a *Nowcasting*, com modelos *bayesianos* para estimar casos que provavelmente já ocorreram, mesmo não oficialmente registrados, como também o cálculo semanal do Rt para verificar a situação da transmissão.

O mecanismo de k-anonimidade espacial foi configurado com k = 5, de modo que uma célula geográfica somente permanece na granularidade original quando contém pelo menos cinco usuários. Para a indexação espacial foi utilizado Geohash com precisão de sete caracteres, (aprox. 150 x 150 metros), com remoção progressiva de caracteres para 6 ou menos) sempre que o volume populacional na célula é inferior a k. Então, quando o número de usuários na célula é inferior ao limiar k, a célula é generalizada para o nível imediatamente superior, reduzindo a resolução espacial e o risco de singularidade. Na prática do *Geohash*, generalização por k-anonimidade (6 caracteres - ex: 7h4v2y), remove o último caractere, a área expande e isso engloba uma vizinhança maior, garantindo que existam pelo menos k pessoas (5 ou mais) naquela mesma célula e impedindo a reidentificação individual dos cidadãos, cumprindo as exigências da LGPD.

Para o levantamento, tratamento de dados, cálculo e testes estatísticos, foi utilizada a linguagem de programação *Python* e o editor de código-fonte *Visual Studio Code*.

A. Ferramentas estatísticas

A metodologia proposta combina o Método dos Pesos de Entropia (*EWM - Entropy Weight Method*) para avaliar a dispersão da informação interna das variáveis explicativas com o Coeficiente de Correlação de Postos de Spearman para identificar a direção e força da relação com a variável alvo. O processamento computacional dos fatores epidemiológicos adota uma abordagem combinada para mitigar vieses de escala e capturar interações não lineares. Inicialmente, para equalizar as grandezas das variáveis ambientais e socioeconômicas, aplica-se a transformação Min-Max, mapeando os valores observados no intervalo $[0, 1]$, conforme a Equação 2:

$$x'_{ij} = \frac{x_{ij} - \min(x_j)}{\max(x_j) - \min(x_j)} + \epsilon \tag{2}$$

Posteriormente, a mensuração do grau de ordenação fundamenta-se na Entropia de Shannon, que mede o grau de ordenação ou aleatoriedade dos dados, com n = 26 anos (período de 2000 até 2025), por meio da Equação 3:

$$e_j = -\frac{1}{\ln(n)} \sum_{i=1}^{n} p_{ij} \ln(p_{ij}) \tag{3}$$

O gradiente de divergência mapeia a utilidade intrínseca da informação. Quanto maior a divergência (1 - ej), maior o peso final da variável.Onde m é o número total de variáveis explicativas (m = 9). Equação 4:

$$d_j = 1 - e_j, \quad w_j = \frac{d_j}{\sum_{j=1}^{m} d_j} \tag{4}$$

A entropia avalia apenas a estrutura interna da variável, sendo necessária a correlação de Spearman ρ para capturar associações, lineares ou não com o total de casos de dengue no Brasil. O sinal do coeficiente determina a classificação final, com "Aumento (+)"ou "Redução (-)", conforme Equação 5:

$$\rho = 1 - \frac{6 \sum_{i=1}^{n} d_i^2}{n(n^2 - 1)} \tag{5}$$

O EWM é fundamentado na Teoria da Informação de Shannon e esse indicador atribui maior peso às variáveis com maior variabilidade e menor redundância [15]. Complementarmente, foi empregado o coeficiente de correlação para avaliar a direção e a intensidade da associação entre cada variável e os casos de dengue na região selecionada, indicando relações positivas quando ambas variam no mesmo sentido e negativas quando variam em sentidos opostos [16].

A detecção de multicolinearidade também foi realizado no estudo das variáveis, para corrigir problemas quando o modelo não consegue separar o impacto individual de uma variável sobre a variável alvo, gerando intepretações equivocadas e distorção das Entropias, com as variáveis colineares funciona como um "voto duplo". A detecção foi realizada por meio do Fator de Inflação da Variância (*Variance Inflation Factor* - VIF), que é a métrica que calcula o quanto a variância de um coeficiente está inflada devido à colinearidade com os outros preditores, conforme Equação 6. Para a classificação do valor de VIF, adotou-se o critério sugerido por Hair et al. (2019) e Montgomery et al. (2021): nenhuma correlação (VIF=1); colinearidade moderada (VIF> 5) e multicolinearidade crítica (VIF> 10).

$$\text{VIF}_j = \frac{1}{1 - R_j^2} \tag{6}$$

B. Riscos epidemiológicos e limitações metodológicas

Foram identificados três potenciais riscos metodológicos inerentes ao estud: (i) agregação espaço-temporal anual e consequente viés ecológico; (ii) a dependência temporal e a sazonalidade das séries epidemiológicas; e (iii) a possibilidade de correlações espúrias decorrentes de tendências temporais comuns e da multicolinearidade entre variáveis explicativas.

O primeiro risco está relacionado à utilização de dados agregados em escala anual, o que pode reduzir a capacidade de representar adequadamente a dinâmica temporal da transmissão da dengue, pois a biologia do vetor (*Aedes aegypti)* responde à variações semanais ou mensais e assim perde-se o sinal dos picos de transmissão na escala anual. Entretanto, a utilização de dados anuais teve caráter apenas exploratório, para uma prévia visualização do comportamento dos fatores epidemiológicos em diferentes regiões do país e esse risco é mitigado pela integração do AlertaSUS ao Infodengue, cuja base de dados é estruturada por semana epidemiológica, permitindo capturar com maior a variabilidade espaço-temporal da transmissão.

O segundo risco decorre da estrutura temporal das séries epidemiológicas e climáticas, que violam a independência entre observações. A dengue apresenta forte sazonalidade, além de elevada autocorrelação temporal, pois está intimamente relacionado ao comportamento epidemiológico dos períodos anteriores. Esse padrão pode ser explicado pela circulação viral, pelas condições ambientais favoráveis à proliferação do vetor e pela dinâmica de imunidade populacional, fatores que conferem memória temporal às séries analisadas. Como forma de mitigação, o modelo prevê a participação de epidemiologistas na emissão de alertas, permitindo a incorporação de conhecimento contextual e a validação dos resultados no sistema.

O terceiro risco está associado à correlações espúrias entre variáveis. Tanto o cálculo da Entropia da Informação quanto o coeficiente de correlação de Spearman não consideram explicitamente estruturas de defasagem temporal (*lags*), podendo atribuir elevada relevância estatística a variáveis que compartilham apenas uma tendência temporal comum, sem necessariamente apresentarem relação causal. Para mitigar essa limitação, adotou-se um protocolo de filtragem parametrizado via VIF com limiar de corte (VIF > 5). Sob esse critério, foram descartadas da regressão subsequente as variáveis que exibiram multicolinearidade crítica: Densidade Demográfica, Cobertura de Abastecimento de Água e o Índice de Gini. Adicionalmente, as variáveis Umidade Relativa do Ar e Precipitação Pluviométrica foram tratadas de forma mutuamente exclusiva, retendo-se apenas a precipitação como preditor dinâmico do modelo em virtude de sua menor inflação de variância residual (VIF $< 3,1$). Dessa forma, o conjunto final de preditores restringiu-se às variáveis não redundantes: Temperatura Média, Intensidade do *El Niño* e Sorotipo Viral Predominante.

C. Estrutura de privacidade AlertaSUS

A estrutura proposta para privacidade do AlertaSUS é baseado na técnica de Segregação Lógica de Responsabilidades com Acoplamento Cego via Pseudonimização Espacial. O sistema opera a partir de duas bases de dados isoladas logicamente: base epidemiológica e a base de comunicação. A base epidemiológica é submetida a algoritmos de k-anonimidade espacial, com as coordenadas de geolocalização dos pacientes indexados por um identificador geográfico (ID_Espacial), o que promove a mitigação de risco. Já a base de comunicação gerencia dados identificáveis de contato do cidadão, coletados via consentimento livre (*opt-in*). O anonimato clínico em todo processo reduz o risco de operadores humanos da plataforma ou *gateways* terceiros de mensageria instantânea estabeleçam correlações causais entre a identidade do cidadão notificado e o vetor de infecção local. Com base nesse cenário, a Figura 1

apresenta a arquitetura de dados AlertaSUS, por meio de um diagrama de blocos e dividida em camadas funcionais.

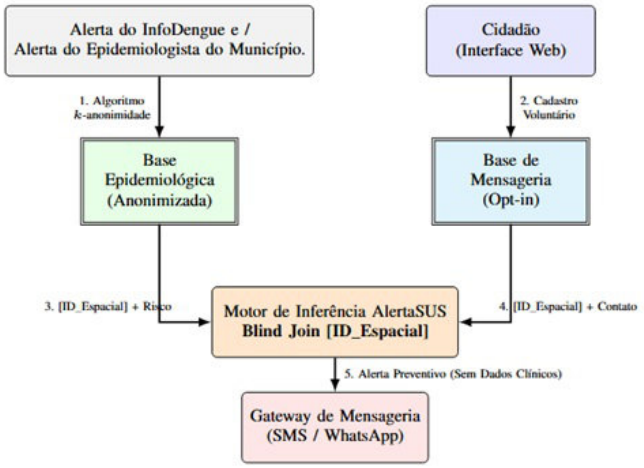

Figura 1. Diagrama de Arquitetura de Dados do AlertaSUS: segregação lógica de bases e acoplamento cego via ponte espacial (*Spatial Bridge*)

O diagrama de blocos proposto operacionaliza o fluxo de informações do sistema AlertaSUS, dividindo-o em quatro camadas interdependentes, porém isoladas logicamente:

(i) Camada Fontes de Dados (*Input Layer)*: é a entrada do sistema, com duas fontes de naturezas distintas, que operam de forma assíncrona. O Fluxo Epidemiológico é composto por alertas automáticos orinundos do Infodengue e alertas manuais emitidos pelos epidemiologistas dos municípios. Antes de ingressar no banco do AlertaSUS, esses dados passam pelo Filtro de k-Anonimidade Espacial. O endereço linear do paciente é descartado na origem e transformado em um código de área (ex: *Geohash*). Se o número de residentes nessa área for menor que o limiar k, a célula é generalizada para um nível macro, impedindo que o paciente seja identificado por exclusão geográfica. O bloco Cidadão e o Fluxo de Consentimento é a interface pública onde o cidadão interage voluntariamente com o sistema, por meio do fluxo de *opt-in*, o usuário fornece seu contato (telefone, *e-mail*, endereço).

(ii) Camada de Persistência Segregada: o AlertaSUS utiliza duas bases logicamente isoladas, uma Base Epidemiológica Anonimizada que contém apenas registros tabulares contendo a série temporal de casos, variáveis epidemiológicas e o ID_Espacial, não contemplando chaves primárias que remetam a indivíduos. A Base de Mensageria (*Opt-in*), que contém os dados de contato dos usuários, pareados unicamente com o ID_Espacial escolhido, ignora qualquer dado clínico.

(iii) Camada de Processamento: O ID_Espacial como Ponte é o motor de inferência do AlertaSUS e atua no centro do diagrama, executando a Junção Cega (*Blind Join*). O motor de agentes varre a Base Epidemiológica e calcula se o volume de casos ou variáveis epidemiológicas que viola os limiares de segurança estatística. Para um cenário de risco em uma célula (ex: ID_Espacial= geo_7b2a), o motor emite uma instrução de disparo restrita a esse *token* geográfico. O motor realiza a intersecção matemática, busca na base de mensageria quais os contatos estão vinculados à *string* geo_7b2a. A quebra do vínculo causal é por meio do cruzamento puramente topológico. O sistema emparelha um "índice de risco territorial"com uma "lista de usuários do território". O motor funciona sob o princípio Segregação Lógica de Responsabilidades com Acoplamento Cego via Pseudonimização Espacial, com ação preditiva sem que cruze a identificação da pessoa doente com o destinatário da mensagem.

(iv) Camada de Saída: o *gateway* de mensageria centraliza o disparo de mensagens via *e-mail* e redes sociais. Como o tráfego de dados processado pelo motor de inferência envia apenas o contato e o texto de prevenção ("Atenção: sua região registrou aumento de casos de dengue."), nenhuma informação médica trafega por redes terceirizadas, fortalecendo o sistema contra vazamentos de dados sensíveis.

D. Avaliação Quantitativa da Privacidade e Hiperlocalidade

Foram implementadas quatro métricas para quantificar o grau de privacidade:

(i) Número médio de usuários por célula;

$$R_s = \frac{C_{n<k}}{C_{\text{total}}} \tag{7}$$

(ii) Percentual de células generalizadas;

$$P_{gen} = \frac{C_{gen}}{C_{\text{total}}} \times 100 \tag{8}$$

(iii) Perda de resolução espacial, com comparação entre a resolução original com a resolução após generalização.

$$\bar{n} = \frac{1}{C} \sum_{i=1}^{C} n_i \tag{9}$$

Conforme apresentado na Equação 7, o risco de singularidade é calculado pela proporção de células com população inferior ao parâmetro k.A proporção de células generalizadas é calculada conforme a Equação 8.O risco pós generalização é calculada conforme a Equação 9.

Com base nas simulações de densidade populacional e nos parâmetros de k-anonimidade e precisão de Geohash adotados no estudo, foi simulado para regiões de menor densidade e preenchidos na Tabela I.

Para Geohash 5 (aprox. 4,9 km x 4,9 km) há uma baixíssima generalização, pois agrupa grandes blocos populacionais, garantindo alta média de usuários por célula, porém sacrificando a hiperlocalidade (rua/bairro).Caso da Geohash 6 (aprox. 1,2 km por 0,6 km) equilibra o dimensionamento de bairros, onde o aumento de k de 3 para 10 eleva expressivamente a necessidade de generalização (aprox. 12,4 % para 45,6%). Já a Precisão de Geohash 7 (aprox. 150 m por 150 m -

Tabela I
ANÁLISE DE SENSIBILIDADE DA PRECISÃO ESPACIAL E DO PARÂMETRO k.

Geohash	k	Células generalizadas (%)	Usuários/célula
5	3	4,20%	42,6
5	5	8,50%	42,6
5	10	18,10%	42,6
6	3	12,40%	11,2
6	5	24,80%	11,2
6	10	45,60%	11,2
7	3	31,50%	3,8
7	5	58,20%	3,8
7	10	81,90%	3,8

adotada no protótipo), garante a resolução hiperlocal (micro-quadra/residência), mas sofre maior impacto em áreas de baixa densidade, exigindo que células com menos de k usuários sejam generalizadas (alcançando $58,2\%$ de generalização para $k = 5$).

IV. RESULTADOS

A pesquisa envolveu a mensuração fatores epidemiológicos associados ao número de casos prováveis de dengue no Brasil, baseada no conceito de Entropia da Informação de Shannon e os Coeficiente de Correlação de Postos de Spearman, no período de 2000 até 2025. A análise dos dados foi especificamente para o Brasil e Regiões (Norte, Sul, Nordeste, Sudeste, Centro-Oeste), Ceará e Fortaleza, sendo apresentadas no artigo apenas as matrizes que mostraram maior divergência, por limitação de espaço. A Figura 2 e 3 apresentam os resultados da Matriz de pesos de entropia e coeficiente de correlação do Brasil e da Região Sul, como também do Estado do Ceará e Município de Fortaleza.

Figura 3. Matriz de pesos de entropia e coeficiente de correlação do Ceará e de Fortaleza.

A precipitação pluviométrica demonstrou não linearidade em relação aos surtos históricos, pois os maiores índices de dengue no país foram registradas em anos com baixo índice de chuva, a exemplo do recorde histórico de 2024 (1.480 mm). Essa relação paradoxal é explicada pela mudança comportamental da população durante períodos de estiagem, forçando o armazenamento improvisado de água e multiplicando criadouros artificiais [3].

A umidade relativa do ar, embora mantendo médias anuais elevadas e favoráveis em âmbito nacional (acima de 74%), não demonstrou correlação linear com as grandes explosões nacionais de casos, sugerindo que o limiar térmico e criadouros artificiais exercem maior dominância na transmissão.

O *El Niño* opera de forma heterogênea nas regiões do país, pois enquanto no Norte e Nordeste induz secas severas, com aumento de armazenamento de água inadequado, no Sul e Sudeste induz tempestades que geram acúmulo de água em áreas abertas e também anomalias térmicas que aceleram o período de incubação extrínseca do vírus.

Do ponto de vista socioeconômico e estrutural, indicadores como saneamento básico (abastecimento de água) e desigualdade de renda (Índice de Gini) revelaram limitações quando agregados na escala nacional. Apesar da expansão gradativa da rede de água (84,9%) [17], o volume de casos continuou elevado, o que reflete a dominância das anomalias climáticas sobre os avanços sociais, saneamento precário, densidade demográfica assimétrica, que são suavizadas em análises globais. [18], [19].

O sorotipo predominante revelou-se o fator de maior entropia nos picos de transmissão. A introdução de um sorotipo suscetível em uma população previamente imunizada para outras cepas rege o comportamento epidêmico do país, sobrepondo-se temporariamente às condições ambientais. Esse comportamento é catalisado pelo fluxo turístico, sendo o principal vetor de dispersão do patógeno, acelerando a introdução de novos genótipos. [20].

Nas Figuras 2 e 3, foi calculado o VIF, que funciona como um "indicador de redundância". Para o Brasil, as variáveis de densidade, índice Gini e abastecimento de água exibiram

VIF elevados (VIF $>$ 10), pois a população e a cobertura de água cresceram de forma gradativa, enquanto a pobreza e a desigualdade caíram. As variáveis precipitação e umidade são interligadas, com VIF alto, porque anos com muita chuva são anos com médias altas de umidade. Nas Figuras 4 e 5 apresentam os resultados da detecção da multicolinearidade dos dados epidemiológicos para o Brasil, Região Sul, estado do Ceará e para Fortaleza. Apesar do estudo ter avaliado as demais regiões do país, por limitação de espaço não foram apresentadas as demais tabelas.

Após removidas as variáveis com VIF acima de 5, foi aplicado o teste de significância estatística, que o indicador é o p-valor, que sugere o quão confiável é a relação entre duas variáveis. Dessa forma, avalia-se a correlação de alguns fatores epidemiológicos com o número de casos de dengue para confirmar se correlação não é apenas um ruído estatístico.

Figura 5. Comparativo de Multicolinearidade das região Sul e o Município de Fortaleza

Analisando a matriz de pesos do Brasil, a temperatura tem relevância estatística para prever casos de dengue mesmo quando controlada por outros fatores (P> [t] = 0,007). O seu R-quadrado é de 0,398, o que demonstra que um modelo linear simples, utilizando apenas três variáveis, consegue explicar 39,8% de toda a variação histórica dos casos de dengue no Brasil entre 2000 e 2025. Para um modelo epidemiológico de escala nacional, anual e puramente ecológico, os outros 60% refletem fatores locais que o modelo macro não capta, como imunidade de rebanho para sorotipos específicos, índices municipais de infestação predial. Embora o fluxo de pessoas seja importante para a introdução de novos sorotipos, a variação volumétrica anual de casos no país como um todo é governada por fatores ambientais e vetoriais, e não pela flutuação de turistas, porém essa realidade nacional não se reproduz em outras regiões do Brasil, como por exemplo na região nordeste.

Na região Sul, o teste de significância mostrou que a dengue é um fenômeno quase puramente governado pelo clima. Enquanto no modelo nacional o R-quadrado foi de 40%, no Sul ele saltou para 66,6%. O Sul do Brasil é historicamente uma região de "fronteira ecológica"para o *Aedes aegypti* devido aos invernos intensos. A temperatura média anual e a precipitação acumulada atuaram como os preditores positivos dominantes. Ao contrário do Nordeste, onde o mosquito sobrevive o ano todo e a dinâmica depende mais de fatores sociais.

Diferente do resultado da Região Sul, em Fortaleza não apresentou preditores estatisticamente significantes. Esse resultado evidencia o contraste socioecológico da dinâmica de transmissão do vírus nas duas regiões. Enquanto no Sul o clima é um preditor determinante, a capital cearense apresenta estabilidade térmica perene em patamares ideais para o ciclo biológico do *Aedes aegypti* . Assim, a variabilidade climática macro-anual perde poder explicativo direto no modelo global. A dinâmica de transmissão da dengue em Fortaleza é complexa, multifatorial e não-linear, pois um aumento na temperatura não gera um aumento linear nos casos e variáveis como temperatura, umidade e chuva em Fortaleza são colineares. Este resultado prova que modelos tradicionais de regressão linear global são insuficientes para o monitoramento municipal, justificando a necessidade de arquitetura capaz de lidar com regras de decisão locais, interações não-lineares e comportamentos adaptativos, considerando todos os fatores epidemiológicos.

Os pesos de entropia calculados ajudam na configuração dos gatilhos no AlertaSUS. Em Fortaleza, onde *El Niño*(wj = 0,2949) e sorotipo (wj = 0,2283), o epidemiologista priorizaria alertas manuais. Na Região Sul,com temperatura (wj = 0,0832) e precipitação (wj = 0,0689), o sistema é configurado com gatilhos automáticos (Infodengue). A Figura 6 apresenta a Tela *Dashboards* de alertas.

Figura 6. Tela de Aprovação de Alertas.

Para avaliar a estabilidade do AlertaSUS, testou-se o comportamento do sistema variando o γ em uma faixa de $\pm 20\%$, para medir o impacto dessas oscilações no tempo de resposta e no surgimento de falsos alarmes. Os testes mostraram que o protocolo de acoplamento cego se manteve estável dentro desse intervalo e reduções severas em γ causam um disparo excessivo de mensagens, sem benefício algum. Por outro lado,

elevar demais o limiar atrasa o envio dos alertas. O ponto de equilíbrio ideal foi definido com Rt locais ($Rt \approx 1,2$), o que evitou alertas desnecessários e garantiu a precisão geográfica dos disparos.

Os testes realizados no protótipo confirmaram que a base epidemiológica fica anonimizada por blocos espaciais de k-anonimidade e o sistema apenas cruza o ID espacial do risco com os assinantes daquela célula espacial, assegurando que o fluxo de dados desconheça a condição clínica individual dos cidadãos localizados na célula geográfica afetada.

V. Conclusão

A previsão de surtos baseada apenas em variáveis climáticas possui limitações, pois em 2002 a temperatura e a chuva foram moderadas e houve uma explosão de casos no Brasil com a introdução do DENV-3 [21], como também entre 2013 e 2016 concentrou o maior fluxo de pessoas no país (Olimpíadas e Copa), o que facilitou a circulação de novos sorotipos no país. Então para minimizar as lacunas identificadas para alguns fatores epidemiológicos nos modelos preditivos atuais, o AlertaSUS incorpora a validação ativa do epidemiologista no fluxo de decisão e disparo de alertas.

A arquitetura do AlertaSUS possui um diferencial em não cruzar dados de saúde por meio de chaves diretas. Faz-se por meio de uma ponte espacial transparente (ID_Espacial), que se encontram apenas por meio do *hash* geográfico agregado, que desvincula os dados do usuário dos dados de saúde.

Este estudo apresenta algumas limitações, pois a arquitetura proposta precisa ser avaliada em secretarias de saúde, principalmente em relação ao desempenho, condições operacionais de larga escala, a integração com infraestruturas de saúde pública e a aplicabilidade do mecanismo de k-anonimidade espacial em municípios de pequeno porte, onde a densidade demográfica por célula geográfica pode ser insuficiente para garantir o limiar k configurado, exigindo generalização para células de maior área ou mecanismos alternativos de privacidade diferencial. Cabe delimitar que a validação é de natureza arquitetural e funcional, pois o fluxo de criação, aprovação e envio de alertas, e a integração com o Infodengue foi testada em ambiente de desenvolvimento.

A perspectiva é dar continuidade a esse projeto, contemplando as seguintes melhorias no AlertaSUS: conectar com outros modelos preditivos; integrar com as Ovitrampas (armadilhas de monitoramento do *Aedes aegypti*); comunicação bidirecional com Inteligência Artificial; conectar com os boletins do SUS; ampliar o rol de alertas; conectar com outras redes digitais da saúde; realizar projeto piloto em âmbito municipal.

Abstract*—This study aimed to systematically review the evidence on AI-enabled and digital health technologies supporting individuals with autism spectrum disorder (ASD), their caregivers, and families. The review was reported according to PRISMA 2020 and prospectively registered in PROSPERO (No. 1166432). Databases were searched from April to June 2026 using controlled vocabulary and keywords related to ASD, artificial intelligence, chatbots, caregivers, and digital support. Risk of bias was assessed using the Cochrane RoB 2 tool for the randomized studies, QUADAS-2 for the diagnostic accuracy study, and the CASP Qualitative Checklist for the qualitative study. Of 90 records identified across four databases, 15 were assessed at full text and 5 met the eligibility criteria; among the 10 full-text exclusions, one was removed owing to a post-publication retraction on integrity grounds. The included studies addressed ChatGPT-delivered physical activity support, mobile app-assisted parent training, an AI-based diagnostic device integrated into primary care, caregiver perspectives on an AI-assistive device supporting daily functioning, and an educational application of AI framed from a public-health perspective. Preliminary evidence suggests feasibility, acceptability, and potential gains in engagement, knowledge acquisition, diagnostic workflow efficiency, and caregiver-perceived support for adaptive functioning; however, clinical effectiveness remains uncertain due to methodological heterogeneity, small samples, and limited external validation. Future studies should adopt standardized outcomes, larger samples, and longer follow-up to move beyond feasibility toward clinical effectiveness.

***Keywords*—autism spectrum disorder; artificial intelligence; digital health; chatbots; caregivers; assistive technology; systematic review**

I. Introduction

Autism spectrum disorder (ASD) is a neurodevelopmental condition characterized by persistent deficits in social communication and interaction, together with restricted and repetitive patterns of behavior. Recent estimates from the Autism and Developmental Disabilities Monitoring Network of the United States Centers for Disease Control and Prevention indicate a prevalence of approximately 1 in 31 children aged 8 years [1], following an upward trend over recent decades. Care for people with ASD imposes substantial demands on caregivers and families, frequently associated with emotional burden, difficulty accessing reliable information, diagnostic delay, and gaps in continuous support from health services.

These access barriers, along with the need for guidance available outside service hours, represent a relevant problem for biomedical engineering, as they call for technological support solutions that are usable, safe, and integrable into the clinical workflow. In this context, digital technologies have been proposed as tools to support care. It is important, however, to distinguish categories often treated as equivalent: generative AI systems and chatbots based on large language models; AI-based diagnostic support devices; digital health (mHealth) applications without explicit AI; and AI-assistive devices designed to support adaptive functioning in daily activities. Not every digital technology incorporates AI, and this conceptual delimitation is necessary to properly appraise the evidence. Such technologies have been proposed for offering continuous availability, personalization of interactions, and the potential to broaden access to information and support [2]-[5].

Accordingly, this systematic review seeks to answer the following question: what is the evidence on the feasibility, acceptability, and outcomes of AI-enabled and digital health

technologies in supporting individuals with ASD, caregivers, and families? The objective is to map and critically appraise this evidence, with attention to the distinction between technology types and to the methodological quality of the studies.

II. Methods

A. Protocol and registration

This systematic review was reported in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 statement [7] and was prospectively registered in the PROSPERO database under number 1166432.

The review question and inclusion criteria were structured using the PICOS framework. Population: individuals with ASD, their caregivers and families. Intervention/exposure: AI-enabled or digital health technologies, such as chatbots, virtual assistants, mobile applications, and diagnostic support devices. Comparator: usual care, no intervention, or pre-post comparison, where applicable. Outcomes: feasibility, acceptability, usability, engagement, knowledge acquisition, emotional support, time to diagnosis, and clinical effectiveness. Study designs: randomized controlled trials, pilot studies, and observational studies.

B. Search strategy

From April to June 2026, the literature search was conducted in the PubMed electronic databases (US National Library of Medicine), Scopus, Web of Science, and IEEE Xplore. The search strategy combined controlled descriptors (MeSH) and keywords using Boolean operators (AND/OR), restricted to studies published within the last five years. The five-year window is justified by the recent emergence of generative AI and large language models in health care, a field whose expressive growth occurred within this period. The State of the Art through Systematic Review (StArt) software supported the organization of the procedures. The entire process is reported through the PRISMA flow diagram (Fig. 1).

The MeSH descriptors and keywords were: *("Autism Spectrum Disorder" OR ASD) AND ("Artificial Intelligence" OR chatbot OR "virtual assistant" OR "digital support") AND ("Caregivers" OR Family OR "Mental Health" OR "Social Support")*.

C. Selection, extraction, and eligibility

Records were imported into StArt, with automatic removal of duplicates, followed by title and abstract screening and full-text reading of the remaining articles. Explicit exclusion criteria were defined: studies not employing AI or digital technologies in the ASD context; studies without empirical data, such as editorials, commentaries, and reviews; studies not involving individuals with ASD, caregivers, or families; and studies of low methodological quality. Extracted outcomes covered usability, acceptability, engagement, emotional support, knowledge acquisition, time to diagnosis, adverse events, and clinical effectiveness. Screening and study selection were conducted independently by two reviewers, following the protocol previously registered in PROSPERO, with a third reviewer available to resolve any disagreements. The two reviewers reached full agreement on all eligibility decisions at the full-text stage, so no third-reviewer adjudication was required.

D. Methodological quality assessment

Risk of bias in the included studies was assessed independently by two reviewers using the Cochrane Risk of Bias tool, version 2 (RoB 2) [8] for the two randomized controlled trials, the Quality Assessment of Diagnostic Accuracy Studies 2 (QUADAS-2) [9] for the diagnostic accuracy study, and the Critical Appraisal Skills Programme (CASP) Qualitative Checklist [10] for the qualitative study, in line with reviewer feedback that PEDro and an adapted Newcastle-Ottawa Scale do not adequately capture the specific risks of an AI-based diagnostic device. RoB 2 judgments were made at the domain level (randomization process; deviations from intended interventions; missing outcome data; measurement of the outcome; selection of the reported result), each rated as low risk, some concerns, or high risk, with an overall judgment derived from the highest level of concern across domains. QUADAS-2 judgments were likewise made at the domain level (patient selection; index test; reference standard; flow and timing). The CASP Qualitative Checklist appraises 10 domains covering the clarity of aims, the appropriateness of the qualitative methodology and research design, recruitment and data collection, the researcher-participant relationship, ethical considerations, rigor of data analysis, clarity of findings, and the value of the research, with an overall judgment of low, some, or high concern derived from the pattern of responses across domains.

III. Results

A. Study selection and quality

In the identification stage, 87 records were retrieved from PubMed, Scopus, Web of Science, and IEEE Xplore; an updated search subsequently added 3 further candidate records, yielding 90 records overall. After title and abstract screening, 15 studies were considered potentially relevant and selected for full-text reading. At this stage, 9 studies were excluded because they did not address the use of AI or digital technologies to support people with ASD, caregivers, or families, and one further candidate record was excluded after a post-publication retraction on integrity grounds, the retraction note citing an inadequately described framework, an AI-generated figure, undisclosed absence of code, and unverifiable datasets [15]. Ultimately, 5 studies met all criteria, including minimum methodological quality, and were included in the qualitative synthesis [2]-[6].

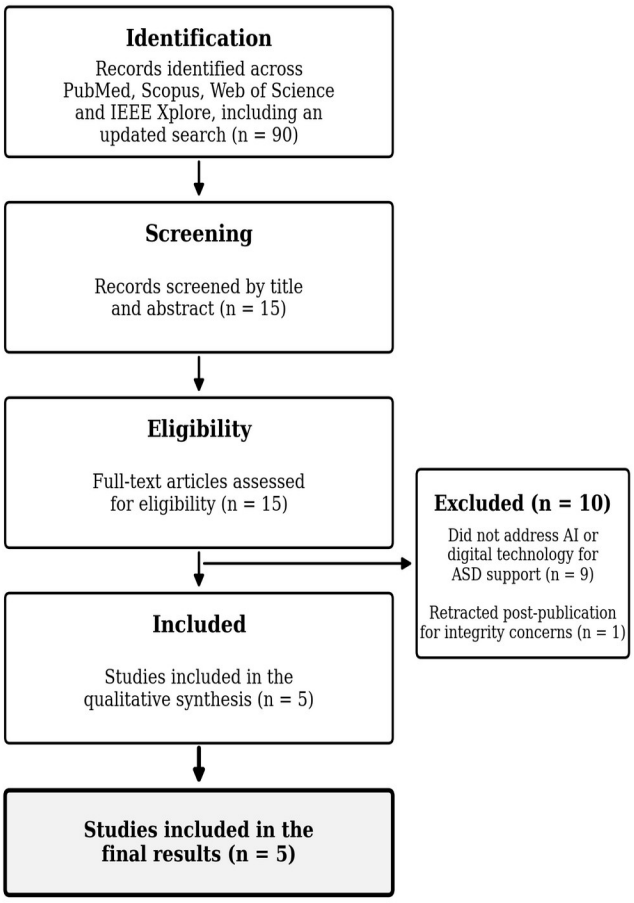

Fig. 1. PRISMA flow diagram of the identification, screening, and inclusion of studies.

The risk-of-bias and quality appraisal of the included studies is shown in Tables I-III. Both randomized controlled trials [2], [3] were judged at overall high risk of bias under RoB 2, chiefly due to unblinded, self-reported outcomes and, for Lee et al. [3], substantial and differential attrition. The diagnostic accuracy study [4] was likewise judged at overall high risk of bias under QUADAS-2, driven by an undisclosed potential conflict of interest in the index-test domain (co-authorship by employees of the device manufacturer) and by incorporation bias in the reference-standard domain, since the final clinical diagnosis was made with knowledge of the device output. The qualitative study [5] was judged at overall some concerns under the CASP Qualitative Checklist: aims, methodology, design, ethical conduct, and analytical rigor (independent second coding, saturation, audit trail) were appropriate, but recruitment drew on a clinic-based, industry-partnered sample skewed toward the more severe range of the spectrum and toward early technology adopters, and data completeness may have been affected by the AI device's own responsiveness problems during data collection.

TABLE I. Risk-of-bias assessment of the randomized controlled trials (Cochrane RoB 2, domain-level judgments).

RoB 2 domain	Aydemir (2025) [2]	Lee et al. (2024) [3]
D1. Randomization process	Some concerns (random allocation stated; sequence generation and allocation concealment not described)	Low risk (independent third-party computer-generated stratified block randomization, block size 4)
D2. Deviations from intended interventions	Some concerns (unblinded parent-delivered intervention; analysis approach for missing implementation not detailed)	Some concerns (open-label; primary analysis per-protocol rather than intention-to-treat)
D3. Missing outcome data	Low risk (no dropouts reported; all 26 dyads completed the study)	High risk (25% overall attrition post-randomization, higher in the intervention arm: 8/28 vs 3/28)
D4. Measurement of the outcome	High risk (self-reported outcome; parents aware of intervention status)	High risk (parent-reported primary outcome; open-label, unblinded assessment)
D5. Selection of the reported result	Some concerns (no prospective trial registration identified)	Low risk (prospectively registered, CRIS KCT0007841; pre-specified outcomes fully reported)
Overall judgment	High risk	High risk

Abbreviations: RoB 2 = Cochrane Risk of Bias tool, version 2.

TABLE II. Risk-of-bias assessment of the diagnostic accuracy study (QUADAS-2, domain-level judgments).

QUADAS-2 domain	Sohl et al. (2025) [4]
Patient selection	Some concerns (real-world sample drawn only from primary care clinics enrolled in the ECHO Autism: EDx training program, which may not represent general primary care settings)
Index test (AI diagnostic device)	High risk (3 of 10 co-authors are employees of Cognoa Inc, the manufacturer of the evaluated device; independent, blinded interpretation of device output not described)
Reference standard	High risk (final clinical diagnosis was made with knowledge of the device output, which the workflow explicitly incorporates as an input — incorporation bias)
Flow and timing	Some concerns (device produced a determinate output in only 52.5% of cases; handling of

	indeterminate cases in the time-to-diagnosis analysis not fully detailed)
Overall judgment	High risk (chiefly due to the index test and reference-standard domains)

Abbreviations: QUADAS-2 = Quality Assessment of Diagnostic Accuracy Studies 2.

TABLE III. Quality appraisal of the qualitative study (CASP Qualitative Checklist, domain-level judgments).

CASP domain	Perry et al. (2026) [5]
Aims and methodology	Low concern (clearly focused aim to explore caregiver perspectives on an AI-assistive device; inductive qualitative content analysis appropriate for an underresearched area)
Research design and recruitment	Some concerns (clinic-based, industry-partnered purposive sample of 10 caregivers; skewed toward Level 2-3 ASD severity and early technology adopters, limiting transferability)
Data collection	Some concerns (two audio/video-recorded, transcribed focus groups; the device's own slow, unresponsive performance may have affected participant engagement and data completeness)
Reflexivity and researcher-participant relationship	Low concern (researchers' positionality documented; no prior relationship with participants; independent second coder blinded to initial coding)
Ethical considerations	Low concern (institutional ethics approval and informed consent obtained; industry funder disclosed with no role in analysis or interpretation)
Rigor of data analysis	Low concern (independent coding of 25% of data with 81.7% agreement; analytical memos; saturation confirmed across two focus groups; audit trail maintained)
Clarity and value of findings	Low concern (three themes reported with illustrative quotations; authors explicitly discuss limits to generalizability)
Overall judgment	Some concerns (chiefly due to sample selection and possible device-performance effects on data collection)

Abbreviations: CASP = Critical Appraisal Skills Programme.

B. Study and participant characteristics

The characteristics of the studies and participants are presented in Table IV. Five studies were included, conducted in different contexts and populations, involving individuals with ASD as well as their caregivers and families across different age groups. The included technologies span conceptually distinct categories, as indicated in the table, ranging from generative AI to an AI-based diagnostic device, a digital health application, an AI-assistive device for daily functioning, and an educational application of AI addressed from a public-health perspective. Notably, the last of these [6] differs from the others in design: rather than reporting an intervention with human participants, it proposes and validates a public-health-oriented AI model for social-skills support. It was retained because it directly addresses AI applied to the education and support of children with ASD, the phenomenon of interest of this review, while its distinct, non-empirical nature is made explicit and weighed in the synthesis.

TABLE IV. Study and participant characteristics.

Study (year), country	Technology type	Target user	Sample	Participants (age)
Aydemir (2025), Turkey [2]	Generative AI (chatbot)	Patient and caregiver	26 families (parent-child dyads); 13 intervention and 13 control	Children with ASD and their parents
Lee et al. (2024), South Korea [3]	Digital health (mobile app)	Caregiver	64 enrolled; 42 children in the program (20 intervention, 22 control)	Parents of children with ASD aged 36-84 months (median 49 months)
Sohl et al. (2025), USA [4]	AI-based diagnostic device	Professional	80 children and 7 primary-care clinicians	Children aged 18-72 months with suspected developmental delay, and their caregivers
Perry et al. (2026), Australia [5]	AI-assistive device (tablet)	Caregiver	10 caregivers (5 mothers, 5 fathers); 2 focus groups	Children aged 6.3-8.4 years with ASD (Level 2-3) and their caregivers (mean age 42.8 years)
Lan et al. (2025), China [6]	Educational AI application (public-health perspective)	Children with ASD (educational context)	Conceptual/ analytical study; model validated on benchmark language datasets	School-aged children with ASD (educational setting)

Abbreviations: AI = artificial intelligence; ASD = autism spectrum disorder.

C. Synthesis of main findings

Table V summarizes the interventions, instruments, and main findings, distinguishing primary from secondary outcomes. Overall, the use of chatbots, applications, AI-based devices, and an AI-assistive device was associated with feasibility, acceptability, and potential gains in engagement, knowledge, diagnostic workflow efficiency, and caregiver-perceived support for adaptive functioning, rather than with established clinical effectiveness.

TABLE V. Interventions, instruments, and main findings of the included studies.

Study	Intervention	Instruments	Main findings

Aydemir (2025) [2]	ChatGPT-recommended physical activities delivered by parents	LTEQ; feasibility questionnaire	Significant increase in physical activity in the intervention group; intervention rated feasible and useful by parents
Lee et al. (2024) [3]	ABA-based parent training assisted by a mobile app for 12 weeks, added to usual care	K-CBCL (primary); CGI-S; K-SCQ; K-PSI-4-SF	Feasibility demonstrated, no adverse events; small reduction in K-CBCL total score (median difference -0.5; 95% CI -4.5 to 3.0), confidence intervals crossing the null
Sohl et al. (2025) [4]	AI-based diagnostic device (Canvas Dx) integrated into the ECHO Autism primary-care workflow	Electronic questionnaires; chart review; device outputs	Mean time to diagnosis of 39.2 days (vs. 180-264 in specialized centers); 93% caregiver satisfaction; determinate outputs in 52.5% of cases, all consistent with final clinical determination
Perry et al. (2026) [5]	Focus groups exploring caregiver use of an AI-assistive device (Pixi Home-Hub) for daily functioning support	Semi-structured focus groups; inductive content analysis (NVivo)	Caregivers valued goal-tracking and scheduling features and proposed the device as a digital support navigator for disability-funding processes (NDIS); usability limited by slow, unresponsive AI voice interaction; no quantitative outcome measures
Lan et al. (2025) [6]	Analysis of AI applications in the education of children with ASD, framed from a public-health perspective	Narrative/ analytical synthesis; model validation on benchmark datasets	Discusses potential of AI to support individualized education and emotion recognition for children with ASD; conceptual contribution rather than empirical clinical outcomes; reinforces the argument for AI potential in educational support

Abbreviations: ABA = applied behavior analysis; AI = artificial intelligence; CGI-S = Clinical Global Impression-Severity; CI = confidence interval; ECHO = Extension for Community Healthcare Outcomes; K-CBCL = Korean Child Behavior Checklist; K-PSI-4-SF = Korean Parenting Stress Index, 4th Edition Short Form; K-SCQ = Korean Social Communication Questionnaire; LTEQ = Leisure-Time Exercise Questionnaire.

IV. Discussion

The findings of this review indicate preliminary evidence of feasibility and acceptability for AI-enabled and digital health technologies in ASD care support, with possible gains in engagement, knowledge acquisition, and diagnostic workflow efficiency. The included studies used distinct technologies and designs, spanning conceptually different categories: a physical activity intervention mediated by a generative-AI chatbot [2], a parent training program assisted by a digital health mobile app [3], an AI-based diagnostic support device integrated into primary care [4], an AI-assistive device supporting caregiver-reported adaptive functioning [5], and a conceptual, public-health-oriented AI modeling study on education for children with ASD [6]. This conceptual diversity — spanning a generative-AI chatbot, a mobile application without explicit AI, and an AI-based diagnostic device, among others — together with heterogeneous samples and outcomes, limits any joint conclusion about "AI-enabled and digital technologies" as a single category, and reinforces the need to appraise each technology type on its own terms. Because five heterogeneous studies were included, no quantitative synthesis was appropriate, and the findings should be interpreted as exploratory.

A recurring pattern across the included studies is the mediation of technology use by a caregiver or a professional, rather than direct, unmediated use by the individual with ASD. In Aydemir [2], ChatGPT-generated recommendations were interpreted and delivered by parents; in Lee et al. [3], the mobile application supported a parent-training program rather than interacting directly with the child; in Sohl et al. [4], the diagnostic device was operated within a clinician-led workflow; and in Perry et al. [5], caregivers alone interacted with the AI-assistive device across two focus groups, with no direct use by the child reported. No included study relied on unmediated interaction between the individual with ASD and the technology, which suggests that human mediation, whether by caregivers or professionals, remains a structural feature of current AI and digital health applications in this population, with implications for how usability and safety should be evaluated in future studies.

Effect magnitude, however, varied. In Lee et al. [3], the reduction in behavioral problems measured by the K-CBCL was small and the confidence intervals crossed the null value, which limits conclusions about efficacy and reinforces the exploratory nature of the study. The results of Sohl et al. [4] suggest a marked gain in diagnostic efficiency, with a substantial reduction in time to diagnosis compared with the waiting list of specialized centers.

Continuous availability and personalization of interactions are central attributes of these technologies, with potential to reduce access barriers in settings with scarce specialized services. Such tools may complement, without replacing, professional follow-up. From a biomedical engineering standpoint, however, their incorporation into care depends on requirements that the included studies still address only to a limited extent: performance validation, usability, interoperability, integration into the clinical workflow, and regulatory compliance. These elements are decisive for turning a promising proof of concept into a genuinely usable health technology.

Intermediate outcomes must be distinguished from clinical effectiveness. The included studies mainly measure feasibility, satisfaction, and engagement, which are legitimate but insufficient to demonstrate sustained clinical benefit, especially without long-term follow-up. The adoption of these technologies also entails risks that require explicit attention: privacy and protection of sensitive data, algorithmic bias, generation of incorrect information by large language models (hallucinations), clinical safety, and the need for professional

supervision. Poorly validated support tools may, moreover, displace the human bond rather than reinforce it, a particularly sensitive risk for families already experiencing isolation. These aspects remain underexplored in the available literature.

These findings converge with recent reviews. Scoping and systematic reviews on generative AI and large language models applied to ASD have likewise pointed to a predominance of preliminary evidence, scarce external validation, and the need for caution regarding bias and safety [11], [12]. In the field of diagnostic AI and social-behavior tracking in ASD, the literature also highlights the potential for screening and prioritization alongside implementation and interoperability gaps [13]. More broadly, reviews on AI in mental health reinforce issues of transparency, interpretability, and validation limitations that apply directly to the present context [14]. This work adds to that emerging body by conceptually delimiting technology types and by making explicit the still preliminary nature of the evidence.

The screening process also surfaced one candidate record that illustrates emerging risks to evidence synthesis in this fast-moving field. A report proposing an explainable-AI diagnostic framework was retracted after publication over concerns of an inadequately described method, an AI-generated figure, and unverifiable training and validation datasets [15], underscoring the need for reviewers to check the current status of AI-related publications rather than relying on the title and abstract alone. Excluding this retracted record at full-text review, rather than incorporating it into the synthesis, reinforces the robustness of the eligibility process adopted here.

V. Conclusion

The available evidence indicates that AI-enabled and digital health technologies applied to ASD care are promising but still preliminary. Because the five included studies evaluate conceptually distinct technologies — a generative-AI chatbot, a mobile application without explicit AI, an AI-based diagnostic device, an AI-assistive device for caregiver-reported adaptive functioning, and an educational application of AI — with heterogeneous samples, designs, and outcomes, any conclusion that treats "AI-enabled and digital technologies" as a single, undifferentiated category is necessarily limited. The main finding of this review is the feasibility and acceptability of these tools, rather than the robust demonstration of clinical effectiveness, which remains uncertain given the methodological heterogeneity, small samples, and limited external validation. Screening was conducted independently by two reviewers across four databases, with a third reviewer available for adjudication, and the protocol was prospectively registered, strengthening the reliability of the selection process; nonetheless, the small number of eligible studies and their heterogeneity remain the main constraints. Future studies should adopt standardized outcomes and longer follow-up to move beyond feasibility toward clinical effectiveness. For biomedical engineering, the advancement of the field will depend on performance validation, safe integration into the care workflow, and attention to regulatory requirements. By delimiting technology types and mapping existing gaps, this review contributes to guiding the future development of AI solutions for ASD care support.

Abstract*—Thyroid nodules are common endocrine findings, and ultrasonography remains the primary modality for screening, risk stratification, and guidance for fine-needle aspiration. Although artificial intelligence (AI) increasingly supports segmentation, detection, and classification, annotated thyroid ultrasound datasets remain constrained by annotation cost, interobserver variability, ethical considerations, and equipment heterogeneity. This PRISMA-informed structured qualitative review maps physical, statistical, hybrid, and AI-based approaches relevant to thyroid nodule simulation. The historical evidence set included 39 sources, and a separately reported targeted update added three recent sources. During revision, two reviewers independently reassessed 88 full-text reports (94.3% agreement; Cohen's $\kappa = 0.88$, 95% CI: 0.77–0.98). A design-sensitive appraisal applied QuADS across heterogeneous empirical designs, CLAIM 2024 to eligible medical-imaging AI studies, and PROBAST+AI to applicable prediction-model studies without collapsing the instruments into a common score. Physics-based simulators provided explicit acoustic control but were seldom linked to thyroid-specific downstream tasks. Recent thyroid-focused work introduced clinically guided diffusion, real-background inpainting with synthesis-linked masks and external segmentation gains, and externally evaluated synthetic contrast-enhanced ultrasound. Nevertheless, explicit clinical control, automatic annotation, real-background synthesis, and thyroid-specific AI validation remain incompletely integrated. The review separates evidence-derived observations from a conceptual research agenda and identifies testable opportunities rather than a single optimal simulator architecture.

***Index Terms*—ultrasonography, thyroid nodule, synthetic data, ultrasound simulation, artificial intelligence.**

I. Introduction

Thyroid nodules are highly prevalent in the general population, and their detection has increased with the wider use of high-resolution ultrasonography. Although most nodules are benign, distinguishing low- from high-risk cases directly affects decisions on follow-up, fine-needle aspiration biopsy, and surgery [1]–[3]. Clinical guidelines organize diagnostic stratification around descriptors such as composition, echogenicity, shape, margins, and echogenic foci. However, their interpretation remains operator-dependent and subject to intraobserver and interobserver variability [2], [3].

In parallel, deep learning-based decision-support systems increasingly address thyroid nodule detection, segmentation, and classification [4], [5]. Their performance depends strongly on the quantity, diversity, and quality of annotations. Manual annotation is costly because lesion boundaries may be poorly defined, local contrast is low, speckle modifies texture, and clinically relevant findings such as microcalcifications and posterior shadowing may be subtle or heterogeneous [6], [7]. Public datasets provide complementary but incomplete resources: DDTI is single-center [8], TN3K provides nodule masks [7], [9], and the larger TN5000 supports detection and classification with bounding boxes rather than pixel-level masks [10].

The gap between growing model complexity and limited annotated data makes synthetic data attractive. A simulator can provide scalable generation, parametric control, privacy preservation, and automatic reference annotations. It can also support controlled robustness experiments, isolate changes in echogenicity and texture, increase representation of rare patterns, and test whether synthetic augmentation improves generalization. Historically, however, ultrasound simulation developed along two weakly connected tracks: physics-based simulators emphasizing acoustic fidelity and operator training, and AI methods emphasizing visual synthesis or downstream augmentation [11]–[15].

For the thyroid, most AI studies still classify or segment real images. Earlier synthesis studies mainly addressed augmentation, classification, or domain adaptation [16]–[18]. Recent work has broadened this scope: Dai *et al.* developed a clinical-knowledge-guided, text-conditioned diffusion frame-

work for rare thyroid cancer subtypes; Prochazka and Zeman inserted synthetic nodules into real ultrasound backgrounds and measured cross-dataset segmentation gains; and Lai *et al.* generated synthetic thyroid contrast-enhanced ultrasound (CEUS), evaluated by radiologists and on an external cohort [19]–[21]. The contribution of this review is therefore not an absolute claim that synthetic data, lesion insertion, or automatic labels are unavailable, but a structured account of the relationship among physical simulation, generative synthesis, clinically meaningful thyroid semantics, synthesis-linked reference masks, and validation in thyroid-specific AI tasks. Adjacent literature is included only when it contributes a clearly transferable methodological component.

This work organizes simulation into physical, statistical, hybrid, and AI-driven classes; synthesizes thyroid-specific evidence; compares parameterization, annotation generation, code and data availability, validation, and reproducibility; and separates evidence-derived requirements from conceptual choices for future simulators.

II. Theoretical background

A. Ultrasound in thyroid nodules

B-mode ultrasound is the modality of choice for the initial evaluation of thyroid nodules because it is accessible, portable, free of ionizing radiation, and sensitive to nodular morphology [2], [3]. Stratification systems, such as ATA and ACR TI-RADS, use visual features extracted from these images to infer malignancy risk [2], [3]. In practice, however, these signs are influenced by transducer frequency, gain, focus, depth, compression, adjacent structures, and speckle noise. Consequently, the perception of irregular margins, halo sign, punctate echogenic foci, a taller-than-wide shape, and hypoechoic patterns can vary substantially across observers and equipment [5].

From a computational standpoint, thyroid nodule segmentation is challenging because a lesion may occupy only a small image region, have diffuse borders, be partly obscured by posterior shadowing, or coexist with heterogeneous glandular tissue. Traditional methods often reported favorable results on small, single-center datasets, whereas deep learning improved performance while increasing dependence on annotated data [6]. Recent systems still rely largely on manually delineated masks, limiting scalability, standardization, and reproducibility [7], [22], [23].

B. Ultrasound simulation

Ultrasound simulation represents, at different levels of abstraction, interactions among the acoustic beam, tissue, scatterers, the transducer, and the image-formation chain. Foundational work by Bamber and Dickinson and by Foster *et al.* established that B-mode appearance depends on medium statistics and the spatial response of the imaging system, enabling computational synthesis of speckle, cyst contrast, and processing effects [24], [25]. Field II subsequently consolidated ultrasound-field and pulse–echo simulation through transducer and scatterer models [11]. k-Wave extended wave-propagation modeling to heterogeneous media and more complex propagation phenomena [12], while CREANUIS incorporated nonlinear radiofrequency imaging for harmonic scenarios [26].

Beyond full-wave simulators, open tools support signal processing, beamforming, and benchmarking. The MATLAB UltraSound Toolbox (MUST) includes SIMUS, a frequency-domain simulator benchmarked against Field II and k-Wave [27], [28]. The UltraSound ToolBox (USTB) supports beamforming and reconstruction pipelines for simulated and experimental data [29]. The Challenge on Ultrasound Beamforming with Deep Learning (CUBDL) provides an open benchmark for learning-based image formation, but its scope is signal reconstruction rather than generation of clinically annotated datasets [30], [31].

Despite their technical maturity and physical grounding, these frameworks were not primarily designed to produce AI-ready annotated datasets. They generally provide more direct control over acoustic, geometric, and signal-processing parameters than over clinical descriptors such as microcalcifications or posterior shadowing. Thyroid-specific lesion models, consistent automatic masks, and reproducible Python integration also remain secondary features [14]. Statistical, convolutional, and hybrid approaches offer a complementary compromise between computational cost, controllability, and visual realism [13], [32].

C. AI in ultrasound imaging

AI in ultrasound evolved from handcrafted-feature classifiers to deep networks that learn image representations directly. In biomedical segmentation, U-Net became a reference architecture by combining multiscale context with spatial precision through skip connections [33]. Thyroid applications subsequently introduced attention, anatomical priors, and multitask learning, including TRFE-Net/TRFE+, enhanced U-Net architectures, automated pipelines, and multicenter models [7], [9], [22], [23], [34]. Reliable generalization nevertheless requires larger, more diverse, and consistently annotated datasets.

Ultrasound also imposes modality-specific constraints on AI. B-mode appearance depends strongly on acquisition protocol, probe orientation, operator pressure, gain, dynamic range, and equipment manufacturer. These factors alter speckle, boundary contrast, shadowing, and local texture, directly affecting feature learning and transferability. Models trained at one center or on one device may therefore perform well internally but degrade on external data. In thyroid imaging, this sensitivity is compounded by small lesions, low lesion–parenchyma contrast, and clinically important subtle findings such as punctate echogenic foci, irregular margins, and posterior artifacts [5]–[7]. Evaluation should consequently assess both task performance and stability across acquisition conditions while verifying preservation of clinically meaningful descriptors.

Generative adversarial networks (GANs) are an established family of methods for image synthesis and domain adaptation in medical imaging [15], [35]. Ultrasound studies have demonstrated realistic and editable synthesis for augmentation and segmentation [36]–[39]. Diffusion models have since been

applied to ultrasound texture generation and, more recently, to thyroid-specific text-guided synthesis and inpainting [19], [20], [40]. Thyroid CEUS translation has also progressed to external-cohort and radiologist evaluation [21]. These advances narrow the earlier gap, although their control mechanisms, outputs, and validation targets remain complementary rather than fully integrated.

D. Synthetic data and ground truth

Synthetic data are particularly valuable for low-prevalence patterns, costly annotations, and controlled experiments. Beyond increasing sample volume, they enable variable isolation, analysis of relationships between acquisition parameters and image appearance, and deterministic reference annotations when the simulated scene is known. Unlike manual masks, which remain subject to observer uncertainty, a simulator can generate segmentation masks, boxes, probability maps, and lesion metadata together with the image. These references are exact with respect to the simulation model, although not necessarily to real anatomy.

Synthetic-data value should not be assessed by visual similarity alone. Structural Similarity Index (SSIM) and Peak Signal-to-Noise Ratio (PSNR) quantify aspects of structural fidelity and degradation [41], while Dice and Intersection over Union (IoU) evaluate segmentation. Stronger evidence links synthesis to target-task utility by testing models trained with synthetic or mixed data on held-out real examinations [16], [20], [39]. For thyroid ultrasound, the link among realism, synthesis-linked annotation, and downstream benefit remains incompletely characterized.

III. Methodology

PRISMA 2020 was used to structure the reporting of this PRISMA-informed qualitative review [42]. The review distinguishes the historical screening process from the subsequently conducted targeted literature update so that the two components are not interpreted as a homogeneous database rerun. During revision, the historical flow was cross-checked against the available aggregate records and the independent reassessment of all full-text reports. This verification does not alter the study-by-study technical comparisons; it only limits exact replication of the original database search. The protocol was not prospectively registered, and qualitative synthesis was selected because the studies differed substantially in domain, objectives, inputs, outputs, and evaluation metrics. Evidence from non-thyroid organs was used exclusively to identify anatomy-independent methodological building blocks—including acoustic image formation, controllable synthesis, paired image–annotation generation, and downstream synthetic-to-real validation—and was not interpreted as direct evidence of clinical effectiveness in thyroid imaging.

A. Research questions

Six questions guided the review: RQ1, classes of B-mode simulation methods; RQ2, modeled acoustic, anatomical, and textural phenomena; RQ3, uses of GANs, diffusion models, and other AI techniques; RQ4, thyroid-specific evidence; RQ5, automatic masks and downstream validation; and RQ6, underexplored combinations of parametric control, annotation, reproducibility, and AI evaluation. In PICOS terms, the population/context comprised ultrasound-imaging studies; interventions were physical, statistical, hybrid, and generative approaches; comparisons involved methods or real/synthetic training regimes; outcomes covered realism, control, annotation, task performance, and reproducibility; and study designs comprised peer-reviewed journal and conference papers.

B. Databases, period, and search expressions

Searches were performed in IEEE Xplore, Scopus, PubMed, and Web of Science for publications from January 2000 through April 30, 2026. Foundational works published before 2000 were considered only through backward citation searching and were tracked separately from database records. On August 20, 2026, a targeted update identified three eligible papers that had been available online before the cutoff but were absent from the original evidence set [19]–[21]. These papers were analyzed as a distinct update to the 39-source historical evidence set rather than as products of a homogeneous rerun of the original searches. The strategy combined English-language concepts for ultrasound, simulation or synthesis, generative AI, and thyroid imaging. Table I summarizes the four Boolean concept blocks, with syntax adapted to each database.

Table I
BOOLEAN CONCEPT BLOCKS USED IN THE SEARCH STRATEGY.

Code	Concept block (adapted per database)
S1	(`ultrasound` OR `ultrasonography`) AND (`simulation` OR `synthetic` OR `synthesis`) AND (`B-mode` OR `speckle` OR `scatterer` OR `acoustic`)
S2	`ultrasound` AND (`deep learning` OR `GAN` OR `diffusion` OR `generative model`) AND (`synthetic` OR `synthesis` OR `augmentation`)
S3	`thyroid` AND `ultrasound` AND (`segmentation` OR `classification` OR `detection`) AND (`deep learning` OR `U-Net` OR `GAN`)
S4	`thyroid` AND `ultrasound` AND (`simulation` OR `synthetic` OR `augmentation` OR `generative`)

In Table I, S1 and S2 capture general simulation and generative methods, whereas S3 and S4 narrow retrieval toward thyroid-specific AI and synthesis. The layered logic retains transferable contributions that may not explicitly use "thyroid."

C. Inclusion and exclusion criteria

Eligible studies were peer-reviewed, English-language, full-text journal or conference papers with auditable methods and results on ultrasound simulation, synthesis, relevant AI tasks, or thyroid nodules. Abstracts, editorials, tutorials without experiments, non-ultrasound studies, and operator-training papers without image formation were excluded. Non-thyroid studies required at least one transferable component: general image formation, controllable acoustic or lesion parameters, conditioned synthesis, paired image–annotation generation, or downstream validation. Their organ-specific performance was not treated as direct thyroid evidence. Seminal architecture, metric, and framework descriptions were retained as complementary methodological sources when required to interpret the reviewed pipelines; the MONAI preprint was used only for implementation context and not as clinical thyroid evidence.

D. PRISMA process and data extraction

The database searches returned 612 records: 126 from IEEE Xplore, 181 from Scopus, 143 from PubMed, and 162 from Web of Science. After removing 164 duplicates, 448 titles and abstracts were screened; 360 were excluded. Of 88 database-derived full-text reports, 55 were excluded and 33 retained. Backward citation searching contributed six sources, producing a historical evidence set of 39 sources. The targeted update added three separately identified papers, yielding an expanded qualitative synthesis of 42 sources. The independent reassessment conducted after screening confirmed the full-text screening totals reported in Fig. 1.

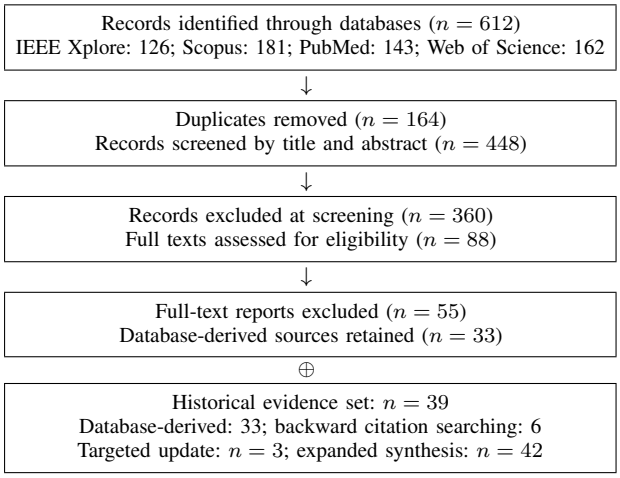

Figure 1. PRISMA-style flow separating the historical evidence set from the targeted update.

The largest reduction occurred during title and abstract screening, followed by 55 full-text exclusions. Reporting the additional routes separately prevents pre-2000 foundational sources from being attributed to the time-limited database search and makes the targeted addition of recent thyroid-generation papers explicit. Backward citation searching was used principally to retain foundational models of B-mode formation, speckle, and ultrasound-system simulation, including Bamber and Dickinson, Foster *et al.*, and Jensen [11], [24], [25].

During manuscript revision, two reviewers independently reassessed all 88 full-text reports against the predefined eligibility criteria before consensus discussion. Pre-consensus agreement was 94.3% (83/88), with Cohen's $\kappa = 0.88$ (95% CI: 0.77–0.98), indicating high agreement beyond chance. Five reports were classified differently and were resolved by structured consensus; third-reviewer adjudication was predefined but not required. Following consensus, 33 sources were retained and 55 reports excluded at the full-text stage. The primary reviewer extracted domain, method, inputs and outputs, parameterization, annotations, downstream AI integration, metrics, code and data availability, and external validation using a predefined framework. A second reviewer independently verified the extracted information, and discrepancies were resolved by consensus. The remaining coauthors reviewed the technical narrative, manuscript consistency, and English-language presentation but did not determine eligibility.

E. Methodological reporting and appraisal framework

Methodological appraisal used a design-sensitive strategy rather than a universal risk-of-bias score. QuADS was applied to heterogeneous empirical designs using its native 13-item, 0–3 structure [43]. CLAIM 2024 was applied at item level to eligible medical-imaging AI studies using its Yes, No, and Not Applicable categories [44]. PROBAST+AI was restricted to applicable diagnostic or prediction-model studies, with model-development quality, model-evaluation risk of bias, and applicability assessed separately [45]. Two reviewers independently completed the applicable appraisal forms, and disagreements were resolved by consensus. No common numerical score was created across the instruments because their constructs and intended applications differ substantially. Table IV summarizes the principal domain-level findings.

IV. Results and Evidence Synthesis

A. Overview of the corpus

The expanded 42-source synthesis comprised a historical evidence set of 39 sources and a targeted three-source update. It covered physical/wave, statistical, hybrid, generative, and thyroid-specific AI approaches, together with explicitly identified contextual sources. Classical simulators emphasized acoustic control [11], [12], [24]–[26], whereas data-driven studies increasingly used masks, sketches, clinical knowledge, or text conditioning [19], [38], [39]. Physics-based studies generally described system parameters well but seldom addressed annotations or thyroid AI. Generative and segmentation studies emphasized realism or task performance, while reporting code, clinical control, calibration, and external validation inconsistently.

The design-sensitive appraisal revealed a consistent contrast between methodological clarity and external validation. Across QuADS assessments, study objectives and technical procedures were generally better documented than sampling rationale, stakeholder involvement, and reproducibility-related information. CLAIM-based assessment of eligible AI studies showed improved reporting of dataset partitioning, performance metrics, and external testing in the most recent studies, while code availability, calibration procedures, and complete data provenance remained heterogeneous. Among studies eligible for PROBAST+AI, the principal concerns involved retrospective or single-center datasets, incomplete reporting of missing-data handling, limited calibration analysis, and absence of independent external evaluation. These findings were used to qualify the narrative synthesis rather than to rank fundamentally different study designs.

B. Physical simulation

Bamber and Dickinson, together with Foster *et al.*, established statistical scatterer-based synthesis of speckle and contrast [24], [25]. Field II modeled pulse–echo responses and transducers [11], k-Wave addressed heterogeneous propagation

[12], and CREANUIS incorporated nonlinear RF imaging [26]. These interpretable tools provide causal acoustic control, but clinically meaningful thyroid descriptors, automatic lesion masks, and downstream AI evaluation were generally outside their scope.

C. Statistical simulation

Statistical or convolutional models approximate scatterers, the point spread function, and speckle at lower computational cost. Marion and Vray, for example, simulated moving 3D scatterers and validated image statistics [32]. Their efficiency benefits signal-processing and dynamic studies, but pathology is often represented as local statistical change rather than controlled echogenicity, texture, calcifications, margins, or posterior artifacts.

Tables II and III compare studies selected for thyroid-specific synthesis, controllable generation, synthesis-linked annotation, or downstream AI validation. Their symbols are defined directly below each table and apply only to these descriptive comparisons, not to the methodological instruments summarized later.

Table II
DATA, GENERATION CONTROL, AND SYNTHESIS-LINKED ANNOTATION.

Study	Data/background	Generation control	Synthesis-linked reference/mask
Alsinan *et al.* [39]	Bone US	Label-conditioned	Y
Liang *et al.* [38]	Lung, hip, ovary	Mask + editable sketch	Y
Liang and Chen [16]	Thyroid US; dataset NR	Latent augmentation	N
Yang *et al.* [17]	Thyroid US; dataset NR	Clinical/class knowledge	N
Zhao *et al.* [18]	Multimodal thyroid US	Semantic/domain control	N
Dai *et al.* [19]	Thyroid US + reports	Text/clinical descriptors	P
Prochazka and Zeman [20]	TN3K + real backgrounds	Masked inpainting	Y
Lai *et al.* [21]	Grayscale US to CEUS	Three-phase translation	NA

Note: Y = directly demonstrated and adequately reported; P = partial, indirect, or incomplete evidence; N = explicitly absent or unused; NR = insufficient reporting; NA = not applicable. In the final column, Y requires a spatial reference generated or preserved with, and aligned to, the synthetic target; a conditioning or input-only mask does not qualify as Y.

Table II shows that explicit synthesis-linked references or masks are concentrated in label-conditioned, sketch-guided, and inpainting methods. Earlier thyroid-specific GAN studies primarily controlled latent, class, or semantic information, while recent diffusion models introduced stronger text-based or spatial control. This distinction motivates a separate comparison of validation and accessibility.

Table III
VALIDATION, EXTERNAL TESTING, ACCESS, AND REPRODUCIBILITY.

Study	AI/reader validation	External	Code/data	Repro.
Alsinan *et al.* [39]	Downstream segmentation	N	NR/NR	P
Liang *et al.* [38]	User study + segmentation	N	Y/NR	P
Liang and Chen [16]	Augmentation utility	NR	NR/NR	NR
Yang *et al.* [17]	Classification	NR	NR/NR	NR
Zhao *et al.* [18]	Adaptation/classification	NR	NR/NR	NR
Dai *et al.* [19]	Classification + generation	Y	Y/P	Y
Prochazka and Zeman [20]	Three segmenters	Y	Y/Y	Y
Lai *et al.* [21]	Metrics + radiologists	Y	P/NR	P

Note: Y = directly demonstrated and adequately reported; P = partial, indirect, or incomplete evidence; N = explicitly absent or unused; NR = insufficient reporting; NA = not applicable. Code/data entries report code and data separately. "Repro." denotes reported artifacts and documentation, not independent replication.

Table III indicates that downstream testing has become more rigorous in recent thyroid studies. Prochazka and Zeman combined real-background insertion, synthesis-linked masks, public code and data, and cross-dataset segmentation tests; Dai *et al.* emphasized clinical text control; and Lai *et al.* added external-cohort and radiologist evaluation. Nevertheless, access to clinical data, calibration, and independent replication remain inconsistent.

Table IV
DESIGN-SENSITIVE METHODOLOGICAL APPRAISAL SUMMARY.

Instrument	Applied to	Main finding	Interpretive qualification
QuADS [43]	Cross-design evidence	Aims and methods were clearer than sampling rationale, stakeholder involvement, and reproducibility	No quality cutoff was imposed; item patterns informed the synthesis
CLAIM 2024 [44]	Medical-imaging AI subset	Recent studies more clearly reported partitions, metrics, and external tests	Code/data access, calibration, and provenance remained heterogeneous
PROBAST +AI [45]	Applicable prediction studies	External evaluation improved in recent thyroid studies	Retrospective data, calibration, and missing-data reporting remained recurrent concerns

Table IV reports the principal findings derived from each instrument within its applicable scope without collapsing the three frameworks into an artificial common scale. The table provides a concise domain-level synthesis rather than a common numerical ranking. Tables II and III show that the remaining technical fragmentation lies in combining complementary strengths within one thyroid B-mode pipeline, not in the absence of every individual component.

D. Hybrid methods

Hybrid methods retain selected physical principles while reducing computational cost. Goksel and Salcudean combined deformable 3D anatomy with B-mode synthesis [13], while subsequent approaches incorporated ray models, convolution, anatomical volumes, and GPU acceleration [14]. These methods can balance anatomical plausibility and controllability, but thyroid specialization, radiological descriptor interfaces, automatic masks, and downstream AI validation remain insufficiently evaluated. Superiority over fully physical or data-driven alternatives has not been established.

E. GANs and generative models

Generative ultrasound studies include breast DCGANs [36], [37], sketch-conditioned synthesis [38], musculoskeletal diffusion [40], and paired bone image–label generation [39]. Earlier thyroid work emphasized GAN augmentation, knowledge-guided classification, or domain adaptation [16]–[18]. Dai *et al.* subsequently demonstrated text-based and clinical-feature control, while Prochazka and Zeman demonstrated real-image inpainting with synthesis-linked masks and cross-dataset segmentation gains [19], [20]. The remaining question is whether descriptor control, lesion insertion, synthesis-linked annotation, and broad validation can be combined without introducing simulator-specific shortcuts.

F. AI for segmentation

Thyroid U-Nets and attention networks report strong segmentation, including TRFE+ on TN3K and multicenter Dice scores above 0.91 [7], [23]. DDTI is small and single-center [8], TN3K uses manual masks [7], [9], and TN5000 provides boxes rather than pixel masks [10]. Prochazka and Zeman showed that diffusion-based augmentation improved cross-dataset generalization: DeepLabV3+ Dice on TDID increased from 38.2% to 59.1%, with gains also reported on TUCC [20]. These results establish the feasibility of synthesis-linked reference masks, although their clinical fidelity still requires evaluation.

G. Studies on the thyroid

Thyroid generative evidence now covers augmentation [16], knowledge-guided classification [17], multimodal adaptation [18], text-guided diffusion [19], real-background inpainting with external segmentation tests [20], and synthetic CEUS with external-cohort and radiologist evaluation [21]. No single study combined all of the following: explicit TI-RADS-like descriptor control, real-background B-mode insertion, synthesis-linked masks, acoustic/device variation, and prospective clinical or multicenter downstream validation. This is a corpus-bounded integration gap, not an absence of the individual capabilities.

H. Integrated interpretation of the comparison

The synthesis indicates that acoustic control, paired labels, clinical semantics, public thyroid data, and external validation are now demonstrable but remain distributed across different implementations [19]–[21]. A real–synthetic hybrid simulator is therefore one author-derived hypothesis for integrating these capabilities, not evidence that physical, label-conditioned, GAN, or diffusion alternatives are inferior.

V. Discussion

A. Limitations and risks of synthetic data

Synthetic data may contain artifacts, limited diversity, implausible descriptor combinations, or simulator-specific correlations that models learn instead of disease features. Generative systems may also underrepresent rare phenotypes or reproduce biases present in their training data [15], [40]. Evaluation should therefore combine expert review, descriptor fidelity, artifact and memorization checks, calibration, target-task utility, and external real-world data.

B. Validation, reproducibility, and review limitations

Validation ranged from qualitative realism, SSIM, and PSNR to Dice, IoU, classification, radiologist assessment, and external-cohort testing. Recent studies broadened this profile but did not consistently combine perceptual, acoustic, downstream, multicenter, and cross-equipment evaluation [19]–[21]. The review may have omitted relevant work not indexed in the four selected databases, and retrieval remained sensitive to the scope and English-language formulation of the search terms. In addition, the rapid evolution of generative models—particularly diffusion-based methods—makes this synthesis time-sensitive. Verification of the historical screening flow during revision does not alter the study-by-study technical comparisons, but it limits exact replication of the original search process. The targeted update is therefore reported separately from the historical evidence set. Foundational architecture, metric, guideline, review, and framework sources broaden methodological coverage but are interpreted as contextual rather than thyroid-specific clinical evidence.

VI. Research gaps and future directions

A. Critical gaps

Four integration gaps remain underexplored: combining TI-RADS-like descriptor control with real-background insertion and synthesis-linked masks; parameterizing acquisition factors such as manufacturer, transducer frequency, gain, dynamic range, focus, and depth; testing real-only, synthetic-only, and mixed training across centers and devices; and linking image realism to calibration, clinical decisions, and prospective utility. Physical, statistical, hybrid, and generative designs offer different ways to address these gaps and should be compared empirically.

B. Evidence-informed future research directions

Future experiments could compare architectures that jointly control nodule shape, margins, echogenicity, echogenic foci, location, and posterior artifacts while preserving a synthesis-linked mask [19], [20]. Conditional GAN, diffusion, physical, and hybrid alternatives should be compared with conventional augmentation and CEUS translation rather than ranked a priori [21]. Validation should stratify manufacturers, transducer

frequencies, gain and dynamic-range presets, focus/depth settings, and operator variability; use blinded readers and standardized TI-RADS descriptors; and perform leave-one-center/device-out and preregistered real-only, synthetic-only, and mixed-training experiments. Python and MONAI may aid integration [46], but reproducibility depends on versioned code, weights, environments, parameters, and data provenance.

VII. Conclusion

This review maps the rapidly evolving intersection of ultrasound simulation, thyroid semantics, synthesis-linked annotation, and AI validation. Recent text-guided diffusion, real-background inpainting, and synthetic CEUS studies demonstrate the feasibility of several previously separated capabilities, while their integration remains insufficiently evaluated. Rather than favoring a single architecture, future work should compare physical, statistical, hybrid, GAN-based, and diffusion-based approaches under common experimental and clinical validation protocols. Their value should be judged by controllability, annotation fidelity, reproducibility, external generalization, and clinically meaningful utility.

***Abstract* — The increase in life expectancy has been accompanied by a higher prevalence of osteoporosis, especially among postmenopausal women, due to estrogen deficiency, and, consequently, by an increased risk of proximal femoral fractures. Understanding the mechanical behavior of the osteoporotic femur under different loading conditions may contribute to the development of preventive and therapeutic strategies. In this context, the Finite Element Method (FEM) provides a computational approach for investigating stress and displacement distributions under controlled loading conditions. The objective of this study was to investigate the mechanical response of an osteoporotic femur under orthostatic loading and a lateral fall onto greater trochanter, with emphasis on the distribution of principal stresses and displacement in the proximal femur. Computed tomography images from an 84-year-old female patient with osteoporosis were used to reconstruct the femoral geometry. Three-dimensional reconstruction, BioCAD modeling, finite element preprocessing, and numerical simulations were performed using InVesalius®, Rhinoceros®, SimLab®, and OptiStruct, respectively. The model included cortical and trabecular bone with distinct elastic properties and was subjected to loads ranging from 500 to 2500N in the orthostatic and lateral fall configurations. The results demonstrated changes in the magnitude and spatial distribution of principal stresses according to the loading condition and applied force. The lateral fall configuration produced higher compressive stress magnitudes at higher loads, with stress concentrations predominantly located in the proximal femur and femoral neck. These findings indicate greater mechanical demand in the femoral neck under lateral fall loading; however, stress concentration alone does not establish the occurrence or probability of fracture. Therefore, the present results should be interpreted as an assessment of mechanical stress distribution rather than direct evidence of fracture.**

Key-words — femur, elderly, osteoporosis, finite element method.

São Paulo Research Foundation (FAPESP) – 2021/04579-0

I. Introduction

Life expectancy has been increasing worldwide, with the population in this age group growing by 18% over five years in Brazil, surpassing the 30.2 million mark for adults aged 60 and older in 2017, according to data from the Brazilian Institute of Geography and Statistics [1]. The growing size of this age group is accompanied by an increase in bone diseases, such as osteoporosis; and, consequently, a rise in the incidence of fractures.

Osteoporosis is a progressive metabolic bone disease characterized by a gradual decrease in bone mass, accompanied by changes in the microarchitecture of bone tissue, leading to increased bone fragility and a higher risk of fractures. This loss is most prevalent in elderly patients, particularly in postmenopausal women, given the estrogen deficiency observed, which can lead to an accelerated decrease in bone density of up to 5% per year in trabecular bone and 2% to 3% per year in cortical bone [2].

Among fractures, the most common are those of the femur, particularly in the proximal region, for which osteoporosis is a significant risk factor [3], with a higher incidence among postmenopausal women. According to Soares et al. [4], the incidence of femoral fractures in women aged 60 years or older was 67% higher than that in men in the same age group.

In this context, the incidence is expected to triple by 2050, potentially reaching 6.5 million femur fractures worldwide [5], contributing to growing public health challenges due to the high cost of treatment and the impact on quality of life.

Since the skeletal structure is viewed as a load-bearing system subjected to a set of forces that can lead to deformities, biomechanics serves as a valuable tool for analyzing human structure and function, aiding in the study and understanding of the loads applied and their consequences, and acting as a fundamental link between the exact and biological sciences [6]. Thus, the understanding of proximal femur fractures can be achieved through software analysis, which, in this study, was performed using the Finite Element Method.

Therefore, the objective of the present study was to investigate the distribution of principal stresses and

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

displacement in an osteoporotic femur subjected to orthostatic loading and a lateral-fall configuration onto the greater trochanter. The analysis focused on identifying regions subjected to greater mechanical demand under the investigated loading conditions.

II. Material and Methods

A. Material

The research material consists of computed tomography (CT) images of an 84-year-old female patient with osteoporosis, obtained from the database of the Hospital Ortopédico de Medicina Especializada (HOME) in Brasília, Federal District. The study was approved by the Research Ethics Committee under protocol number (CAAE: 32179520.0.0000.0023) for the use of the CT images. This dataset was used for the reconstruction femoral geometries for subsequent Finite Element Method simulations.

B. Modeling of the Femoral Structure

The computed tomography images of the femur, obtained in .DICOM file format, were imported into the InVesalius® software (Fig. 1), where a three-dimensional reconstruction of the structure of interest was performed (Fig. 2) in .STL (Stereolithography) format.

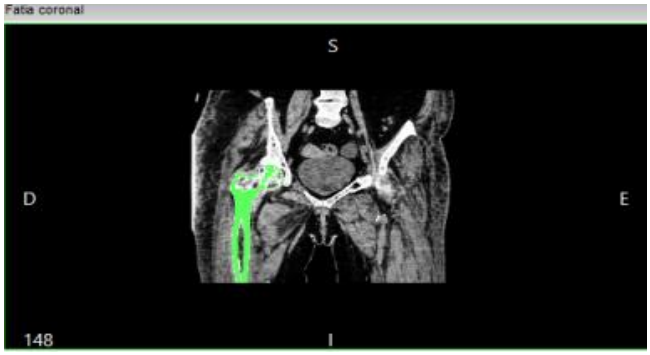

Fig. 1. Tomographic image in InVesalius® - area of interest.

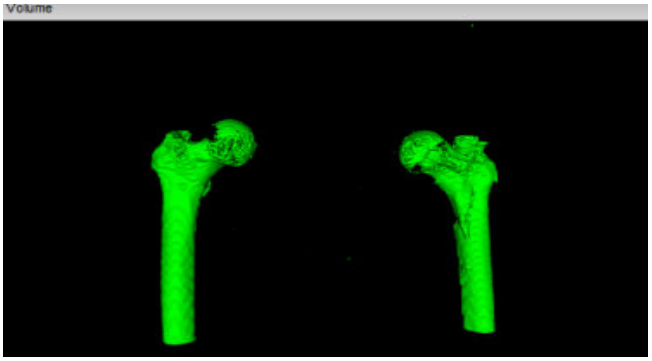

Fig. 2. Three-dimensional reconstruction of the femur in InVesalius®.

The .STL files were then imported into Rhinoceros® software to create the BioCAD® design. The cortical and trabecular regions were separately represented in the model, with minimal overlap between the two regions. This approach was adopted to represent the cortical and trabecular compartments of the os

The bone model was positioned with 9° of internal rotation and 10° of adduction—in the orthostatic position—and 10° of diaphyseal rotation and 10° of internal rotation—the lateral fall mechanism position over the greater trochanter (Figs. 3 and 4). These orientations were defined to reproduce the angles of position of the trauma.

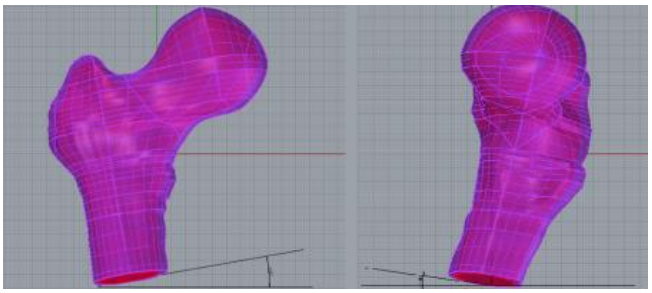

Fig. 3. Femur in the orthostatic position with angulation.

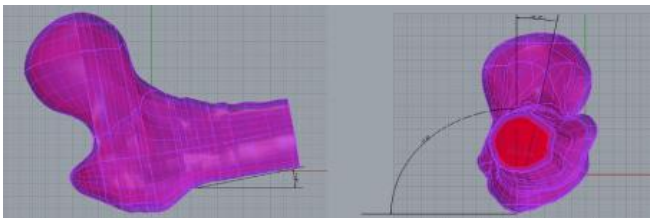

Fig. 4. Femur in a lateral fall position over the greater trochanter with angulation.

C. Finite Element Method Simulations

Once BioCAD® was finalized, a .STEP file (Standard for the Exchange of Product Model Data) was generated and imported into SimLAb® (Altair/HyperWorks), where finite element simulations were performed.

To analyze stress distribution using SimLAb®, the following steps were performed: mesh identification, control, and generation, as well as the determination of material properties—Young's modulus and Poisson's ratio [7] (Table 1).

TABLE 1. Properties of Materials

Material	Total elements	Total nodes	Modulus of Elasticity	Poisson's ratio
Cortical bone	332047	526384	13700	0.30
Trabecular bone	347637	552337	1370	0.30

Although these properties allow the numerical model to be solved, the present model does not incorporate a voxel-wise relationship between CT attenuation and local bone density. Consequently, the material properties should be considered region-specific homogeneous approximations rather than direct representations of the spatial heterogeneity of osteoporotic bone.

Finally, the osteoporotic femur model was subjected to loads in the orthostatic position and in a lateral fall scenario onto the greater trochanter, adhering to the boundary conditions to ensure that the system remained perfectly aligned without any displacement or rotation. These conditions were maintained consistently among the simulations to permit comparison between loading magnitudes and configurations. (Figs. 5 and 6).

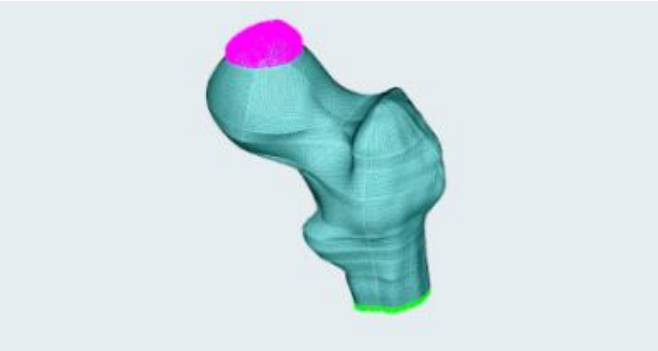

Fig. 5. Boundary conditions for the femur in the orthostatic position. Load application region (pink) and fixed region (green).

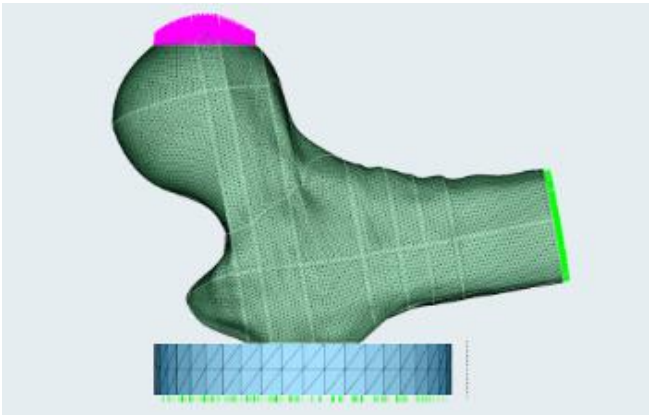

Fig. 6. Boundary conditions for the femur in the lateral drop mechanism position over the greater trochanter. Load application region (pink) and fixed region (green).

As a result, the locations with the highest stress concentrations were observed in the region of the proximal end of the femur, and the values for the principal maximum and minimum stresses and displacement were obtained.

III. Results

The osteoporotic femur model was subjected to five different loads—500 N, 1000 N, 1500 N, 2000 N, and 2500 N—represent different body-weight conditions that may be encountered among patients, both in the orthostatic position and in a lateral fall onto the greater trochanter. The parameters analyzed were: Displacement, Maximum Principal Stress, and Minimum Principal Stress.

A. Displacement

The displacement analysis showed a progressive increase in femoral deformation with increasing applied load in both loading configurations (Tables 2 and 3). In the orthostatic position, displacement increased from 0.286 mm at 500 N to 1.431 mm at 2500 N. In the lateral-fall configuration over the greater trochanter, displacement increased from 0.141 mm to 0.706 mm over the same loading range.

For both configurations, the displacement increased approximately proportionally to the applied load, indicating a consistent mechanical response of the model within the investigated loading range. The relationship between load and displacement resulted in calculated stiffness values of 1746.72 N/mm for the orthostatic position and 3539.82 N/mm for the lateral-fall configuration.

The progressive increase in displacement with increasing load, together with the changes observed in the principal stress distributions, demonstrates that the magnitude and configuration of the applied load influence the mechanical response of the proximal femur. In particular, the displacement results provide complementary information to the stress analysis by describing the overall deformation of the femoral model under the different loading conditions.

TABLE 2. Displacement and Relative Stiffness – Orthostatic Position.

Loading	Displacement (mm)	Relative Stiffness
500 N	0.286	1746.72 N/mm
1000 N	0.572	
1500 N	0.859	
2000 N	1.145	
2500 N	1.431	

TABLE 3. Displacement Value and Relative Stiffness – Position of the Lateral Fall Mechanism Over the Greater Trochanter.

Loading	Displacement (mm)	Relative Stiffness
500 N	0.141	3539.82 N/mm
1000 N	0.282	
1500 N	0.424	
2000 N	0.565	
2500 N	0.706	

B. Maximum Principal Stress

The spatial distribution of maximum principal stress demonstrated that the location of tensile stress concentrations changed according to the loading configuration.

In the orthostatic configuration, the highest tensile stress concentrations were predominantly located in the superior region of the femoral neck. In the lateral fall configuration, the highest tensile stress concentrations were observed primarily in the anterolateral region at the base of the femoral neck (Fig. 7).

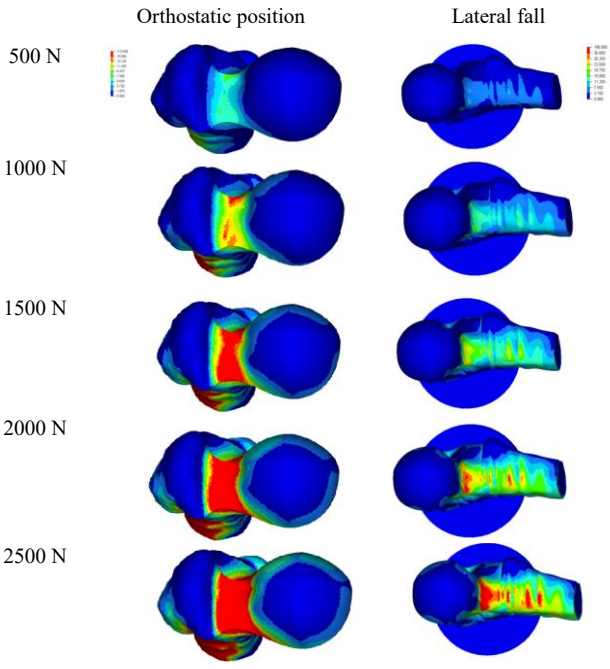

Fig. 7. Maximum Principal Stress – orthostatic position and lateral fall position over the greater trochanter.

The maximum principal stress values increased with increasing load. In the orthostatic configuration, the values increased from 8.358 at 500N to 32.856 at 2500N. In the lateral fall configuration, the corresponding values ranged from 8.901 to 35.497 (Table 4).

These results indicate that increasing the applied load resulted in greater tensile mechanical demand and that the loading configuration influenced the spatial distribution of this demand.

TABLE 4. MAXIMUM PRINCIPAL STRESS VALUES (MPA).

Loading	Orthostatic	Lateral fall over the greater trochanter
500 N	8.358	8.901
1000 N	15.534	14.904
1500 N	23.301	21.610
2000 N	28.727	32.924
2500 N	32.856	35.497

C. Minimum Principal Stress

The minimum principal stress demonstrated a different spatial distribution from that observed for the maximum principal stress.

In the orthostatic configuration, the greatest compressive stress concentrations were predominantly observed in the anterolateral region at the base of the femoral neck. Under lateral fall loading, the concentration shifted toward the superior region of the femoral neck (Fig. 8).

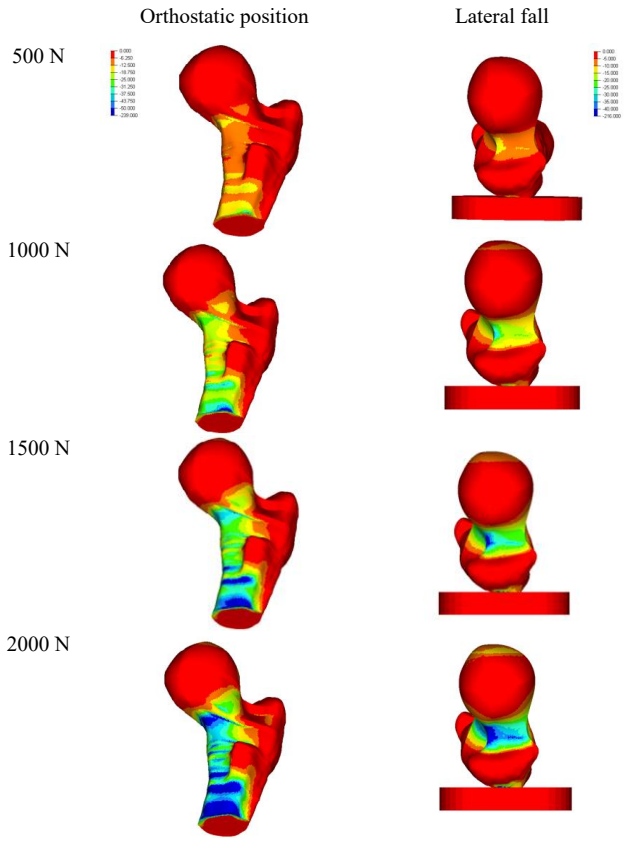

Fig. 8. Minimum Principal Stress – orthostatic position and lateral fall position over the greater trochanter.

The magnitude of the minimum principal stress increased progressively with the applied load. In the orthostatic configuration, values ranged from –13.135 at 500N to –62.504 at 2500N. In the lateral fall configuration, the values ranged from –12.977 to –72.374 (Table 5).

Thus, among the investigated loading conditions, the lateral fall configuration generated greater compressive stress magnitudes at the higher applied loads.

TABLE 5. MINIMUM PRINCIPAL STRESS VALUES (MPA).

Loading	Orthostatic	Lateral fall over the greater trochanter
500 N	-13.135	-12.977
1000 N	-26.302	-29.729
1500 N	-42.117	-43.424
2000 N	-50.003	-57.899
2500 N	-62.504	-72.374

The numerical results demonstrate that both the magnitude and location of principal stresses depend on the applied load and femoral loading configuration. The femoral neck consistently represented a region of elevated mechanical demand, although the precise location of the maximum and minimum principal stresses changed according to the loading condition. The results therefore provide a mechanical description of the response of the modeled osteoporotic femur and establish a basis for future analyses incorporating heterogeneous CT-derived material properties, sensitivity analysis, and validated fracture criteria.

IV. DISCUSSION

The present study investigated the mechanical response of an osteoporotic femur under two loading configurations: an orthostatic condition and a lateral fall onto the greater trochanter. The finite element simulations demonstrated that both the magnitude and spatial distribution of principal stresses were influenced by the loading configuration and applied force.

The femoral neck exhibited the most relevant stress concentrations in both configurations. Under orthostatic loading, tensile stresses were concentrated predominantly in the superior region of the femoral neck, whereas lateral-fall loading resulted in a shift in the tensile stress concentration toward the anterolateral region at the base of the femoral neck. A corresponding change was observed for compressive stresses, which were concentrated primarily in the anterolateral region of the femoral neck during orthostatic loading and in the superior region during lateral-fall loading.

These findings are qualitatively consistent with previous biomechanical investigations of the proximal femur. Bakker et al. [8] reported that during sideways falls, compressive stresses are concentrated in the superior region of the femoral neck, whereas tensile stresses may develop near the base of the femoral neck. Similarly, Lotz et al. [9] demonstrated that the distribution and magnitude of stress within the proximal femur vary substantially between normal gait and fall conditions. The agreement between these studies and the present numerical results supports the relevance of the modeled loading configurations for investigating mechanical demand in the proximal femur.

The present simulations also showed that the absolute magnitude of the minimum principal stress increased with increasing load and was greater in the lateral-fall configuration at the higher loading levels. For example, at 2500 N, the minimum principal stress was −72.374 in the lateral-fall configuration compared with −62.504 in the orthostatic configuration. This indicates that the lateral-fall condition generated greater compressive mechanical demand within the modeled femoral structure.

However, the present results can only indicate regions subjected to relatively greater mechanical demand. Besides that, the robustness of the present findings should also be investigated through sensitivity analysis. Validation represents another important consideration. The present study was based on a single osteoporotic femur and did not include direct experimental validation. Consequently, the numerical stress values should not be interpreted as experimentally validated fracture thresholds.

Despite these limitations, the present study provides a computational assessment of how orthostatic and lateral-fall loading conditions alter the distribution of mechanical stresses in an osteoporotic femur. The results emphasize the importance of the femoral neck as a region subjected to substantial mechanical demand and demonstrate that loading configuration affects both the magnitude and location of principal stresses.

Therefore, the main contribution of this study is not the prediction of fracture itself, but the characterization of the mechanical stress distribution under two clinically relevant loading configurations. The results provide a basis for subsequent, more comprehensive finite element investigations.

V. Conclusion

Finite Element Analysis demonstrated that the mechanical response of the osteoporotic femur is strongly influenced by the loading configuration and magnitude of the applied force. The femoral neck presented the most relevant concentrations of principal stresses, with changes in their location between orthostatic and lateral-fall conditions. The lateral-fall configuration produced greater compressive stress magnitudes at the higher loads investigated, indicating increased mechanical demand in the proximal femur under this loading condition. The present findings should therefore be regarded as a preliminary computational assessment of stress distribution in a single osteoporotic femur.

Abstract*—Language models remain unreliable when a clinical answer must be computed from a continuous glucose monitoring (CGM) series. This paper evaluates which computational *harness* resources are required by different classes of CGM question. The harness is the controlled execution environment that fixes which representation of the patient data an agent may read and which operations it may run. Extending the LLM-CGM benchmark to an agentic setting, we hold the patient data and the clinical question fixed and vary the harness across eleven configurations, from prompt-only access to executable code, a curated CGM tool library, and a family that reads a rendered PDF report; a deterministic oracle that no agent can query defines correctness. Over 30 patients, three model families and 22 executed system instances, the largest gain with the model held fixed comes from replacing text prompting with executable code (48.3% to 71.4% under Gemma), and the increments above the code level are small. The curated-tool-only configuration produced the most dangerous false negatives of any raw-data route, its cleaning step having removed the sensor-gap information the anomaly questions depend on, whereas the P0–P3 report-only routes recorded no such failure while answering only about a third of the matrix. Sampling parameters were left at model-specific serving defaults, and beyond a 30 s per-call timeout no token or step ceiling was imposed, so contrasts between model families are descriptive, the contrasts above the code level are not iso-compute, and latency and token usage support no ranking. Separately, three endocrinologists assessed 30 automatically generated Ambulatory Glucose Profile (AGP) reports, one reviewer per report: fidelity to the source on the nine core glycemic metrics was 97.41%, though a retrospective, single-center, single-reader assessment supports the plausibility of the pipeline rather than its clinical validity. Across these conditions the accuracy differences attributable to harness configuration exceeded those observed between model families, an outcome specific to the models and settings evaluated.

***Index Terms*—continuous glucose monitoring, language models, agentic systems, benchmark, ambulatory glucose profile, clinical evaluation, time in range**

I. Introduction

Continuous glucose monitoring generates dense physiological time series that must be turned into standardized metrics, temporal patterns and clinically actionable interpretations [3], [4]. Language models have recently been applied to this task, generating narrative summaries and answering natural-language questions about CGM data [2]; the LLM-CGM benchmark formalized it over four guideline-derived question categories with real and synthetic patients [1]. Direct reasoning over long series, however, remains vulnerable to numerical and temporal errors, and one established remedy delegates arithmetic and signal processing to executable code [7].

Most existing evaluations vary the language model and leave the surrounding computational harness fixed. We invert that design: patient data and clinical questions are held constant while the input representation and the computational resources available to the agent vary across raw time series, graphical representations, executable code, curated CGM functions and rendered clinical reports. The question is operational: which harness resources each category of CGM question requires before the answer is accurate and safe enough, and where additional resource ceases to help. We are not aware of a previous CGM-interpretation benchmark that manipulates harness resources this way while holding data, questions and evaluation criteria constant. Efficiency is left out of that judgement, since the runs were bounded only by a per-call timeout (Section V-A) and their cost was not standardized.

By *computational harness* we mean the controlled execution environment mediating between the language model and the patient data: it fixes which representation of the signal the agent may read, bounds it to a declared set of permitted actions, and executes any code in a local sandbox. That sandbox is what makes local-only processing possible, since

at the code, tool and hybrid levels the model receives the schema, its own code and the values that code returns, never the series itself, which meets a data-governance requirement in clinical settings; the prompt-only levels are the deliberate exception, and Section V-A states per level what was sent. Varying the *harness resource* means varying this bundle while the model, the patient and the question stay fixed. By *oracle* we mean, in the established sense of a ground-truth test oracle [28], a deterministic reference implementation that computes the correct answer to each question from the raw signal, contains no language model, and is never exposed to the agents; it defines correctness and the ceiling against which every configuration is scored.

We contribute a harness-resource-stratified extension of LLM-CGM, defined by a matrix of resource levels, a task taxonomy with explicit interpretation axes, the deterministic oracle as ground truth and pre-specified hypotheses relating resource transitions to accuracy and to safety. We additionally evaluate an automatic AGP report-generation pipeline, combining an objective fidelity checklist with a Likert instrument for clinical usefulness, and compare eleven configurations across three model families (Gemma 4 31B, Kimi K2.7 Code, DeepSeek-V3.2) over a paired patient–question matrix, identifying the transitions that improve performance and the configurations that introduce clinically relevant failure modes.

II. Background and Related Work

CGM metrics are estimates derived from an irregularly sampled series subject to gaps when the sensor disconnects or saturates, consolidated by the Ambulatory Glucose Profile into a standardized two-week report embedded in contemporary diabetes care [5], [6]. Our oracle and safety definitions follow the international consensus: time-in-range targets and episode definitions [3], the glucose management indicator [4], and time in range as validated against microvascular outcomes [12]. Interpretation depends on the integrity and coverage of the signal as much as on its values: a missing interval degrades every derived metric, while a missed nocturnal hypoglycemia or an unreported time below 54 mg/dL is a direct safety risk. Evaluation therefore has to separate accuracy from coverage, abstention and clinically consequential false negatives.

The LLM-CGM benchmark queries CGM data across four guideline-anchored categories over five real and five synthetic patients, reporting that text-only prompting of long series is expensive and numerically fragile [1]; an earlier case study characterized the accuracy limits of LLM summaries of 14 days of data [2], and multidimensional medical-LLM benchmarks report sharp drops in high-risk scenarios [10]. A complementary approach makes the model a reasoning engine that selects analytic functions while a sandbox executes the arithmetic, avoiding numerical error and keeping raw data local; it builds on program-aided reasoning [7] and on interleaved reasoning and acting [8]. Our code, curated-tool and agentic levels operationalize distinct points along that axis.

Performance does not equate to clinical safety. The literature on evaluating medical LLMs motivates human evaluation along factuality, reasoning and potential harm rather than correctness alone [13], reports sensitivity to the order and amount of information [14], documents limited uncertainty calibration and abstention [15], and argues for workflow-level rather than model-level evaluation [16]. We therefore frame this work as an early-stage evaluation of a clinical decision-support system, following DECIDE-AI [19], TRIPOD+AI [20] and the IMDRF guidance [21]. No public dataset is used: the study rests on anonymized LibreView reports from real patients of a single service.

III. Benchmark Design

A. Resource Levels and Configurations

The unit of comparison is the *harness configuration*: an agent paired with a fixed bundle of inputs and capabilities. Fig. 1 lays out the eleven, with what each reads on the left and what it may execute on the right. At the agent-only level there is a representation and no actions: the raw series as text (C0), a line or AGP chart as PNG (C1), the report as page images (P0) or as text and tables (P1). A sandbox adds free-form code over the dataframe, in one shot (C2) or in a feedback loop (C3), and a PDF parser (P2); C4 replaces free-form code with a curated CGM library. The top level combines representation and actions over the raw signal (C5) or over the report (P3, and P-Ext+Tools).

P-Ext+Tools is named for what it receives: the digitized report, the series already extracted from it, and a deterministic library step for episode and trend questions. Its results characterize that bundle and not optical character recognition. Fig. 1, generated before the configuration was renamed, still labels the row by its OCR-extracted input.

The raw-data (prefix C) and report (prefix P) families share the oracle but differ in what the agent can access. A *model family* is one of the three evaluated models, and a *system instance* is a configuration paired with a model, the unit that the leaderboard and the mixed model score; of the 33 possible instances, 22 were executed.

B. Task Taxonomy

The benchmark defines 30 objective questions in four categories, of which 28 are evaluated; Q25 and Q26 are excluded by design as hardware artifacts. Each is scored along three difficulty axes, computational load, domain knowledge and visual reading, and appears with its category and grading tolerance in Table I. Severe (Q11) and nocturnal (Q21) hypoglycemia carry direct clinical risk and weigh in the safety analysis. A REPORT_SUPPORTED set marks the nine questions a standard AGP report can answer; the rest tend to fail in the P family, and that gap is part of the measurement.

C. Ground-Truth Oracle and Representations

Write $y^\star = O(s, q)$ for the oracle answer to question q on the complete signal s, and $\hat{y}_\pi = A_\pi(o_\pi, q; H_\pi)$ for the answer of configuration π, which sees only o_π and may invoke only H_π. The isolation stated in Section I is enforced by construction: no configuration can query O, and no oracle

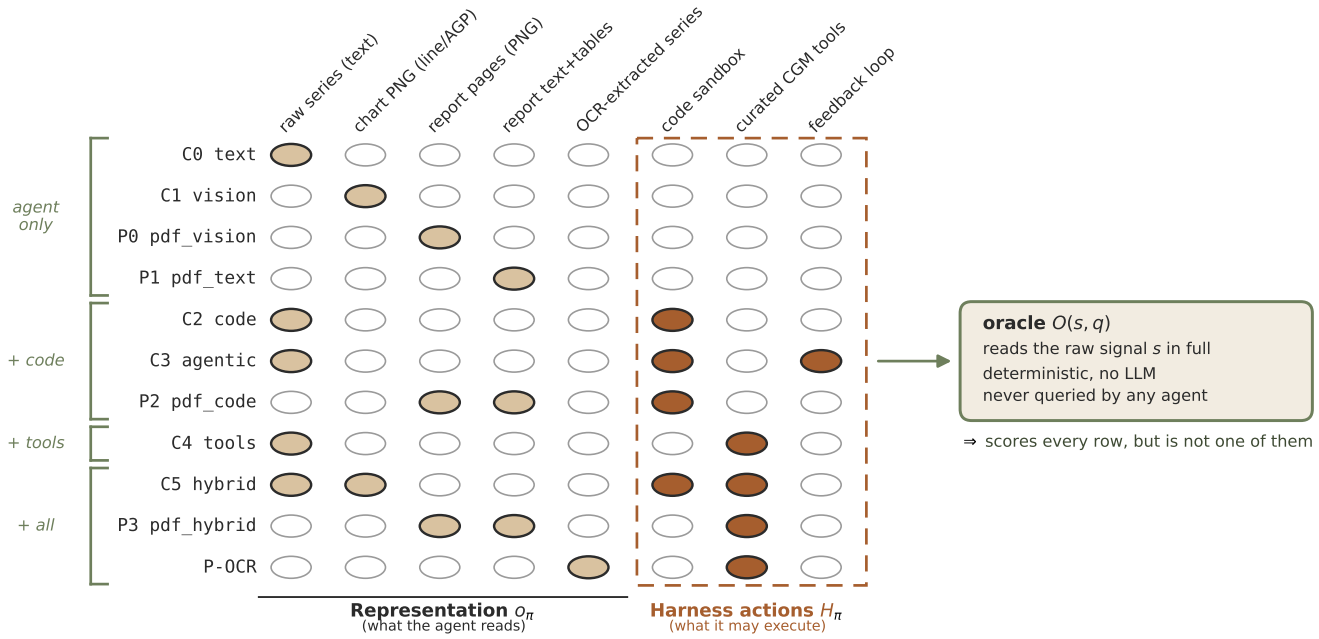

Figure 1. Harness-resource stratification. Each row is a configuration; filled circles mark what it receives (left block, the representation o_π) and what it may execute (dashed block, the action set H_π). This separates two constraints a scalar notion of "resource" would conflate: C0 holds the full series but has $H_\pi = \emptyset$, whereas C1 has an equally empty action set and a lossy representation as well. The row labelled by its OCR-extracted input is P-Ext+Tools, which receives the digitized report, the extracted series and the deterministic library at once and is not a visual route. The oracle is not a configuration: it reads s in full and is never exposed to any agent.

Table I
THE 28 OBJECTIVE BENCHMARK QUESTIONS (Q1–Q24, Q27–Q30); Q25 AND Q26 ARE EXCLUDED BY DESIGN. CAT.: MET = METRIC, TMP = TEMPORAL, ANO = ANOMALY, PAT = PATTERN. TOL. IS THE GRADER TOLERANCE AND FIXES THE ANSWER TYPE (ROUND. = NUMERIC; PP = PERCENTAGE POINT; SAME DAY = DATE; INTEGER = COUNT; YES/NO = BOOLEAN; LABEL = CATEGORICAL; ±10 MG/DL = WINDOWED MEAN). Q11 AND Q21 CARRY DIRECT CLINICAL RISK.

Q	Cat.	Tol.	Statement	Q	Cat.	Tol.	Statement
Q1	met	round.	Mean glucose (mg/dL)	Q15	tmp	same day	Onset of most recent hypo. episode (<70)
Q2	met	round.	Maximum glucose (mg/dL)	Q16	tmp	round.	Duration (min) of last hypo. episode
Q3	met	round.	Standard deviation (mg/dL)	Q17	tmp	round.	Duration (min) of longest hyper. episode
Q4	met	round.	Minimum glucose (mg/dL)	Q18	tmp	integer	Number of hypo. episodes (<70)
Q5	met	±0.5 pp	Time in range, 70–180 mg/dL	Q19	tmp	±10 mg/dL	Mean glucose, 00:00–06:00 (mg/dL)
Q6	met	±0.5 pp	Time above range, >180 mg/dL	Q20	tmp	label	Meal with highest glucose
Q7	met	±0.5 pp	Time below range, <70 mg/dL	Q21	tmp	yes/no	Any hypo. (<70) in 00:00–06:00?
Q8	met	±0.5 pp	Coefficient of variation (%)	Q22	tmp	±10 mg/dL	Highest glucose, 17:00–22:00 (mg/dL)
Q9	met	±0.5 pp	Time >250 mg/dL	Q23	ano	±0.5 pp	Time with active sensor (%)
Q10	met	round.	Estimated HbA1c (eA1c, %)	Q24	ano	integer	Number of sensor disconnections
Q11	met	±0.5 pp	Time <54 mg/dL (severe)	Q27	pat	yes/no	Today's mean better than yesterday's?
Q12	tmp	same day	Day of highest glucose	Q28	pat	yes/no	This week's TIR better than last week's?
Q13	tmp	same day	Day with most time out of range	Q29	pat	yes/no	Today's maximum lower than yesterday's?
Q14	tmp	same day	Day of lowest glucose	Q30	pat	yes/no	Less time <70 this week than last?

output enters any prompt. Harness-resource stratification is the manipulation of (o_π, H_π) with s and q fixed.

The oracle is distinct from the LibreView source report: it defines correctness for the leaderboard over the raw signal, while the report defines fidelity for the study of Section VII over printed values. We reserve *accuracy* for agreement with the oracle and *fidelity* for agreement with the source.

For each patient the oracle normalizes the exports to a canonical schema, fixes an analysis anchor and computes each answer from the raw signal, with episode boundaries, gap handling and thresholds from the consensus [3]. From the same dataframe the harness renders what each configuration consumes: a text bundle, line, AGP and heatmap charts, and a clinical PDF report. Meal windows and the definition of a week are frozen and treated as a sensitivity analysis.

IV. Evaluation Metrics

Four metric families are reported. *Objective accuracy* is rounding-tolerant agreement with the oracle, per question and aggregated. *Coverage and abstention* separate what an instance answers from what it gets right: the parse rate is the fraction of cells returning a value the typed parser accepts, and non-answers, whether a rejected output or a timed-out call, are

counted separately and never as correct. *Clinical safety* counts dangerous false negatives (DFN), an explicit negative answer on a cell whose oracle value indicates a hazard, restricted to the nocturnal and severe hypoglycemia questions and to the sensor-artifact questions that mask them; this is the failure mode with the shortest route to an incorrect insulin dose. A DFN requires an emitted answer, so an instance that abstains cannot accumulate them, and Section VIII-A treats that asymmetry as a result. *Expert assessment* (Section VII) aggregates Likert means and top-rating proportions per dimension. Error magnitude and chart-task rubrics were collected and are omitted for space; latency and token cost were collected but not ranked, the runs not being budget-controlled.

V. Experimental Protocol

The protocol is shown in Fig. 2. From the normalized signal s, two branches run in parallel and meet only at the grader: the oracle computes ground truth, while the renderer produces the representations o_π. The instance-by-patient-by-question-by-repetition matrix is then executed, with the parsed value, latency, steps and any error recorded per cell. The generated AGP report follows a third path, to the endocrinologist panel, whose ratings are collected blind, and to the LLM judge.

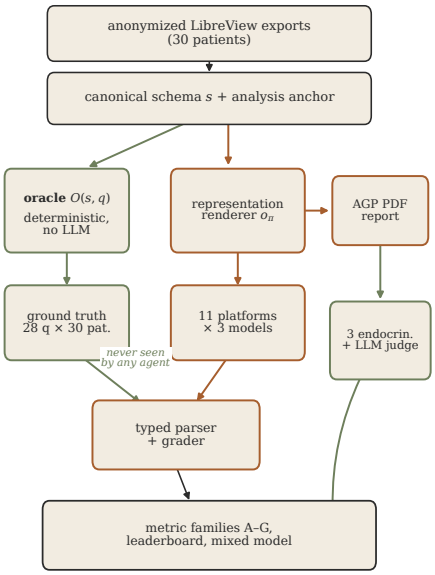

Figure 2. Experimental pipeline. The oracle (left, green) computes ground truth deterministically from s and is never exposed to the agents; it meets the configurations only at the grader. The instance matrix (right, clay) consumes only rendered representations o_π. The generated AGP report additionally feeds the endocrinologist panel and the LLM judge.

A. Model and Harness Configuration

Three model families were evaluated: Gemma 4 31B [24], a dense open generalist with native vision; Kimi K2.7 Code [25], a code-specialized checkpoint of the Kimi K2 family; and DeepSeek-V3.2 [26], a text-only mixture-of-experts model, all instruction-tuned and served unquantized through Ollama Cloud in the last two weeks of June 2026 with thinking mode enabled. Each cell of the instance-by-patient-by-question matrix was run in triplicate ($r = 3$), giving 2,520 calls per instance and 55,440 in total, and the repetitions collapse to one observation per cell by majority vote, the self-consistency rule declared before execution; dispersion across repetitions is retained only as a consistency measure.

The payload reaching the served model differs by level, which matters for data governance. At the code, tool, agentic and hybrid levels the prompt carries the canonical schema and the task, not the readings: the agent writes code, a local sandbox executes it, and only the returned values re-enter the conversation, so the series never leaves the local machine. At the prompt-only levels the representation itself is transmitted, as the text bundle (C0), a rendered chart (C1) or report pages and text (P0, P1). All exports were de-identified beforehand, and no direct identifier appeared in any transmitted payload.

Sampling parameters were not unified: each model kept its own serving defaults, so temperature and top-p differ between them, and unifying them would have meant overriding the recommended settings of checkpoints tuned under different regimes, which we judged worse than a nominal parity. Consequently, no between-family contrast is sampling-controlled and all are read descriptively; the contrasts carrying the central claim hold the model fixed and vary only the harness.

No token or step ceiling was imposed. Each model call was bounded by a 30 s wall-clock timeout, and the code and agentic configurations were otherwise stopped only on non-terminating loops, so per-call latency is right-censored at 30 s while end-to-end latency per cell is not, an agentic cell issuing several calls. Token usage in turn reflects an unstandardized number of calls, input lengths, output lengths and steps. Neither quantity supports a ranking or a cost per correct answer, and efficiency stays out of the leaderboard.

Without a common budget the iterative configurations also had access to a potentially different amount of compute, so the contrasts above the code level are not iso-compute. We cannot establish the direction or the magnitude of that confounding without a budget-controlled analysis. A ceiling can truncate productive and unproductive trajectories alike, and a token ceiling binds single long generations as well as multi-step ones. The single-shot configurations are not equivalent in cost either, since C0 carries the entire series in the prompt where C2 carries only the schema. A budget-controlled replication is what would make the cost axis interpretable, and it may change the magnitude or the ordering of the contrasts above code.

Because DeepSeek-V3.2 accepts no image input, the vision-dependent routes (C1, C5, P0) are infeasible under it by construction rather than by failure: the modality the harness offers, and not the model's competence, decides whether those cells can be run at all.

VI. Statistical Analysis

Because each instance is evaluated on the same patients and questions, the observations are paired and non-independent,

with correlation within patients and within questions. Accuracy is analyzed as a paired, hierarchical binary outcome with a logistic mixed model, *correct* $\sim$ instance $\times$ category with random intercepts for patient and question, which keeps easy questions or particular patients from dominating the estimate [22]. Fitted over the 22 executed instances and the 18,480 majority-vote outcomes, it yields the contrasts in Table IV, prespecified and corrected for multiplicity by false-discovery-rate control [23], with bootstrap intervals reflecting the clustered structure. Where agreement is high but one margin is nearly constant, kappa collapses under extreme prevalence, a paradox that motivates reporting delta, agreement range and correlation instead [27].

Five hypotheses were fixed before execution, each mapped to one contrast, with rounding-tolerant accuracy as the primary outcome except in H4, which is also a safety hypothesis. H1: a code sandbox added to a prompt-only configuration increases accuracy (C2 vs C0). H2: combining representations and actions increases accuracy beyond code alone (C5 vs C2). H3: a chart-only representation, being lossy, yields lower accuracy than the raw series in text (C1 vs C0). H4: a curated library in place of free-form code does not increase accuracy and may reduce safety when its definitions diverge from the oracle (C4 vs C2). H5: an agentic feedback loop recovers single-shot failures and exceeds one-shot code (C3 vs C2). Every contrast holds the model family fixed.

VII. Endocrinologist Assessment of the Automatic AGP Report Generation

Before running the full matrix we assessed one representation, the clinical PDF report the P family consumes. The pipeline extracts numerical data from a source LibreView report, generates a structured interpretation, and carries an automatic fidelity audit against the source. It is also the calibration set for the LLM judge.

A. Instrument, Participants and Data

The instrument has three parts. Part A is an objective 16-item fidelity checklist, each item asking whether a quantity in the generated report matches the LibreView source (yes, no, or not applicable), the human analogue of the automatic audit. Parts B to D are 5-point Likert items (1 strongly disagree to 5 strongly agree) covering technical quality, interpretive quality and clinical usefulness, and an overall assessment. Three endocrinologists assessed 30 generated reports, one reviewer per report and no report read twice.

That design bounds what the assessment can establish. It is expert opinion under a fixed protocol, not a validation study: with a single reader per report there are no replicate ratings, no inter-rater coefficient can be estimated, and an isolated divergence cannot be assigned either to a stricter but faithful reviewer or to a genuine defect. The sample is small (30 patients, one service, one documentary source) and retrospective. The reader confounding is mitigated, not removed, by checking whether divergences concentrate in one reviewer and by the automatic audit below.

B. Objective Fidelity

We call *core glycemic metrics* the nine consensus-defined quantities the extraction schema exposes as scalars, and that the automatic audit covers: mean glucose, GMI, CV, TIR, TBR $<$70, TBR $<$54, TAR $>$180, TAR $>$250 and sensor capture [3], [4]. The rest are provenance or qualitative items with no scalar counterpart, and the two groups fail for different reasons and at different rates.

Table II reports the per-item agreement rate. Aggregated over the nine core metrics, fidelity is 97.41% (263 of 270 item–report pairs), from 93.33% (TBR $<$54) to 100.00%, and the failures concentrate outside the core. Identification of automatically confirmed data is the largest single gap at 80.00%: the report communicates poorly which values were confirmed automatically and which were flagged for manual review. Ceiling saturation at 350 mg/dL or above is flagged inconsistently (89.29% of the 28 applicable reports), and time below 54 mg/dL is the only core metric under 96%. Divergences are spread across reports: 14 of the 30 drew at least one flagged item and 4 drew two or more.

Table II
Objective fidelity against the LibreView source (n = 30 patients). Rates are $k/30$ unless noted; †25/28, excluding two not-applicable reports. ‡Sensor capture, TIR 70–180, CV, TBR $<$70, TAR $>$250. Items at 100.00% omitted (period, mean glucose, GMI, TAR $>$180, estimated/missing data, technical alerts). Core-metric aggregate: 97.41% (263/270).

Checklist item	% agree	failures
Identification of confirmed data	80.00	6 no
Ceiling saturation $\geq$350 mg/dL	89.29†	3 no, 2 n/a
Time below 54 mg/dL (TBR)	93.33	2 no
Declared number of days	96.67	1 no
Manual-review flagging	96.67	1 no
Five further core metrics‡	96.67	1 missing each

C. Clinical Usefulness Ratings

All Likert responses fell in the 4 to 5 range, with a global mean of 4.90, 90.4% at the top of the scale, per-section means between 4.88 and 4.97 and three items at a perfect 5 from every reviewer. The lowest-rated are the clarity of patient-facing language (4.57, with 13 of 30 evaluations giving only partial agreement) and the usefulness of the suggested-management section (4.70); the adoption item, "I would use this report as clinical decision support, provided it is reviewed by a qualified professional," scored 4.93. The ceiling effect limits discrimination between reports and prevents these means from being interpreted as a general estimate of pipeline performance.

D. Human versus Automatic Audit

An automatic audit compared the report scalars with the source PDF on the nine core metrics and returned *consistent* in all 30 cases, agreeing across all valid pairs (28–30 per metric) for the eight numerical metrics with dual coverage. The five isolated human "no" answers have no counterpart in the audit,

which is more consistent with reviewer interpretation than with a pipeline defect; on TBR <54, two reviewers marked "no" on reports the audit confirmed as faithful, plausibly judging how prominently severe hypoglycemia was highlighted rather than whether the number was present. The audit is suggestive and not decisive here, since it reads the same extracted representation the pipeline produces and checks values, not presentation. Every defect it can see lies in the items *without* automatic coverage, across at least 9 reports; on the qualitative items the ambiguity remains, and only multiple readers per patient would resolve it.

E. Calibration of the LLM Judge against the Panel

The same 30 reports and six dimensions went to an LLM judge, an auxiliary triage instrument and not a substitute for the panel, drawn from a model family distinct from those evaluated to mitigate the self-preference, position and verbosity biases documented for LLM judges [9]. All 30 were judged without error (global mean 4.80; 26 pass, 4 pass with caveats, no fail), and its ordering of dimensions reproduces the panel's, with actionability (4.57) lowest and clinical safety (5.00) highest, so both locate the weakness in the management text, not in the arithmetic. Its mean is within 0.20 point of the endocrinologist's (SD 0.29), but the correlation between the two sets of means is only moderate, $r = 0.49$ ($p = 0.006$), so close average agreement is not close agreement report by report. Where they diverge the judge is the stricter reader, penalizing internal numerical inconsistencies ("10 of 14 days" in the text against 9 in the table) that the reviewer let pass.

Weighted kappa is again uninformative, all endocrinologist means rounding to 5. And although none of the 77 panel-annotated hazards was omitted, no synthetic hazards were seeded and no non-hazard controls annotated, so specificity is unmeasured and a detector flagging indiscriminately would reach the same recall of 1.00. A seeded-error study is the next step.

VIII. Results: Leaderboard and Model Contrasts

The matrix spans 30 patients and 28 questions, giving 840 pairs per instance; Table III orders the instances by global accuracy with bootstrap CIs. Kimi and DeepSeek replicate the code, agentic, tool and hybrid routes whenever the input is textual; absent instances were not run.

With the model fixed, accuracy rises 23.10 pp from C0 (text) to C2 (code), the largest transition on the scale, supporting H1. Above C2 the increments are small, the hybrid C5 landing 5.6 points above code, and chart reading (C1) falls below text-only, consistent with H3. The agentic loop (C3) ties with or falls slightly below one-shot code in all three families, so H5 is not supported, though how the contrast behaves under a common budget remains untested. Between families the spread is small and there is no single winner, the code-specialized model surpassing the generalist in pattern recognition and losing in anomaly detection. These family contrasts are descriptive, the models having been served under model-specific sampling defaults.

C4, which replaces free-form code with the curated library, sits below C2 in accuracy and produced the largest number of dangerous false negatives among the raw-data configurations, 24 to 25 against 6 to 11 for code and hybrid. The mechanism is specific to this implementation: its cleaning routine removes the signal gaps before computing metrics, discarding the sensor-absence information the anomaly questions (Q23, Q24) require, and C4's anomaly accuracy falls to 7% against 97% for C2. A tool layer therefore does not by itself reduce risk, and here the effect follows from a single preprocessing choice.

P-Ext+Tools achieved the highest observed accuracy, with 2 dangerous false negatives, the lowest count among routes answering all 28 questions. This result does not isolate visual report interpretation, since the configuration also receives the extracted series and the deterministic library step (Section III). The aligned-versus-template pair quantifies the H4 risk: with the library parameters misaligned from the oracle (`min_gap` 5 vs 60 min), accuracy drops 17.14 pp and disconnection detection collapses, 320 reported against a true 1. For this configuration, performance depended strongly on alignment between the library definitions and the oracle, and the mismatch produced no visible signal in the output; configurations writing their own code were less sensitive to it.

Global accuracy of the report-based configurations (P0–P3, 23.6 to 31.1%) is bounded by coverage: only 9 of the 28 questions are answerable from a standard AGP report, so their parse rate is correspondingly low (28 to 32%); on covered questions with an emitted answer, accuracy reaches 96% (P1, P3).

Table III
LEADERBOARD (N = 30 PATIENTS, 28 QUESTIONS, 840 PAIRS PER INSTANCE): GLOBAL ACCURACY, 95% BOOTSTRAP CI, PARSE RATE AND DANGEROUS FALSE NEGATIVES (FN). FN COUNTS ARE CONDITIONAL ON AN EMITTED ANSWER AND ARE NOT COMPARABLE ACROSS ROWS WITH DIFFERENT PARSE RATES. G = GEMMA 4 31B, K = KIMI K2.7 CODE, D = DEEPSEEK-V3.2; BETWEEN-MODEL DIFFERENCES ARE DESCRIPTIVE, SAMPLING PARAMETERS NOT HAVING BEEN UNIFIED. A. Dangerous False Negatives and Abstention

A dangerous false negative requires an emitted answer, and the instances abstain at very different rates, so the safety column of Table III is not interpretable without its parse rate. The report family (P0–P3) records zero such failures while answering about a third of the matrix, mostly the metric questions an AGP report prints. Under a convention that treated a non-answer on a risk-bearing question as a missed hazard, their position in the ordering would change, but by how much cannot be derived from the global parse rate: an instance may abstain heavily on the questions an AGP report does not cover and still answer most risk questions. Deciding this needs coverage measured on the risk cells themselves (Q11, Q21 and the sensor-artifact questions), which we did not compute for this version and which the benchmark will report next.

Coverage bounds the raw-data family too. C4 and C3 under Gemma parse 59% and 69% of cells, so their counts of 25 and 11 may understate the denials that full coverage would have produced. The comparison between C4 and C2 is less exposed, since C4 under DeepSeek parses 98% and still records 24 against Gemma's 25 at 59% coverage, which points to the preprocessing and not to the model. Among the instances that answer essentially every cell the counts cluster between 6 and 11.

B. Mixed-Model Contrasts

The mixed model of Section VI resolves the five hypotheses (Table IV). H1 is supported and is the largest effect on the scale, and H3 is supported, with isolated visual reading below text. Above code the results diverge: H5 is not supported, the agentic loop tying with one-shot code, while H4 is supported on accuracy, the curated library falling significantly below code in both families where it ran. H2 holds only partly, since the hybrid exceeds code under Gemma but not under Kimi, which a naive paired test would have obscured. Per axis, higher computational load and visual-reading difficulty reduce correctness, while the positive domain-knowledge sign is confounded with report-covered metric questions and is not read as causal. Question-level variance (ICC 0.125) exceeds patient-level variance (ICC 0.033).

Table IV
CONTRASTS AND EFFECTS OF THE LOGISTIC MIXED MODEL (22 SYSTEM INSTANCES, 18,480 MAJORITY-VOTE OUTCOMES). OR >1 FAVORS THE LEFT-HAND CONFIGURATION, OR THE INCREASE ALONG THE AXIS; p WITH BENJAMINI–HOCHBERG CORRECTION. ALL CONTRASTS HOLD THE MODEL FAMILY FIXED. G = GEMMA 4 31B, DS = DEEPSEEK-V3.2.

Contrast / effect	OR	95% CI	p_{BH}
C2 code vs C0 text (H1)	3.91	3.06–4.98	4×10^{-27}
C1 vision vs C0 text (H3)	0.50	0.40–0.62	6×10^{-9}
C3 agentic vs C2 code (H5, G)	0.81	0.58–1.13	0.33
C4 tools vs C2 code (H4, G)	0.54	0.37–0.78	0.004
C4 tools vs C2 code (H4, DS)	0.54	0.36–0.80	0.006
C5 hybrid vs C2 code (H2, G)	1.58	1.09–2.27	0.037
C5 hybrid vs C2 code (H2, K)	0.85	0.55–1.31	0.49
Computational load (per level)	0.79	0.78–0.81	$< 10^{-78}$
Domain knowledge (per level)	1.26	1.22–1.29	$< 10^{-70}$
Visual reading (per level)	0.72	0.70–0.73	$< 10^{-188}$

IX. DISCUSSION

The largest observed accuracy gain occurred in the C0-to-C2 transition, where executable code was introduced. Above that level, an iterative loop, a chart alongside the series and a library of ready-made functions each changed accuracy by a few points at most, and in one case reduced it, in every model evaluated.

A cleaning routine inside the C4 tool library deleted the sensor gaps before any metric was computed, which is defensible for a mean and destructive for counting disconnections: anomaly accuracy fell to 7% and dangerous denials more than doubled, so C4 recorded the lowest safety among the raw-data routes despite having the largest amount of surrounding machinery. The finding is specific to this implementation. It illustrates a general mechanism nonetheless: a tool library encodes definitions, and a divergence between those definitions and the reference produces no visible signal in the output.

The report pipeline was faithful on the core metrics and near the ceiling on perceived usefulness. The defects worth prioritizing are all addressable in the template: two reports whose narrative underplayed severe hypoglycemia although the numbers were right, inconsistent ceiling-saturation flagging, and identifying which values were automatically confirmed, a provenance issue and not a glycemic one.

Agentic orchestration is not demonstrated to be superior, since C3 ties with C2 and the hybrid leads narrowly under one family only. The expert instrument saturates (mean 4.90, three zero-variance items), so it validates this report but cannot discriminate between configurations; with one reviewer per report, strictness and report defect stay partly confounded on the qualitative items, and 30 retrospective reports from a single service are a narrow base for generalization. The safety column depends on an accounting convention and on coverage measured at the risk cells, which we do not yet report (Section VIII-A); sampling was not unified, so every between-family comparison is descriptive; budgets were open, so the cost of each level is unquantified; and 11 of the 33 instances were never run. Benchmark scores that ignore data, task and metric choices readily create an illusion of clinical readiness [11], [13], [14].

A clinically relevant next step is to evaluate interpretation support under human review, including whether clinician–model collaboration improves performance and when the system should abstain [17], [18]. Such a study would require external reports, multiple independent evaluators per case with adjudication, and abstention and calibration metrics [15], [16], reported under contemporary guidelines [19], [20]. Because a glucose error can propagate to an incorrect insulin dose, safety is the priority axis, and deployment would bring software-as-a-medical-device framing into scope [21].

X. CONCLUSION

We presented a harness-resource-stratified benchmark for CGM interpretation, an expert assessment of an automatic AGP report pipeline over 30 patients, and a leaderboard

over 22 system instances. Under the models and conditions evaluated here, varying the harness produced larger accuracy differences than those observed between model families, the text-to-code transition being the largest. Because the between-family contrasts were not sampling-controlled and only three model families were evaluated, this difference should be interpreted as specific to the present experimental conditions; a budget-controlled replication may also change the magnitude or the ordering of the contrasts above the code level.

A curated tool layer can reduce safety when its preprocessing discards information a task depends on, and the failure is silent. A false-negative count of zero can also reflect abstention rather than hazard recognition, so safety has to be reported together with coverage, and with coverage measured on the risk questions themselves. Neither result licenses clinical deployment, which would require external data, multiple adjudicated evaluators, a collaboration arm and prospective evaluation; those, with a seeded-error study for judge specificity and a budget-controlled replication, are our next steps.

***Abstract*—Wearable Internet of Things systems for health monitoring combine sensors, local wireless links, gateways, application protocols, and remote services. This paper presents an exploratory layered analysis that distinguishes connectivity technologies from application-layer protocols. Bluetooth Low Energy (BLE) and Wi-Fi are examined at the wireless connectivity layer, whereas MQTT, HTTP/REST, and WebSocket are discussed according to their roles after IP connectivity is available. Zigbee, Thread, LoRaWAN, NB-IoT, and LTE-M are included as architectural alternatives outside the implementation scope. The reference architecture distinguishes the functions of the wearable, gateway, network access, remote service, storage, and monitoring interface. Preliminary observations used a Redmi Watch 5 Active as a closed commercial reference and an ESP32-PICO-D4-based M5StickC Plus as an open prototyping platform. The implementation was limited to Wi-Fi association, simulated physiological-message generation, payload structuring, and functional connectivity verification. Controlled measurements of energy per message, latency distribution, application-message loss, goodput, reconnection time, memory use, scalability, interference, offline buffering, and security overhead were not performed. Therefore, the study does not establish quantitative superiority or clinical suitability. Its contribution is a requirements-based framework that separates published evidence from bench observations and defines a reproducible protocol for subsequent controlled experiments.**

***Index Terms*—wearable IoT, health monitoring, Bluetooth Low Energy, Wi-Fi, MQTT, HTTP, WebSocket, ESP32, communication architecture**

I. Introduction

The Internet of Things (IoT) integrates sensors, embedded devices, communication networks, and digital services [1], [2]. In healthcare, this integration supports remote monitoring, home follow-up, physiological telemetry, and continuity of care outside hospitals [3]–[5]. Wearable systems are particularly relevant because they can acquire heart rate, oxygen saturation, temperature, movement, and activity data periodically or continuously [6], [7].

Communication is not a single interchangeable component in these systems. Wireless connectivity technologies determine how a wearable reaches a nearby gateway or access network. Application protocols determine how data are exchanged after a compatible network path exists. Treating BLE, Wi-Fi, MQTT, HTTP, and WebSocket as direct alternatives obscures this layering and can lead to unsupported rankings. BLE and Wi-Fi occupy the connectivity portion of the architecture, whereas MQTT, HTTP/REST, and WebSocket operate at the application layer over IP-based transport. Gateways may bridge non-IP links, perform local processing, buffer data, and forward selected records to remote services [4].

BLE is widely used for short-range, battery-constrained wearable links and smartphone integration [8]–[10]. Wi-Fi provides direct access to local IP networks and commonly available Internet infrastructure, but its energy cost depends on association, radio state, traffic pattern, and power-management configuration [11], [12]. Other technologies may be appropriate for different constraints. Zigbee and Thread use IEEE 802.15.4-based low-power networking and generally require a coordinator or border router. LoRaWAN targets low-power wide-area communication through gateways and network servers. NB-IoT and LTE-M use managed cellular infrastructure [13]–[16]. These alternatives are discussed in this paper but were not implemented.

At the application layer, MQTT uses a brokered publish/subscribe model and supports different quality-of-service levels [17]. HTTP defines request-response semantics commonly used by REST APIs [18], [19]. WebSocket establishes persistent bidirectional communication after an HTTP handshake [20]. Published experiments show that protocol behavior depends on payload, loss conditions, security, and implementation, so no application protocol can be declared universally superior from architectural descriptions alone [21], [22].

Security and privacy are also system properties, not labels inherent to a protocol name. BLE pairing mode, credential management, authorization, TLS configuration, storage protection, and key lifecycle all influence the actual risk. Wearable and medical IoT systems therefore require explicit threat and performance evaluation [23]–[25]. A connectivity check cannot demonstrate security, autonomy, clinical reliability, or resilience

to attacks.

This study asks how communication technologies and application protocols for wearable health monitoring can be organized according to their architectural roles and measurable requirements without assuming equivalence or unsupported quantitative superiority. Its contributions are: 1) a layered reference architecture that separates wireless links, gateways, IP access, application protocols, and remote services; 2) an explicit distinction between published evidence, preliminary bench observations, unmeasured properties, and a proposed benchmark; 3) a requirements matrix without subjective suitability scores; and 4) a reproducible protocol for subsequent measurement. The paper does not claim clinical validation or comparative performance results.

II. Methodology

A. Study Design and Evidence Classification

This is an exploratory technical study combining a focused narrative review with preliminary functional observations. It is not a systematic review, meta-analysis, or controlled protocol benchmark. Sources were selected to cover wearable health architectures, BLE and Wi-Fi behavior, application protocol definitions and performance, security, and the official specifications of the devices and additional connectivity technologies.

Every statement in the analysis is assigned to one of four evidence classes: *literature-supported*, when based on a cited publication or standard; *bench-observed*, when directly observed in the preliminary implementation; *not measured*, when the study collected no comparable data; and *proposed benchmark*, when a parameter is specified only for a future controlled experiment. This classification prevents literature-based expectations from being reported as measurements made by the authors.

B. Reference Architecture

Fig. 1 separates six roles: wearable or sensor node; smartphone or dedicated gateway; network access; broker or application server; storage; and dashboard or research interface. A commercial wearable may expose measurements only through a proprietary smartphone application. An open device may connect directly to Wi-Fi and then reach an application service. MQTT, HTTP/REST, and WebSocket are positioned only after IP connectivity. A gateway is an intermediary computing and translation role, whereas the cloud is a deployment location for services and storage; the two terms are not used interchangeably.

C. Devices and Preliminary Procedure

The closed commercial reference was a Redmi Watch 5 Active. The manufacturer specifies Bluetooth 5.3 connectivity, a heart-rate sensor with a blood-oxygen sensor, and a 470-mAh battery [27]. The watch was used only to observe pairing and the dependence on its mobile application. No proprietary BLE packet was intercepted, modified, or treated as a physiological ground truth.

The open platform was an M5StickC Plus, product K016-P, built around an ESP32-PICO-D4 and supplied with a 120-mAh battery [28]. The SiP provides 2.4-GHz IEEE 802.11b/g/n Wi-Fi, Bluetooth 4.2/BLE, 520 KB of SRAM, and 4 MB of in-package flash [12]. The exact historical IDE and board-core revisions used during the initial exploratory work were not retained. For subsequent replication, a reference software baseline is defined using Arduino IDE 2.3.10 and Arduino-ESP32 core 3.3.11 [29], [30]. These versions define the proposed repeatable baseline and should not be interpreted as retrospectively verified details of the initial exploratory implementation.

Only Wi-Fi association and simulated-message handling were implemented on the M5StickC Plus. The observations verified that the platform could join a local 2.4-GHz network, generate a structured record resembling physiological data, and expose connection state for debugging. MQTT, HTTP/REST, and WebSocket were not implemented side by side under an identical workload. The exact original payload, sending interval, test duration, distance, message count, and number of repetitions were not logged. No original latency trace, packet-loss log, current trace, reconnection series, or memory profile is available. Therefore, the Results section reports no reconstructed numeric result.

D. Architectural Alternatives Outside the Bench Scope

Table I positions additional wireless technologies relevant to wearable IoT health-monitoring architectures. The entries describe roles and constraints supported by standards and official technical material; they are not performance results from the M5StickC Plus. Zigbee and Thread are relevant when mesh coverage and low-power IEEE 802.15.4 radios are available. Thread preserves IP networking through a border router, while Zigbee uses its own stack and coordinator model. LoRaWAN is relevant to sparse low-rate telemetry over a wide area, but requires LoRa-capable hardware, gateways, and a network server. NB-IoT and LTE-M use a cellular modem, subscriber provisioning, and operator coverage. None is native to the ESP32-PICO-D4 used here.

E. Requirements Matrix

To avoid unsupported ordinal rankings, candidate technologies are screened against explicit system requirements, as shown in Fig. 2 and Table II. Quantitative limits should be defined according to the intended use case before protocol selection. A research dashboard, a store-and-forward activity logger, and a safety-critical clinical alarm do not share the same latency, availability, or risk requirements.

F. Proposed Controlled Benchmark

Fig. 3 specifies a future benchmark and must not be read as an executed experiment. The reference UTF-8 JSON payload is:

```
{"device":"M5C01","seq":"000001",
"ts":"2026-08-25T12:00:00Z",
"hr":78,"spo2":98,"temp":36.6}
```

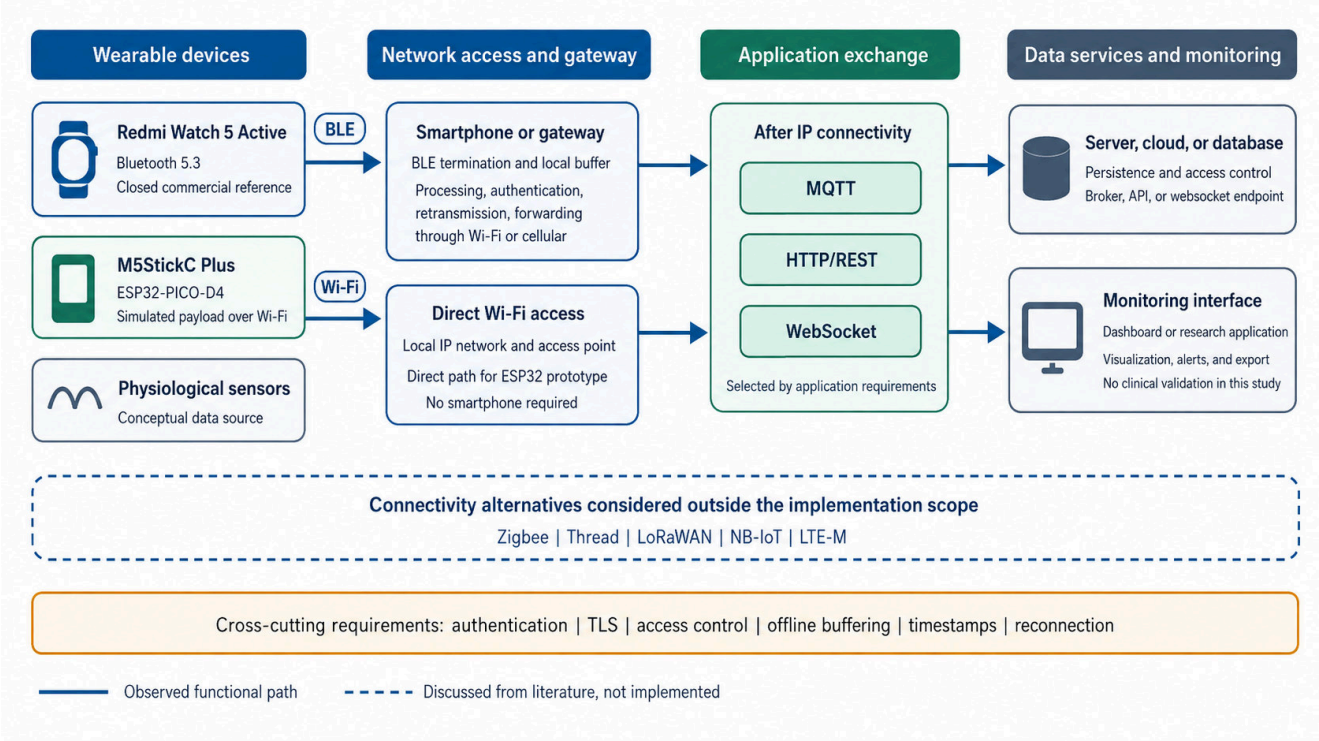

Fig. 1. Layered reference architecture for wearable IoT health monitoring. The Redmi Watch 5 Active represents a BLE-assisted gateway path, whereas the M5StickC Plus can access a local IP network directly through Wi-Fi. MQTT, HTTP/REST, and WebSocket are application protocols, not alternatives to BLE or Wi-Fi. The dashed band identifies wireless alternatives discussed from official specifications but not implemented.

TABLE I
WIRELESS CONNECTIVITY ALTERNATIVES AND THEIR ARCHITECTURAL ROLES

Technology	Network role	Typical intermediary	Selection questions	Evidence in this study
BLE	Short-range wearable link	Smartphone or BLE gateway	Required autonomy, connection interval, payload size, phone dependence, pairing policy	Literature; commercial pairing observation only
Wi-Fi	Direct local IP access	Access point or router	Association energy, coverage, congestion, credentials, local/cloud route	Literature; functional association and simulated messages
Zigbee	Low-power mesh over IEEE 802.15.4	Coordinator and gateway	Mesh density, coordinator availability, stack interoperability, interference	Standards discussion; not implemented
Thread	IPv6-based low-power mesh over IEEE 802.15.4	Thread border router	Border-router availability, IPv6 integration, mesh density, commissioning	Standards discussion; not implemented
LoRaWAN	Low-power wide-area uplink/downlink	Gateway, network server, application server	Regional band, duty cycle, payload frequency, downlink demand, coverage	Specification discussion; not implemented
NB-IoT / LTE-M	Managed cellular IoT access	Operator network and cellular modem	Coverage, subscription, mobility, latency budget, energy profile, certification	3GPP discussion; not implemented

The payload contains 91 bytes without a terminating newline and is generated once per second. Each condition comprises 600 messages over 10 minutes and three independent repetitions at 1, 5, and 10 m. The Wi-Fi access point uses a fixed 2.4-GHz channel, 20-MHz channel width, WPA2, and a wired local server to reduce uncontrolled backhaul variation. MQTT QoS 0 and QoS 1, HTTP POST, and a WebSocket text message use the same application content. Device and server timestamps require a documented synchronization method; otherwise only round-trip latency may be reported.

The benchmark shall report latency distributions, application-message loss, duplicates, useful goodput, energy per delivered message, reconnection time, and memory use. A programmable interruption shall test reconnection and offline buffering. Security tests shall compare unprotected local communication only as an instrumented baseline against TLS-protected MQTT, HTTPS, and secure WebSocket, using the same authentication policy. Reported overhead shall separate initial handshake cost from steady-state records. Co-channel traffic shall be recorded or controlled, and an interference condition shall be reported separately. Scalability requires additional concurrent publishers and cannot be inferred from a single device.

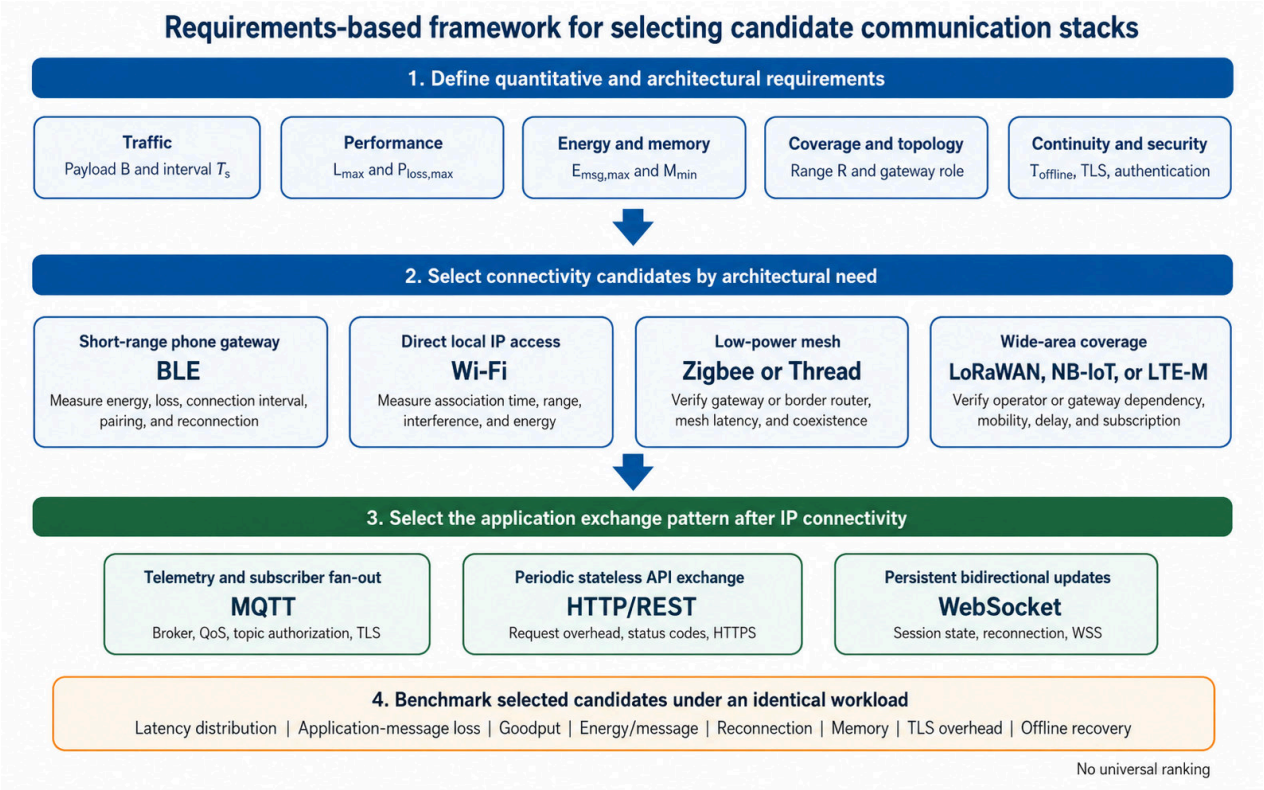

Fig. 2. Requirements-based framework for selecting candidate wireless technologies and application protocols. Candidate selection is conditioned on quantitative limits and followed by controlled benchmarking under an identical workload. The framework does not assign universal suitability scores.

TABLE II
QUANTITATIVE REQUIREMENTS AND REPORTING UNITS

Requirement	Unit	Minimum report
Payload size	byte	Application and on-wire sizes
Generation interval	s	Nominal interval and jitter
One-way or round-trip latency	ms	Definition, p50, p95, p99
Application-message loss	%	Sent, received, lost, and duplicate messages
Goodput	bit/s	Useful payload per elapsed time
Energy per delivered message	mJ/msg	Voltage, current trace, delivery count
Reconnection time	s	Trigger and distribution
Memory use	KB	Free/peak heap and stack method
Offline recovery	msg, s	Buffer capacity and replay time
Security overhead	ms, byte, mJ	Handshake and steady-state deltas

III. RESULTS

A. Bench-Observed Results

The Redmi Watch 5 Active paired with its smartphone application, demonstrating the user-facing behavior of a closed commercial architecture. Direct access to raw sensor packets, connection parameters, and application-protocol selection was not available within the study. Consequently, the watch served as an architectural reference, not as a benchmark instrument or source of clinically validated physiological data.

The M5StickC Plus joined a local Wi-Fi network and supported generation and structuring of simulated records. These observations confirmed functional connectivity and implementation flexibility. They do not quantify latency, application-message loss, goodput, energy consumption, reconnection time, memory use, interference, security overhead, or scalability. Because the original exploratory activity did not retain fixed workload parameters or repeated measurements, no mean, standard deviation, confidence interval, or significance test can be validly calculated.

B. Layered Decision Synthesis

At the wearable-to-gateway link, BLE is a candidate when a nearby smartphone or gateway is acceptable and the device sends small, intermittent records. Wi-Fi is a candidate when direct local IP access is required and the energy budget can accommodate association and active-radio periods. Zigbee and Thread become candidates when an IEEE 802.15.4 mesh and its infrastructure are part of the intended deployment. LoRaWAN, NB-IoT, and LTE-M address wider-area paths with substantially different hardware and infrastructure assumptions. These statements define screening conditions, not a ranking.

After IP connectivity is established, MQTT is a candidate for brokered telemetry and multiple consumers; its QoS level, session state, retained messages, and broker availability must be specified. HTTP/REST is a candidate for stateless resource-oriented integration and periodic uploads; connection reuse and batching affect overhead. WebSocket is a candidate for a persistent bidirectional session, including continuously updated interfaces; keep-alive, reconnection, and server state must be

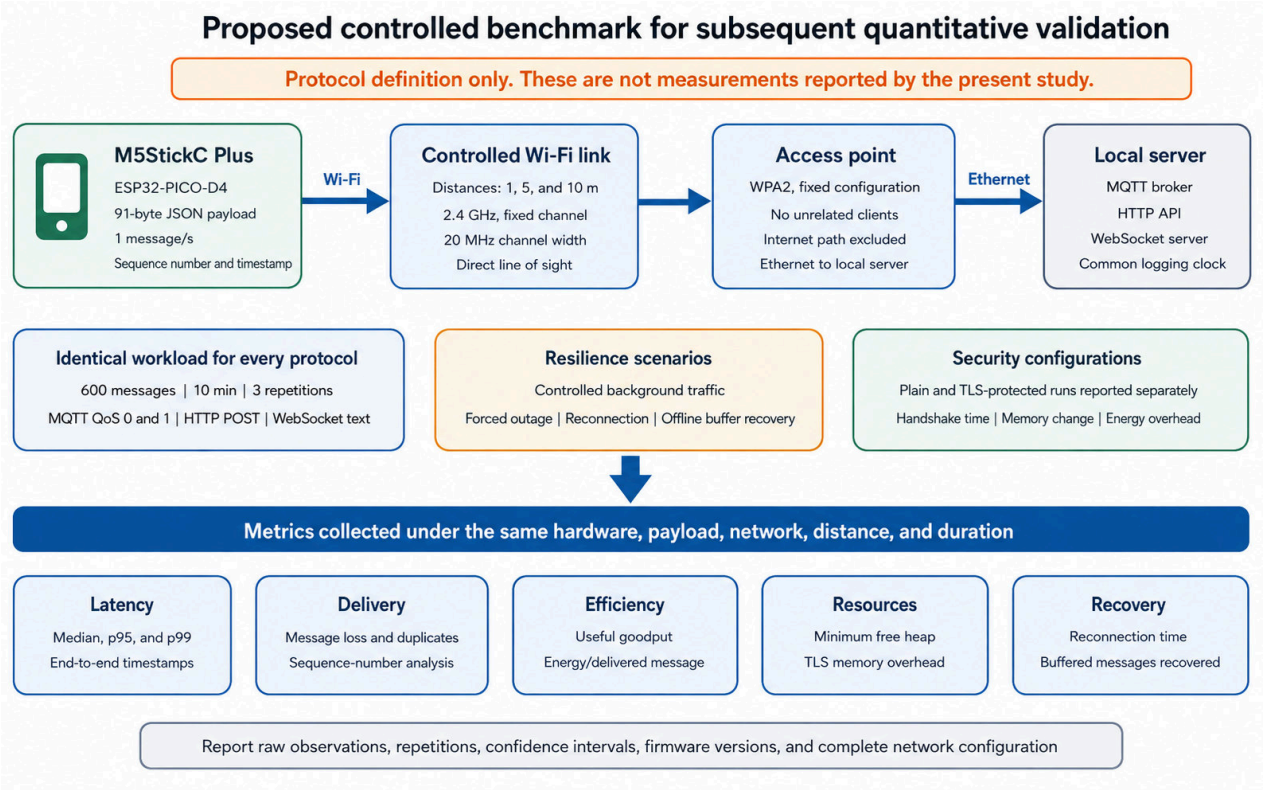

Fig. 3. Proposed controlled benchmark for subsequent quantitative validation. Payload, interval, distance, Wi-Fi configuration, duration, and repetitions are fixed across application protocols. The parameters define future work and are not measurements reported in this paper.

measured. More than one application protocol may coexist, for example MQTT for device ingestion and WebSocket for dashboard delivery.

C. Security, Offline Operation, and Interference

No resilience claim follows from the preliminary connectivity check. A secure implementation requires authenticated onboarding, least-privilege access, credential protection, transport encryption where applicable, replay handling, software update policy, logging, and data minimization [23]–[26]. TLS adds handshake traffic, state, memory use, computation, and energy cost that must be measured rather than assumed from the protocol specification. Similarly, MQTT QoS does not by itself guarantee end-to-end persistence unless client, broker, database, and application behavior are all defined.

Offline buffering is necessary when continuity of the record matters during network loss. A valid test must specify buffer size, overwrite policy, timestamp source, ordering, duplicate detection, replay rate, and behavior after power failure. Because BLE, Wi-Fi, Zigbee, and Thread can share the 2.4-GHz band, interference tests should document channel allocation, coexisting traffic, received signal strength, and environmental conditions. These requirements are included in the proposed benchmark but were not evaluated in the present bench observations.

IV. Discussion

A central contribution of this study is the taxonomic and evidential separation of communication technologies according to their architectural roles. Connectivity technologies and application protocols solve different parts of the communication path, and a health-monitoring architecture often needs one from each category. A BLE sensor may use a smartphone gateway that later sends data through Wi-Fi or cellular access using MQTT or HTTPS. A Wi-Fi prototype may publish through MQTT while a remote service distributes updates through WebSocket. Direct rankings across these categories therefore have no clear experimental meaning.

The requirements matrix supports protocol selection through explicit, measurable requirements rather than universal scenario-based rankings. Selection begins with measurable limits for energy consumption, latency, application-message loss, goodput, range, offline duration, memory use, security overhead, and infrastructure constraints. Only candidates that satisfy architectural constraints should proceed to identical-workload measurements. This approach also prevents a literature result obtained with another radio, board, payload, broker, or network from being presented as a result of the M5StickC Plus observations.

The two devices illuminate different design constraints but do not represent the diversity of current wearables. The Redmi Watch 5 Active is a single closed consumer product. The

M5StickC Plus is a compact development platform, not a medical device, and its ESP32-PICO-D4 is an older SiP that the vendor now marks as not recommended for new designs [12]. Results from either device cannot be generalized to other radios, firmware stacks, antennas, batteries, or clinical workflows.

The contribution is consequently methodological and architectural. The paper provides a transparent methodological basis for a subsequent instrumented study but does not claim to provide a quantitative comparison among protocols. The principal limitations are the absence of controlled repetitions and saved traces; simulation instead of real physiological acquisition; no implementation of MQTT, HTTP, or WebSocket under the same workload; no energy or network instrumentation; no TLS or attack evaluation; no controlled interference; and one example per device category.

Future validation should execute the proposed benchmark on additional platforms and radios, publish firmware and analysis scripts, and report raw traces with clock and instrument uncertainty. It should also transmit data from calibrated physiological sensors under an approved protocol. Any study involving participants or clinical decision support must obtain the required ethical and institutional approvals and define clinical endpoints separately from network performance.

V. Conclusion

This paper reorganized communication choices for wearable IoT health monitoring into a layered architecture. BLE, Wi-Fi, Zigbee, Thread, LoRaWAN, NB-IoT, and LTE-M are connectivity alternatives with different infrastructure assumptions. MQTT, HTTP/REST, and WebSocket are application-layer options used after a suitable network path exists. They should not be ranked as one set of direct alternatives.

The only bench-supported findings are that the Redmi Watch 5 Active exhibited a closed smartphone-mediated workflow and that the M5StickC Plus associated with Wi-Fi and handled simulated structured records. No quantitative, security, autonomy, clinical-suitability, or universal performance claim is made. The requirements matrix and proposed fixed-workload protocol provide a reproducible next step for measuring latency distributions, application-message loss, goodput, energy per delivered message, reconnection, memory use, offline recovery, interference, scalability, and security overhead.

***Abstract*—The rise and spread of multidrug-resistant bacteria have been recognized as a global public health problem. Under selective pressure from the abusive and uncontrolled use of antibiotics by humans, bacteria develop or enhance resistance mechanisms shared within the microbial community in the environment. Multidrug-resistant pathogens in hospital settings overburden healthcare systems and generate considerable global economic costs due to prolonged hospital stays. The ESKAPE pathogens (*Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa,* and *Enterobacter* spp.) were considered a significant challenge, especially in hospital settings where patients with compromised immune systems are particularly susceptible to bacterial infections. The main objective of this study was to investigate the genomic diversity and antimicrobial resistance profile in *Pseudomonas aeruginosa* isolates from environmental, hospital, and animal niches. To this end, a comparative analysis of complete genomes deposited in GenBank and the International Pseudomonas Consortium Database was performed using bioinformatics techniques. The results indicate significant variation in the number of antimicrobial resistance genes (ARGs) among the isolates analyzed. Although the profiles of hospital and environmental genomes were highly similar, the data indicated a trend toward differentiation among chicken isolates, as evidenced by distinct clustering and a higher ARG load. Pangenome analysis revealed a set of highly plastic genes, highlighting the species adaptive capacity. The results of this work contribute to a better understanding of antimicrobial resistance dissemination in *P. aeruginosa* and may assist in developing more effective strategies to control infections caused by this pathogen.**

Index Terms*—*Pseudomonas aeruginosa; antimicrobial resistance; comparative genomics; bioinformatics.

I. Introduction

Antimicrobial resistance (AMR), a natural process, is recognized by global organizations, such as the World Health Organization and the World Bank, as one of the greatest threats [1]. It is estimated that, in 2019, AMR was associated with 4.95 million global deaths, with 1.27 million directly attributed to bacterial resistance [2], [3]. The rapid bacterial adaptation and the stagnation of new antimicrobial class development since the 1960s [4], [5] threaten the safety of essential medical procedures such as surgeries and cancer treatments increasing mortality and hospital costs [6], [7]. This problem, however, is not restricted to the hospital environment, as the spread of multidrug-resistant strains is an inevitable consequence of the use of antibiotics. This broad spectrum of contamination favors the selection of highly versatile bacteria, capable of moving and thriving between natural reservoirs and the clinical environment [8], [9]. Within this context, one of the main examples is *Pseudomonas aeruginosa*. This gram-negative opportunistic pathogen stands out for its versatility and ability to grow in diverse environments, from soil and water to hospital surfaces. It is an aerobic bacterium, with motility provided by one or more polar flagella [10], and it belongs to the ESKAPE group of pathogens — *Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa,* and *Enterobacter* spp. — [11], [12]. This pathogen represents a serious threat to public health, infecting patients with various conditions such as burns, immunodeficiency, and cancer, in addition to being dominant in chronic infections such as cystic fibrosis and chronic obstructive pulmonary disease. Its pathogenic action can affect the lungs, bloodstream, and urinary tract, resulting in acute and chronic infections [13], [14].

P. aeruginosa possesses a large and variable genome (GC content of 65–67%, 5–7 Mb) that significantly contributes to its adaptability. Its arsenal of virulence factors and antimicrobial resistance mechanisms confers remarkable metabolic flexibility and the ability to adapt to diverse conditions, including the host's immune response [15].

This adaptability is reflected in its prevalence as one of the bacteria with the highest number of multidrug-resistant strains to almost all commonly used antibiotics, including aminoglycosides, cephalosporins, fluoroquinolones, and especially carbapenems, resulting in high morbidity and mortality [16]. Due to these characteristics, it is responsible for approximately 10% of hospital-acquired infections. Carbapenem-resistant *P. aeruginosa* was classified by the WHO as a "critical group" pathogen in 2017 and subsequently reclassified as a "high group" pathogen, requiring urgent efforts in the development of new antimicrobials [17].

II. Materials and Methods

A. Data collection

Genomic data from 32 *P. aeruginosa* isolates representing diverse ecological niches — including natural environments (n = 11), animal hosts (e.g., cattle, cows, and chickens; n = 10), and hospital settings worldwide (n = 11) — were analysed [18], together with the reference genomes PAO1 (GCA_000006765.1) [19] and PA14 (GCF_025490475.1). To build this dataset, pre-assembled genomes and raw sequence reads were retrieved from public repositories based on strict curation and selection criteria: (i) raw sequence reads from the Sequence Read Archive (SRA) were required to have complete metadata for all collection parameters, corresponding to the columns in Table I; (ii) isolation sources were chosen to be highly diverse to ensure a broad and general ecological representation; (iii) the origins of the genomes were balanced (n = 10 per niche) to prevent representation bias; and (iv) de novo assemblies were required to have a genomic completeness of 98% or more and preferably a maximum of 300 contigs. Assembled environmental genomes and reference strains were obtained from the International Pseudomonas Consortium Database [20] and GenBank, respectively. The outcomes of the data pre-processing workflow are summarised in Table I.

B. Analysis of genomic sequences

For raw sequence reads, quality control and read filtering were performed using fastp v1.3.3 [21]. The filtered reads were subjected to de novo assembly using SPAdes v3.15.5 [22]. The quality of all genome assemblies was evaluated using QUAST v5.0.2 [23]. Structural and functional annotation of the bacterial genome was conducted using Prokka v1.14.5 [24]. The predicted protein sequences (*.faa) generated by Prokka were used as input for the identification of ARGs with CARD RGI [2], applying the "perfect" and "strict" hit algorithms for genome data.

To infer evolutionary relationships and identify duplication events among the identified ARGs, predicted protein sequences were clustered into orthogroups using OrthoFinder v2.5.5 [25]. Orthogroup assignments were subsequently integrated with RGI-derived annotations via unique protein identifiers. This cross-referencing enabled the extraction of orthogroups containing ARGs, allowing for the targeted identification of intra-genomic duplications and assessment of their distribution across isolates.

The Average Nucleotide Identity (ANI) was calculated using FastANI v1.34 [26] in all-vs-all mode, estimating a 95% limit for species delimitation. The pan-genome was analyzed with Roary [27]. Statistical analyses and visualizations were conducted in R v4.6.0, utilizing the tidyverse packages [28], ComplexHeatmap [29], and PCAtools (Bioconductor) [30].

To evaluate the differences in ARG abundance across ecological niches and isolation sources, data normality was assessed using the Shapiro-Wilk test [31]. Due to the nonnormal distribution, the nonparametric Kruskal-Wallis test was used to compare the abundance of ARGs among groups. Furthermore, a Spearman test [32] was calculated to investigate whether the observed variation in ARG abundance correlates with genome size, thereby evaluating potential genome size bias.

III. Results

A. ANI and Pan-genome

In comparative genome analyses, the ANI values ranged from 98% to 99% across all genomes, without clustering associated with the sources of isolation. The species pangenome was characterized as open, having a core genome consisting of 4,694 genes and an accessory genome with 13,442 genes (Fig. 1).

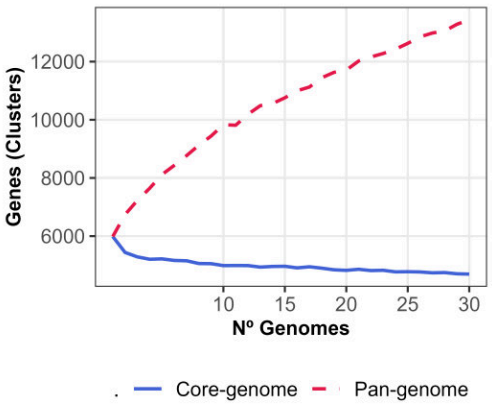

Fig. 1. Analysis of the *P. aeruginosa* pangenome.

B. Resistome Profiling and Resistance Determinants

Resistome profiling of the present dataset revealed substantial heterogeneity among the 32 sequenced *P. aeruginosa* genomes, with total ARG) load ranging from 57 to 80 genes per genome. Chicken-derived isolates exhibited the highest ARG burdens (66–80 genes per genome), whereas genomes from remaining sources exhibited narrower ranges (57–66 genes). Notably, hospital-derived genomes showed ARG abundance comparable to, or slightly lower than, those observed in environmental isolates. Absolute ARG abundance per genome deviated from normality (Shapiro–Wilk: $W = 0.69, p < 0.001$). Spearman rank correlation analysis indicated a weak, nonsignificant association between genome size and ARG abundance (Spearman's $\rho = 0.18, p = 0.317$). In addition, ARG abundance did not differ significantly among major ecological niches (Kruskal–Wallis: $X^2 = 4.32, df = 2, p = 0.115$) (Fig. 2). Given the limited sample sizes within specific isolation sources, downstream comparisons at this level were confined to descriptive analyses.

Across all niches, was identified 64 core ARGs conserved in every genome. This core resistome predominantly comprised genes encoding intrinsic multidrug efflux systems and antibiotic inactivation determinants. The accessory resistome displayed pronounced niche-associated structuring, with discrete ARG subsets shared between specific pairs of niches or uniquely restricted to a single isolation source (Fig. 4.

Genomes starting with SRR or ERR denote raw sequencing data processed through the quality control pipeline.

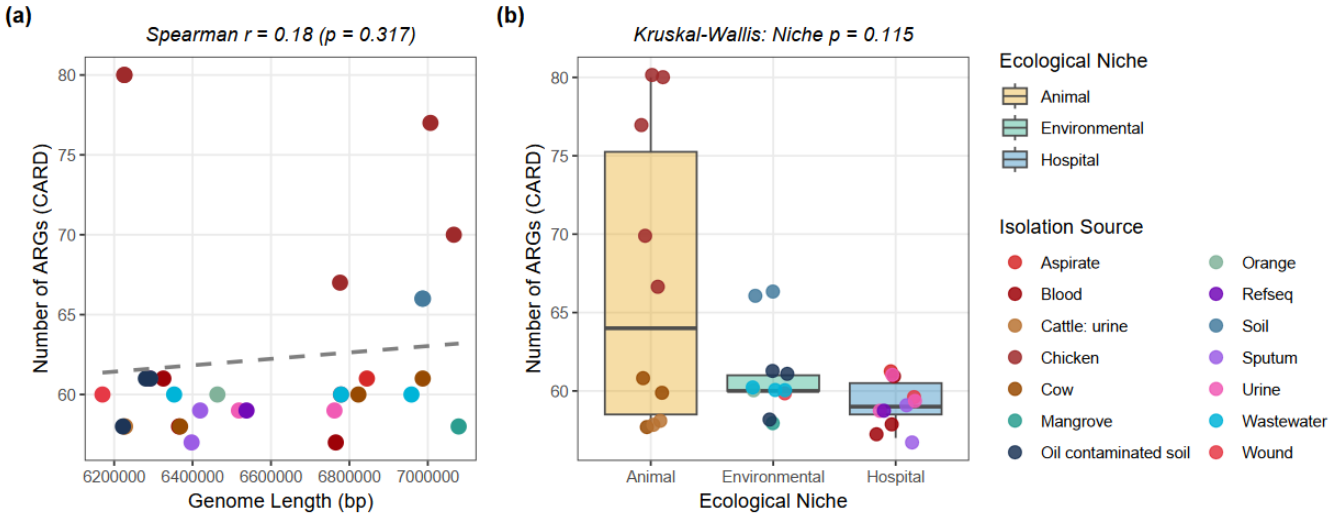

Fig. 2. ARG content analysis in *P. aeruginosa* isolates across ecological niches: (a) Spearman rank correlation analysis between total genome length (bp) and ARG abundance ($\rho = 0.18$, $p = 0.317$); (b) distribution of ARG abundance grouped by major ecological niche (Kruskal–Wallis test, $p = 0.115$).

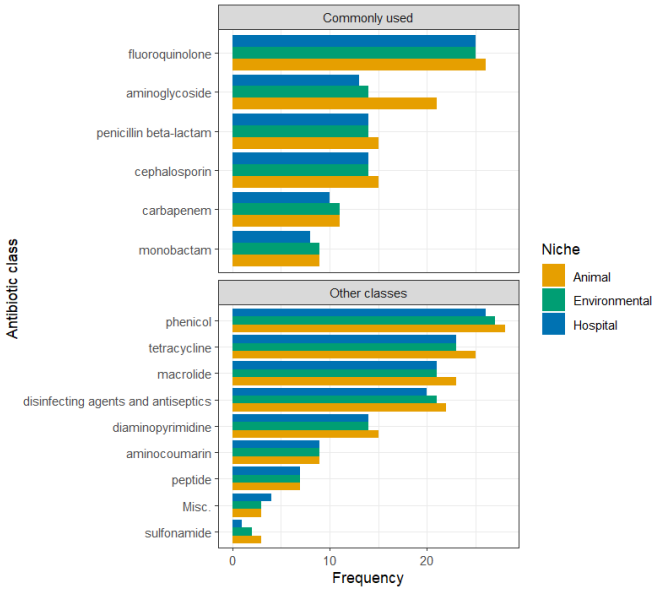

Fig. 3. Frequency of resistance compared across sample origins

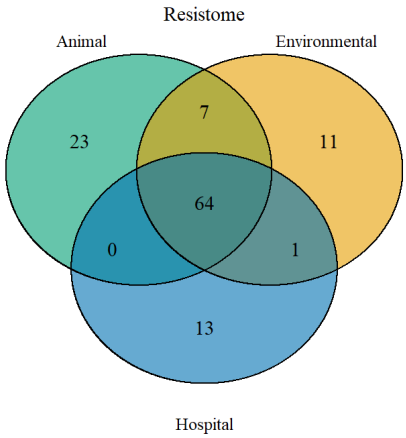

Fig. 4. A Venn diagram showing ARG data, categorized by the origin of the samples.

To assess whether niche-exclusive ARGs were associated with specific resistance mechanisms, a contingency table was created showing the relationship between resistance mechanism category and ecological niche, based on the sets of exclusive genes derived from the Venn diagram (Table: II). Given the small and unevenly distributed cell counts, Fisher's exact test was used as the primary test ($p = 0.685$). The chi-square test was performed as a complementary check ($X^2 = 7.28, df = 8, p = 0.507$). Both tests indicated no statistically significant association between mechanism type and ecological niche in the exclusive resistome. This suggests that, in this dataset, the resistance mechanisms captured in niche-exclusive genes are broadly distributed rather than niche-specific.

The predominant classes represented were fluoroquinolones, macrolides, tetracyclines, and peptides. Animal-derived isolates generally showed the highest frequency of resistance

TABLE II
EXCLUSIVE ARGS AND MECHANISMS ACROSS ECOLOGICAL NICHES.

	Target alteration	*vanT* gene in *vanG* cluster

determinants across most antibiotic classes, with a particular enrichment of aminoglycoside resistance genes. The overall frequency classes in hospital-derived genomes remained similar to or slightly lower than that detected in isolates from natural environments (Fig. 3).

Chicken-derived genomes were further distinguished by the presence of target protection (*QnrVC1* and *msrE*) and target replacement (*dfrA22*) mechanisms, which were otherwise detected only in three environmental genomes (Fig. 7b). The *KPC-β-lactamase* gene, originally described in *Klebsiella pneumoniae* [33], was identified in two environmental genomes. Compared to other strains, one mangrove isolate lacked several genes associated with efflux systems (*mexM, oprM, muxA, mexS,* and *pmpM*), suggesting a gene deletion event in this isolate.

Several examples of ARG duplication were observed among all genomes studied. Duplication events were observed in the main efflux systems of the bacterium, such as *rsmA, bcr-1, mexY, mexD, mexI, mexS,* and *opmH*. Hospital- and chicken-derived genomes showed duplication in the *APH(6)-Id* genes, which confer resistance to aminoglycosides through an inactivation mechanism (Fig. 5).

C. Resistome Topology, Clustering, and Ordination Analysis

To explore whether similarity in resistome profiles among isolates is associated with phylogeny or influenced by niche-specific selective pressures, a tanglegram analysis was performed comparing whole-genome ANI with resistome topology (Jaccard distance of ARG presence/absence). This comparison revealed marked topological discordance, characterized by frequent line crossings connecting environmental and hospital isolates across both dendrograms. Concordance was restricted to a single pair of soil isolates with shared spatio-temporal origin (Brazil, 2020; highlighted in red). This pattern indicates that while vertical clonal expansion contributes to maintaining resistome structures in select lineages, the accessory resistome

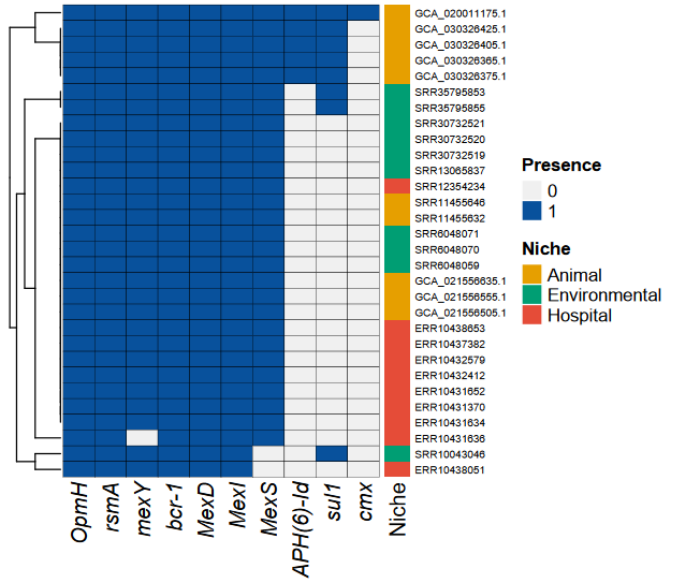

Fig. 5. Presence–absence matrix of duplicated ARG across environmental, animal, and hospital isolates.

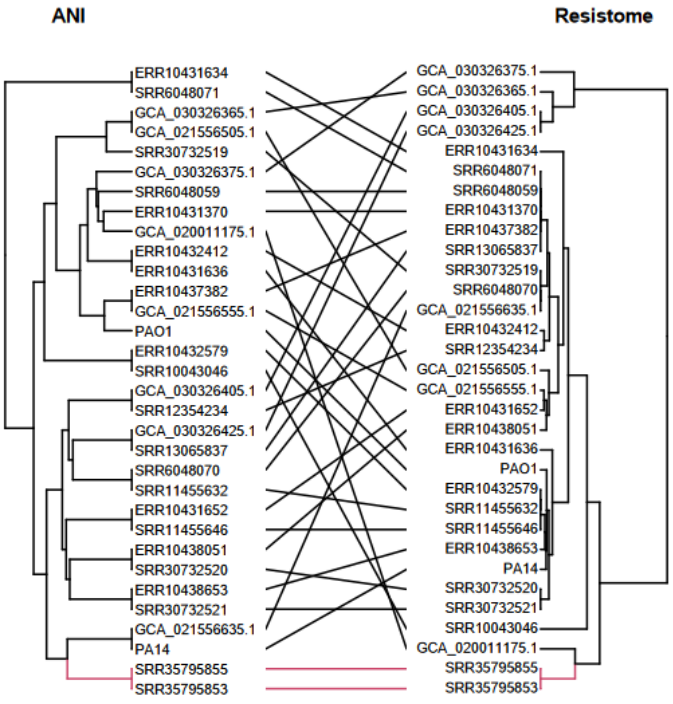

Fig. 6. Tanglegram comparing the genomic background (ANI, left) and the resistome profile (Jaccard distance of ARG presence/absence, right) of *P. aeruginosa* isolates. Lines connect identical isolates across both trees.

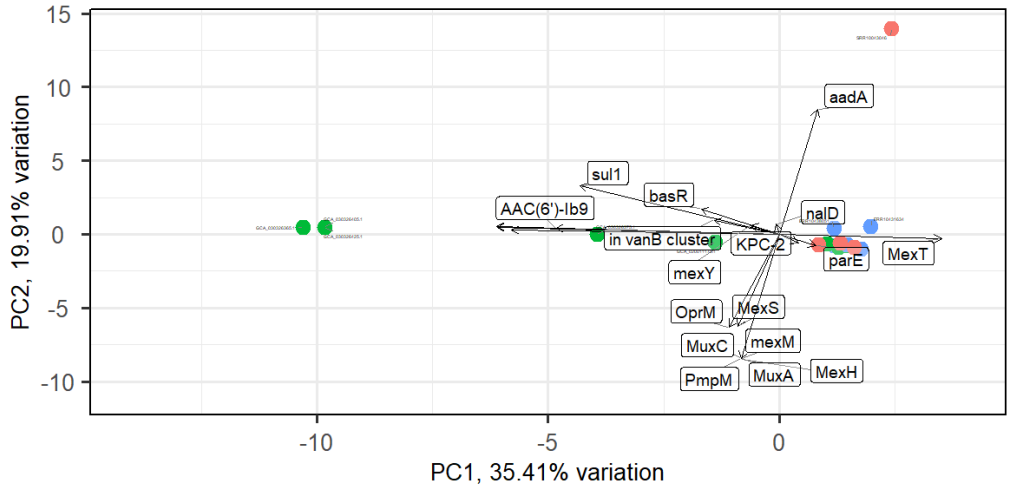
of *P. aeruginosa* is highly dynamic and reshaped primarily by localized selective pressures and independent acquisition or loss of resistance determinants (Fig. 6).

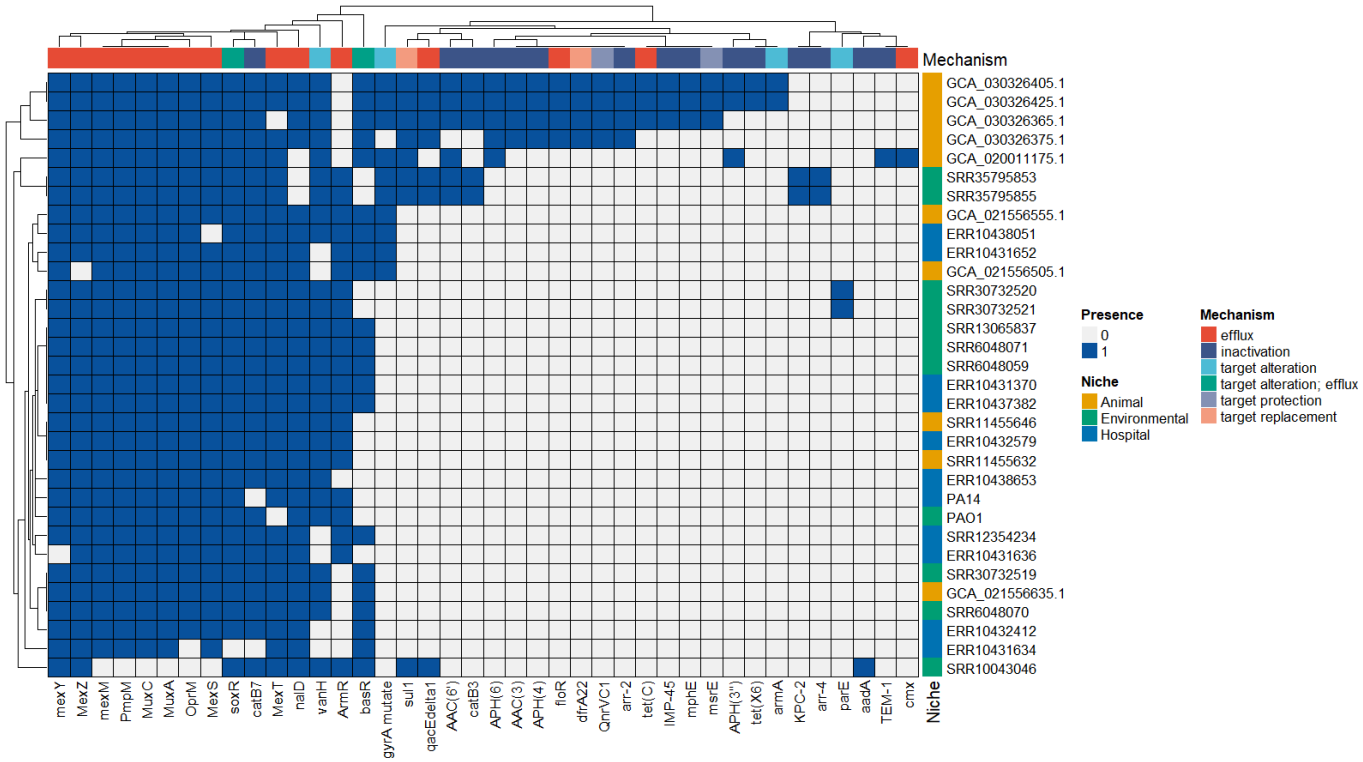
Principal component analysis (PCA) was conducted to identify the antimicrobial resistance genes (ARGs) that most strongly contributed to the separation among genomic sample groups. The first two principal components explained 55.32% of the total variance, with PC1 accounting for 35.41% and PC2 for 19.91% (Fig. 7a). A distinct and well-separated cluster comprising chicken-derived isolates was observed relative to the remaining groups. This dispersion was strongly associated with a broad complement of acquired resistance determinants, particularly *arr-2, dfrA22,* and *floR*, in addition to multiple aminoglycoside-resistance gene variants (*AAC(3)-IVa, AAC(6')-Ib9, APH(3')-Ia, APH(3')-VIa, APH(4)-Ia,* and *APH(6)-Id*).

In contrast, genomes of environmental and hospital-derived largely overlapped in ordination space or were separated by only small distances, forming a cohesive cluster indicative of highly similar resistome profiles. The modest separation between these niches was primarily attributable to variation in genes linked to intrinsic resistance mechanisms—most notably efflux system components (*armR*, *mexM*, *muxA*, *muxC*, and *pmpM*)—rather than differences driven by acquisition of additional resistance genes.



IV. Discussion

In this comparative genomic analysis, ANI values across all genomes ranged from 98% to 99%. This finding indicates that, although the strains were isolated from distinct ecological niches, they retain a highly conserved core genome. Conversely, the open pangenome of *P. aeruginosa* is consistent with substantial genomic plasticity and ecological versatility, encompassing accessory genes and virulence-associated determinants that may facilitate colonization of diverse environments and adaptation to niche-specific selective pressures [34].



This genomic plasticity is reflected by niche-specific molecular signatures. The detection of *blaKPC* in two environmental isolates suggests that clinically critical carbapenem resistance determinants circulate outside hospital settings, although this finding alone does not establish the direction or frequency of transmission. In addition, the absence of specific efflux pump genes (*mexM*, *pmpM*, *muxA*, *muxC*, *oprM*, and *mexS*) in the mangrove-derived isolate may reflect relaxed selective pressure in natural habitats.

Duplication events involving key RND efflux components and regulatory genes (*mexY, MexI, MexS, and OpmH*) and in the *APH(6)-Id* gene, in hospital and chicken isolates, point to an adaptive gene dosage mechanism essential for amplifying antimicrobial tolerance in environments with greater exposure [35]. Gene duplication can generate new genes with distinct functions, facilitating rapid adaptation to environmental changes. The copies can evolve toward advantageous functions, with a preference for functional classes involved in transcription, metabolism, and defense mechanisms. The copy, being free to accumulate mutations and acquire new functions, allows for the preservation of the original function, avoiding the risk of loss that could occur in direct mutation [36], [37].

Elevated ARG content was observed in the profiles of animal-derived isolates, with overall resistance levels exceeding those in other genomes. This pattern is particularly reflected in the

(a) Principal Component Analysis.

(b) Resistome heatmap.

Fig. 7. Comparative resistome profiling of *P. aeruginosa* isolates across ecological niches: (a) PCA ordination plot displaying sample segregation based on resistance gene profiles; (b) matrix of presence–absence AGRs across environmental, animal, and hospital isolates.

chicken isolates, which stood out by presenting between 66 and 80 ARGs. Notably, the resistance mechanisms among ***P. aeruginosa*** genomes isolated from chickens and certain environmental isolates differ from those in other genomes due to the presence of target protection (*QnrVC1* and *msrE*) and target replacement (*dfrA22*) mechanisms.

While the number of ARGs varies between isolation sources, there does not appear to be a direct relationship between the quantity of ARGs and the isolation source. Chickens-derived isolates showed the highest number and diversity of ARGs, acquiring resistance to carbapenems, cephalosporins, monobactams, penicillin, and aminoglycosides. The genes that confer resistance to aminoglycosides are the most frequent. This class of broad-spectrum antibiotics is commonly used in poultry farming. The genes that confer resistance to aminoglycosides are the most frequent. This class of broad-spectrum antibiotics is commonly used in poultry farming [38], [39]. Although it is presumed that there are more cases of multidrug-resistant strains in hospital settings, studies suggest that the prophylactic use of antibiotics in animal production as growth promoters exerts equal or greater selective pressure. The lack of restrictive control over antibiotic use, as seen in hospital settings and in animal production, favors the emergence and spread of strains adapted to specific classes of antibiotics [40].

V. Conclusion

P. aeruginosa exemplifies bacterial adaptability, exhibiting the capacity to colonize environments ranging from natural ecosystems to complex clinical settings. This ecological versatility is driven by an open pangenome and a diverse repertoire of resistance and virulence determinants that facilitate both acute and chronic infections. Despite high overall sequence similarity, substantial genomic plasticity—evidenced by gene duplication, localized gene loss, and the capacity to acquire clinically relevant resistance determinants (e.g., *KPC-β-lactamase*, *APH*, and *AAC* genes) —supports rapid niche adaptation. Although the absolute number of resistance determinants does not unambiguously distinguish across isolation sources studied. Across all groups, fluoroquinolone resistance constituted the most prevalent mechanism, whereas resistance to aminoglycosides and β-lactams was disproportionately represented among animal-derived isolates. These observations indicate that the *P. aeruginosa* resistome is heavily shaped by specific selective pressures; however, larger datasets and further functional validation are required to better delineate these ecological and mechanistic relationships.

***Abstract*—Automatic facial emotion recognition has emerged as an important research area in Applied Computational Intelligence due to its applications in intelligent systems, human-computer interaction, education and healthcare. This paper compares PCA and ICA associated with Random Forest, SVM and MLP using the FER2013 dataset. Performance was evaluated using accuracy, precision, recall and F1-score. ICA combined with Random Forest achieved the best overall performance, demonstrating the relevance of dimensionality reduction for efficient intelligent systems with potential biomedical applications.**

***Index Terms*—Facial Emotion Recognition, PCA, ICA, Machine Learning, Computer Vision, Biomedical Engineering.**

I. Introduction

Automatic facial emotion recognition has consolidated itself as an important research area in Biomedical Engineering and Applied Computational Intelligence due to its potential to support intelligent patient monitoring systems, mental health assessment, cognitive rehabilitation, telemedicine, and human-computer interaction [1], [2]. The automatic identification of emotional states through facial images allows the development of systems capable of interpreting behavioral information objectively, contributing to applications in clinical, educational, and assistive environments.

With recent advances in Computer Vision and Machine Learning, different approaches have been proposed for automatic facial emotion recognition [10]. Among them, both deep learning-based architectures and classical machine learning methods stand out. Although Convolutional Neural Networks (CNNs) present high performance in various applications, traditional algorithms remain relevant due to lower computational cost, higher interpretability of results, and ease of implementation, especially in scenarios with limited computational resources.

The Facial Expression Recognition 2013 (FER2013) database has become one of the main datasets used in the evaluation of facial emotion recognition algorithms, being widely employed as a reference for comparing classification methods [3]. The dataset consists of approximately 35,000 grayscale facial images distributed into seven emotional categories, constituting a consolidated benchmark for pattern recognition and image processing research.

In addition to the choice of the classification algorithm, the representation of features extracted from images exerts a direct influence on the performance of the models. In this context, dimensionality reduction techniques, such as Principal Component Analysis (PCA) and Independent Component Analysis (ICA), are widely used to reduce computational complexity while preserving relevant information for the classification task [7], [8]. Despite the wide use of these techniques, studies that perform a systematic comparison between PCA and ICA simultaneously associated with Random Forest (RF), Support Vector Machine (SVM), and Multilayer Perceptron (MLP) classifiers using the same experimental protocol on the FER2013 database are still relatively scarce [4]– [6].

Thus, this work aims to comparatively analyze the performance of PCA and ICA dimensionality reduction techniques when combined with Random Forest, Support Vector Machine, and Multilayer Perceptron classifiers for automatic facial emotion recognition using the FER2013 database. The experiments were conducted under the same methodological protocol, employing the same pre-processing steps and evaluation metrics, allowing the analysis of exclusively the influence of the dimensionality reduction technique on the performance of the models. Accuracy, precision, recall, and F1-score metrics were used to evaluate the classifiers.

The results obtained demonstrate that both techniques preserve relevant information for facial emotion classification, with an advantage observed for ICA in the conducted experiments, especially when associated with the Random Forest classifier. These results reinforce the importance of proper selection of the dimensionality reduction technique in the development of intelligent automatic emotion recognition systems with potential application in Biomedical Engineering.

II. Theoretical Background

A. Facial Emotion Recognition

Facial emotion recognition is a research area that combines Computer Vision, Image Processing, and Artificial Intelligence techniques to identify emotional states through human facial expressions, constituting an important application of modern face recognition systems [11]. This technology has been widely applied in human-computer interaction systems, education, healthcare, security, and behavioral analysis. The advancement of machine learning algorithms has significantly contributed to increasing the accuracy of emotional recognition systems [1].

In Biomedical Engineering, automatic facial emotion recognition presents relevant applications in patient monitoring, assessment of neurological and psychiatric disorders, monitoring of therapeutic treatments, telemedicine, and the development of assistive technologies. Objective identification of emotional states can provide complementary information to support clinical decision-making and for the development of intelligent healthcare systems [2].

B. FER2013 Dataset

The FER2013 (Facial Expression Recognition 2013) database is one of the most widely used in research related to automatic facial emotion recognition [3]. The dataset consists of approximately 35,000 grayscale facial images with a resolution of 48×48 pixels, distributed across seven emotional categories: happiness, sadness, anger, fear, surprise, disgust, and neutral. Each image has 2304 attributes corresponding to pixel values, making it necessary to use dimensionality reduction techniques to decrease the computational complexity of the models.

The widespread use of FER2013 as a benchmark enables standardized comparison between different emotion recognition algorithms, promoting experiment reproducibility and objective evaluation of models proposed in the literature.

C. Principal Component Analysis (PCA)

Principal Component Analysis (PCA) is a statistical technique used for dimensionality reduction [7]. Its objective is to transform a set of correlated variables into a new set of orthogonal components, called principal components. These components are ordered according to the amount of explained variance, allowing the reduction of the number of attributes while preserving most of the information present in the original data.

In addition to reducing computational cost, PCA helps minimize redundancies among attributes and reduce the influence of noise present in images, favoring the performance of classification algorithms in various pattern recognition applications. This characteristic makes the technique particularly useful in problems involving large volumes of data, such as those found in biomedical imaging applications.

D. Independent Component Analysis (ICA)

Independent Component Analysis (ICA) is a signal separation technique based on statistical independence between extracted components [8]. Unlike PCA, which seeks to maximize data variance, ICA aims to identify independent sources underlying the observed data. This feature makes the method particularly interesting in pattern recognition and signal processing applications.

In addition to facial emotion recognition applications, ICA-based techniques are also widely employed in processing physiological signals, such as electroencephalograms (EEG) and electrocardiograms (ECG), for source separation and artifact removal. This versatility highlights the technique's potential in different problems related to biomedical signal and image processing.

E. Classifiers Used

In this work, three classification algorithms widely used in pattern recognition problems were evaluated. Random Forest (RF) is a method based on multiple decision trees, capable of reducing overfitting problems and improving generalization capacity [4]. Support Vector Machine (SVM) seeks to find hyperplanes that maximize the separation between different classes, showing good performance in high-dimensional classification problems [5]. Multilayer Perceptron (MLP) consists of an artificial neural network composed of multiple layers of neurons, capable of learning complex relationships between input and output data [6].

These algorithms remain widely used in applications requiring low computational cost, ease of implementation, and greater interpretability of results, which are important characteristics in various intelligent systems applied to Biomedical Engineering.

F. Related Works

Automatic facial emotion recognition has received growing attention from the scientific community due to its applications in human-computer interaction, intelligent systems, healthcare, education, and security. The advancement of Computer Vision and Machine Learning techniques has driven the development of increasingly accurate methods for identifying emotional states from facial images. In this context, the availability of the FER2013 database established one of the main benchmarks for evaluating facial expression recognition algorithms, making standardized comparison between different approaches developed in the literature possible [3].

In early research on automatic facial emotion recognition, classical machine learning techniques associated with feature extraction and reduction methods were widely employed. Among these techniques, Principal Component Analysis (PCA) stands out for reducing data dimensionality while preserving most of the image variance, decreasing computational cost and favoring the performance of different classifiers [7]. Complementarily, Independent Component Analysis (ICA) began to be used to represent data through statistically independent components, enabling the extraction of relevant information for pattern recognition tasks [8].

Among traditional classifiers, Random Forest remains a robust alternative for supervised classification problems. Wang et al. [13] demonstrated that using Random Forest in facial expression recognition systems provides good generalization capability and reduces overfitting problems, especially when combined with efficient feature extraction techniques. Although recent research prioritizes architectures based on deep learning, Random Forest continues to be employed due to its low computational cost, ease of interpretation, and good generalization capacity.

Support Vector Machine (SVM) also ranks among the most used algorithms in facial emotion recognition. Jayaswal et al. [9] highlight that this classifier performs well on high-dimensional datasets when associated with dimensionality

reduction techniques, remaining one of the primary traditional approaches used in facial expression recognition systems.

Another widely used approach is the Multilayer Perceptron (MLP). Qutab et al. [15] proposed an emotion recognition method based on the integration of PCA, Recursive Feature Elimination (RFE), and MLP, obtaining high accuracy rates on the CK and JAFFE databases. The results demonstrated that dimensionality reduction contributes to reducing training computational costs and improving facial feature representation.

Recent reviews indicate that despite the growth of Deep Learning-based architectures, traditional methods continue to play a relevant role in applications requiring lower computational cost, higher interpretability, and simplified implementation [9], [10]. In particular, Jayaswal et al. [9] highlight that techniques such as PCA, ICA, SVM, and Random Forest remain widely used in experimental research and constitute important references for comparison with Deep Learning models.

However, it is observed that most recent research focuses on proposing deep architectures, while systematic comparisons between classical dimensionality reduction techniques simultaneously associated with Random Forest, SVM, and MLP classifiers using the FER2013 database are still relatively scarce.

In this context, the present work seeks to contribute to this gap by comparing, under the same experimental protocol, the PCA and ICA dimensionality reduction techniques associated with Random Forest, Support Vector Machine, and Multilayer Perceptron classifiers. In addition to providing a consistent comparative analysis, the obtained results can subsidize the development of intelligent systems for automatic emotion recognition, contributing to applications in Biomedical Engineering that demand computationally efficient, interpretable, and reproducible models.

III. Methodology

A. Dataset

To perform the experiments, the FER2013 (Facial Expression Recognition 2013) database, made available on the Kaggle platform [16], was used. The dataset consists of approximately 35,000 grayscale facial images with a resolution of 48×48 pixels, distributed across seven emotional categories: anger, disgust, fear, happiness, sadness, surprise, and neutral. For the development of this work, the database was divided into training and testing subsets, allowing the performance evaluation of the studied classifiers.

Using the FER2013 database enables direct comparison of the obtained results with previously published works, since it is one of the main benchmarks employed in automatic facial emotion recognition research.

B. Computational Tools

The experiments were developed using the Python programming language on the Google Colab platform, an environment widely used in research involving machine learning due to the availability of cloud computing resources. To implement the methodology, the NumPy and Pandas libraries were used for data manipulation, Matplotlib for graphical visualization of the results, Scikit-Learn [12] for implementing the machine learning algorithms, and OpenCV for reading, processing, and preparing the facial images used in the experiments.

Using these libraries, which are widely consolidated in the scientific community, contributes to the reproducibility of the proposed methodology and facilitates the replication of experiments in different computing environments.

C. Pre-processing

Initially, the images from the FER2013 database were subjected to pre-processing stages, aiming to distinguish and standardize the data before applying the machine learning algorithms. The images were organized into numerical matrices, normalized, and prepared for computational processing. Then, the dataset was divided into training and testing subsets, enabling the evaluation of model performance on data not used during training.

This step aimed to reduce undesired variations between images and provide a standardized representation of the data, contributing to greater stability in the training and evaluation process of the classifiers. The image preparation and organization procedures followed classical principles of Digital Image Processing [14].

D. Dimensionality Reduction

After pre-processing, two dimensionality reduction techniques were applied: Principal Component Analysis (PCA) and Independent Component Analysis (ICA). These techniques were used to reduce the dimensionality of the data present in the FER2013 database, decreasing the computational complexity of the models while preserving the most relevant information for the facial emotion classification task. The use of PCA and ICA also made it possible to compare the impact of different data representation strategies on the performance of the evaluated classifiers.

The comparison between PCA and ICA was conducted while maintaining the same experimental conditions for both methods, allowing the analysis of exclusively the influence of the dimensionality reduction technique on the performance of the classifiers used in this study.

E. Classifiers Used

After dimensionality reduction, the obtained attributes were used to train and evaluate three machine learning algorithms widely used in supervised classification problems: Random Forest (RF), Support Vector Machine (SVM), and Multilayer Perceptron (MLP). All classifiers were trained using the same datasets, allowing a direct comparison between models when associated with PCA and ICA dimensionality reduction techniques. The comparison between classifiers was performed under the same experimental conditions, allowing the analysis of exclusively the influence of dimensionality reduction techniques on the performance of each model.

Using a standardized experimental protocol guaranteed equivalent conditions for all evaluated classifiers, ensuring greater reliability in the comparison of the obtained results.

F. Methodological Flowchart

Fig. 1 presents the flowchart of the methodology proposed in this work, illustrating the main stages of the automatic facial emotion recognition process, from dataset acquisition to classifier performance evaluation.

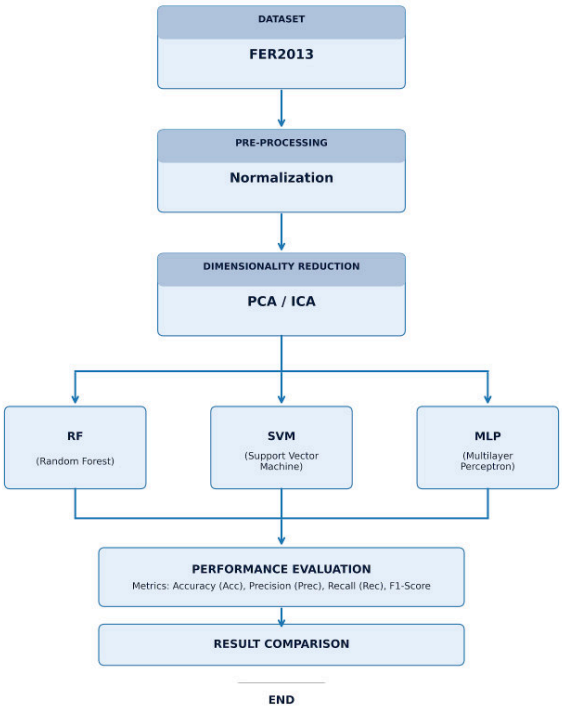

Fig. 1. Flowchart of the facial emotion classification process.

Initially, the images from the FER2013 database were subjected to pre-processing steps. Then, PCA and ICA techniques were applied to reduce data dimensionality. Subsequently, the extracted attributes were used in training the Random Forest, SVM, and MLP classifiers. Finally, the performance of the models was evaluated using accuracy, precision, recall, and F1-score metrics.

The adoption of this methodological flow sought to guarantee the standardization of the experimental stages, favoring the reproducibility of the study and the consistent comparison between the different evaluated models.

G. Evaluation Metrics

The performance of the classifiers was evaluated through accuracy, precision, recall, and F1-score metrics, which are widely used in supervised classification problems to analyze the ability of models to correctly identify the facial emotions present in the FER2013 database.

Accuracy represents the total proportion of correct classifications made by the model relative to the total number of evaluated samples. Precision indicates the proportion of correctly classified samples within each predicted class. Recall, also called sensitivity, measures the classifier's ability to correctly identify samples belonging to each emotional category. In turn, the F1-score corresponds to the harmonic mean between precision and recall, being a metric widely used to evaluate the balance between these two measures, especially in multiclass classification problems.

The joint analysis of these metrics enables a more comprehensive evaluation of classifier performance, allowing a comparison of the impact of dimensionality reduction techniques (PCA and ICA) on the Random Forest, Support Vector Machine, and Multilayer Perceptron algorithms employed in this work. Using multiple metrics provides a more consistent analysis of model behavior, reducing dependence on a single performance measure and allowing a more complete evaluation in multiclass classification problems.

IV. Results and Discussion

In this section, the results obtained in the facial emotion recognition experiments using the FER2013 dataset are presented and discussed. The models were evaluated by combining dimensionality reduction techniques (PCA and ICA) with three classification algorithms: Random Forest (RF), Support Vector Machine (SVM), and Multilayer Perceptron (MLP). The quantitative performance of each approach is summarized in Table I.

Using a standardized experimental protocol for all models allowed a direct comparison between the dimensionality reduction techniques and the evaluated classifiers, ensuring greater methodological consistency and reliability in interpreting the obtained results.

TABLE I
Performance of Classification Models on the FER2013 Dataset

Model	Reduction	Accuracy	Precision	Recall	F1-Score
Random Forest	ICA	0.427029	0.441716	0.427029	0.400523
Random Forest	PCA	0.406304	0.426830	0.406304	0.378584
MLP	ICA	0.399861	0.392345	0.399861	0.395080
MLP	PCA	0.390630	0.386177	0.390630	0.388032
SVM	ICA	0.366249	0.330730	0.366249	0.316851
SVM	PCA	0.366249	0.331972	0.366249	0.317710

The graphical comparison presented in Fig. 2 complements the results of Table I, allowing a clearer visualization of the performance differences between classifiers when associated with PCA and ICA techniques.

The comparative analysis of the results presented in Table I demonstrates that the Random Forest classifier achieved the best performance among the evaluated models. The combination of Random Forest and ICA presented the highest accuracy (42.7%), followed by the combination of Random Forest and PCA (40.6%). The results indicate that both dimensionality reduction techniques were able to preserve relevant features for the facial emotion recognition task, although ICA showed a slight advantage in the conducted experiments. In contrast,

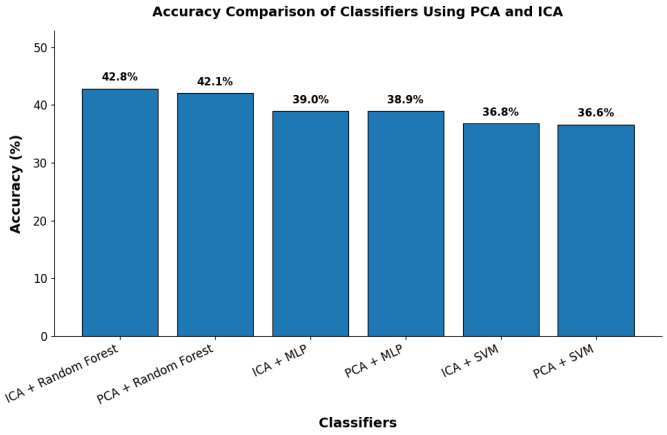

Fig. 2. Bar chart showing the comparison of classifier accuracy using PCA and ICA.

the lowest performance values were observed in models based on SVM, regardless of the dimensionality reduction technique used.

The obtained results indicate that the choice of dimensionality reduction technique directly influences classifier performance, reinforcing that the data representation step is a determining factor for automatic facial emotion recognition.

The difference observed between the results obtained with PCA and ICA may be related to the specific characteristics of the FER2013 dataset and how each technique represents the information present in the facial images. While PCA seeks to represent the data through components that explain most of the observed variance, ICA tries to identify statistically independent components. In the conducted experiments, both approaches showed similar performance, with a slight advantage for ICA in some classifier combinations.

This behavior suggests that the representation based on independent components preserves more discriminative features of facial expressions, favoring the classification stage without a significant increase in computational complexity. This result reinforces ICA's potential in applications that require computationally efficient models and good generalization capacity.

Fig. 2 shows that ICA-based models performed equal to or better than their PCA-based counterparts in most evaluated scenarios. The most significant difference was observed in the Random Forest classifier, whose accuracy went from 40.6% with PCA to 42.7% with ICA. Although the observed percentage gain was relatively modest, its consistency across different evaluation metrics indicates that ICA constitutes a promising alternative for automatic facial emotion recognition applications and intelligent systems geared toward Biomedical Engineering.

In addition to the general comparison between classifiers, a more detailed analysis of the model's behavior was performed using the confusion matrix. This representation allows the identification of correctly classified emotions and those that presented a higher degree of confusion during the classification process. Although the Random Forest combination associated with ICA achieved the best overall performance, the confusion matrix of the Random Forest model associated with PCA was used to illustrate the classifier's behavior regarding the different emotional classes of the FER2013 database, allowing a detailed analysis of correct matches and confusions among the evaluated categories.

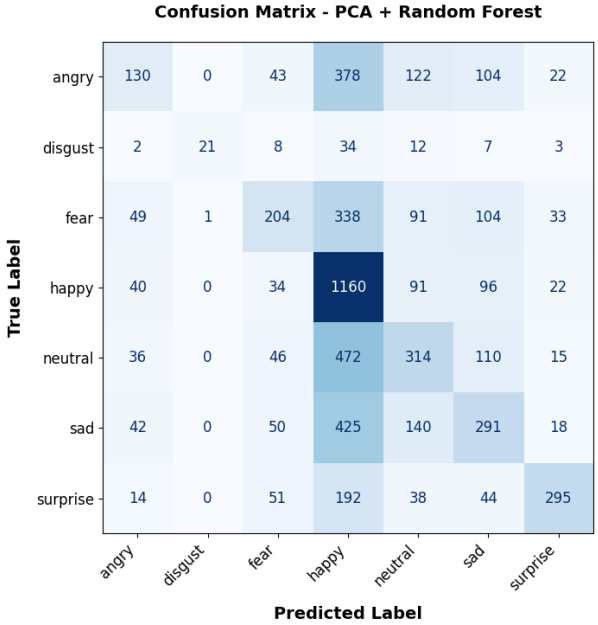

Fig. 3. Confusion matrix obtained by the PCA + Random Forest model in classifying the emotions of the FER2013 dataset.

The confusion matrix presented in Fig. 3 allows a more detailed analysis of the behavior of the Random Forest model associated with PCA. Although this combination did not yield the best overall performance, its analysis allows an understanding of the classifier's behavior when facing the different emotional classes present in the FER2013 database. It is observed that certain emotions were classified with high precision, while others presented a higher degree of confusion, especially between classes with similar facial features. This behavior is expected in facial emotion recognition databases in non-controlled environments, where different emotional states can share similar visual patterns.

This behavior highlights the inherent difficulty in classifying emotions with similar facial patterns, representing a recurring challenge in computer vision-based emotion recognition systems.

In addition to the global analysis of model performance, an individual evaluation of each emotional class was conducted, and the results are presented in Table II. This analysis allows the identification of which emotions were classified with higher or lower precision by the Random Forest model associated with PCA.

It is observed that the "happy" emotion presented the highest recall value (0.8018), indicating greater ease of identification by the model. In contrast, emotions such as "fear" and "sad" presented lower recall rates, highlighting the greater

TABLE II
CLASSIFICATION METRICS PER EMOTION OBTAINED BY THE PCA + RANDOM FOREST MODEL

Emotion	Precision	Recall	F1-Score	Support
angry	0.405316	0.152691	0.221818	799.00
disgust	1.000000	0.275862	0.432432	87.00
fear	0.407489	0.225610	0.290424	820.00
happy	0.380592	0.801802	0.516172	1443.00
neutral	0.367725	0.279960	0.317896	993.00
sad	0.345628	0.261905	0.297998	966.00
surprise	0.721839	0.495268	0.587465	634.00
accuracy	0.406304	0.406304	0.406304	0.406304
macro avg	0.518370	0.356157	0.380601	5742.00
weighted avg	0.426830	0.406304	0.378584	5742.00

difficulty in discriminating between categories with similar facial characteristics.

The results presented in Table II show differences in model performance across emotional classes. Emotions with more distinct facial characteristics tend to show higher precision and recall values, while visually similar emotions show higher rates of confusion.

This analysis demonstrates that the model's performance depends not only on the classification algorithm employed but also on the inherent complexity of each emotional category present in the dataset, showing that visually similar emotions tend to produce higher confusion rates.

Among the evaluated classifiers, Random Forest stood out against SVM and MLP. Being a method based on an ensemble of decision trees, Random Forest demonstrated greater resilience to overfitting and a better ability to map the feature space reduced by PCA. SVM showed an acceptable intermediate performance, but its efficiency was slightly penalized by the complexity of defining optimal hyperplanes in highly overlapping multiclass problems. Finally, MLP obtained the lowest accuracy rates; this behavior suggests that fully connected networks of moderate size face difficulties in converging optimally when fed purely with components extracted without a dedicated spatial architecture, such as convolutional ones.

In general, the results obtained demonstrate that classical machine learning algorithms, when associated with appropriate dimensionality reduction techniques, continue to represent viable alternatives for automatic facial emotion recognition problems, especially in applications that demand lower computational cost, higher interpretability, and ease of implementation. Furthermore, the presented results reinforce that the dimensionality reduction stage exerts a significant influence on the performance of the classifiers, with ICA being the approach that yielded the best results in the conducted experiments. These findings highlight the potential of the proposed methodology for applications in Biomedical Engineering, such as intelligent patient monitoring systems, behavioral analysis, assistive technologies, and clinical decision-making support by healthcare professionals, in which computational efficiency, reliability, and reproducibility are fundamental requirements.

V. CONCLUSION

This work presented a comparative analysis between the dimensionality reduction techniques Principal Component Analysis (PCA) and Independent Component Analysis (ICA) applied to automatic facial emotion recognition using the FER2013 dataset. For emotion classification, the Random Forest (RF), Support Vector Machine (SVM), and Multilayer Perceptron (MLP) algorithms were evaluated, considering accuracy, precision, recall, and F1-score metrics.

The obtained results demonstrated that the Random Forest classifier achieved the best performance among the evaluated models, standing out especially when associated with the ICA technique. In general, it was observed that both dimensionality reduction techniques preserved relevant information for facial emotion classification, with ICA being slightly superior in some classifier combinations.

The results evidenced that the dimensionality reduction step exerts a significant influence on the performance of classification models, reinforcing the importance of choosing appropriate data representation techniques in the development of intelligent systems for automatic emotion recognition. The systematic comparison between PCA and ICA, associated with Random Forest, Support Vector Machine, and Multilayer Perceptron classifiers under the same experimental protocol, allowed a consistent evaluation of the impact of these techniques on model performance, constituting one of the main contributions of this study.

In addition to the contribution to the area of Applied Computational Intelligence, the proposed methodology presents potential for applications in Biomedical Engineering, especially in intelligent systems aimed at patient monitoring, behavioral analysis, emotional state evaluation, assistive technologies, and decision-making support for healthcare professionals. The use of classical machine learning methods associated with dimensionality reduction techniques also demonstrates that computationally efficient solutions remain relevant in scenarios that demand lower computational cost, interpretability, and ease of implementation.

As limitations of this study, we highlight the use of the FER2013 database, which consists of low-resolution images, as well as the evaluation restricted to classical machine learning methods. Furthermore, different hyperparameter tuning settings for the classifiers were not investigated, nor were other feature extraction strategies, factors that can directly influence model performance.

As future work, it is suggested to investigate the influence of the number of components extracted by dimensionality reduction techniques on classifier performance, seeking to determine an optimal cutoff point. It is also proposed to evaluate other facial emotion recognition databases to analyze the generalization capability of the methodology across different experimental scenarios.

Additionally, it is intended to explore hybrid pre-processing and feature selection techniques, as well as to compare the classical methods evaluated in this work with Deep Learning architectures, especially Convolutional Neural Networks

(CNNs) and Vision Transformer (ViT) models, investigating the trade-off between performance, computational cost, and interpretability.

Finally, the obtained results reinforce that classical dimensionality reduction techniques, when properly combined with machine learning algorithms, continue to represent effective alternatives for automatic facial emotion recognition. Thus, this work contributes to broadening the understanding of the impact of PCA and ICA techniques on the performance of traditional classifiers, providing insights for the development of intelligent systems applied to emotion recognition and future applications in Biomedical Engineering.

***Abstract*—Diabetic peripheral neuropathy (DPN) is a common chronic complication of diabetes mellitus (DM). Nerve conduction studies provide objective measurements of peripheral nerve function, but their integration into modular health platforms also requires software for examination management, signal processing, parameter extraction, and organized data storage. This work presents X-NCS, a Python/PyQt5 software module integrated into the SDC-X platform for research-oriented nerve conduction workflows. X-NCS combines patient and session management, asynchronous WebSocket communication with an experimental acquisition unit, signal visualization, digital filtering, automatic and manual annotation of the stimulation artifact and compound muscle action potential (CMAP) landmarks, electrophysiological parameter extraction, and structured local storage. Functional evaluation used motor median nerve recordings from 14 participants without DM. Completion was defined as successful execution of data loading, visualization, filtering, landmark generation and review, extraction of distal latency, amplitude, duration, area, and motor nerve conduction velocity (MNCV), and local storage without a processing error that prevented completion. X-NCS completed this workflow for all 14 datasets, and no manual repositioning of the automatically generated landmarks was required during the evaluated workflow. Mean (SD) amplitude was 7.6 (1.9) mV, distal latency 4.2 (0.9) ms, and MNCV 62.8 (10.0) m/s; these values were used as a physiological plausibility check against published reference ranges. Because the study did not include an independent expert annotation set or a reference nerve-conduction system, the absence of manual corrections does not establish annotation accuracy or measurement agreement. Communication-failure robustness and diagnostic validity were also outside the scope of this functional evaluation. X-NCS provides a research-oriented computational layer for organizing and processing nerve conduction examinations within the SDC-X ecosystem.**

I. Introduction

Diabetes mellitus (DM) represents one of the leading global burdens of chronic disease. The 11th edition of the International Diabetes Federation (IDF) Diabetes Atlas estimated that, in 2024, approximately 589 million adults aged 20–79 years were living with diabetes, with this number projected to reach 853 million by 2050 [1]. Among the chronic complications of DM, diabetic peripheral neuropathy (DPN) is one of the most common and clinically significant, affecting approximately half of all adults with diabetes during their lifetime and being associated with pain, sensory loss, foot ulcers, and lower-limb amputations [2], [3].

DPN is characterized by the progressive dysfunction of peripheral nerves, predominantly affecting distal sensory and motor fibers, thereby directly impairing patients' functional capacity and quality of life [3].

Early screening is essential to reduce the risk of long-term complications. The American Diabetes Association guidelines recommend screening for DPN at the time of diagnosis in patients with type 2 diabetes and after five years of disease duration in patients with type 1 diabetes, followed by periodic reassessment [4]. Clinical examination, sensory testing, and nerve conduction studies (NCS) are used in a complementary manner. NCS provide objective measurements of peripheral nerve function; however, their use for large-scale screening is limited by the need for specialized equipment, standardized procedures, and trained personnel [5]–[7].

Motor NCS assess the functional integrity of peripheral motor fibers through the compound muscle action potential (CMAP), from which latency, amplitude, duration, area, and conduction-related measurements can be obtained. The parameters used in X-NCS are described in Section II. Previous work has investigated automated CMAP acquisition and event annotation because manual cursor placement can contribute to measurement variability, especially when waveform morphology or stimulus artifacts make the landmarks less evident [8],

[9].

Beyond the acquisition hardware, integration with a digital platform also requires software that keeps the examination steps and their data together. In practice, this includes patient and session management, recording of metadata, signal visualization, digital filtering, parameter calculation, and structured local storage of recordings, extracted parameters, metadata, and timestamps. These functions are compatible with the broader organization of Ubiquitous Health (U-Health) platforms, in which sensing, computing resources, and data infrastructure are combined to support health monitoring, disease prevention, and patient follow-up [10]–[12].

The Screening for Diabetes Complications (SDC-X) platform, developed at the Biomedical Engineering Institute of the Federal University of Santa Catarina (IEB-UFSC), is being structured into modular components for the acquisition, organization, and analysis of physiological signals associated with the screening of DM complications [13], [14]. Within this architecture, the X-CARDIO, X-EYE, X-ESC, and X-QST modules are dedicated to cardiovascular autonomic assessment, pupillometry analysis, sudomotor assessment, and quantitative sensory testing based on thermal thresholds, respectively [14]–[18]. X-NCS was developed as an additional module so that nerve-conduction recordings could follow the same general SDC-X organization of patient selection, examination setup, signal review, parameter extraction, and result storage.

The physical acquisition and stimulation unit served as the experimental source of the nerve-conduction recordings. This study focuses on the X-NCS software layer rather than on metrological validation of the acquisition hardware. The evaluation therefore addresses integration with the SDC-X workflow, acquisition and analysis interfaces, filtering and CMAP-annotation procedures, electrophysiological parameter extraction, local organization of examination data, and execution of the complete workflow with real motor median nerve recordings from 14 volunteers.

A. Related Work

Conventional NCS remain the reference standard for the objective electrophysiological assessment of myelinated peripheral nerve fibers. However, their widespread use for screening may be limited by the need for specialized infrastructure, trained personnel, and rigorous standardization of both signal acquisition and event annotation [19], [20].

Among these approaches, automated devices for sural nerve assessment, such as NC-stat/DPNCheck, have received considerable attention. Early studies demonstrated a high correlation with conventional NCS and clinically relevant diagnostic performance for the detection of diabetic polyneuropathy [21], [22]. More recent studies, however, suggest that although these devices may provide objective and accessible measurements, their use for longitudinal monitoring and their agreement with different screening tools still require careful interpretation [23], [24]. In addition, simplified approaches that combine point-of-care nerve conduction measurements with other physiological signals, such as electrocardiogram (ECG)-derived parameters, have been proposed to improve the accessibility of electrophysiological assessment in individuals with diabetes [25].

II. Methodology

A. Scope and Software Module Architecture

The X-NCS module was developed to support research-oriented NCS workflows within the SDC-X platform. For the experiments presented in this study, the software was connected to an experimental acquisition and stimulation unit developed at IEB-UFSC, operating at a sampling rate of 30 kHz using an analog-to-digital converter and an ESP32 microcontroller. This sampling rate is compatible with the frequency range of motor nerve signals, which has been reported in the literature to extend from approximately 2 Hz to 10 kHz [20].

X-NCS was organized into three main interfaces that correspond to the stages followed during an examination: *Acquisition*, *Exam*, and *Results*. The first interface is used for examination setup and signal acquisition; the second is used to inspect the waveform, apply processing, and review the CMAP annotations; and the third consolidates the electrophysiological parameters, including motor nerve conduction velocity (MNCV). Table I summarizes the functionality available at each stage, and Fig. 1 shows how these parts are connected within the module.

The graphical interfaces were implemented in Python using PyQt5. Communication with the acquisition device uses WebSocket over the Transmission Control Protocol (TCP). This communication runs in a thread separate from the graphical user interface event loop; the separation was adopted so that data exchange with the acquisition unit would not block the interface while the user is acquiring, playing back, or inspecting a recording.

The communication path was used during the acquisitions analyzed in this study. However, communication faults were not deliberately introduced into the protocol. The available data therefore do not characterize software behavior after WebSocket interruption, reconnection, timeout, or incomplete transmission. These conditions remain specific verification tests for a subsequent robustness study.

B. Integration with the SDC-X Platform

The X-NCS module was incorporated as a new computational protocol within the SDC-X ecosystem, which already includes modules dedicated to the screening of DM complications [13], [14], [18]. The home screen allows patient registration and selection, while the examination window includes X-NCS as an available protocol. The version evaluated here runs locally and is not synchronized with the SDC-X cloud infrastructure. Cloud synchronization, role-based access control, and distributed audit mechanisms are therefore requirements for a future connected deployment rather than features of the prototype evaluated in this study.

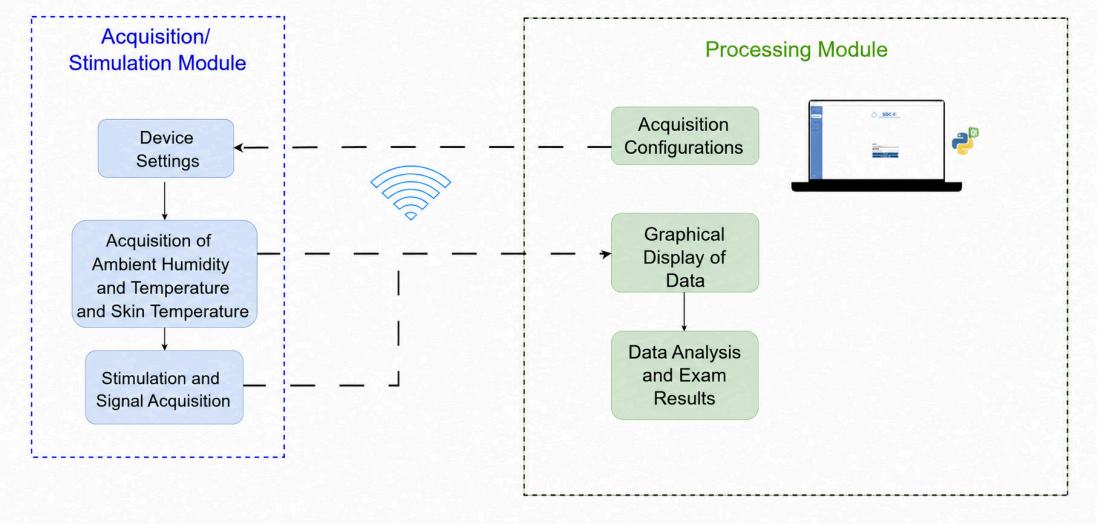

Fig. 1. Overall architecture of the X-NCS module integrated into the SDC-X platform. The physical acquisition unit provides the electrophysiological signals, while the software module manages the examination workflow, processes the recordings, and stores the results locally.

TABLE I
FUNCTIONALITIES IMPLEMENTED IN THE X-NCS MODULE.

Category	Implemented functionality
Management	Patient registration and selection, X-NCS protocol selection, and organization of recordings by patient, nerve, and examination session.
Communication	WebSocket communication over TCP implemented in a dedicated thread to prevent blocking of the graphical user interface.
Acquisition	Session configuration, metadata acquisition, monitoring of signal acquisition, and real-time signal visualization.
Processing	Sampling frequency estimation, digital filtering, and waveform inspection.
Annotation	Automatic and manual annotation of the stimulation artifact and CMAP landmarks: stimulation artifact, onset, peak, and end.
Results	Extraction of distal latency, amplitude, duration, area, and MNCV, together with storage of time-series data, extracted parameters, and metadata.

C. Acquisition and Visualization Workflow

Within the *Acquisition* interface, the examination workflow follows a guided sequence consisting of device connection, examination configuration, recording of environmental variables (temperature and humidity), signal acquisition, and file storage. Signals are saved as text files containing time (ms) and amplitude (mV) columns, together with summary files storing session metadata, including stimulation distances, environmental measurements, and timestamps.

The current implementation uses structured file-based storage rather than a database backend. Accordingly, no relational database schema is defined in the evaluated prototype. Its persistent data model consists of signal files and session-summary files organized by patient, nerve, and examination session. These files retain the signal time series, extracted results, examination metadata, stimulation distances, environmental measurements, and timestamps. This structure provides record-level traceability within the local file hierarchy, although it is not a user-level audit trail. Signal-processing timing is derived from the time vector stored with each recording, while session timestamps are used for record organization. Because the evaluated workflow did not require independent devices to share a common clock, distributed multi-device synchronization was not assessed.

In this study, S1 denotes the distal stimulation site and S2 the proximal stimulation site, following the motor NCS protocol used to calculate MNCV [19], [20]. Fig. 2 summarizes the operational workflow, from patient selection and examination setup to parameter extraction and result storage.

D. Signal Processing Pipeline and Parameter Extraction

Within the *Exam* interface, the sampling frequency is estimated from the average temporal interval between consecutive samples, allowing the module to process both recordings acquired with the experimental unit and imported comma-separated values (CSV) or plain-text (TXT) files.

The default preprocessing pipeline consists of a sequence of second-order digital filters applied using zero-phase bidirectional filtering: (i) a Butterworth high-pass filter (cutoff frequency ≈ 2 Hz) to remove baseline drift and low-frequency oscillations; (ii) notch filters centered at 60 Hz and 120 Hz, with a bandwidth of 5 Hz, to suppress power-line interference and its second harmonic; and (iii) a Butterworth low-pass filter with a cutoff frequency of 10 kHz to remove spectral components outside the frequency band of interest for motor nerve signals [20]. Bidirectional filtering was adopted to preserve waveform timing relationships, which are critical for accurate latency estimation.

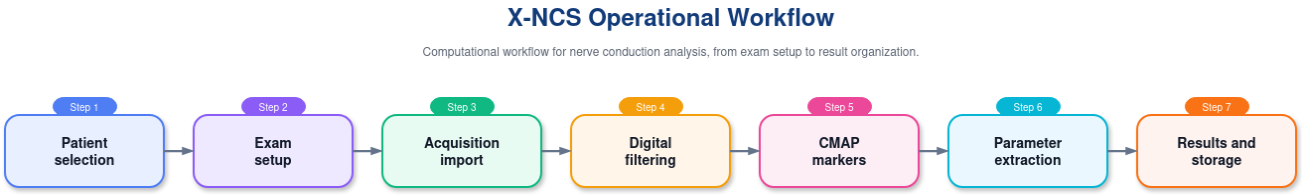

Fig. 2. Operational workflow of the X-NCS module, including patient selection, protocol selection, examination setup, signal acquisition, filtering, CMAP annotation, parameter extraction, and result storage.

Signal analysis is performed over a 100-ms window starting from the beginning of each recording. The software applies four operational landmark rules: (i) the stimulation-artifact marker is assigned to the maximum absolute peak occurring between 8 and 11 ms after the beginning of the recording; this interval corresponds to the expected temporal position of the electrical stimulation artifact in the acquisition protocol and does not define the CMAP response window; (ii) the operational CMAP-onset marker is assigned to the first baseline crossing occurring at least 1 ms after the detected stimulation artifact and is refined by linear interpolation; (iii) the CMAP peak is the sample with the maximum absolute amplitude after onset; and (iv) the CMAP-end marker is the subsequent baseline crossing after the peak, delimiting the negative phase used by the implemented algorithm [19], [26]. Thus, the 8–11 ms search interval is used only to localize the stimulation artifact generated by the acquisition protocol and should not be interpreted as a physiological latency interval or as the expected location of the CMAP itself.

These landmarks are used to calculate distal latency, amplitude, duration, area, and MNCV. In the implemented pipeline, the time of stimulation is operationally represented by the detected stimulation-artifact marker; distal latency is therefore calculated as the interval between this marker and the CMAP onset. Amplitude is defined as the magnitude of the maximum negative deflection relative to baseline. Duration corresponds to the interval between CMAP onset and end. Area is calculated as the absolute value of the numerical integral of the negative CMAP phase between onset and end, expressed in mV·ms. All amplitude-dependent parameters are calculated from samples converted back to the original signal scale after digitization by compensating for the system gain. MNCV is calculated as

$$\mathrm{MNCV} = \frac{\Delta d}{\Delta t} = \frac{d_{S2} - d_{S1}}{t_p - t_d}, \tag{1}$$

where $d_{S2} - d_{S1}$ is the distance between the proximal and distal stimulation sites, and $t_p - t_d$ is the difference between proximal and distal latencies [19], [20].

In motor NCS, S1 provides the measurements of amplitude, latency, duration, and area, whereas S2 is used for MNCV calculation. The user may choose either automatic processing or manual editing mode, allowing individual markers to be removed, restored, or repositioned. The software interface resulting from this implementation is presented in Section III-A.

E. Results Consolidation

Within the *Results* interface, the extracted electrophysiological parameters are presented in tables and graphical summaries. Whenever available, age- and sex-specific normative reference values are used; otherwise, general reference ranges reported in the literature are adopted for exploratory interpretation [20], [27]. When a normative mean and standard deviation are available, the standardized value displayed for each parameter is calculated as $z = (x - \mu_{\mathrm{ref}})/\sigma_{\mathrm{ref}}$, where x is the measured value and μ_{ref} and σ_{ref} are the corresponding reference mean and standard deviation. Dashed horizontal lines at $z = -2$ and $z = +2$ delimit the exploratory reference region. This visualization follows the strategy previously adopted in the X-QST module of the SDC-X platform [17]. The interface also displays the amplitude-versus-conduction velocity plane together with environmental variables, when available. Since skin temperature, age, and other physiological factors may influence nerve conduction parameters, normative comparisons should be interpreted with caution [26]–[28]. The implemented interface is presented with the software results in Section III-A.

F. Functional Evaluation Using Real Recordings

The functional evaluation was performed using real motor median nerve recordings obtained in a pilot study involving 14 participants without a diagnosis of DM (9 males and 5 females). Signals were acquired at a sampling rate of 30 kHz with a system gain factor of 6. After digitization, the recorded samples were rescaled to the original signal amplitude by compensating for this gain, and the resulting values were expressed in millivolts before being stored as text files and imported into the X-NCS module for processing.

The experimental protocol employed a surface stimulation electrode with saline-moistened felt, an active recording electrode positioned over the abductor pollicis brevis muscle, and a reference electrode placed on the thumb. The S1 and S2 stimulation sites were located at the anterior wrist and medial upper arm, respectively, following the conventional distal and proximal stimulation protocol for motor median NCS [19], [20]. The distance between the S1 stimulation site and the active recording electrode was approximately 8 cm. Fig. 3 illustrates the experimental setup used for acquisition of the motor median nerve recordings.

The goal of this evaluation was narrower than clinical or metrological validation: it was to determine whether X-NCS

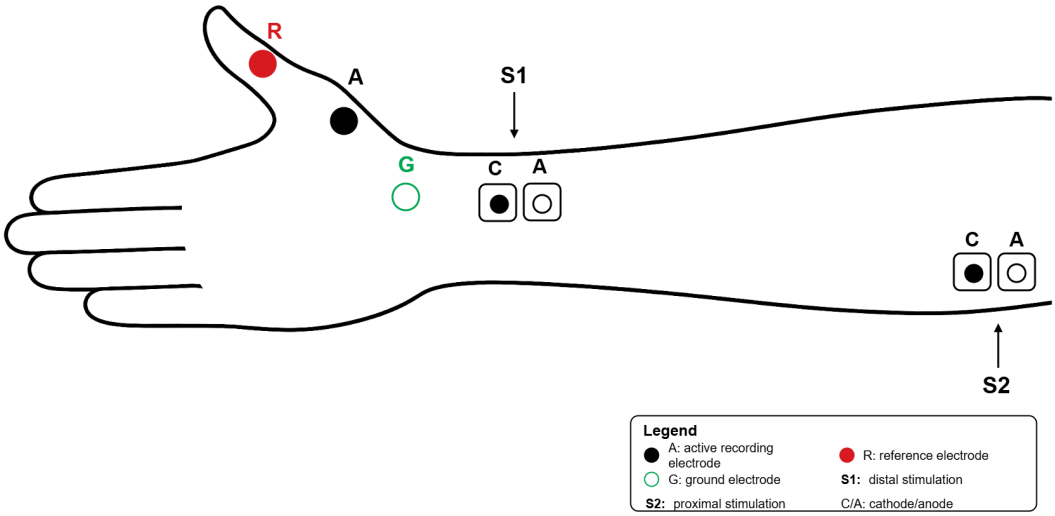

Fig. 3. Simplified experimental setup used for motor median nerve acquisition. The active electrode (A) was positioned over the thenar eminence, the reference electrode (R) on the thumb, and the ground electrode (G) between the recording site and the stimulation sites. S1 and S2 represent the distal and proximal stimulation sites, respectively; the distance between S1 and the active recording electrode was approximately 8 cm.

could execute the implemented computational workflow with real electrophysiological recordings. The evaluation checkpoints followed the software functions summarized in Table I and the operational sequence shown in Fig. 2. Functional completion was defined as successful data loading, waveform visualization, digital filtering, CMAP landmark generation and review, extraction of latency, amplitude, duration, area, and MNCV, and local storage of the resulting data and metadata without an error that prevented completion of the pipeline. The protocol did not include comparison with a commercial nerve-conduction system, independent expert annotation, deliberate communication-failure testing, or metrological characterization of the acquisition hardware. Published normative values were used only to examine whether the extracted parameters were physiologically plausible for the analyzed sample [20], [27].

G. Ethical Aspects

The pilot study is part of the project entitled *Methodologies for the Assessment of Autonomic Function Applied to the Prevention, Diagnosis, and Treatment of Diabetes Mellitus*, approved by the Human Research Ethics Committee of UFSC under CAAE 74863023.7.0000.0121 and approval report No. 6.450.185. Ethical approval was granted on November 5, 2023. Written informed consent was obtained from all participants before the study procedures.

The evaluated implementation operated locally. Deployment-level privacy controls, role-based access control, and user-level audit logging were therefore not exercised in this study. These mechanisms will need to be specified and verified before a future cloud-connected X-NCS version is used beyond the local research setting.

III. Results and Discussion

A. Implemented Software Module

The X-NCS module adds a dedicated NCS workflow to the SDC-X platform. It supports patient selection, session setup, communication with the experimental acquisition unit, signal visualization, digital filtering, parameter extraction, and structured local storage. By separating asynchronous communication from the graphical interface, the software remained responsive during both signal acquisition and playback.

Fig. 4 presents the implemented *Exam* interface, in which the user can inspect the filtered waveform, review the automatically detected stimulation-artifact marker and CMAP landmarks, and manually correct individual annotations when necessary. Fig. 5 presents the *Results* interface, which consolidates the extracted electrophysiological parameters and provides an exploratory Z-score visualization relative to normative reference values. The dashed lines identify the $z = -2$ and $z = +2$ limits used for contextualization; the display does not constitute an independent diagnostic classification.

B. Functional Evaluation of the Pipeline

Using the functional-completion definition given in Section II-F, the module completed the full workflow for all 14 participant datasets, corresponding to 14/14 (100%) completed datasets in the analyzed sample. No software-processing error prevented completion of the pipeline for these files. This result applies only to the available recordings and does not characterize failure behavior under deliberately induced communication faults. For each dataset, the software loaded the distal and proximal recordings, displayed the waveforms, applied the digital filters, identified the stimulation artifact and generated the subsequent CMAP landmarks, extracted latency, amplitude, duration, area, and MNCV, and stored the time series, parameters, and metadata locally.

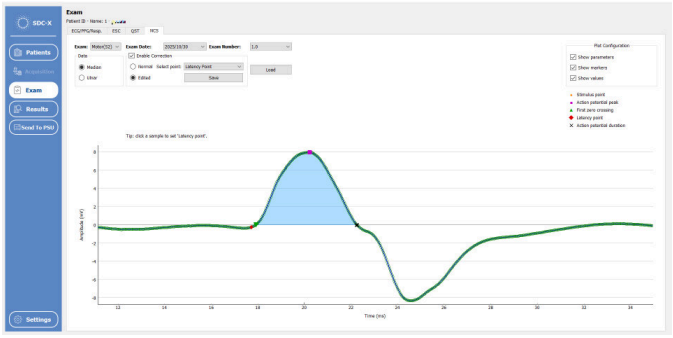

Fig. 4. *Exam* interface displaying the filtered signal, the automatically detected stimulation-artifact marker and CMAP landmarks, and tools for manual correction of event annotations.

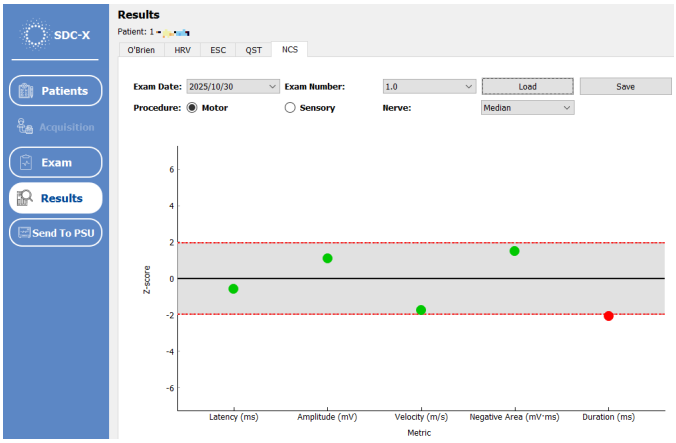

Fig. 5. *Results* interface displaying the exploratory Z-score visualization of the electrophysiological parameters extracted by the X-NCS module. Dashed horizontal lines indicate $z = -2$ and $z = +2$. The visualization provides normative contextualization and does not constitute a diagnostic classification.

Individual markers could be reviewed and manually repositioned when needed. In the 14 datasets included in the functional evaluation, no manual repositioning of the automatically generated stimulation-artifact or CMAP landmarks was required (0/14 datasets). This observation describes operator use of the implemented workflow; it does not establish annotation accuracy because the automatic landmarks were not compared with an independent expert reference. Inter-rater agreement and reproducibility across operators were likewise not assessed.

The availability of manual correction remains important because NCS recordings can be affected by baseline fluctuations, residual stimulus artifacts, waveform morphology, electrode placement, temperature, and cursor positioning, all of which can influence measurement variability [8], [9], [27].

C. Plausibility of the Extracted Parameters

Table II summarizes the parameters extracted from the analyzed recordings. Table III shows the proportion of measurements that fell within the normative ranges reported in the literature.

TABLE II
DESCRIPTIVE STATISTICS FOR THE MOTOR MEDIAN NERVE, S1 PARAMETERS, AND MNCV ($n = 14$ PARTICIPANTS). SD: STANDARD DEVIATION; CV: COEFFICIENT OF VARIATION; AMP.: AMPLITUDE; LAT.: LATENCY; DUR.: DURATION.

	Amp. (mV)	**Lat.** (ms)	**Dur.** (ms)	**Area** (mV·ms)	**MNCV** (m/s)
Mean	7.6	4.2	6.6	19.7	62.8
SD	1.9	0.9	1.5	5.8	10.0
Median	7.9	4.0	6.5	18.4	65.2
Min.	3.9	2.8	4.1	9.4	38.6
Max.	10.6	6.1	9.1	29.1	74.8
CV (%)	25.2	22.0	22.5	29.2	15.9

TABLE III
PLAUSIBILITY ASSESSMENT RELATIVE TO NORMATIVE REFERENCES [20] ($n = 14$ FOR EACH PARAMETER).

Parameter	**Cases within range**	**Percentage (%)**
S1 amplitude	14/14	100.0
S1 area	13/14	92.9
S1 duration	13/14	92.9
MNCV	13/14	92.9
S1 latency	10/14	71.4

The mean amplitude was 7.6 ± 1.9 mV, the mean distal latency was 4.2 ± 0.9 ms, and the mean MNCV was 62.8 ± 10.0 m/s. These values are consistent with those generally reported for the motor median nerve in healthy adults [20], [27].

S1 latency was the parameter with the lowest proportion of measurements within the consulted normative range: 10 of the 14 recordings (71.4%). Several factors may contribute to this finding, including individual variability, skin temperature, anthropometric differences, and differences between the present acquisition protocol and the populations or methods used to establish the published reference limits. This is relevant because nerve-conduction reference values are not completely interchangeable across laboratories and protocols, and their interpretation should therefore consider the conditions under which the measurements were obtained [27].

The normative ranges were used to check whether the values produced by the pipeline were physiologically plausible. They do not provide an estimate of measurement error because no reference instrument or independent expert annotation was available. The dataset is also unsuitable for estimating sensitivity, specificity, predictive value, or diagnostic performance for DPN: the sample was small, included only volunteers without DM, was restricted to the motor median nerve, and was collected under controlled experimental conditions. The results should therefore be interpreted as a functional software evaluation rather than as diagnostic validation.

D. Limitations and Future Work

The first limitation concerns automatic landmark annotation. No manual repositioning was required in the 14 datasets analyzed, but the automatic stimulation-artifact, onset, peak, and

end markers were not compared with independent expert annotations. The present study therefore cannot establish annotation accuracy, inter-rater agreement, or reproducibility between operators. A dedicated annotation study should preserve the original automatic landmarks, register any manual edits, and compare both landmark positions and derived measurements with independent expert markings.

Robustness and reproducibility were evaluated only within the controlled workflow used here. Examinations were not repeated across sessions or operators, recording conditions were not systematically varied, and multiple hardware configurations were not tested. Processing time was also not formally benchmarked. In addition, WebSocket interruption, reconnection, timeout, and incomplete-transmission conditions were not stress-tested. The 14/14 completion result is therefore specific to the available recordings and tested operating conditions. Formal usability and operating-system portability assessments also remain to be performed.

The experimental scope was limited to motor median nerve recordings from volunteers without DM, and the acquisition unit was used as the signal source rather than as the object of metrological validation. Calibrated-signal tests, electronic characterization, comparison with an established nerve-conduction system, repeated-session assessment, and reproducibility across hardware configurations are separate validation steps. Future studies should also examine additional peripheral nerves and include participants with DM and DPN.

The evaluated version runs locally and does not use the SDC-X cloud infrastructure. Its structured files support record-level organization and traceability, but cloud synchronization, role-based access control, user-level audit logging, and deployment-related privacy controls were not evaluated. These functions belong to a future connected version of the platform. At its current stage, X-NCS is intended as a research tool that provides a consistent workflow for acquisition, review, filtering, CMAP annotation, parameter extraction, and structured local storage; it is not a substitute for a validated clinical nerve-conduction system.

IV. Conclusion

X-NCS was developed as an SDC-X module for organizing and processing motor NCS data. It connects patient and session management with acquisition-unit communication, signal visualization, digital filtering, CMAP event annotation, parameter extraction, and structured result storage.

When applied to motor median nerve recordings from 14 participants without DM, X-NCS completed the defined functional workflow for all 14 datasets. The distal and proximal recordings were processed, CMAP landmarks were generated and reviewed, electrophysiological parameters were calculated, and the results were stored locally. No manual landmark repositioning was required in the evaluated datasets, and the extracted values were physiologically plausible for the analyzed sample. Because no independent expert annotation or reference nerve-conduction system was included, these findings establish functional execution of the workflow rather than annotation accuracy, measurement agreement, diagnostic performance, or clinical equivalence.

The next validation steps address three separate questions: annotation performance against independent expert markings; repeatability and robustness across sessions, operators, recording conditions, and communication failures; and metrological characterization of the acquisition chain using calibrated signals and an established nerve-conduction system. Larger studies can then extend the evaluation to additional nerves and participants with DM and DPN. A future cloud-connected version will also require verified privacy, access-control, and audit mechanisms. Until those validation stages are completed, X-NCS should be used as a research tool for organizing, processing, and reviewing NCS data, with interpretation remaining the responsibility of qualified professionals.

Acknowledgment

The authors thank IEB-UFSC for its technical, institutional, and infrastructure support. This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) – Finance Code 001.

***Abstract*—Oral cavity disorders represent a clinical challenge due to their diverse presentations and the need for accurate diagnosis, particularly in potentially malignant conditions. In this context, artificial intelligence-based tools have demonstrated significant potential to support the analysis of medical images; however, their development depends on the availability of well-organized, representative, and properly annotated datasets. This study aimed to construct a dataset of oral lesion images from scientific literature for future application in artificial intelligence computational models. The methodology consisted of a literature survey in scientific databases, selection of publications containing clinical images of oral disorders, organization of the collected files in a virtual environment, and categorization of the images into seven main classes: oral potentially malignant disorders and malignancies; reactive and traumatic lesions; normal anatomical variations and benign conditions; immunologically mediated conditions; viral, fungal, and bacterial infections; benign salivary gland disorders; and benign pigmented lesions. Subsequently, the selected materials were uploaded to the IA Bucal Files platform for file management and manual annotation of lesion regions and anatomical structures of the oral cavity. As a result, a total of 3,303 images were collected from approximately 2,100 scientific publications. To date, approximately 56.1% of the images have undergone manual annotation, resulting in 4,170 lesion annotations generated during the construction of the image dataset. It is noteworthy that the annotation process is still ongoing, allowing further expansion and refinement of the dataset. The developed dataset has the potential to support future applications involving the development, training, and evaluation of artificial intelligence models for the detection and classification of oral lesions, thereby contributing to the development of computer-aided diagnostic tools in oral medicine.**

***Keywords*—Dataset; Oral lesions; Image annotation; Convolutional neural networks.**

I. Introduction

Dental care, particularly in the context of oral diseases and disorders, remains a persistent challenge for healthcare systems due to the complexity of diagnosing, treating, and monitoring these conditions. In Brazil, the implementation of the National Oral Health Policy (Política Nacional de Saúde Bucal – PNSB), known as the "Brasil Sorridente" (Smiling Brazil) program, by the Ministry of Health in 2004 represented a significant milestone in expanding access to dental services, contributing to improvements in oral healthcare delivery and the overall oral health of the population [1].

The implementation of this policy also enabled the reorganization of primary oral healthcare, mainly through the expansion of Oral Health Teams integrated into the Family Health Strategy, as well as the strengthening of secondary care through the establishment of Specialized Dental Centers (Centros de Especialidades Odontológicas – CEOs) and Regional Dental Prosthesis Laboratories (Laboratórios Regionais de Próteses Dentárias – LRPDs). These initiatives increased service capacity and promoted a more integrated approach to oral healthcare [2].

Despite the advances achieved through public health policies, the identification and monitoring of oral disorders remain challenging. According to the Brazilian National Cancer Institute (Instituto Nacional de Câncer – INCA), an estimated 17.190 new cases of oral cavity cancer are expected annually in Brazil during the 2026–2028 triennium, corresponding to an estimated risk of 7,98 cases per 100.000 inhabitants. Of these, approximately 12.260 cases are expected to occur in males and 4.930 in females. Excluding non-melanoma skin cancer,

oral cavity cancer ranks as the seventh most common type of cancer in the country [3].

According to Leal, Emmi, and Araújo (2021) [4], an evaluation of Specialized Dental Centers (CEOs) revealed that 34.45% of the analyzed units did not have a specialist in Oral Medicine (Stomatology), whereas only 65.55% had professionals working in this specialty. This scenario highlights a gap in specialized oral healthcare, particularly considering the essential role of Oral Medicine in the diagnosis and early detection of oral disorders, including oral cancer.

In this context, the development of technological tools capable of supporting the diagnostic process has emerged as a promising alternative to assist healthcare professionals in clinical decision-making and improve diagnostic support. However, the development of image-based diagnostic technologies still faces several challenges.

Studies in this field have shown that, despite the advances in deep learning-based models, the availability of representative datasets remains one of the major challenges for their application to medical imaging. The diversity of clinical presentations and the need for large volumes of annotated images directly influence the performance of computational models [5].

More recently, deep learning techniques have been explored as auxiliary tools for medical image analysis, enabling the automated identification of patterns associated with clinical abnormalities. In the context of oral lesions, previous studies have demonstrated the potential of deep neural networks for the detection and classification of oral disorders, contributing to strategies for early diagnosis [5].

In this context, this study proposes a methodological workflow for collecting, categorizing, and manually annotating oral cavity lesion images extracted from scientific literature published under an open-access model. The primary contribution of this work lies in establishing a standardized clinical taxonomy comprising seven major disorder classes, along with a structured clinical image annotation protocol implemented on the IA Bucal Files platform. It is important to emphasize that this research represents an ongoing study, with dataset expansion and manual annotation actively in progress. Nevertheless, this work establishes a solid framework for organizing heterogeneous literature-derived image collections into standardized structures, aiming for the future utilization of this dataset in training neural networks applied to computer-aided oral diagnosis .

II. Materials and Methods

This study is characterized as an exploratory and methodological investigation aimed at constructing an image dataset of oral lesions through the collection, organization, and annotation of images obtained from scientific literature. The dataset was structured into seven main categories of oral disorders: oral potentially malignant disorders and malignancies; reactive and traumatic lesions; normal anatomical variations and benign conditions; immunologically mediated conditions; viral, fungal, and bacterial infections; benign salivary gland disorders; and benign pigmented lesions. The construction of the image dataset followed a methodological workflow composed of sequential stages, as illustrated in Figure 1. Initially, scientific digital libraries were selected as data sources, from which publications containing images of the target oral lesions were identified. Subsequently, the selected files were stored and organized in a virtual environment according to their clinical categories. After cataloging, the documents were uploaded to the IA Bucal Files platform, where the images underwent analysis and manual annotation of the regions corresponding to oral lesions and anatomical structures of the oral cavity. At the end of the process, an organized and annotated image dataset was obtained, containing information associated with the identified oral disorders and intended for future applications involving artificial intelligence-based computational models.

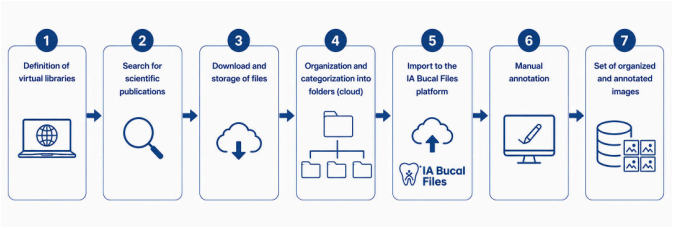

Fig. 1. Methodological Workflow

A. Literature Review

The initial stage of dataset development consisted of a literature survey of scientific references related to oral lesions. For this purpose, academic databases and scientific digital libraries were used, including Google Scholar, Scientific Electronic Library Online (SciELO), CAPES Journal Portal, Scopus, and PubMed, encompassing publications up to 2026. The selection of these sources considered the breadth of their collections, the availability of open-access publications, and the relevance of the literature to the research domain.

The information retrieval strategy employed combinations of keywords and Boolean operators in both English and Portuguese. As an example of the search string applied across the digital platforms, the query used was: (”oral lesions” OR ”oral pathology” OR ”mouth neoplasms”) AND (”clinical presentation” OR ”case report” OR ”diagnosis”). The use of multiple search engines and combined strategies expands access to scientific production and optimizes the identification of suitable clinical images, as different platforms utilize distinct information retrieval algorithms [6].

In addition to traditional databases, the Connected Papers platform was utilized as a complementary tool for mapping and exploring the scientific literature. The platform enables the identification of relationships between articles by using a seed article, keyword, or Digital Object Identifier (DOI), generating a visual representation based on publication similarity. This approach facilitated the tracking of related works and the expansion of the initial literature survey.” .

B. Inclusion and Exclusion Criteria

During the selection process of scientific publications, documents containing clinical images of oral lesions relevant to dataset construction were included. Publications were excluded if they lacked images associated with the investigated disorders or presented visual records unsuitable for annotation, including low-quality images, inadequate lighting, superimposed textual elements over the anatomical site, insufficient information for lesion identification, or features that prevented proper delimitation of the region of interest. To mitigate the inclusion of duplicate cases, same clinical case or image reused in different publications, the upload process on the IA Bucal Files platform incorporated an automated verification mechanism that identified and flagged previously existing images in the repository.

In addition to image availability, aspects related to the scientific relevance of the publications were considered, including analysis of the study context, references used by the authors, and their contribution to the literature in the field. Citations in other scientific works were used as a complementary parameter to evaluate the relevance and academic dissemination of the selected publications.

At the end of the survey process, approximately 2,100 scientific publications containing 3,303 images suitable for subsequent organization, categorization, and annotation stages were selected.

C. Organization and Categorization of Scientific Publications

Following the selection of scientific publications and identification of target images, the materials were organized in a virtual storage environment using a hierarchical folder structure and subsequently uploaded to the IA Bucal Files platform. The organization was structured according to the clinical classification of oral lesions, enabling data standardization and facilitating subsequent selection and annotation steps. The manual annotations were performed by undergraduate students in Dentistry and Biomedical Engineering who underwent dedicated training on the target oral lesions, with their work reviewed by a Master's researcher specializing in Oral Medicine (Stomatology) alongside image management workflow.

The image dataset was divided into seven main categories of oral disorders: (1) oral potentially malignant disorders and malignancies; (2) reactive and traumatic lesions; (3) normal anatomical variations and benign conditions; (4) immunologically mediated conditions; (5) viral, fungal, and bacterial infections; (6) benign salivary gland disorders; and (7) benign pigmented lesions.

The first category comprised disorders with malignant potential and malignant neoplasms, including squamous cell carcinoma, verrucous carcinoma, lymphomas, adenoid cystic carcinoma, oral melanoma, and Kaposi's sarcoma, as well as potentially malignant conditions such as leukoplakia, erythroplakia, erythroleukoplakia, actinic cheilitis, and oral lichen planus.

The reactive and traumatic lesions category included disorders associated with proliferative responses or irritating agents, such as traumatic fibroma, mucocele, thermal burns, inflammatory papillary hyperplasia, pyogenic granuloma, peripheral giant cell lesion, and traumatic ulcers.

The normal anatomical variations and benign conditions category included alterations without significant pathological characteristics, such as fissured tongue, geographic tongue, Fordyce granules, linea alba, palatal and mandibular tori, and exostoses.

The immunologically mediated conditions category was organized to include manifestations such as recurrent aphthous stomatitis, pemphigus vulgaris, mucous membrane pemphigoid, and oral manifestations of systemic lupus erythematosus.

Infections were grouped according to their etiological origin, encompassing viral, fungal, and bacterial conditions such as candidiasis, herpes simplex, HPV-associated squamous papilloma, condyloma acuminatum, paracoccidioidomycosis, and syphilis.

Benign salivary gland disorders included pleomorphic adenoma, sialadenitis, sialolithiasis, and ranula. Finally, the benign pigmented lesions category comprised alterations such as amalgam tattoo, smoker's melanosis, melanocytic nevus, and melanotic macule.

This organizational structure enabled the image dataset to be arranged into distinct classes, promoting greater standardization of the collected information and preparing the dataset for annotation tasks while facilitating reference to the original source articles during the oral cavity lesion annotation process

D. File Registration and Image Annotation Process

For the organization and annotation stages, the IA Bucal Files computational platform, previously developed for the management and annotation of oral lesion images, was employed. The platform served as the working environment for dataset registration and for annotating the regions corresponding to the identified oral disorders.

Initially, a new dataset was created within the platform, including information regarding the oral lesion category, dataset description, and source identification. After creating the dataset, the scientific publications selected during the literature review were uploaded in PDF format. During this process, the IA Bucal Files platform automatically extracted the images using Optical Character Recognition (OCR), adding to the dataset only the images contained in each uploaded PDF document.

After the files were uploaded, the manual annotation process of the clinical images began. Using the annotation tools available within the platform, the regions corresponding to oral lesions and their associated anatomical structures were manually delineated. It is important to note that a single image may contain multiple lesion annotations as well as multiple anatomical region annotations, allowing a more detailed representation of the information contained in the dataset.

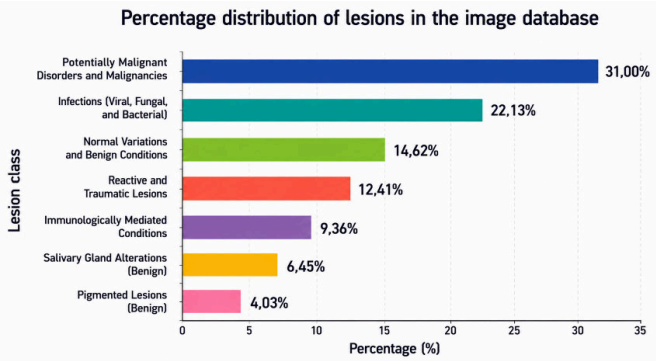

Fig. 2. Number of Images per Oral Lesion Category

At the end of this stage, a structured and annotated image dataset was obtained, containing information associated with the identified lesions and their corresponding anatomical regions. This dataset provides a foundation for future applications involving medical image processing and artificial intelligence-based computational models.

III. Results and Discussion

The literature review conducted for the seven categories of oral lesions resulted in the selection of approximately 2.100 scientific publications, which were stored in a virtual repository. These publications were uploaded to the IA Bucal Files platform, leading to the initial construction of a dataset containing 3.303 clinical images of oral lesions extracted from scientific publications. As shown in Figure 2, the highest concentration of images was observed in Category 1 (Oral Potentially Malignant Disorders and Malignancies), whereas Category 7 (Benign Pigmented Lesions) contained the smallest number of images.

The unequal distribution of images among the categories is associated with the number of clinical conditions included in each category and may also reflect the availability of scientific publications containing clinical images of these conditions. The Oral Potentially Malignant Disorders and Malignancies category exhibited the largest representation in the dataset because it encompasses a greater number of oral disorders and conditions of high clinical relevance, particularly those associated with the diagnosis of oral cancer. In contrast, categories comprising fewer clinical conditions, such as Benign Pigmented Lesions, contained fewer available images.

This variation in class distribution represents an important consideration for future artificial intelligence applications, as imbalanced datasets may affect the learning process of computational models by favoring classes with greater representation while reducing their ability to generalize to underrepresented categories [7]. Therefore, the continuous expansion of the dataset and the pursuit of a more balanced class distribution are essential steps toward the development of more robust models for oral lesion detection and classification.

At the time of analysis, the dataset contained 4.170 lesion annotations, distributed among benign (3.150), malignant (491), and potentially malignant (529) lesions. However, the annotation process was still ongoing, with approximately 56.1% of the images having undergone manual annotation. This stage is essential for the construction of datasets suitable for computational modeling, as annotation quality directly influences the learning capability and generalization performance of algorithms applied to medical imaging [8].

During the annotation process, an additional image quality control procedure was performed. Images presenting superimposed artifacts within the regions of interest, low resolution, blur, inadequate illumination, or insufficient information regarding their source were excluded from the dataset. Furthermore, both the images and their corresponding annotations were reviewed by dental professionals to improve the reliability of the identification of oral disorders represented in the dataset.

Annotation quality is a determining factor in the reliability of medical image datasets, since inconsistencies introduced during this stage may compromise the construction of the reference annotations used for artificial intelligence applications. Inter-observer variability and the absence of standardized annotation protocols have been identified as important challenges in the development of medical datasets, potentially affecting the consistency and reproducibility of computational models. Therefore, structured expert review procedures, together with well-defined annotation criteria and workflows, are essential to improve the reliability of datasets used for artificial intelligence applications [9], [10].

IV. Conclusion

This study enabled the construction of a structured image dataset of oral lesions derived from scientific literature, comprising 3303 images organized into different clinical categories and subjected to standardization and manual annotation using the IA Bucal Files platform. The development of this dataset demonstrates the feasibility of using scientific literature as a source for creating datasets intended for future computational applications in healthcare.

The organization and quality assurance of the images represent fundamental steps in the development of artificial intelligence-based tools, as data quality directly influences the analytical capability and performance of computational models. Consequently, the developed dataset has the potential to be integrated into future computer-aided systems for the detection and classification of oral lesions, serving as a supportive tool for dental and healthcare professionals.

As future work, the proposed directions include expanding the literature review, incorporating additional images into the dataset, improving the balance among lesion categories, and employing the structured dataset to develop and evaluate artificial intelligence models for integration into computer-aided diagnostic systems in Oral Medicine.

***Abstract*—Digital image analysis and processing have become essential tools for enhancing objectivity and statistical rigor in biomedical research. However, widely reproduced experimental protocols, such as the *in vitro* scratch wound healing assay, are still heavily limited by manual segmentation subjectivity, poor standardization, and substantial human labor, which ultimately lower their reproducibility and scientific impact. To overcome these limitations, this paper introduces CORA (Cell Open-Region Analyzer), an open-source desktop application developed in Python designed to support the quantification of cellular migration via automated image-based analysis. CORA streamlines the research workflow by automatically generating binary masks of the scratch area for subsequent user validation, calculating wound sizes, and computing closure rates over time. To rigorously validate the software's operational readiness, reliability and computational efficiency, we performed a comprehensive benchmarking evaluation under multiple stress conditions, measuring CPU utilization, RAM throughput, and execution times across singular and extensive batch processing (up to 60 images). Furthermore, a robotic interaction algorithm was deployed to simulate low- and high-intervention human workload scenarios. The results demonstrate that CORA achieves outstanding computational efficiency, executing automated segmentation in just 14 seconds per image (for single and 60 batch tests) — representing up to an 8-fold speedup compared to traditional manual tracing (120 s/image). By significantly reducing processing bottlenecks and providing an integrated workflow for automated segmentation and expert review, CORA establishes a standardized, high-performance, and user-friendly framework that drastically improves reproducibility and quantitative throughput in cellular wound healing studies.**

I. Introduction

Ever since digital imaging equipment entered the world of science, life scientists have collaborated with computer scientists to apply image-processing techniques to analyze biomedical data. The aim is to use computational processes to accelerate repetitive tasks while also obtaining quantitative results, since statistical results are much more compelling, scientifically speaking, than qualitative observations [1].

In vitro scratch wound healing assay, a simple and low-cost technique that works along with other image analysis tools is one of the most widely used 2D methods to determine the cellular migration and proliferation in processes such as regeneration and disease. In this regard, the scratch or migration assay is a widely used tool for *in vitro* studies of the rates of migration, angiogenesis, movement, proliferation, and healing in response to different novel drug candidates [2]. To obtain data from the assay, images of different exposures must be taken over a period at the exact same spot to compare the movements of the migration [3].

Data acquisition and analysis in most wound healing assays is done at least to some extent manually. The manual extraction of data from micrograph is always time-consuming, error-prone, and the data output is very subjective depending on the individual researcher. Thus, analyzing a large set of data still remains the bottleneck of many assays. Also, the comparison of data from different tools and/or different experimenters is not very reliable [4]. Despite being widely employed, the

scratch wound healing assay is poorly standardized both in its execution (e.g., gap creating strategies and wound surface quantification protocols) and in the techniques used to quantify its results. These aspects significantly increase the variability and reduce the accuracy of the measurement [5].

Advances in biomedical image-processing techniques have allowed for the corroboration of research outcomes by quantifying them in a rigid, statistical manner while simultaneously raising the bar for life science research when it comes to substantiating scientific observations [1].

To bridge this gap, this study introduces CORA (Cell Open-Region Analyzer), an open-source, desktop software application developed in Python designed to streamline and standardize the image-analysis workflow used for the quantification of cellular migration in scratch assays. By embedding an intuitive graphical user interface (GUI) with interactive refinement tools, the software aims to democratize access to robust image-processing pipelines for life science researchers without programming expertise. Furthermore, this work presents a comprehensive benchmarking evaluation of the software's computational performance, quantifying CPU, memory throughput, and operational efficiency under simulated user workloads validating its computational performance and usability in high-throughput, reproducible research tool.

II. Materials and Methods

A. Software Architecture

To streamline laboratory workflows, CORA was designed to provide life science researchers with immediate, decentralized access to automated segmentation masks and numerical wound dynamics. To provide an integrated understanding of the system's runtime execution, the overall logical sequence, algorithmic modules, and step-by-step user interactions are systematically mapped out in Fig. 1. Furthermore, to guarantee full reproducibility and transparency for open-source collaborative deployment, the comprehensive repository architecture, licensing framework, core development metadata, and complete technical dependencies required to run the environment are detailed in Table I.

The application architecture was implemented in Python utilizing the Tkinter graphical library for desktop environment management, which inherently supports efficient event handling, layout customization, and low overhead [8]. The development of this interactive graphical user interface (GUI) was intentionally prioritized to abstract the underlying computer vision complexities, delivering an intuitive, plug-and-play tool tailored for operators with no prior programming experience.

The application starts with the request of folders containing the images to process and the folder to save its results. The software expects a standardized file naming convention, such as filename-XXX.tif, where XXX represent the specific time of acquisition of the image (0 hour, 24 hours, or 48 hours), and it accepts other formats of images as well. Based on the information contained on the file's names, the software divides the images in groups with each time sequence, used to calculate further data related to the variation of area.

These images are shown by groups on the screen, using the Matplotlib library, a comprehensive library for creating static, animated, and interactive visualizations in Python. Matplotlib makes easy things easy and hard things possible [9]. This modularity enables users to correct grouping errors or customize configurations directly, being used through the whole procedure, to facilitate the user to visualize the progression of the segmentation.

Next, the program starts processing all the images selected by the user. A progression bar appears, showing the remaining time to end the processing as well as showing which images are being processed. With the segmentation, the program calculates the size of each area in pixels (A), as well as the progression of closure, denoted by 1, where Y represents the

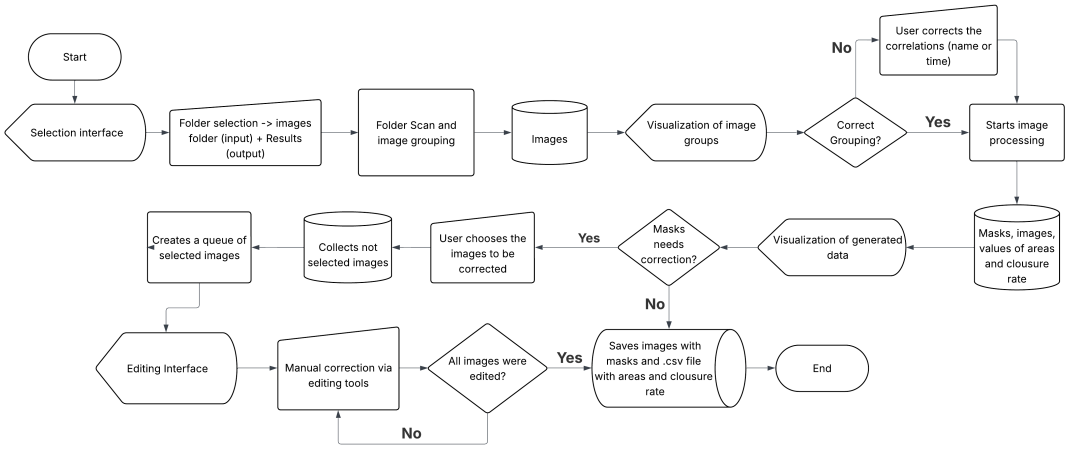

Fig. 1. Methodological architecture and user operational workflow of CORA (Cell Open-Region Analyzer). The block diagram maps the sequential software logic, including input folder scanning, automated multi-time-point image alignment, image processing execution, interactive mask validation, and final data export to structured files.

time point:

$$C_Y = \frac{A_0 - A_Y}{A_0} * 100\% \quad (1)$$

While the core image processing algorithms lie outside the immediate scope of this evaluation, they utilize an established computational pipeline, using adaptive filtering for image enhancement, gradients for edge detection, filters for texture analysis, mathematical morphology for region refinement, and image segmentation, continuously developed and optimized by our research group in parallel with this software integration.

On the visualization page, the resulting segmented images of the groups separately will be displayed. From this point, the user has two options: either to maintain the automatic segmentation and save as is, or to put it in a queue to edit the contour to what they think is appropriate.

The editing page consists of using Matplotlib for the visualization of the segmented image and combining OpenCV, which is an open-source library that includes several hundreds of computer vision algorithms [10], and Numpy, a Python library that provides a multidimensional array object and an assortment of routines for fast operations on arrays [11], for the modeling part of the mask.

After this stage, all the changes made to the masks substitute the origin of the base processing, including the variation on the related values of areas and percentages. All numerical data will be provided in a .csv file together with the segmented images.

B. User Workflow

The software receives the full package of files that the user chooses to be segmented and divides them by groups of equal naming but varies by dates, process and calculate the area of the wound as well as the percentage of closure for each image grouping. We advise the user of using the same pattern when giving names for the files, since the calculations uses the exact sequence of timing (for example, the percentage of closure of a 24-hour image depends on the value of that same image on 0 hour).

The resulting segmented images are shown to the user by the stated division, as well as the values of these segmentations in pixels. The user can either accept the segmented contour and its size value, or they can reshape it with the editing tool. When selecting the images for the editing session, it is forced to the user to visualize every group of selected images, to guarantee optimal usage of the software. After the analysis, the selected segmented images are saved with a report that contains all the comparative data generated through the processing and revision stages and the ones unchecked, if any, will be delegated to the editing queue.

The editing will be made with tools that enables the user to modify the contour, maintaining the overall structure of the segmentation. After finishing the session, the user returns to the visualization page with the changes made and all the images automatically marked to be saved.

As a Python application, all technical dependencies listed in Table I must be installed on the user's machine.

C. Software Performace

The testing will consist of three analysis using an AMD Ryzen 7 5800H, SSD 475GB, 32 GB RAM DDR4 computer. For each of these tests, we will analyze data related with its performance (CPU and RAM usage) and time usage of the user, to determine how viable it is to use this application instead of other existent tools. The environments of these tests were summarized on I.

III. RESULTS

A. Interface Appearance

The graphical interface comprises three core operational modules: the selection and configuration interface (Fig. 2), the visualization and validation panel (Fig. 3) and the interactive editing workspace (Fig. 4).

The selection page successfully acquires and distributes all the images within the designated input directory into temporal groups while filtering out any duplicates recognized by the algorithm, as systematically presented in Fig. 2. This module also supports dynamic group renaming and displays real-time image previews to facilitate early dataset organization. Following this initial setup, the application transitions to the visualization page, which effectively displays the processed

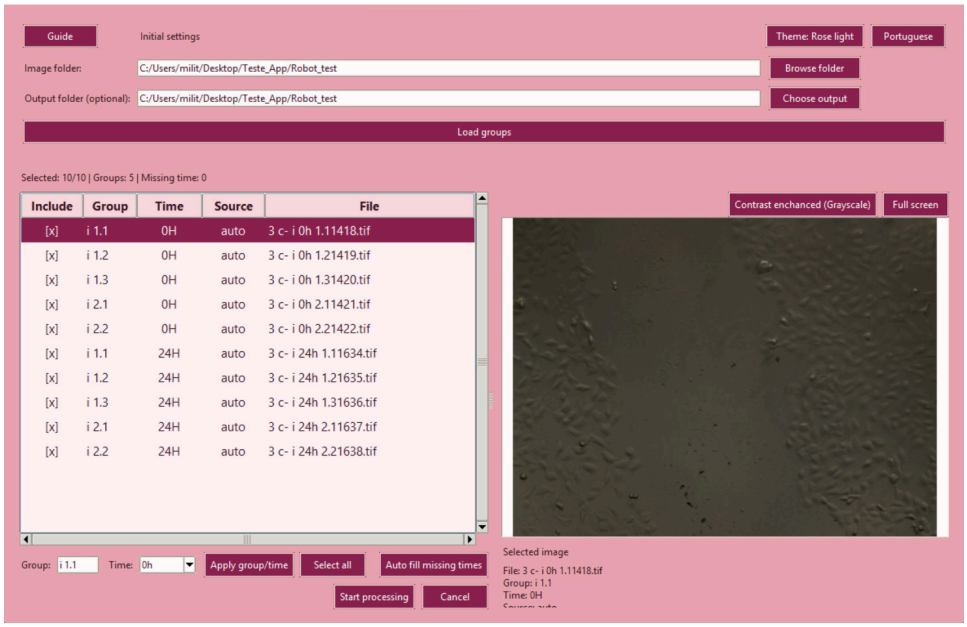

Fig. 2. CORA selection and configuration interface. This module automatically parses file naming conventions to parse and group time-series images (0 h, 24 h, and 48 h), automatically filters duplicated files, and provides a real-time side panel for visual verification of image grouping prior to segmentation processing.

image groups arranged horizontally with the automated segmentation masks seamlessly overlaid, as illustrated in Fig. 3. Within this panel, users can actively review the initial area calculations, evaluate computed closure rates, and determine whether specific boundaries require manual configuration or should be rolled back to the original automated state.

The editing page exhibits the image with an editable mask utilizing custom tools that enable the operator to modify the boundaries by erasing, rearranging the contours, or creating a mask from scratch, as displayed in Fig. 4. To prevent human-induced bias, these tools are calibrated to balance localized user curatorial interventions with the structural integrity of the underlying automatic segmentation morphology. For enhanced visual acuity of the scratch margins, a ”Contrast Enhanced” feature converts the image into a high-contrast grayscale version. Furthermore, step-by-step user guides are integrated into every sub-page, which also feature multi-lingual support for English and Portuguese alongside multiple dark and light color themes to optimize long-term operational comfort in laboratory environments.

B. Interface Testing

The first test consists of evaluating the complete operational routine of the application for one image focusing on time spent on processing segmentation using the python standard library time module, used for acquiring this data [12], and the maximum usage of RAM memory and CPU during the process with the library psutil(process and system utilities) is a cross-platform library for retrieving information on running processes and system utilization (CPU, memory, disks, network, sensors) in Python [13], for the operating data of these internal components. After processing, the results are presented in Table II.

TABLE II. Computational performance metrics for single-image processing in CORA.

Metric	**Mean ± SD ($\mu \pm \sigma$)**
Image loading time (s)	0.0225 ± 0.002
Segmentation time (s)	14.232 ± 1.108
Peak RAM usage (MB)	1052.42 ± 24.885
Peak CPU usage (%)*	33.70 ± 6.588

*CPU usage values were normalized by the number of logical cores.

The second will evaluate the same data as the first one, but focusing on batch processing, varying from 10, 24 and 60 images, with the same protocol from the first test, focusing on the stability of the application with an extensive task. To analyze, we used the same routine for the data and the results were put on Table III.

TABLE III. Benchmarking evaluation under graded batch processing configurations

Metric	**Images x Iterations ($\mu \pm \sigma$)**		
	10x10	**24x10**	**60x10**
Total time (s)	146.320 ± 1.014	339.417 ± 1.957	877.424 ± 17.934
Peak RAM usage (MB)	1429.66 ± 18.31	1987.64 ± 56.40	3414.42 ± 28.96
Peak CPU usage (%)*	43.93 ± 7.43	53.14 ± 6.26	47.84 ± 4.42
Images per minute	4.10 ± 0.03	4.25 ± 0.02	4.10 ± 0.08

*CPU usage values were normalized by the number of logical cores.

And the last test will be a simulation of two routines of possible outcomes when using the app: the no-editing scenario (A), when editing images is not needed, and the full-editing scenario (B), when all images need to be edited. To simulate a user-interface interaction, we utilized a bot algorithm with the library pywinauto, a set of python modules to automate the Microsoft Windows GUI. At its simplest it allows you to send

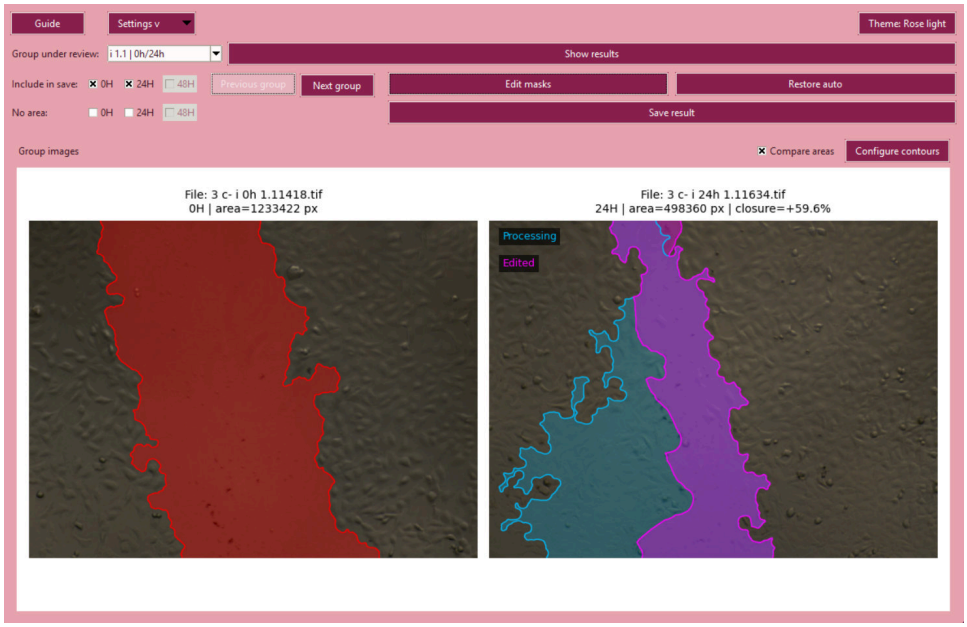

Fig. 3. CORA visualization panel exhibiting side-by-side comparative analysis between automated segmentation (red overlay) and manually adjusted boundaries (purple/blue overlay). This visual monitoring allows instant validation of area calculations and closure rate computations, enabling users to rollback or redo contour modifications.

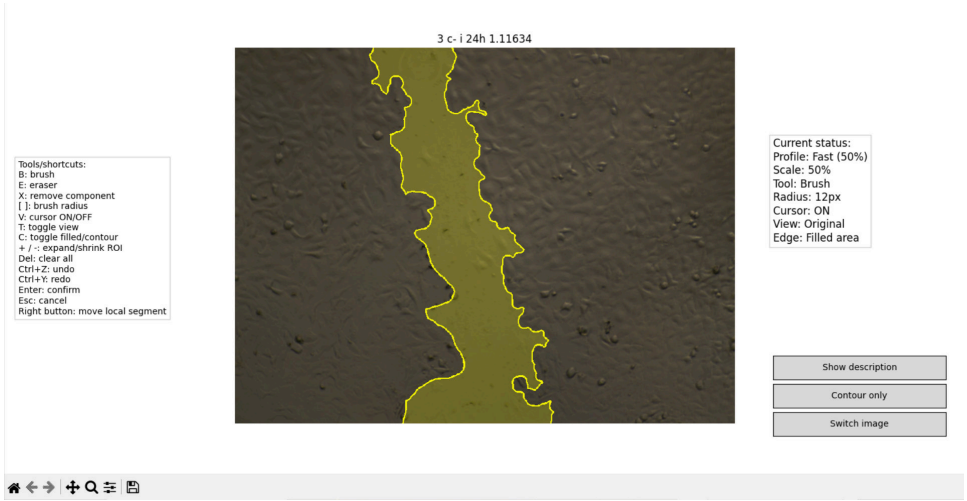

Fig. 4. CORA interactive editing workspace and manual curation panel. The interface integrates dedicated drawing tools for fine-grained mask manipulation, including local brush adjustments, component erasing, and rapid system navigation via keyboard shortcuts such as brush size controls, standard undo (Ctrl+Z), and redo (Ctrl+Y) mechanisms. To ensure optimal visual acuity under diverse experimental conditions, operators can dynamically toggle the segmentation mask overlay between a semi-transparent filled-area mode or a boundary-only contour profile. Additionally, the workspace supports real-time color customizability of the segmented region alongside local contrast enhancements, meticulously balancing user-guided editing flexibility with the morphological fidelity of the underlying cell monolayer.

mouse and keyboard actions to windows dialogs and controls [14], to emulate the actions of the user. The bot reproduced the clicks and interactions necessary to execute those tests, with a delay of 1 second for each click and 15 seconds for editing one image.

To ensure a rigorous and standardized assessment of user-interface pathways, the software includes a dedicated benchmarking control dashboard, which allows operators to systematically monitor execution runtimes across distinct workloads, as illustrated in Fig. 5. The operational timeline data compiled via this robotic interface emulation, contrasting the execution latencies across all primary sub-pages under both no-editing and full-editing interaction conditions, is quantitatively consolidated and presented in Table **??**.

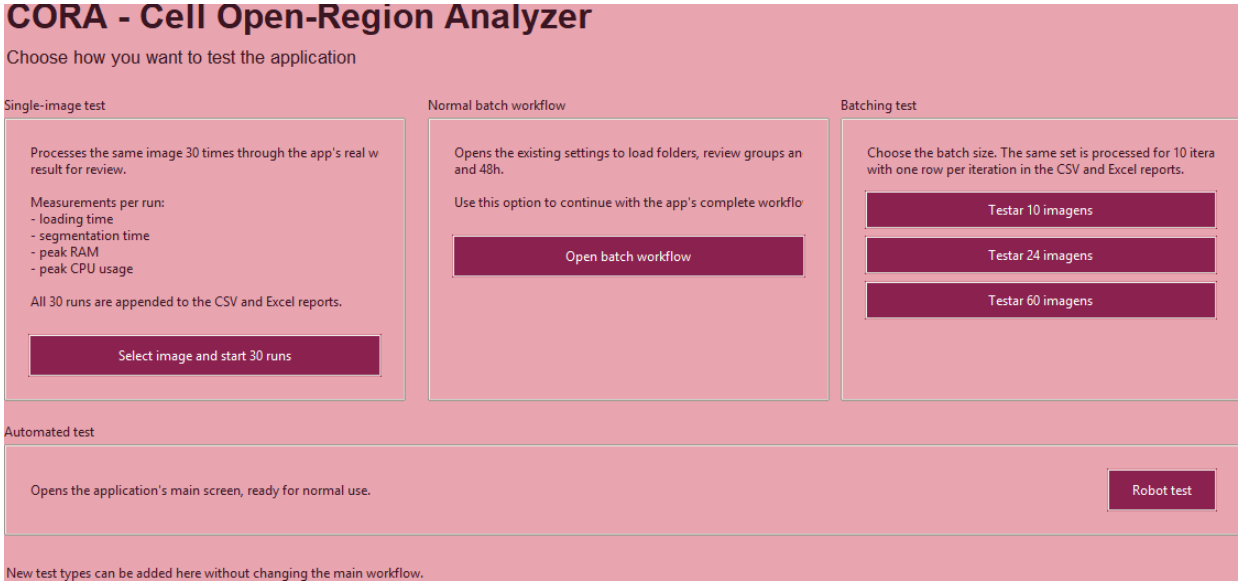

Fig. 5. CORA automated testing and benchmarking dashboard interface. This module coordinates the execution of standardized performance assessments, enabling the user to launch single-image reliability trials, trigger graded multi-image batch workloads (10, 24, and 60 micrographs), or execute UI-driven robotic interaction emulations via pywinauto to benchmark operational workflows under controlled operational latencies.

TABLE IV. Interface Operational Time for Automated Workload Simulations (Robot Tests A and B)

Time on Pages (s)	**Test A** ($\mu \pm \sigma$)	**Test B** ($\mu \pm \sigma$)
Selection	7.567 ± 1.407	8.491 ± 1.346
Configuration	6.190 ± 0.004	6.161 ± 0.094
Visualization	10.844 ± 0.106	8.060 ± 0.097
Editing	0	159.568 ± 0.010

Operational data compiled using pywinauto emulation to replicate no-editing (Test A) and full-editing (Test B) human interactions.

IV. Discussion

The assessment of *in vitro* wound healing images is critical for determining the efficacy of the therapy-of-interest that may influence the wound healing process. Existing methods suffer significant limitations, such as user dependency, time-consuming nature, and lack of sensitivity, thus paving the way for automated analysis approaches [15]. For these reasons, the development of applications that can facilitate the evaluation of these images by automatically quantifying the wound area, and thus, the closure rate is of paramount importance to accelerate these types of studies.

Our software demonstrated high operational throughput, achieving an automated segmentation speed of approximately 14 seconds per individual micrograph. When subjected to extensive batch processing configurations (such as the 60-image stress test), the system maintained strict stability, yielding an efficiency rate of over 4 images processed per minute. This computational performance drastically outperforms manual operations, with an average analysis time of 120 s/image and highly dependent on the user's ability of consistently elaborating all the images [5]. Ultimately, with the time of 1 image of manual determination, we can generate three segmented images with partial participation of the user or eight images without their intervention.

Regarding the performance validation of the automated scratch detection layer, the algorithm achieved a baseline area extraction consistency of 82% for the 0-hour micrographs when compared directly against the manual annotations performed by specialized biological researchers. For the more challenging 24-hour post-scratch time points, where hyper-fragmented cell monolayers and localized cellular debris naturally obscure the gap boundaries, the raw automated algorithm experienced a characteristic overestimation trend, yielding an average area deviation ratio of +76% prior to user intervention. Crucially, the programmatic inclusion of the interactive editing module successfully mitigates this computational variance; the intuitive layout of the manual reshaping tools allows operators to rapidly audit, refine, and correct these algorithmically complex boundary segmentations, effectively aligning the final quantitative output with the rigorous morphological consensus established by expert biological ground truth.

A key conceptual advantage of CORA is that it avoids the rigid, automated 'black-box' processing paradigms common to many fully autonomous computer vision tools. In complex, cross-contaminated, or highly irregular *in vitro* biological cultures, traditional segmentation strategies frequently collapse or demand unfeasible parameter recalibrations due to cell debris, non-uniform cell proliferation, and poorly defined wound fronts. Instead of enforcing a rigid, fully autonomous execution that would inevitably yield scientifically flawed data under these stressful conditions, CORA embraces a human-in-the-loop computing architecture. The underlying processing pipeline performs approximately 90% of the intensive

computational segmentation in seconds, while the graphical interface—implemented via Tkinter with future scalability targeted for advanced PySide6 multi-threading modules built upon the Qt Framework [16] —serves as an interactive quality control layer. This architectural synergy empowers domain experts to rapidly audit, refine, or validate the generated masks, ensuring that only highly accurate and reproducible biological data is exported to the final structured report.

Regarding system resource allocation, the peak computational consumption observed during the trials deserves careful architectural consideration. As reported in Tables II and III, memory allocation varied from a baseline medium peak of 1052.42.66 MB during single-image workflows to 3414.42 MB under the maximum 60-image batch stress test. This memory footprint behavior is tied directly to how Python manages high-resolution arrays (2048 x 1534). To enable interactive graphical features, such as real-time canvas updates, image contrast enhancements, and multi-step undo/redo histories, the software must retain multiple copies of heavy NumPy matrices and Matplotlib visualization buffers concurrently in active memory. While a 3.5 GB peak usage is considerable, it is completely compatible with standard modern laboratory workstations equipped with 8 GB or 16 GB of RAM, confirming that CORA is fully viable for routine laboratory environments without specialized server hardware.

While the literature frequently highlights that the scratch wound healing assay suffers from poor standardization in its execution and quantification protocols, CORA actively mitigates this vulnerability by establishing a deterministic computational workflow. By locking the mathematical extraction of the wound boundaries into standardized digital pipeline, and restricting manual intervention to strictly monitored contour scaling tools, the software effectively eliminates the subjective variance introduced by different human experimenters.

From a software engineering standpoint, evaluating user workflows using human test subjects can often bias system benchmarks due to uncontrolled external variables, such as operator fatigue, distraction, or varying motor reflexes. Utilizing an automated UI-driven bot framework via pywinauto provided a highly rigorous, reproducible method to evaluate CORA's interface efficiency. By clamping user actions to strict timing rules, exactly 1 second between navigation clicks and a fixed 15-second block for localized mask manipulations, the simulation successfully isolated human performance variance from the raw performance of the software architecture. This level of rigorous stress-testing guarantees that the documented execution timelines represent a reliable upper bound for operational throughput, a methodological step that adds substantial software engineering validity to the application.

V. Conclusion

This paper presented CORA (Cell Open-Region Analyzer), an open-source, desktop software application designed to support and standardize the image-analysis workflow for quantifying cellular migration via automated image analysis in *in vitro* scratch wound healing assays. By combining dynamic digital image processing pipelines with an intuitive, multi-lingual graphical user interface developed in Python, the software successfully bridge the gap between complex computational vision and laboratory life science research. CORA delivers automated segmentation masks, precise area measurements in pixels, and objective wound closure rates over time. To ensure high-quality, scientifically sound outputs, the application integrates targeted user curatorial tools that seamlessly balance expert human intervention with the underlying algorithmic structure, providing a more standardized image-analysis workflow while retaining expert oversight.

The computational readiness of the tool was rigorously validated through benchmarking performance assessments and automated workload emulations using robotic interaction algorithms. The statistical data compiled across single-image and graded batch processing stress tests confirm that CORA maintains remarkable operational throughput under extensive tasks. Executing individual automated segmentations in approximately 14 seconds, the application demonstrates an approximate 8-fold computational speedup compared to traditional manual digital tracing protocols, which average 120 seconds per micrograph. Furthermore, the editing function of the application easy to use and efficient enough to make any deviation of the automatic process easily fixable. Even under simulated full-editing user interaction profiles (where every generated boundary mask is subjected to full manual reshaping) the overall human-software hybrid workflow caps execution times at 39 seconds, effectively shifting the data acquisition bottleneck commonly observed in high-throughput biological screening assays.

Future research and technical developments will focus on expanding the architectural features of CORA to broaden its clinical and research utility. The authors intend to incorporate advanced, adaptive processing methods capable of handling diverse image modalities, such as phase-contrast, fluorescence, and non-uniform low-contrast microscopy, which often present distinct boundary noise characteristics. Furthermore, we aim to deploy deep-learning-based segmentation modules, such as U-Net architectures, as alternative backend processing engines to enhance boundary prediction in hyper-infected or highly fragmented monolayers. By incorporating feedback and tool suggestions from the open-source scientific community, CORA is poised to evolve into a highly versatile, scalable, and indispensable collaborative ecosystem for quantitative biomedical imaging analysis.

Acknowledgment

The authors are thankful for the received financial support from the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES—Brazil), CNPq—Brazil, and FAPEMIG—Brazil, as well as the scientific and technical support provided by the Laboratório de Imunofisiologia da Reprodução (LABIFIR).

***Abstract*—Ambulatory Blood Pressure Monitoring (ABPM) produces time-series data whose interpretation requires the calculation and organization of clinical metrics, including 24-hour, awake, and asleep averages, nocturnal dipping, blood pressure variability, and blood pressure load. This study presents CORE-ABPM-FHIR, a web-based prototype that retrieves blood pressure measurements represented as FHIR Observation resources, automatically calculates metrics according to selected clinical guidelines, and consolidates the results in a DiagnosticReport resource for visualization and analysis support. The system was developed using React and TypeScript and functionally verified using a 24-hour window containing 50 hospital blood pressure measurements from the MIMIC-IV Clinical Database Demo as proxy input for the processing pipeline. An internal heuristic inspection based on Nielsen's principles was also independently conducted by two authors. For the evaluated dataset, the prototype calculated and displayed the implemented metrics according to the selected guideline. The inspection identified the lack of help and documentation elements as a severity level 3 issue, along with minor interface and accessibility problems. The results support the feasibility of the proposed FHIR-based workflow, while clinical validation using actual ABPM recordings and usability evaluation involving healthcare professionals remain necessary.**

***Index Terms*—Digital Health Record, Cloud Computing, Health Information Interoperability**

I. Introdução

A Monitorização Ambulatorial da Pressão Arterial (MAPA) é um exame utilizado para a avaliação contínua da pressão arterial ao longo de 24 ou 48 horas, permitindo a análise de padrões temporais e da variabilidade circadiana dos níveis pressóricos ao longo do dia [1], [2]. Diferentemente de medições pontuais, o MAPA permite a obtenção de um conjunto estruturado de dados ao longo do tempo, incluindo informações nos períodos de vigília e de sono [3]. Apesar da disponibilidade desses dados, a interpretação dos exames de MAPA permanece um processo complexo, envolvendo a análise simultânea de múltiplos parâmetros clínicos, como médias por período (24 h, vigília e sono), descenso noturno (*dipping*), variabilidade da pressão arterial e carga pressórica [4]. Esses parâmetros são definidos por diretrizes clínicas, mas sua aplicação prática pode variar entre sistemas, resultando em inconsistências na interpretação e em maior dependência de análises manuais [5]. As principais diretrizes clínicas para a interpretação de exame MAPA incluem recomendações de entidades como a A*merican Heart Association/American College of Cardiology* (AHA/ACC) [6], a *European Society of Hypertension* (ESH) [7], a Sociedade Brasileira de Cardiologia (SBC) [8] e a *Italian Society of Hypertension* (SIIA) [9]. A Tabela I sintetiza as métricas recomendadas por essas diretrizes para a composição de um laudo de MAPA, evidenciando uma convergência quanto aos parâmetros considerados essenciais para sua interpretação e a complexidade envolvida em sua análise clínica.

Com a crescente digitalização dos sistemas de saúde, observa-se a adoção de padrões para a representação estruturada de dados clínicos, como o Fast Healthcare Interoperability Resources (FHIR), que permite a disponibilização de informações entre diferentes plataformas [10]. No entanto, o uso do FHIR tem sido predominantemente voltado à padronização da troca de dados, sem explorar plenamente seu potencial como base para mecanismos de interpretação clínica [11], [12]. Nesse contexto, há uma lacuna entre a padronização dos dados e a de sua interpretação, especialmente em exames que envolvem múltiplas métricas derivadas, como a MAPA [11], [13]. A ausência de abordagens automatizadas e interoperáveis para a extração e a organização dessas métricas limita a eficiência dos sistemas de apoio à decisão e dificulta a integração entre diferentes soluções [13], [14].

TABLE I
COMPARAÇÃO DE MÉTRICAS ENTRE DIFERENTES VERSÕES DAS DIRETRIZES

Diretriz (ano)	Médias	Dipping	Variabilidade	Carga	Classificação	Mín/Max
AHA/ACC (2025) [6]	X	X	X	X	X	
ESH (2023) [7]	X	X	X	X	X	
SBC (2018) [8]	X	X	X	X	X	
SIIA (2024) [9]	X	X	X	X	X	X

O símbolo "X" indica que a métrica correspondente é recomendada pela respectiva versão da diretriz. As versões apresentadas correspondem às referências utilizadas na análise bibliográfica das métricas.

Diante disso, este trabalho propõe um mecanismo padronizado para a interpretação de exames do MAPA, baseado no padrão FHIR. A abordagem utiliza recursos como *Observation* e *DiagnosticReport* para representar os dados e automatizar o cálculo de métricas clínicas recomendadas pelas principais diretrizes, incluindo médias por período, descenso noturno, variabilidade da pressão arterial, carga pressórica e classificação. Essas informações são integradas a uma aplicação *web* para visualização estruturada e apoio à análise. Entre as principais contribuições, destacam-se: (i) a proposta de um mecanismo padronizado de exames MAPA utilizando o padrão FHIR, permitindo a representação estruturada não apenas dos dados, mas também das métricas clínicas; (ii) a implementação de um *pipeline* automatizado para o cálculo de um conjunto consolidado de métricas clínicas, alinhado com as recomendações das principais diretrizes; e (iii) a integração dessas métricas em uma estrutura unificada de apoio à interpretação, reduzindo a dependência de análise manual e promovendo a interoperabilidade entre sistemas clínicos.

II. TRABALHOS RELACIONADOS

A fim de entender como este trabalho se posiciona, foi realizada uma busca de artigos e trabalhos relacionados, analisando aspectos como:

- Uso do padrão FHIR;
- Plataforma de visualização;
- Suporte a informações em tempo real;
- Existência de filtros temporais para consultar as informações.

A partir da Tabela II nota-se que apenas um trabalho usa explicitamente o padrão FHIR, mas com um foco na sua interoperabilidade e uma visualização temporal de informações, como frequência cardíaca e temperatura. Além disso, apenas um dos trabalhos trabalha com uma navegação temporal rica que permite ao usuário filtrar o período de tempo que ele deseja visualizar. Por fim, a maioria foca em IoT (*Internet of Things*) e na aquisição de dados por meio de sensores e dispositivos, não na visualização interativa.

Diante desse cenário, o CORE-ABPM-FHIR reúne aspectos que aparecem de forma parcial ou isolada nos trabalhos analisados. Diferentemente dos trabalhos 1, 2, 3 e 6 que não aderem a nenhum padrão de interoperabilidade, o trabalho proposto se baseia no padrão FHIR, o que pode proporcionar compatibilidade com outros sistemas estabelecidos. Além disso, em contrapartida ao trabalho 7, que, embora use FHIR, não oferece um processamento clínico elaborado, o CORE-ABPM-FHIR calcula automaticamente as métricas específicas do MAPA, como médias por período, cargas pressóricas e descenso noturno, a partir das medições brutas, consolidando esses resultados em um recurso *DiagnosticReport*. Por fim, enquanto os trabalhos 4, 5 e 8 oferecem algum nível de filtragem temporal, esta é limitada a intervalos fixos ou predefinidos, o CORE-ABPM-FHIR disponibiliza uma visualização configurável, na qual o usuário pode ajustar dinamicamente o período, aliando-se à interoperabilidade do FHIR uma camada de análise clínica automatizada que não foi identificada de forma conjunta em nenhum dos demais trabalhos comparados.

III. MÉTODOS

Esta seção descreve a arquitetura do sistema proposto, bem como os mecanismos de modelagem, processamento e cálculo das métricas clínicas. Ao final, apresentam-se os aspectos éticos envolvendo este trabalho.

A. Arquitetura do Sistema

A arquitetura proposta, ilustrada na Figura 1, organiza o sistema em quatro blocos principais: aquisição de dados, armazenamento e interoperabilidade, processamento de informações e aplicação e visualização, evidenciando o fluxo de dados desde a coleta até a visualização clínica. A Figura 1 apresenta a arquitetura conceitual adotada neste trabalho. Os blocos de aquisição e de armazenamento/interoperabilidade representam premissas da solução: assume-se que as medições de MAPA são disponibilizadas em uma infraestrutura compatível com FHIR, estruturadas como recursos clínicos e acessíveis por meio de consultas padronizadas. A contribuição central deste trabalho concentra-se nos blocos de processamento das informações e aplicação/visualização, responsáveis por recuperar os recursos, extrair as medições, organizar os dados por período, calcular métricas clínicas e apresentá-las em uma interface de apoio à interpretação. Além disso, o desenvolvimento da aplicação se baseou no modelo de ciclo de vida em estrela [23] e avaliações de usabilidade por dois dos autores deste trabalho, de acordo com as heurísticas propostas por Jakob Nielsen [24].

B. Avaliação Heurística

A avaliação de usabilidade do sistema foi realizada por meio da avaliação heurística, técnica de inspeção de usabilidade na qual avaliadores analisam uma interface e julgam sua conformidade com um conjunto de princípios de usabilidade

TABLE II
COMPARAÇÃO ENTRE OS ARTIGOS RELACIONADOS A IOT, FHIR E VISUALIZAÇÃO DE SINAIS VITAIS

Nº	Título resumido	Uso do FHIR	Plataforma de visualização	Tempo real	Filtros temporais
1	Development of IoT based Smart System and Data (2024) [15]	Não	*Web* e *Mobile*	Sim	Não
2	Implementation of a Modular MIoT Platform for Healthcare (2025) [16]	Não	*Web* e *mobile*	Sim	Não
3	Effects of technology-enabled blood monitoring (2024) [17]	Não	*Mobile*	Sim	Não
4	Visual Analytics Dashboard Promises to Improve (2021) [18]	Não	*Web*	Não	Sim, mas apenas trimestralmente ou anualmente
5	How can Sensor Data Accessibility be Enhanced in IoT-Based Health Monitoring Systems (2024) [19]	Não	Web	Sim	Sim, mas apenas a intervalos pré definidos
6	An Enhanced IoT-Based Wristband for Remote Monitoring (2024) [20]	Não	*Web* e *Mobile*	Sim	Não

9	CORE-ABPM-FHIR	Sim	*Web*	Não	Sim

reconhecidos (heurísticas), identificando problemas que possam comprometer a experiência do usuário [24]. A avaliação foi conduzida por dois dos autores deste trabalho, que inspecionaram a interface de forma independente, confrontando suas telas e funcionalidades com as dez heurísticas de usabilidade propostas por Jakob Nielsen. Para cada heurística genérica, foram definidos itens específicos de verificação — aqui denominados *heurísticas para web* — que operacionalizam o princípio geral em critérios objetivos e observáveis, aplicáveis ao contexto de sistemas *web*. Cada item foi avaliado individualmente quanto à presença de problemas de usabilidade, sendo registrada, quando pertinente, uma justificativa descritiva da constatação.

Para classificar a gravidade de cada problema identificado, foi utilizada a escala de severidade proposta por Nielsen, que varia de 0 a 4, conforme apresentado no Quadro III.

TABLE III
ESCALA DE SEVERIDADE DE NIELSEN

Grau	Descrição
0	Não representa um problema de usabilidade
1	Problema cosmético, corrigir apenas se houver tempo disponível
2	Problema menor de usabilidade, correção de baixa prioridade
3	Problema maior de usabilidade, correção de alta prioridade
4	Catástrofe de usabilidade, correção obrigatória antes do lançamento

1) Heurísticas e itens avaliados: As dez heurísticas genéricas de Nielsen foram desdobradas nos seguintes itens específicos de avaliação para *web*:

1) **Visibilidade do status do sistema** — Tempo de carga;
2) **Compatibilidade do sistema com o mundo real** — Conteúdo; Precisão do conteúdo; Sons; Imagens; Conhecimento do público-alvo;
3) **Controle do usuário e liberdade** — Controle sobre ações;
4) **Consistência e padrões** — *Links*; Escrita e gramática; Navegação;
5) **Prevenção de erros** — Compatibilidade entre navegadores;
6) **Reconhecimento ao invés de relembrança** — Identificação de elementos de interação;
7) **Flexibilidade e eficiência de uso** — Modos de interação;
8) **Estética e *design* minimalista** — *Background*; Cor; Fontes; Gráficos; *Layout*;
9) **Ajudar os usuários a reconhecer, diagnosticar e corrigir erros** — Mensagens de erro compreensíveis;
10) **Ajuda e documentação** — *Meta tags*; *Copyright*; Informações para contato.

C. Modelagem dos Dados em FHIR

A modelagem dos dados neste trabalho baseia-se no padrão FHIR (versão R5), utilizando recursos modulares como o *Observation* e o *DiagnosticReport* para representar, respectivamente, as medições individuais de pressão arterial e a consolidação clínica do exame MAPA. O recurso *Observation* é utilizado para representar cada medição individual de pressão arterial ao longo do período de monitoramento. Cada observação contém os valores sistólico e diastólico, organizados como componentes identificados pelos códigos LOINC 8480-6 (*Systolic blood pressure*) e 8462-4 (*Diastolic blood pressure*), com valores expressos em mmHg. O conjunto da medição é categorizado pelo código LOINC 85354-9 (*Blood pressure panel*), permitindo a representação estruturada de séries temporais de medições, preservando a granularidade necessária para o cálculo das métricas clínicas. A partir dessas observações, o recurso *DiagnosticReport* é utilizado para consolidar as informações do exame MAPA. Esse recurso mantém referências às *Observations* correspondentes, garantindo rastreabilidade entre os dados brutos e os resultados consolidados. A Figura 2 ilustra a modelagem proposta, destacando a estrutura dos recursos e o vínculo entre medições individuais e o relatório consolidado do exame.

Para fins de validação e demonstração da abordagem proposta, foi selecionado aleatoriamente um paciente da base de

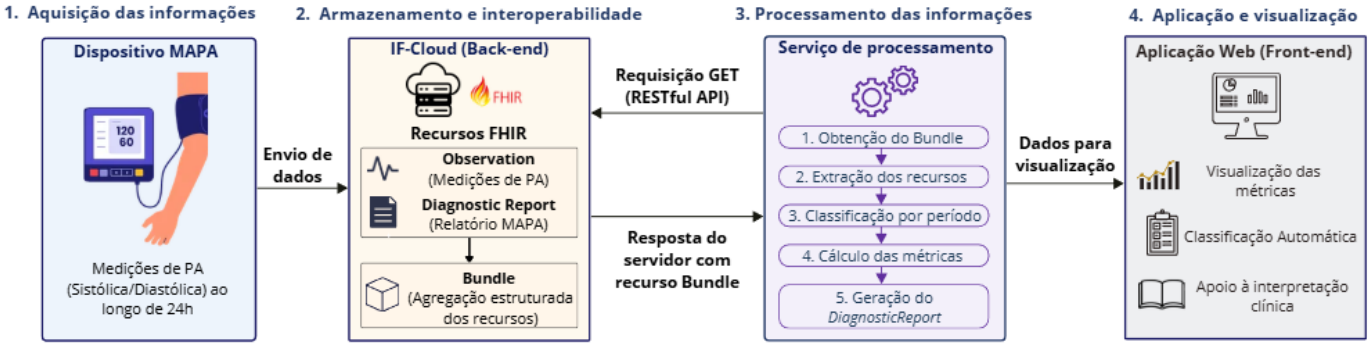

Fig. 1. Fluxo de aquisição, processamento e interpretação de exames MAPA baseado em FHIR

dados disponível, totalizando dois exames de MAPA associados a esse paciente. Cada exame já correspondia a um período de monitoramento de 24 horas, com intervalos de medições variando a cada 30-32 minutos, resultando em um total de 48 a 52 medições por exame. A distinção entre os períodos de vigília e sono é definida por um parâmetro configurável pelo usuário, que pode digitar o horário efetivo de rotina do paciente e na ausência dessa informação, o sistema adota o intervalo das 23h às 7h como período de sono e o restante do dia como período de vigília.

As medições individuais de pressão arterial são modeladas como recursos do tipo *Observation*, enquanto o recurso *DiagnosticReport* consolida essas observações, permitindo a organização estruturada e a interpretação do exame MAPA. Para fins de processamento e recuperação estruturada no *pipeline* descrito na Seção III-D, os recursos são agrupados em um *Bundle*, permitindo sua obtenção conjunta por meio de consultas ao servidor FHIR.

Ao definir a estrutura desses recursos, o FHIR promove a interoperabilidade entre sistemas heterogêneos, ou seja, a troca de informações entre diferentes sistemas é padronizada e consistente. Porém, ele não resolve particularidades locais (como CPF, Cartão Nacional de Saúde, ou terminologias específicas de cada sistema de saúde). Por isso, iniciativas nacionais criam perfis (*profiles*) que restringem e estendem os recursos padrão, tornando obrigatórios certos campos e vocabulários para o seu contexto específico.

D. Pipeline de Processamento de Dados

O *pipeline* de processamento proposto é responsável pela transformação das medições de pressão arterial, representadas como recursos FHIR, em métricas clínicas utilizadas na interpretação do exame MAPA. Para fins de validação do trabalho, os dados são recuperados a partir de um servidor FHIR hospedado na infraestrutura em nuvem IF-Cloud, mantida pelo grupo IF4Health [25], por meio de requisições à sua interface de acesso, retornando um *Bundle* contendo os recursos *Observation* associados ao exame. O uso do *Bundle* permite a obtenção conjunta das medições, garantindo consistência e integridade na recuperação das informações. Em seguida, os recursos são extraídos e organizados em estruturas de dados adequadas para processamento, sendo posteriormente classificados de acordo com o período de aquisição (vigília e sono). Essa segmentação é fundamental para o cálculo de métricas clínicas específicas, como médias por período e descenso noturno. A partir dessa organização, são construídas séries temporais de medições, que servem como base para o cálculo das métricas clínicas descritas na Seção III-E. Por fim, os resultados obtidos são consolidados em um recurso *DiagnosticReport*, que agrega as métricas derivadas e mantém referências às observações utilizadas, permitindo rastreabilidade entre os dados brutos e a interpretação clínica do exame. Esse *pipeline*, implementado com as tecnologias *React* e *TypeScript*, constitui o mecanismo central de interpretação proposto neste trabalho, permitindo a integração entre a modelagem estruturada dos dados e a geração automatizada de resultados clínicos.

E. Cálculo de Métricas Clínicas

Inicialmente, as medições foram segmentadas em três conjuntos: período total de 24 horas, vigília e sono. A média da pressão arterial em cada período foi calculada como a média aritmética das medições disponíveis. A equação (1) apresenta a fórmula da pressão arterial sistólica média,

$$\overline{PAS}_p = \frac{1}{N_p} \sum_{i=1}^{N_p} PAS_i, \tag{1}$$

onde p representa o período de análise (por exemplo: total, vigília ou sono); PAS_i representa a pressão arterial sistólica da i-ésima medição do período p; e N_p representa o número de medições no período p.

O descenso noturno (*dipping*) foi calculado como a variação percentual entre as médias dos períodos de vigília e sono, conforme a equação (2),

$$\text{Descenso noturno} = \frac{\overline{PA}_{\text{vigília}} - \overline{PA}_{\text{sono}}}{\overline{PA}_{\text{vigília}}} \times 100, \tag{2}$$

onde $\overline{PA}_{\text{vigília}}$ é a média da pressão arterial (sistólica ou diastólica) durante a vigília e $\overline{PA}_{\text{sono}}$ é a média da pressão arterial (sistólica ou diastólica) durante o sono.

A classificação do descenso noturno foi realizada com base na variação percentual da pressão arterial sistólica entre vigília

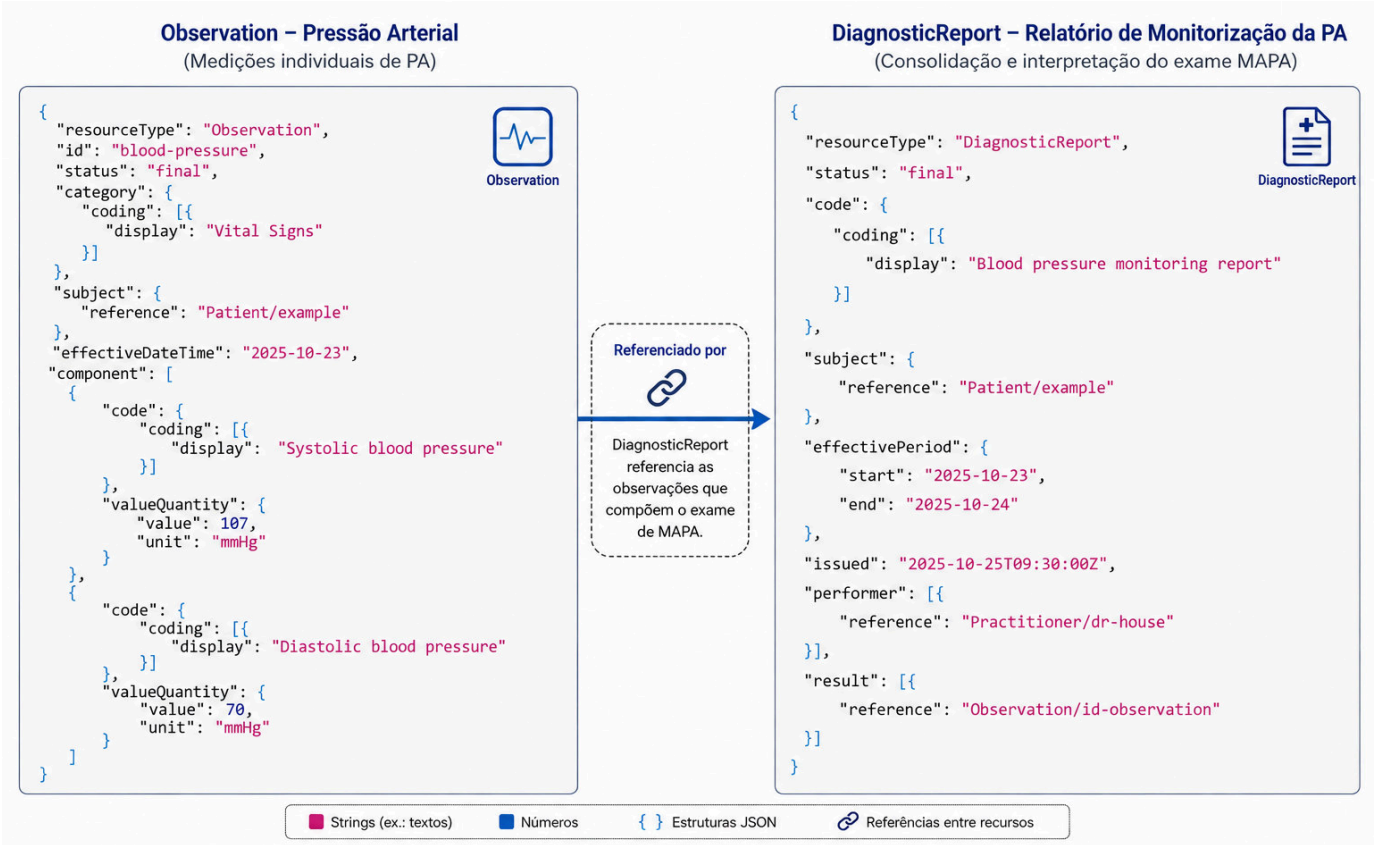

Fig. 2. Representação dos principais recursos FHIR utilizados.

e sono, conforme descrito na literatura e adotado por diretrizes internacionais (ESH, SBC), categorizando-se em reverse dipper (menor que 0%), non-dipper (de 0% a menos de 10%), dipper (de 10% a menos de 20%) e extreme dipper (20% ou mais). Essa métrica permite classificar o padrão circadiano do paciente, sendo amplamente utilizada na interpretação clínica de exames MAPA.

A variabilidade da pressão arterial foi estimada por meio do desvio padrão das medições ao longo do período analisado, conforme a equação (3),

$$DP_{x,p} = \sqrt{\frac{1}{N_p}\sum_{i=1}^{N_p}\left(X_i - \overline{X}_p\right)^2}, \tag{3}$$

onde x é a variável de interesse (pode ser PAS ou PAD); p é o período de análise (total, vigília ou sono); X_i é o valor da variável na i-ésima medida do período p; $\overline{X}_p$ é a média da variável no período p; e N_p é o número de medições válidas no período p.

A carga pressórica é calculada como o percentual de medições, dentro de um período p, em que a pressão arterial excede o limiar de referência, conforme a Equação (4):

$$Carga_p = \frac{NA_p}{N_p} \times 100, \tag{4}$$

em que NA_p é o número de medidas acima do limiar de referência no período p, e N_p é o número total de medidas realizadas nesse mesmo período. A Equação (4) é aplicada separadamente para a pressão sistólica e a pressão diastólica, gerando as métricas $Carga_{sis}$ e $Carga_{dia}$.

Por fim, a classificação diagnóstica da pressão arterial ambulatorial foi baseada na comparação entre as médias de pressão arterial sistólica (PAS) e diastólica (PAD) nos períodos de vigília e sono, em relação aos limiares definidos pela diretriz selecionada. Considerou-se pressão elevada quando a média de PAS e/ou PAD excedeu os respectivos valores de referência para cada período, adotando-se o operador lógico "OU" entre os componentes sistólico e diastólico.

F. Fonte dos Dados

Os dados utilizados neste trabalho foram obtidos a partir da base MIMIC-IV *Database Demo* [26], um conjunto de dados clínicos de acesso público amplamente utilizado em pesquisas na área da saúde, contendo informações de pacientes hospitalizados. Todos os dados disponíveis na base encontram-se previamente anonimizados, não havendo identificação direta dos indivíduos. Como os dados da base selecionada não segmentam em período de vígilia e sono, foi necessário construir esses períodos, do paciente selecionado pelo usuário, conforme o critério configurável descrito na seção III-C. Ressalta-se que os dados presentes na base não correspondem originalmente

a exames MAPA, mas incluem medições clínicas de pressão arterial coletadas em diferentes contextos hospitalares. Neste trabalho, tais medições foram utilizadas como entrada para o *pipeline* proposto, permitindo a validação da modelagem em FHIR, do processamento das informações e da apresentação das métricas clínicas. Dessa forma, o uso da base MIMIC-IV teve como objetivo avaliar a integração entre a estrutura de dados, o mecanismo de cálculo das métricas e a visualização dos resultados, sem validação do *pipeline* dos indicadores obtidos.

G. Aspectos Éticos

Este estudo utilizou exclusivamente dados secundários, previamente anonimizados, provenientes da base pública MIMIC-IV *Database Demo*, sem acesso a informações que permitissem a identificação dos indivíduos. A avaliação heurística consistiu em uma inspeção técnica interna da interface, realizada por dois dos autores, sem recrutamento de participantes externos, envolvimento de pacientes ou profissionais de saúde, intervenção clínica ou coleta de dados pessoais ou sensíveis. Por essas características, o estudo não foi submetido à apreciação de um Comitê de Ética em Pesquisa.

IV. Resultados

Após as sucessivas iterações de *design* e avaliação propostas pelo Ciclo de Vida em Estrela [23], obteve-se como resultado final um *dashboard* funcional para a visualização de exames MAPA. A interface de usuário foi desenvolvida com a finalidade de receber o recurso *Bundle*, realizar o processamento com o *Bundle* obtido e transformá-lo em informações clínicas de fácil visualização e entendimento. A Figura 3 ilustra o visualizador com os exames do paciente selecionado.

O retângulo 1 evidencia as informações gerais do exame de Monitorização Ambulatorial da Pressão Arterial (MAPA), incluindo identificação do paciente e número total de medições.

Na presente tela, o médico tem acesso às principais métricas definidas pelas diretrizes clínicas, apresentadas na forma de cartões informativos, destacado pelo retângulo 2. Tais cartões são configuráveis por meio da funcionalidade "Cartões visíveis", permitindo ao usuário personalizar a exibição conforme sua necessidade. Na Figura 3, todos os cartões encontram-se habilitados.

Os cartões de resultados estão organizados da seguinte forma:

- Os três primeiros apresentam as médias das pressões arteriais por período, sendo que o primeiro número equivale à pressão sistólica;
- O quarto é referente ao descenso noturno, mostrando seu valor e classificação;
- O quinto apresenta a variabilidade da PAS e PAD;
- O sexto apresenta os mínimos e máximos por período das pressões arteriais;
- Por fim, a classificação automatizada indica o resultado obtido segundo os limiares da diretriz selecionada..

Os elementos destacados pelo retângulo 3 representam componentes dinâmicos da interface, cujos valores e classificações são automaticamente atualizados de acordo com a diretriz clínica selecionada, assegurando consistência entre a visualização dos dados e os critérios normativos adotados. Os retângulos 4 delimitam o período de sono considerado na análise, o qual pode ser ajustado pelo usuário diretamente na interface do sistema, por meio dos controles disponíveis na parte superior do painel.

Os resultados apresentados no dashboard são condicionados à diretriz selecionada pelo usuário. Diferentes versões das diretrizes podem ser disponibilizadas para seleção, como AHA/ACC 2017, SBC 2018 e SBC 2025, permitindo a comparação e a aplicação de diferentes critérios de interpretação. Essa seleção possui finalidade distinta da análise bibliográfica apresentada na Tabela I, na qual foram consideradas as versões mais recentes selecionadas para identificar as métricas recomendadas pelas respectivas entidades. Portanto, a versão utilizada na comparação bibliográfica não implica necessariamente sua implementação no protótipo.

A Tabela IV apresenta as entradas do conjunto avaliado, os períodos de vigília e sono, a diretriz selecionada e as respectivas saídas do sistema, incluindo médias, carga pressórica, valores mínimo e máximo, descenso noturno, variabilidade e classificação, com o objetivo de verificar a implementação das Equações (1)–(4).

V. Discussão

A tabela 1 evidencia que há uma convergência significativa entre as principais diretrizes quanto às métricas consideradas primordiais para interpretação clínica em exames MAPA. O trabalho implementa todas as métricas apresentadas, inclusive a mais exigente, demonstrando alinhamento com práticas clínicas estabelecidas e padronizando a apresentação das métricas na interpretação dos exames, além de realizar a identificação automática do dipper e a classificação da hipertensão, sem depender de análise manual do profissional de saúde.

Outro aspecto relevante é a utilização do padrão FHIR, que permite que os dados estejam estruturados de forma padronizada, garantindo a interoperabilidade entre sistemas e facilitando a reutilização deste trabalho, dado que é um padrão adaptado para *web* e se beneficia da arquitetura REST (*Representational State Transfer*), o que permite seu uso com os padrões de requisições HTTP (*Hypertext Transfer Protocol*) como GET, POST, PUT e DELETE. Além de se beneficiar da interface de programação de aplicações (API) e os formatos de estrutura de dados como JSON (*JavaScript Object Notation*) e XML (*eXtensible Markup Language*). Em contrapartida, é um padrão que tem uma curva de aprendizado alta, já que é um padrão com diversos recursos estabelecidos e possui perfis locais (como o da RNDS - Rede Nacional de Dados em Saúde) ainda em evolução, podendo haver lacunas ou inconsistências entre versões. Além disso, sistemas que não usam FHIR perdem a capacidade de conversar facilmente com o resto do ecossistema de saúde e tendem a depender de integrações e modelos próprios, caracterizando o problema NxM: a cada novo sistema desenvolvido, é necessário adaptar

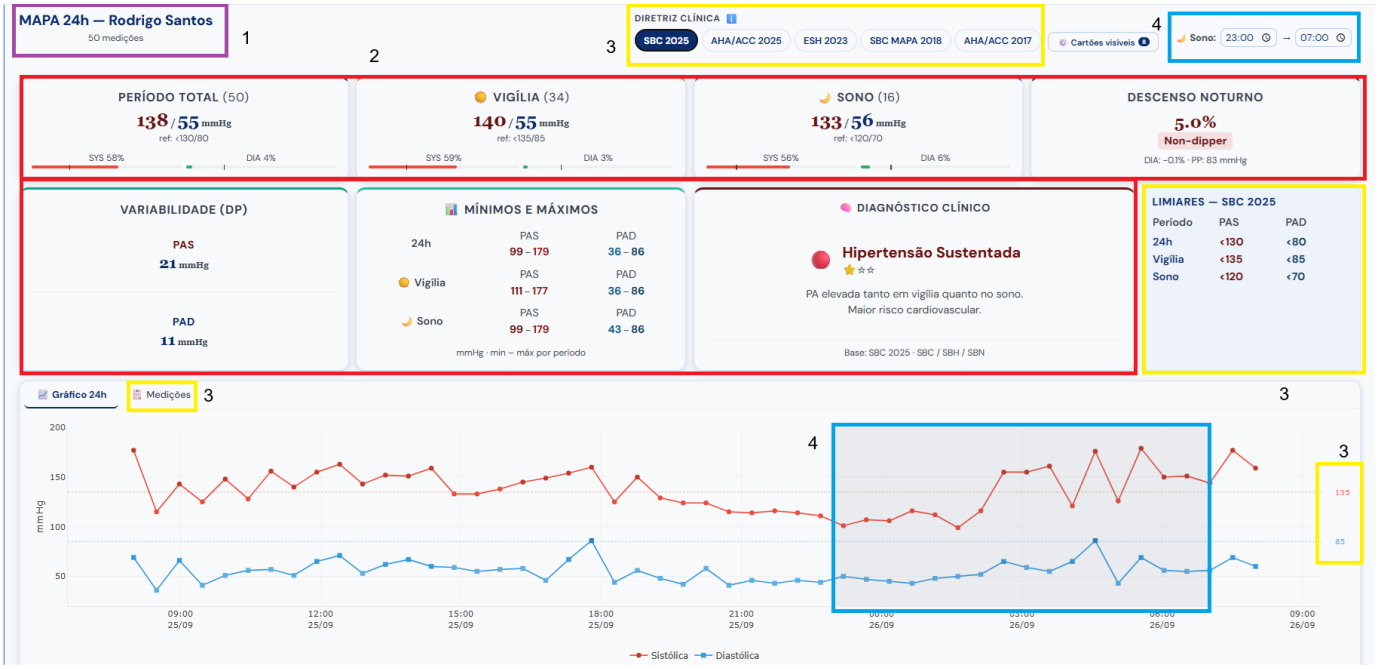

Fig. 3. Interface do CORE-ABPM-FHIR para visualização e interpretação de exames MAPA.

TABLE IV
CONFERÊNCIA INDEPENDENTE DAS MÉTRICAS DO PROTÓTIPO (PACIENTE ÚNICO, EXAME DE 24 H, $n = 50$ MEDIÇÕES; DIRETRIZ SBC 2025).

Período	**Métrica**	**Saída do sistema**
24 h ($n = 50$)	Média (DP) PAS/PAD (mmHg)	138 / 55
24 h ($n = 50$)	Carga pressórica PAS/PAD (%)	58 / 4
24 h ($n = 50$)	Mín–Máx PAS/PAD (mmHg)	99–179 / 36–86
Vigília ($n = 34$)	Média PAS/PAD (mmHg)	140 / 55
Vigília ($n = 34$)	Carga pressórica PAS/PAD (%)	59 / 3
Vigília ($n = 34$)	Mín–Máx PAS/PAD (mmHg)	111–177 / 36–86
Sono ($n = 16$)	Média PAS/PAD (mmHg)	133 / 56

ou criar e manter uma tradução específica, ao contrário do modelo Nx1 em que é viabilizado por um padrão comum.

Uma limitação deste trabalho é a ausência de integração com os perfis locais da RNDS. Essa integração é apontada como um trabalho futuro e exigirá a adequação dos perfis FHIR utilizados, das terminologias propostas, do mecanismo de autenticação e dos demais requisitos técnicos estabelecidos por essa entidade.

Por fim, a avaliação heurística do sistema, baseada nos princípios de Nielsen [24], foi realizada de forma independente por dois avaliadores. O diagnóstico principal apontou uma severidade de nível 3 (grave) na categoria ajuda e documentação, devido à ausência de metadados, informações de contato e licenciamento. Em contrapartida, ajustes pontuais de acessibilidade e interface — como contraste de cores, dependência visual em gráficos e termos em inglês — já foram devidamente corrigidos. Além disso, a arquitetura em single-page proporcionou uma interação simples e previsível e não foram identificados problemas pelos avaliadores internos com o conhecimento do público-alvo.

VI. CONCLUSÕES

O CORE-ABPM-FHIR propõe uma abordagem para visualização de exames de monitorização ambulatorial da

pressão arterial (MAPA), oferecendo suporte à interpretação clínica por meio da apresentação estruturada de métricas recomendadas por diferentes diretrizes internacionais. A utilização do padrão FHIR possibilita interoperabilidade e integração com ecossistemas de saúde digital, ampliando o potencial de adoção da solução. Entretanto, para uma validação clínica mais robusta, torna-se necessária a participação de profissionais médicos na avaliação do sistema, permitindo avaliar a usabilidade e a utilidade prática do sistema, bem como identificar possíveis ajustes. Destaca-se também a ausência de uma padronização consolidada para a representação de exames de MAPA no padrão FHIR, sendo a modelagem proposta neste trabalho fundamentada na literatura disponível. Por fim, este trabalho pode servir como base para iniciativas futuras voltadas à visualização e análise de exames MAPA, com potencial de evolução para oferecer maior suporte à tomada de decisão clínica.

VII. Declaração de uso de IA

A inteligência artificial foi utilizada neste trabalho de forma pontual e auxiliar. Especificamente, foi utilizada a ferramenta ChatGPT (OpenAI, GPT-4) para apoio na revisão gramatical e ortográfica de textos e para sugestões pontuais em trechos específicos de código. Todo o conteúdo gerado pela ferramenta foi revisado pelos autores.

Abstract*—Electromyographic (EMG) signals are widely used in neuromuscular assessment, rehabilitation systems, and assistive technologies. However, acquisition artifacts, electrode displacement, and stochastic noise frequently degrade signal quality, compromising subsequent analysis and interpretation. This work investigates the reconstruction of degraded EMG signals using convolutional Autoencoder and U-Net architectures with increasing levels of complexity. A supervised reconstruction framework was developed using processed ALSNet/EMGLab recordings, where an artificial degradation pipeline was employed to generate paired degraded-reference signals for training and evaluation. Training, validation, and testing were separated at the recording level before window generation, and the final evaluation used 355 normal-EMG recordings from the official test set. Reconstruction performance was assessed using Mean Squared Error (MSE), Root Mean Squared Error (RMSE), Mean Absolute Error (MAE), Pearson Correlation Coefficient (PCC), and Signal-to-Noise Ratio (SNR), together with RMS, median-frequency, and envelope-based metrics. Among the evaluated models, U-Net V3.1 achieved the lowest MSE of 0.000634, RMSE of 0.02314, and MAE of 0.01573, as well as the highest mean SNR of 15.54 dB. AE V1 achieved a slightly higher mean PCC than U-Net V3.1 (0.99400 versus 0.99324). Statistical analysis using Wilcoxon signed-rank tests with Holm correction identified significant differences between U-Net V3.1 and the baseline architecture for most evaluated metrics (adjusted $p < 0.001$), whereas median-frequency error did not differ significantly. These findings indicate that skip-connection-based architectures may provide advantages in reconstruction error and SNR under the evaluated artificial degradation protocol. Their applicability to future neuromuscular monitoring and assistive biomedical applications requires further validation with real artifacts and external datasets.

***Index Terms*—electromyography, EMG reconstruction, deep learning, autoencoder, U-Net, biomedical signal processing**

I. Introduction

Electromyographic (EMG) signals play a fundamental role in biomedical applications, including the assessment of neuromuscular disorders, the analysis of human motor function, rehabilitation systems, and assistive technologies. Because EMG signals provide a direct representation of muscle activation patterns, they have become an important source of information for clinical evaluation and intelligent biomedical systems [1], [2].

However, the quality of EMG recordings is frequently compromised by acquisition artifacts, motion-induced disturbances, electrode displacement, power-line interference, and stochastic noise contamination. Such degradations can distort relevant physiological information and negatively affect subsequent signal processing, clinical interpretation, and machine learning applications [3], [4]. Consequently, reconstruction of degraded EMG signals has become an active area of research [5], [6].

Recent advances in deep learning have introduced data-driven alternatives to conventional denoising and filtering approaches. Convolutional Neural Networks (CNNs), Denoising Autoencoders, and related encoder-decoder architectures can learn nonlinear mappings between degraded and reference signals, reducing the dependence on handcrafted feature extraction [3], [7]. Deep neural networks have been applied to biomedical signal classification, pattern recognition, and signal enhancement [1], [7], [8].

Despite these advances, most studies that involve EMG signals remain focused on classification, gesture recognition, motor intention decoding, or disease diagnosis. Relatively limited attention has been devoted to systematically investigating how architectural complexity affects the quality of the reconstruction of degraded EMG signals. Recent studies suggest that increasing model complexity does not necessarily improve signal fidelity or reconstruction performance, highlighting the need for comparative evaluations of different architectures [5], [9]. This gap motivates the present work, which evaluates convolutional Autoencoder and one-dimensional U-Net architectures for reconstructing degraded EMG signals. The main contribution is a controlled comparison on the same processed ALSNet/EMGLab recordings, artificial degradation procedure,

leakage-free data partition, and complete-record evaluation. The conclusions are restricted to the synthetic corruption distributions and dataset evaluated here.

II. Related Work

A. EMG Signal Reconstruction

Electromyographic (EMG) signals are sensitive to acquisition-related disturbances, including motion artifacts, electrode displacement, power-line interference, and stochastic noise. These degradations can alter signal morphology and spectral characteristics, compromising subsequent analyses and reducing the reliability of clinical and research applications. Consequently, the reconstruction and enhancement of degraded EMG signals have become topics in biomedical signal processing [1], [10], [11].

Historically, signal restoration has relied on conventional denoising techniques such as filtering methods, Independent Component Analysis (ICA), Canonical Correlation Analysis (CCA), and Empirical Mode Decomposition (EMD). These approaches depend on assumptions regarding signal stationarity, source independence, or noise distributions that may not hold in real-world physiological recordings. Their ability to recover complex signal distortions may therefore be limited when dealing with non-stationary EMG signals [1], [4].

B. Deep Learning for Biomedical Signal Restoration

Recent advances in deep learning have introduced data-driven alternatives capable of learning nonlinear relationships directly from raw physiological signals. Unlike traditional signal processing techniques, deep neural networks extract hierarchical representations without requiring handcrafted features [1]. Recent reviews have described the use of deep learning for electromyographic signal analysis in human-machine interaction, prosthetic control, and rehabilitation systems [10], [11].

Several studies have evaluated deep learning models for biomedical signal denoising, enhancement, and reconstruction. Convolutional architectures have been used to model temporal dependencies and suppress noise sources in physiological signal restoration tasks [3], [4], [12]. Similar encoder-decoder strategies have been applied to physiological signal restoration and artifact removal. For example, U-Net-based denoising Autoencoders have been evaluated for reconstructing corrupted EEG recordings [13]. Deep learning has also been applied to signal enhancement, representation learning, and biomedical data analysis [6], [12].

C. Autoencoder and U-Net Architectures

Among deep learning approaches, Autoencoders have been used for signal reconstruction. By learning compact latent representations of degraded signals, these models can suppress noise while retaining temporal and spectral information. Previous studies have applied convolutional Autoencoders to the compression, reconstruction, and enhancement of myoelectric signals [7]–[9].

U-Net-based architectures have also been examined in restoration tasks because they combine an encoder-decoder structure with skip connections. Originally proposed for biomedical image segmentation [14], U-Net architectures propagate features from the encoder to corresponding decoder layers. This mechanism is intended to mitigate information loss caused by bottleneck compression and support the recovery of fine-grained signal characteristics.

Recent investigations have extended U-Net concepts to biomedical signal enhancement and restoration, reporting differences in reconstruction metrics relative to conventional encoder-decoder architectures [3], [5], [12]. Nevertheless, most EMG-related studies remain focused on classification, gesture recognition, motor intention decoding, or assistive control systems. Fewer studies investigate the reconstruction of degraded EMG signals, and few provide systematic comparisons between architectures of different complexity within a unified evaluation framework.

Motivated by these observations, the present study investigates how architectural design influences EMG reconstruction performance by comparing convolutional Autoencoder and U-Net architectures within a common experimental framework. Unlike restoration studies based on multi-channel HD-sEMG spatial structure or different electrophysiological modalities, the present comparison uses single-record processed ALSNet/EMGLab signals, a common artificial corruption model, and complete-record testing.

III. Materials and Methods

A. Materials

The proposed reconstruction framework was implemented in Python 3.11.15 using TensorFlow 2.21.0 and Keras 3.14.1. Data preprocessing, signal manipulation, model training, and performance evaluation were performed using NumPy 2.4.6, SciPy 1.17.1, Pandas 3.0.3, and Scikit-Learn 1.9.0. All experiments were conducted under Ubuntu/WSL2 with CUDA-enabled GPU acceleration.

All experiments were conducted on a workstation equipped with an Intel Core i7-9700F processor, 32 GB of RAM, and a NVIDIA GeForce RTX 5070 GPU with 12 GB of dedicated memory. Model development and training were performed using TensorFlow/Keras with GPU acceleration enabled through CUDA.

The overall experimental workflow adopted in this study is illustrated in Fig. 1.

B. Dataset

The experiments were conducted using the ALSNet/EMGLab dataset, a publicly available collection of electromyographic (EMG) recordings derived from the N2001 EMGLAB database. This dataset was originally employed in the development of ALSNet, a dilated one-dimensional convolutional neural network designed for the identification of Amyotrophic Lateral Sclerosis (ALS) from raw EMG signals [2].

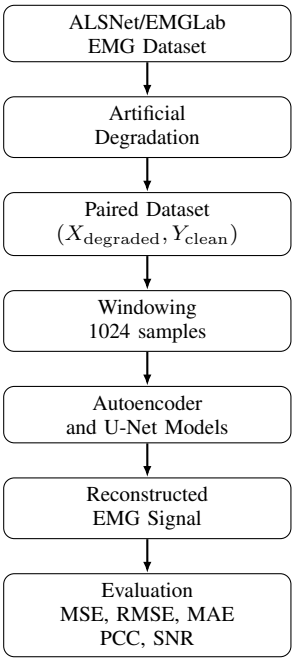

Fig. 1. Conceptual overview of the proposed EMG reconstruction framework.

The distributed processed package contains an official training file with 2,657 recordings and an official test file with 665 recordings. Each recording consists of 23,437 temporal samples acquired at 24 kHz. The present reconstruction study used only normal-EMG recordings (class 0): 1,306 from the official training file and 355 from the official test file [2].

Unlike previous studies that focused on disease identification, the present work addresses a supervised EMG reconstruction problem. The 1,306 normal recordings from the official training file formed the training and validation subsets, whereas the 355 normal recordings from the official test file were retained exclusively for final evaluation. For each reference signal, an artificially degraded counterpart was created using the degradation pipeline described in the following subsection, yielding a dataset of paired samples $(X_{degraded}, Y_{clean})$ suitable for supervised learning.

The resulting dataset served as the foundation for training and evaluating deep learning models under controlled degradation conditions. The processed files preserve recording indices but not explicit participant identifiers; therefore, the official train/test separation is respected, but subject-level independence cannot be independently verified and is treated as a limitation.

C. Artificial Signal Degradation Pipeline

Since the original dataset does not provide paired degraded-reference recordings suitable for supervised reconstruction, an artificial degradation pipeline was developed to generate reconstruction targets. Controlled degradation strategies are commonly adopted in signal restoration studies because they allow the evaluation of reconstruction models under reproducible corruption conditions [3]–[5], [13], [15].

Motivated by controlled synthetic-corruption procedures adopted in previous signal-restoration studies [3]–[5], [13], [15], the degradation model used in this study was defined as:

$$x[n] = g\, m[n] s[n] + \epsilon[n]. \tag{1}$$

In this equation, n denotes the sample index, $s[n]$ is the clean reference EMG signal, and $x[n]$ is its artificially degraded counterpart. The record-level attenuation factor was sampled as $g \sim \mathcal{U}(0.35, 0.75)$; $m[n]$ was an independent Bernoulli keep mask with probability 0.95; and $\epsilon[n]$ was zero-mean Gaussian noise with standard deviation $0.05\,\mathrm{SD}(s)$, where $\mathrm{SD}(s)$ denotes the standard deviation of the clean recording. Thus, the implemented masking removed individual samples independently rather than contiguous temporal segments. Separate seeds 4201, 4202, and 4203 were used for training, validation, and test corruption, respectively..

The resulting dataset consisted of paired samples $(X_{\text{degraded}}, Y_{\text{clean}})$, where the degraded signal served as the network input and the corresponding original recording represented the reconstruction target. This supervised formulation enabled direct optimization of the models for EMG signal restoration.

Although artificially generated artifacts may not fully represent all sources of variability encountered in real-world EMG acquisitions, controlled degradation protocols provide a practical and widely adopted framework for training and evaluating reconstruction models under reproducible conditions. Similar strategies have been employed in signal restoration and denoising studies, where synthetic corruption mechanisms enable systematic performance assessment and direct comparison between competing architectures [13], [15].

D. Window Generation and Data Preparation

To increase the number of training examples and facilitate mini-batch optimization, the paired signals were segmented into fixed-length windows of 1,024 samples. Window-based processing is commonly adopted in EMG and biomedical signal analysis because it preserves local temporal structures while reducing memory requirements and computational complexity during training [1], [7].

Partitioning was completed before window generation. The procedure produced 22,990 training windows from 1,045 recordings, 5,742 validation windows from 261 recordings, and 7,810 test windows from the 355 official-test recordings. Each degraded–reference pair was divided by the maximum absolute amplitude of its clean recording. This reference-based normalization defines a controlled paired reconstruction task and is not a deployment-ready preprocessing procedure because a clean reference would not be available for an unpaired real-world input. Training and validation used 22 complete non-overlapping windows per recording; complete-record testing zero-padded each signal to 23 windows and trimmed the concatenated output to the original 23,437 samples.

E. Deep Learning Architectures

The primary objective of this study was to investigate how architectural complexity influences the reconstruction quality of degraded EMG signals. To this end, two encoder-decoder paradigms were evaluated: a one-dimensional convolutional Autoencoder and a one-dimensional U-Net architecture.

Autoencoder-based frameworks have been widely adopted for signal reconstruction because they learn compact latent representations that suppress degradation artifacts while preserving relevant temporal information [7]–[9]. In this study, the convolutional Autoencoder was implemented as the baseline reconstruction model. The encoder consisted of successive one-dimensional convolutional and pooling operations that progressively compressed the input signal into a latent representation. In contrast, the decoder reconstructed the signal through upsampling and convolutional layers.

To address the information bottleneck associated with conventional encoder-decoder architectures, U-Net-based models were also investigated. Originally introduced for biomedical segmentation tasks, U-Net architectures establish direct connections between the encoder and decoder stages via skip connections, thereby preserving high-resolution information throughout the reconstruction process [14]. In one-dimensional signal reconstruction, this mechanism facilitates feature reuse and helps preserve fine-grained temporal characteristics that may be lost during progressive downsampling operations. Recent studies have shown that U-Net-based approaches are effective for EMG enhancement and restoration tasks, particularly under non-stationary noise and signal degradation conditions [3], [5].

The comparison between these architectures was designed to evaluate whether skip connections and residual blocks produce measurable differences in reconstruction metrics under the specified protocol. A summary of the evaluated architectures and their corresponding numbers of trainable parameters is presented in Table I.

TABLE I
REPRODUCIBLE SUMMARY OF EVALUATED ARCHITECTURES

Model	Filters	Kernel	Main feature	Parameters
AE V1	16–32–64–32	9	2-stage AE	42,049
AE V2.1	32–64–128–256–128–64–32	9	BN, dropout, hybrid loss	1,758,657
AE V2.2	32–64–128–256–128–64–32	9	BN, dropout, MSE	1,758,657
U-Net V3	32–64–128–256–128–64–32	9	concatenated skips	1,952,193
U-Net V3.1	32–64–128–256–128–64–32	15	residual blocks and skips	3,357,217

The evaluated models followed a progressive architectural development strategy. AE V1 used two encoder/decoder stages and ReLU activations. AE V2.1 and AE V2.2 used three stages, batch normalization, dropout, and the same filter sequence; they differed in their loss functions. U-Net V3 added concatenated encoder–decoder skip connections. U-Net V3.1 used kernel size 15 and residual blocks, each comprising two Conv1D operations with batch normalization and LeakyReLU ($\alpha = 0.1$), plus a 1×1 projection when channel dimensions differed.

To overcome the information bottleneck limitations commonly associated with conventional encoder-decoder architectures, one-dimensional U-Net models were investigated. U-Net V3 introduced skip connections between encoder and decoder stages, enabling the preservation of high-resolution temporal features throughout the reconstruction process and increasing the model capacity to approximately 1.95 million parameters.

Finally, U-Net V3.1 incorporated residual learning blocks within the encoder-decoder framework. The resulting architecture contained approximately 3.36 million trainable parameters and was the most complex configuration evaluated.

F. Training Procedure

Model training was performed using TensorFlow/Keras and optimized with the Adam algorithm [16], selected for its adaptive learning-rate mechanism and robust convergence in deep neural network optimization. All models received degraded EMG windows as input and generated reconstructed EMG signals as output. The optimization objective was to minimize the discrepancy between the reconstructed and reference signals.

AE V2.1 was optimized with a hybrid loss comprising MSE plus 0.005 times an RFFT-magnitude loss. AE V1, AE V2.2, U-Net V3, and U-Net V3.1 used MSE. The frequency-domain component was motivated by the importance of spectral information in EMG restoration [5].

The training hyperparameters adopted throughout the experiments are summarized in Table II.

TABLE II
TRAINING HYPERPARAMETERS

Hyperparameter	Value
Window Length	1024 samples
Input Dimension	1024×1
Optimizer	Adam
Initial Learning Rate	0.001
Validation Set	261 recordings (before windowing)
Early Stopping Monitor	Validation Loss
Early Stopping Patience	8 epochs
Restore Best Weights	Enabled

To manage optimization, Early Stopping and ReduceLROnPlateau were employed based on validation loss monitoring, as summarized in Table II.

To evaluate model performance, the official test recordings were kept outside optimization and model selection. This supports evaluation on held-out recordings under the same artificial protocol, not under real acquisition conditions.

G. Experimental Protocol

The 1,306 eligible recordings in the official training file were randomly divided, with seed 42, into 1,045 training

and 261 validation recordings before window generation. Validation recordings controlled early stopping and learning-rate scheduling. The 355 eligible recordings in the official test file were never used for optimization or model selection. Consequently, no windows from one recording occurred in more than one subset. Because participant identifiers were unavailable, residual dependence between different recordings from the same individual cannot be excluded. The principal results below use complete recordings as the statistical unit.

H. Evaluation Metrics

Reconstruction performance was assessed through complementary error, similarity, and signal-quality metrics. Mean Squared Error (MSE), Root Mean Squared Error (RMSE), and Mean Absolute Error (MAE) were employed to quantify reconstruction error. Pearson Correlation Coefficient (PCC) was used to evaluate waveform similarity between reconstructed and reference signals, while Signal-to-Noise Ratio (SNR) quantified signal quality and was computed as [3]:

$$\mathrm{SNR} = 10 \log_{10} \left(\frac{\sum_{n=1}^{N} y[n]^2}{\sum_{n=1}^{N} \left(y[n] - \hat{y}[n] \right)^2} \right). \tag{2}$$

In this equation, $y[n]$ denotes the n-th sample of the clean reference EMG signal, $\hat{y}[n]$ denotes the corresponding sample of the reconstructed signal, and N is the total number of samples in the evaluated recording.

Because all EMG signals were normalized before training and evaluation, MSE, RMSE, and MAE are reported in normalized units. PCC is a dimensionless similarity coefficient, while SNR is expressed in decibels (dB).

Two nonlearned baselines were included: a Wiener filter with a nine-sample window and a Savitzky–Golay filter with an 11-sample window and polynomial order 3. To examine signal descriptors, relative RMS error, absolute median-frequency error, envelope PCC, and envelope normalized RMSE were also calculated. These descriptors provide amplitude, spectral, and envelope checks but do not establish preservation of motor-unit characteristics.

I. Statistical Analysis

AE V1 and U-Net V3.1 were compared using two-sided paired Wilcoxon signed-rank tests, with each of the 355 complete test recordings as one observation [17]. The nine metric-wise p-values were adjusted by Holm's procedure [18]; $\alpha = 0.05$ was applied to adjusted p-values. Rank-biserial correlation was reported as effect size, with its sign oriented so that positive values favor U-Net V3.1.

IV. Results and Discussion

A. Quantitative Reconstruction Performance

Table III summarizes the complete-record reconstruction performance obtained on the 355-recording independent official test set.

The quantitative results varied with architectural design and were not ordered solely by network depth. Although AE V2.1 and AE V2.2 employed deeper encoder-decoder structures than the baseline AE V1, both architectures yielded higher reconstruction errors and lower correlation values.

TABLE III
Mean Complete-Record Performance on the Independent Test Set

Model	MSE	RMSE	MAE	PCC	SNR (dB)
Degraded input	0.004862	0.06552	0.04231	0.96707	6.29
Wiener (9)	0.004813	0.06519	0.04257	0.97832	6.34
Savitzky–Golay (11,3)	0.004679	0.06419	0.04243	0.98942	6.48
AE V1	0.000727	0.02443	0.01706	**0.99400**	15.21
AE V2.1	0.001115	0.03141	0.02053	0.98425	12.66
AE V2.2	0.001154	0.03095	0.02076	0.98937	13.03
U-Net V3	0.000787	0.02561	0.01721	0.99353	14.75
U-Net V3.1	**0.000634**	**0.02314**	**0.01573**	0.99324	**15.54**

U-Net V3.1 obtained the lowest mean MSE, RMSE, and MAE and the highest mean SNR. Relative to AE V1, its mean MSE was 12.8% lower and its SNR was 0.33 dB higher. However, AE V1 obtained the highest PCC (0.99400 versus 0.99324), showing that the ranking depends on the metric and that the absolute differences between the two configurations are modest. All learned models produced lower error than the degraded input and the two filtering baselines under this particular corruption model.

These results are compatible with a benefit from multi-scale feature reuse, but the controlled comparison does not isolate skip connections from every other architectural difference [3], [5], [13].

This behavior is compatible with reports on the use of multi-scale feature fusion and skip connections in biomedical applications [14], [19].

Accordingly, U-Net V3.1 is described as the configuration with the lowest mean errors and highest mean SNR among those tested, while AE V1 retained the highest mean PCC.

The ALSNet/EMGLab dataset used in this study has previously been used in deep learning studies involving EMG signal analysis and classification [2]. The adoption of this publicly available dataset facilitates reproducibility and enables a more direct comparison with related studies in the literature.

Directly comparable supervised reconstruction benchmarks using the same processed ALSNet/EMGLab recordings and degradation protocol were not identified; therefore, numerical comparisons with studies using other datasets or corruption procedures should be interpreted cautiously.

Direct numerical comparison with published restoration studies remains difficult because datasets, artifacts, and evaluation units differ. The present evidence therefore supports only performance on held-out ALSNet/EMGLab recordings subjected to the specified artificial degradation.

B. Signal-Level Evaluation

To assess reconstruction performance without treating correlated windows as independent, complete EMG recordings were reconstructed and evaluated at the signal level. Table IV summarizes the metrics across the 355 independent official-test recordings.

TABLE IV
SIGNAL-LEVEL RECONSTRUCTION PERFORMANCE OF U-NET V3.1

Statistic	MSE	RMSE	MAE	PCC	SNR (dB)
Mean	0.000634	0.02314	0.01573	0.99324	15.54
Median	0.000440	0.02097	0.01409	0.99375	15.56
Std	0.000603	0.00995	0.00753	0.00306	3.13

The signal-level evaluation provides information about performance on complete held-out recordings. While window-based evaluation measures local reconstruction quality, signal-level analysis reflects cumulative reconstruction performance over complete recordings.

The mean PCC of 0.99324 indicates high waveform agreement across the 355 recordings under the controlled synthetic protocol. It does not establish agreement across subjects because participant identifiers were unavailable.

The proximity of the mean and median across the evaluated metrics suggests that performance was not dominated by a small number of recordings with particularly low error.

Additionally, the lower median MSE relative to the mean MSE indicates that a limited number of challenging recordings contributed disproportionately to the overall error distribution. In contrast, most signals were reconstructed with lower error.

TABLE V
SIGNAL-DESCRIPTOR ERRORS ON 355 TEST RECORDINGS

Descriptor	AE V1	U-Net V3.1
RMS relative error	0.1445 ± 0.0902	0.1277 ± 0.0816
MDF absolute error (Hz)	7.50 ± 14.76	7.42 ± 13.89
Envelope PCC	0.9929 ± 0.0039	0.9904 ± 0.0037
Envelope NRMSE	0.1753 ± 0.0757	0.1676 ± 0.0656

U-Net V3.1 had lower mean RMS-relative and envelope-normalized errors; median-frequency errors were similar, while AE V1 had higher envelope PCC. These complementary checks do not demonstrate preservation of motor-unit characteristics, which cannot be reliably derived from the processed single-record representation available here.

C. Qualitative Signal Reconstruction Analysis

Figure 2 presents a representative reconstruction example obtained from an unseen EMG recording.

The qualitative example shown in Fig. 2 complements the quantitative analysis by illustrating the visual similarity between reconstructed and reference signals. Despite degradation in the input signal, the reconstructed waveform follows the principal temporal fluctuations of the reference recording and preserves its overall morphology.

Although visual inspection alone cannot replace quantitative evaluation, the qualitative results support the numerical findings reported in Tables III and IV. The close agreement between the reconstructed and reference waveforms is consistent with the high PCC values observed across the evaluation set.

D. Statistical Analysis

To determine whether the observed differences were statistically significant, paired Wilcoxon signed-rank tests were performed comparing AE V1 and U-Net V3.1 across the nine evaluated metrics. Table VI presents the results for the five primary metrics. Among the four signal descriptors, median-frequency error was the only metric without a statistically significant difference after Holm correction (adjusted $p = 0.326$).

The Holm-adjusted tests identified differences for the five primary metrics, but directions were mixed: U-Net V3.1 was favored for error and SNR, whereas AE V1 was favored for PCC. Statistical significance is interpreted together with effect size and the modest absolute differences.

TABLE VI
WILCOXON SIGNED-RANK TEST RESULTS (AE V1 VS. U-NET V3.1)

Metric	Holm p	Effect	Direction
MSE	5.36×10^{-10}	0.395	V3.1
RMSE	1.75×10^{-8}	0.359	V3.1
MAE	1.22×10^{-19}	0.569	V3.1
PCC	6.23×10^{-13}	-0.455	AE V1
SNR	1.28×10^{-5}	0.282	V3.1

E. Additional-Noise Sensitivity Analysis

The sensitivity of U-Net V3.1 was evaluated under additional Gaussian-noise conditions not observed during training. Table VII summarizes the quantitative results, while Fig. 3 presents the changes under increasing noise levels.

TABLE VII
SENSITIVITY EVALUATION UNDER ADDITIONAL GAUSSIAN-NOISE LEVELS

Added Gaussian SD	PCC	SNR (dB)
0.00	0.9932	15.54
0.01	0.9913	14.96
0.03	0.9670	11.41
0.05	0.9167	7.85

As expected, reconstruction performance gradually decreased with increasing noise intensity. The experiment quantifies sensitivity to additional Gaussian corruption only. It cannot be interpreted as evidence of robustness to electrode motion, displacement, power-line interference, or other real acquisition artifacts.

F. Limitations

The study is limited to artificial degradation of processed normal-EMG recordings. No independently acquired set with real artifacts was available, participant identifiers were not preserved for subject-level splitting, and normalization used the paired clean reference. The classical filters provide transparent baselines but do not represent every recent restoration method. RMS, median-frequency, and envelope analyses add signal-level context, whereas clinical validity and motor-unit preservation remain untested. External datasets with real artifacts

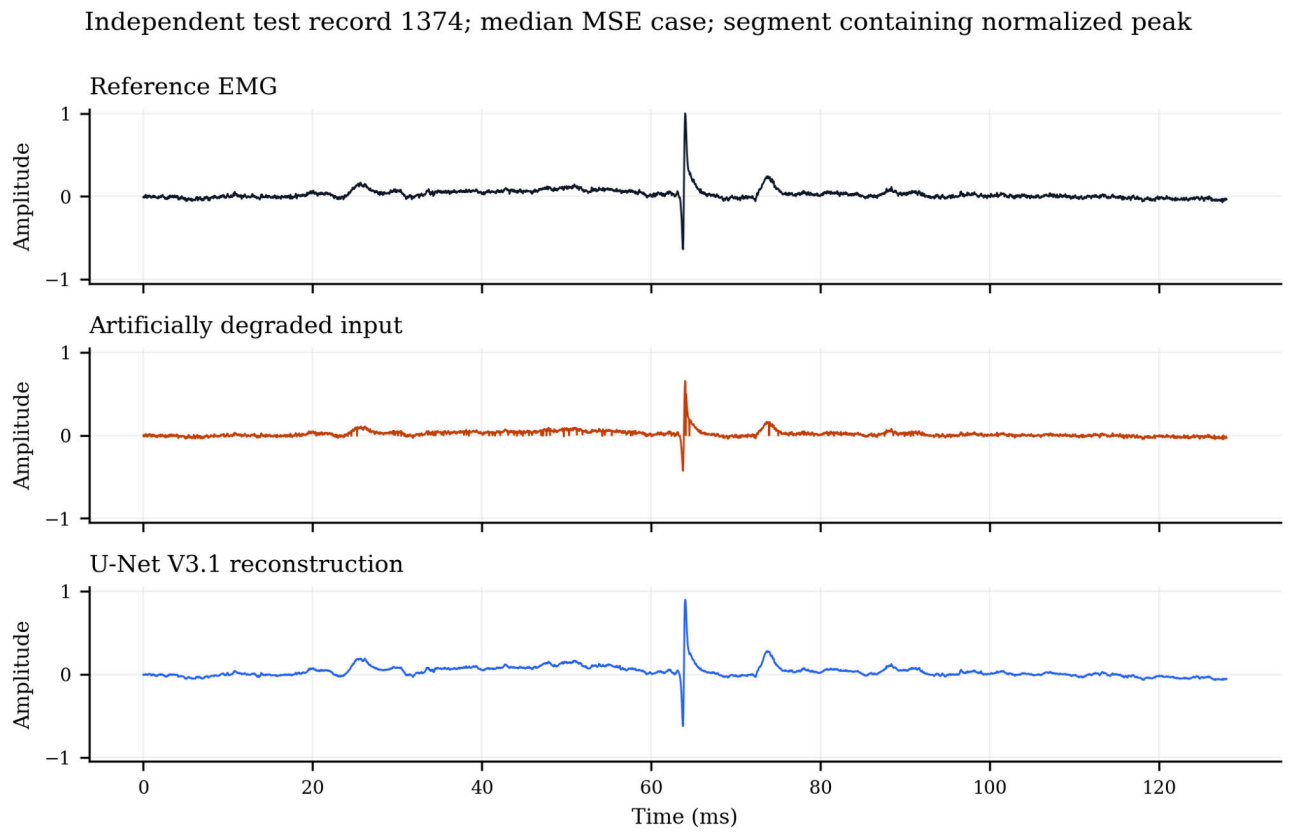

Fig. 2. Representative U-Net V3.1 reconstruction from the independent official test set. A median-MSE recording was selected, and the displayed segment contains the reference signal's normalized peak of 1, following the intended normalized-amplitude presentation.

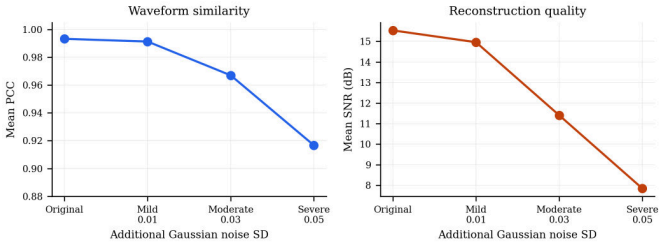

Fig. 3. Sensitivity of U-Net V3.1 to additional zero-mean Gaussian noise on the independent test set.

and participant-level metadata are therefore required before clinical or deployment claims can be made.

V. Conclusion

This study investigated the reconstruction of degraded electromyographic signals using convolutional Autoencoder and one-dimensional U-Net architectures. A controlled comparison was conducted with an explicitly specified artificial degradation pipeline and record-level partitioning before window generation.

Among the tested configurations, U-Net V3.1 obtained the lowest complete-record errors and highest SNR, while AE V1 obtained a slightly higher PCC. These results apply to this dataset and artificial protocol and do not establish clinical validity.

Signal-level evaluation on the independent official test recordings showed high agreement with the artificial reference targets. Additional-noise experiments characterized sensitivity within Gaussian conditions rather than real-world robustness.

Future work should prioritize real electrode artifacts, external datasets, verified subject-level separation, and comparisons with established and recent restoration methods before considering clinical, monitoring, assistive, or embedded applications.

***Abstract*—Automated nanoparticle quantification in transmission electron microscopy (TEM) images is challenging because of variations in contrast, high particle density, small object size, and time required for manual analysis. In this study, we developed a hybrid pipeline that combined neural detection using YOLO11x with classical image segmentation applied within the detected regions of interest. The dataset, exported in the COCO format, contained 1,845 images of 640×640 pixels and 14,829 bounding box annotations. Contrast-limited adaptive histogram equalization (CLAHE) was applied during preprocessing to reduce local contrast and illumination variations. YOLO11x was selected because of its higher representational capacity and the presence of small objects in the images. In the test set, the model achieved an mAP@50 of 66.3%, a precision of 72.5%, a recall of 72.5%, and an F1-score of 72.5%. After neural detection, classical operations, including thresholding, morphological processing, watershed segmentation, and ellipse fitting, were applied to each detected region. This strategy enables approximate particle contours to be obtained without requiring the complete dataset to be manually re-annotated with segmentation masks. The results demonstrate the feasibility of the proposed pipeline for automated nanoparticle localization and provide a practical basis for subsequent morphometric analyses.**

Keywords: Transmission electron microscopy, nanoparticles, YOLOv8, object detection, image segmentation.

I. Introduction

Nanoparticles have several biomedical and theranostic applications, including targeted drug delivery, diagnostic imaging, and the development of combined diagnostic and therapeutic strategies [1], [2]. Transmission electron microscopy (TEM) enables the visualization of these structures at the nanometer scale and can be used to investigate their morphology, distribution, aggregation, and internalization in cells [3].

Despite their relevance, the quantitative analysis of TEM images is frequently based on manual or semi-automated procedures. Manual particle identification is time-consuming, dependent on the evaluator's experience, and susceptible to intra- and inter-observer variability. Conventional thresholding methods can also be affected by variations in image contrast, background intensity, overlapping particles, and cellular structures with similar grayscale values.

Deep learning approaches have been successfully applied to particle analysis in electron microscopy. Neural networks can automate nanoparticle localization and segmentation while reducing the effort required for manual measurements [4], [5]. In cellular TEM images, YOLO-based models have also demonstrated strong potential for the automated detection of internalized gold nanoparticles [6].

The dataset used in the present study contained bounding box annotations but did not contain pixel-level segmentation masks. Consequently, directly training a fully supervised instance segmentation model requires the complete dataset to be manually reannotated. To address this limitation, a hybrid strategy was developed in which YOLO model first detects candidate particles, and subsequently, classical image-processing methods segment each detected region.

Therefore, the proposed method combines the robustness of neural object detection with the interpretability and reduced annotation requirements of classical segmentation. This study aimed to develop and evaluate a hybrid pipeline for detecting nanoparticles in TEM images and generating approximate particle contours for subsequent morphometric analysis.

II. Materials and Methods

A. Dataset

The dataset was obtained in the COCO format with 1,845 TEM images with a spatial resolution of 640×640 pixels. The images were divided into training, validation, and test subsets, comprising 1,293, 368, and 184 images, respectively.

A total of 14,829 bounding box annotations were assigned to the *Nanoparticle* class.

An initial audit of the COCO annotation files was performed to verify the number of images, annotations, categories, and segmentation. The categories were standardized into a single class before being converted to the YOLO format. Approximately 23.5% of the annotated objects had dimensions or areas corresponding to objects smaller than 32×32 pixels. This characteristic was considered during model selection and training because small particles provide limited spatial information and may be lost during successive feature map downsampling operations. Some images did not contain annotations and were retained to represent true-negative samples because background images can help reduce false-positive detections.

B. Image preprocessing

Figure 1 summarizes the proposed approach. The input images were converted to a standardized grayscale representation and normalized before the model training. Contrast-limited adaptive histogram equalization (CLAHE) was applied to improve the local contrast and reduce the effects of non-uniform illumination.

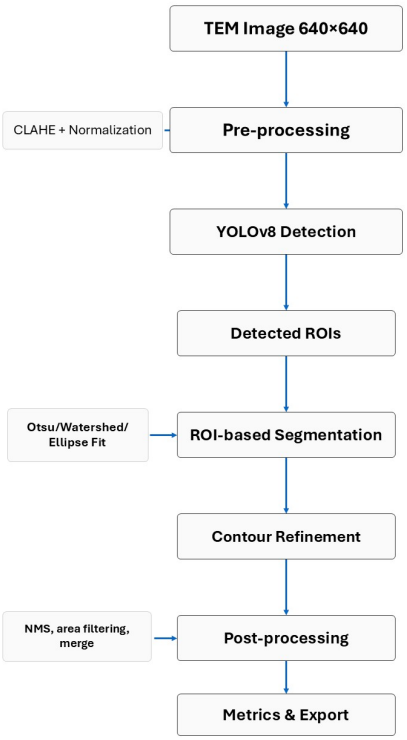

Fig. 1. Proposed pipeline for nanoparticle detection and segmentation.

CLAHE divides an image into local regions and redistributes pixel intensities within each region while limiting excessive contrast amplification. This procedure was selected because the TEM images presented differences in brightness and contrast related to sample thickness, electron density, acquisition conditions, and intracellular background structures.

The preprocessing stage also included automatic orientation verification and resizing to 640×640 pixels. Data augmentation was applied only to the training subset and included horizontal and vertical flips, rotations, moderate brightness and contrast adjustments, Gaussian noise, and blurring, following commonly adopted image augmentation strategies for improving model generalization [7].

Aggressive augmentations were avoided when they produced unrealistic particle morphologies or densities. Mosaic and copy-paste augmentation were applied cautiously because the artificial combination of highly populated TEM regions may generate distributions that are not consistent with original images.

C. Nanoparticle detection

YOLOv8m was used as the standard neural network detector. The medium version (YOLOv8m) was selected because it offered an optimal balance between representational capacity and computational efficiency, and the high proportion of small objects in the dataset. Among the YOLOv8 detection variants, YOLOv8m has a robust number of parameters ($\sim$25.8M), ensuring high representational capacity without the extreme computational cost of larger variants [8], [9].

To ensure reproducibility, the YOLOv8m model was trained for 300 epochs with early stopping patience of 50 epochs. The input image size was set to 640×640 pixels, and the batch size was automatically determined based on the GPU memory constraints (AutoBatch). The AdamW optimizer was used with an initial learning rate of 0.0005, momentum of 0.937, and weight decay of 0.001. Data augmentation strategies included mosaic (1.0), mixup (0.1), translation (0.15), scaling (0.4), and $\pm 90^{\circ}$ rotations, which helped the model generalize to the varying orientations and scales of the nanoparticles.

Transfer learning was performed using the pretrained model weights. During training, a validation subset was used to monitor model convergence and detect potential overfitting. The final performance was evaluated using an independent test subset that was not used for model optimization.

D. Classical segmentation within detected regions

Because the dataset did not contain segmentation masks, classical segmentation was applied after detection. For each bounding box predicted by YOLO, a region of interest was extracted with an additional margin to preserve the information around the particle boundaries.

The region was processed using global or local Otsu thresholding, depending on the intensity distribution [10]. Morphological opening was used to remove isolated pixels, whereas morphological closing and region filling were applied to correct the discontinuities within the particle region.

Watershed segmentation was used when multiple touching or overlapping particles were present in the same region of interest. Candidate components were filtered according to their

area, position, intensity, and compatibility with the expected particle geometry.

The selected particle contours were refined using morphological operations and ellipse fitting. Ellipse fitting was used as an optional contour approximation for particles with predominantly circular or elliptical morphologies. Irregular contours were retained when ellipse fitting introduced a substantial discrepancy from the threshold-derived boundaries.

This hybrid procedure generated approximate segmentation masks without requiring the complete dataset to be manually reannotated at the pixel level.

E. Post-processing and morphometric measurements

Non-maximum suppression was applied to reduce the number of duplicated neural detections. Additional filtering was performed based on the bounding box confidence, detected area, and spatial overlap.

After segmentation, connected components that were judged to belong to the same particle were merged when appropriate. Regions that did not satisfy the minimum area or morphological criteria were excluded as noise.

F. Performance evaluation

The detection performance was evaluated using the precision, recall, F1-score, and mean average precision at an intersection-over-union threshold of 0.50. Precision represents the proportion of predicted objects corresponding to the reference annotations, whereas recall indicates the proportion of annotated particles correctly detected by the model. The F1-score summarizes the balance between precision and recall. The segmentation performance was evaluated separately from the detection performance using a subset of test images that received manual pixel-level ground-truth annotations.
For each detected region, the predicted mask was compared with the corresponding manual mask using four metrics: The Dice similarity coefficient and the Intersection over Union (IoU), which quantify the pixel-wise spatial overlap between the predicted and reference regions, with values closer to 1 indicating a closer match. The area error measures the relative discrepancy between the predicted and reference particle areas independently of their spatial alignment, so that this metric can remain low even when the predicted and reference regions are shifted relative to each other. The boundary distance was computed as the mean of the average nearest-neighbor distances between the contour points in both directions, providing a measure of contour agreement, expressed in pixels. Together, these four metrics capture the complementary aspects of segmentation quality.

III. Results

The neural detection model achieved an mAP@50 of 68.1%, with precision, recall, and F1-score values of 74%. These results indicate a balanced detection performance, as the precision and recall reached similar values, suggesting that the model maintained a similar ability to avoid false-positive detections and identify annotated nanoparticles.

Table I summarizes the performance obtained using the test dataset.

TABLE I
PERFORMANCE OF THE NANOPARTICLE DETECTION MODEL ON THE TEST DATASET.

Model	mAP@50	Precision	Recall	F1-score
YOLO-based detector	0.681	0.748	0.741	0.745

The obtained mAP@50 indicates that the detector could localize a substantial proportion of nanoparticles when a minimum intersection-over-union threshold of 0.50 was considered. A precision of 74.8

To quantitatively validate the classical post-segmentation step, a subset of the test data was manually annotated using pixel-level ground-truth masks. The proposed hybrid approach (YOLOv8m + Otsu/Watershed) was evaluated using the Dice coefficient, Intersection over Union (IoU), area error, and average boundary distance (Table II).

TABLE II
QUANTITATIVE VALIDATION OF THE POST-DETECTION CLASSICAL SEGMENTATION.

Metric	Average Value
Dice Coefficient	0.577
Intersection over Union (IoU)	0.415
Area Error	40.6%
Boundary Distance	14.7 pixels

These preliminary results reflect the intrinsic challenges of applying classical thresholding methods to complex, noisy, and heterogeneously illuminated TEM backgrounds. Although approximate contours provide useful morphometric estimates, such as fitted ellipses, they do not perfectly replace supervised pixel-level segmentation. Furthermore, an ablation study confirmed that when classical segmentation is applied to the full TEM image without prior neural localization, it generates an excessive amount of background noise and false positives, merging adjacent particles. YOLO-based filtering is thus strictly necessary to define a constrained region of interest before applying any classical thresholding.

The representative outputs of the proposed hybrid pipeline are shown in Figure 2. The YOLO-based detector successfully localizes isolated nanoparticles and particle aggregates, whereas the post-detection segmentation stage generates approximate contours and elliptical representations within the detected regions.

IV. Discussion

The detection results demonstrate the feasibility of applying deep learning for the automated identification of nanoparticles in transmission electron microscopy images. The balanced precision and recall values suggest that the model did not strongly favor either excessive detections or overly conservative predictions. Other authors have achieved higher metrics [5], [6]; however, it is difficult to compare the results from different nanoparticles, TEM equipment, and dataset characteristics.

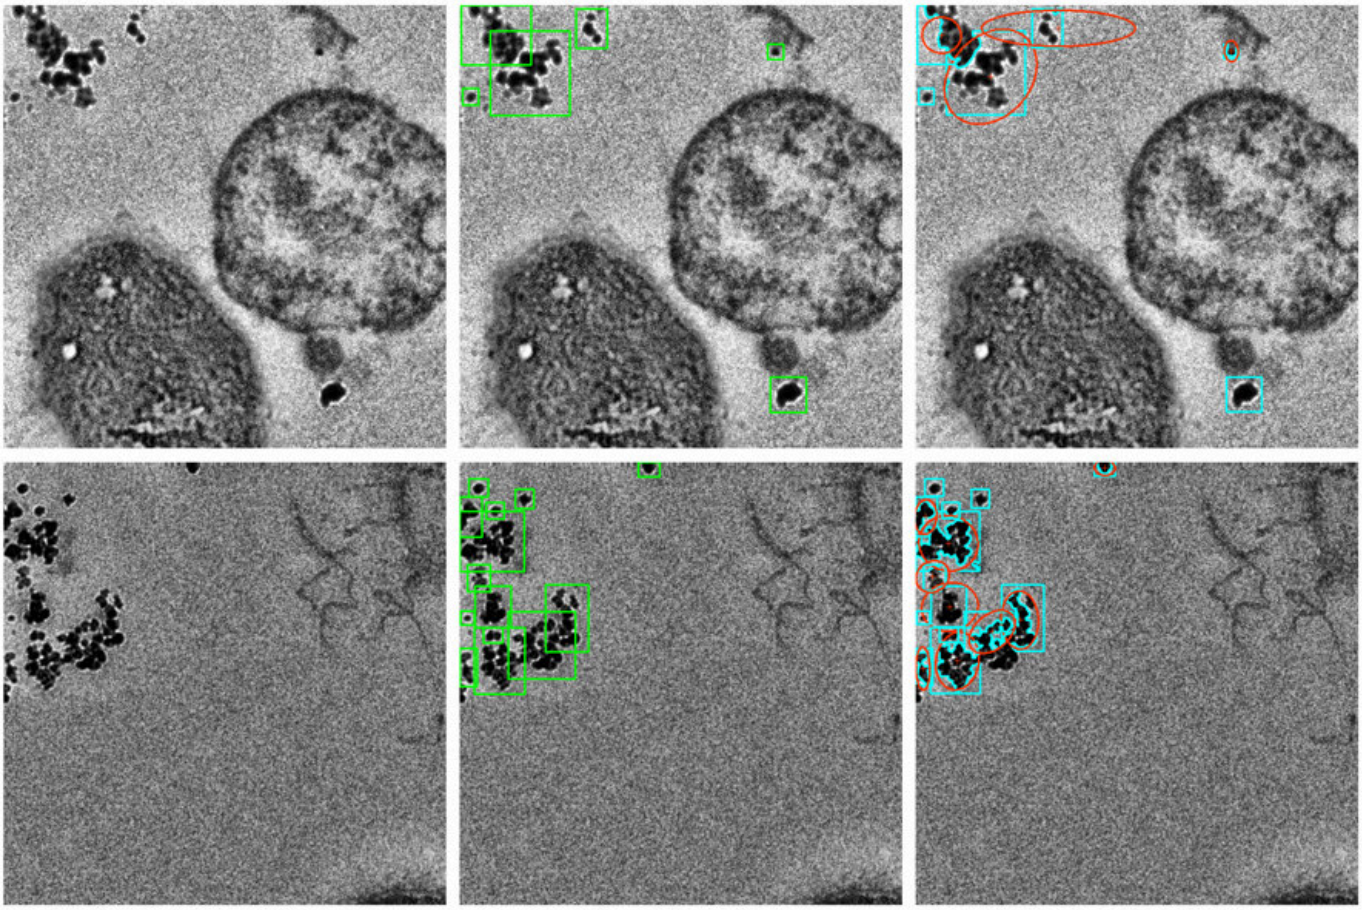

Fig. 2. Representative examples of nanoparticle detection and post-detection segmentation in transmission electron microscopy images. Each row corresponds to a different TEM sample. The first column shows the original images, the second column presents the bounding boxes predicted by the YOLOv8m detector, indicated in green, and the third column shows the results of the hybrid segmentation procedure applied within the detected regions of interest. Cyan contours represent the segmented particle boundaries, whereas red ellipses indicate the fitted geometric approximations.

A central aspect of the proposed approach is the use of contrast-limited adaptive histogram equalization (CLAHE) during image preprocessing. TEM images frequently exhibit local differences in brightness and contrast due to variations in sample thickness, electron density, acquisition conditions, and background illumination. CLAHE improves the local contrast while limiting excessive noise amplification, facilitating the distinction between the nanoparticles and the surrounding cellular structures.

The YOLOv8m architecture was selected as the primary detection model due to its high representational capacity. This choice is particularly relevant because 23.5% of the annotated objects in the dataset have areas smaller than 32×32 pixels. As indicated in the literature, small objects provide limited spatial information and may lose discriminative features across successive downsampling layers, making their detection more difficult at insufficient input or feature map resolutions [11].

Therefore, YOLOv8m was used to improve the feature extraction of small nanoparticles. To justify the extra computational cost, an empirical comparison was conducted with lighter versions of YOLOv8 trained under the exact same conditions. Although the medium-sized model offers a slight performance edge necessary for capturing the smallest nanoparticles, scaling up to extra-large variants does not yield significant improvements and only adds unnecessary computational overhead, confirming YOLOv8m as the optimal architectural choice. The hybrid pipeline also addresses an important limitation of the available datasets. Although the annotations contain bounding boxes, they do not provide pixel-level segmentation. Therefore, training a conventional instance segmentation network requires extensive manual re-annotation. By applying classical segmentation only within the detected regions, the proposed method reduces the search area and minimizes interference from unrelated structures in TEM images.

Otsu thresholding provides an initial separation between the foreground and background pixels, whereas morphological operations can remove isolated noise and fill discontinuities. Watershed segmentation may assist in separating adjacent or partially overlapping nanoparticles from each other. Finally, ellipse fitting provides a smoother approximation of the contour, which is consistent with the approximately circular or

elliptical morphologies of many nanoparticles.

The relatively low segmentation performance, reflected by a mean Dice coefficient of 0.577 and an IoU of 0.415, can be attributed to the high level of noise and background heterogeneity inherent to TEM images. These characteristics frequently generate small high-contrast structures and irregular intensity patterns resembling nanoparticles, particularly those with smaller diameters or a low degree of aggregation. Consequently, the classical segmentation step may partially include background structures as part of the nanoparticle regions or fail to accurately delineate weakly defined particle boundaries, contributing to the observed area error of 40.6% and mean boundary distance of 14.7 pixels. Therefore, these metrics should be interpreted in the context of challenging image characteristics rather than solely as limitations of the segmentation procedure.

Moreover, the accuracy of the classical segmentation stage depends on the image contrast, nanoparticle morphology, aggregation, and presence of intracellular structures with similar intensities. Detection errors are also propagated to the segmentation stage of the process. A missed nanoparticle cannot be recovered during post-processing, whereas an incorrect bounding box may generate a falsely segmented region. The current results should be interpreted primarily in terms of detection performance.

V. Conclusion

This study proposes a hybrid pipeline for nanoparticle analysis using transmission electron microscopy (TEM). This approach combines YOLO-based neural detection with classical post-detection segmentation, avoiding the immediate need to manually re-annotate the entire dataset with pixel-level masks.

The detection model achieved an mAP@50 of 68.1% with precision, recall, and F1-score values of approximately 74%. The combination of neural detection and classical segmentation represents a practical alternative for datasets that contain only bounding box annotations. Future work should include more cases of manual verification of images without annotations, optimization of the YOLO hyperparameters, and quantitative validation of the generated segmentation masks.

***Abstract*—Gadolinium-based contrast agents are widely used in magnetic resonance imaging (MRI) examinations and require technical knowledge related to patient safety, renal function assessment, dose calculation, and adverse event management. However, essential information for professional practice remains dispersed across guidelines, package inserts, and educational materials, making consultation during clinical routines more difficult. This study aimed to identify educational and operational needs related to the use of these agents and to develop a needs-informed digital prototype for continuing education and rapid consultation. A national survey was conducted with 178 MRI professionals using an electronic questionnaire. The results revealed gaps related to the use of contrast agents in special populations, agent classification, renal function assessment, and management of adverse situations, as well as a high demand for quick-reference resources. Based on these findings, a Progressive Web Application (PWA) was developed, containing educational content, contrast dose and estimated glomerular filtration rate calculators, package inserts for contrast agents available in Brazil, and a frequently asked questions section. The prototype integrates educational and operational resources into a single platform and was designed to facilitate access to organized information during MRI practice. The current contribution should be interpreted as a needs-informed functional prototype, not a validated clinical decision-support system. Further studies are required to assess technical validation, usability, and impact on users' knowledge and professional practices.**

***Index Terms*—Magnetic resonance imaging, gadolinium-based contrast agents, continuing education, patient safety.**

I. Introduction

Gadolinium-based contrast agents play a fundamental role in magnetic resonance imaging (MRI), contributing to tissue characterization, lesion detection, and increased diagnostic accuracy in several clinical conditions [1]–[4]. Despite the favorable safety profile of these agents, their use requires technical knowledge related to contrast indication, dose calculation, evaluation of renal function, recognition of risk factors, and management of possible adverse reactions [3]–[6]. Over recent decades, scientific knowledge about these contrast agents has evolved significantly, driven by studies related to nephrogenic systemic fibrosis, gadolinium deposition in tissues, and their use in special populations, such as pediatric patients, pregnant patients, and individuals with impaired renal function [3]. As a result, scientific societies and regulatory agencies have updated guidelines and recommendations, making continuous updates necessary for professionals involved in MRI examinations [3]–[5]. Information relevant to daily practice is often dispersed among guidelines, package inserts, institutional protocols, and educational materials. This fragmentation may hinder timely access to information during clinical routines and contribute to variability in professional practices across institutions and teams. In this context, continuing education plays an important role in supporting patient safety and promoting more consistent professional practices. Simultaneously, advances in digital technologies have expanded the possibilities for health education and support for professional practice, enabling updated content, calculation tools, and quick-reference materials to be made available directly in the workplace [7]–[10]. Thus, this study aimed to identify educational and operational needs related to the use of gadolinium-based contrast agents among MRI professionals and to develop a digital tool to support continuing education and rapid consultation. The scientific contribution of this study lies in developing a needs-informed digital prototype, in which educational gaps identified among MRI professionals were translated into functional require-

ments for a continuing education and rapid consultation tool on gadolinium-based contrast agents.

II. Materials and Methods

A. Study Design

This applied technological development study was conducted in three main stages: a national needs assessment with MRI professionals, definition of educational and functional requirements, and development of a needs-informed digital prototype in PWA format.

B. Needs Assessment

A national survey was conducted among professionals who worked or had worked in magnetic resonance imaging services in Brazil. Data were collected between May 2 and May 29, 2025, using a structured electronic questionnaire made available online and disseminated through professional groups and communication channels in the field. The study used a non-probabilistic convenience sampling strategy. The sample size for the initial needs assessment was estimated considering a population of approximately 10,000 professionals working in magnetic resonance imaging in Brazil, a 95% confidence level, and a 10% margin of error, resulting in a minimum sample size of 96 participants. To account for losses, incomplete responses, and the need for greater robustness in data analysis, the target sample was expanded to 150 to 200 respondents. The instrument was developed based on topics related to the professional use of gadolinium-based contrast agents in MRI, including safety recommendations, package inserts, and issues frequently encountered in clinical practice. It included questions to characterize participants' professional profile, experience in magnetic resonance imaging, prior training on gadolinium-based contrast agents, and knowledge of safety, clinical indications, dose calculation, renal function assessment, contrast agent classification, and adverse events. The questionnaire included objective questions and self-reported items, including Likert-type response options when applicable. A total of 178 professionals participated in the survey. The data were analyzed using descriptive statistics, with absolute and relative frequencies to characterize the sample and identify the main educational and operational demands related to the study topic. Exploratory analyses were performed to investigate associations between previous workplace training and selected outcomes identified in the survey. Previous workplace training was dichotomized as present when participants reported having received training in the current workplace, in previous workplaces, or in all workplaces, and absent when participants reported never having received training. Selected outcomes were dichotomized as adequate when participants answered "yes" or "yes, certainly", depending on the item, and as inadequate or partial for the remaining responses. Categorical variables were compared using Pearson's chi-square test. For 2×2 comparisons, odds ratios with 95% confidence intervals were calculated. A significance level of 5% was adopted. These analyses were interpreted as exploratory, considering the cross-sectional design and the non-probabilistic convenience sampling strategy.

C. Definition of Requirements

The survey results were used to identify knowledge gaps and professional practice requirements. Based on this analysis, the tool's functional and educational requirements were defined. Content related to patient safety, contrast agent classification, renal function assessment, dose calculation, use in special populations, and management of adverse situations associated with contrast agent administration was prioritized. Information selection considered guidelines from the Brazilian College of Radiology and Diagnostic Imaging, the American College of Radiology, and the European Society of Urogenital Radiology, as well as package inserts of contrast agents available in Brazil [3]–[5].

D. Digital Tool Development

Based on the survey findings, the digital tool requirements were defined by linking the main educational and operational needs identified among participants to specific functionalities. The prototype was developed as a Progressive Web Application (PWA), allowing access on mobile devices and desktop computers without requiring installation through app stores. The application was organized into independent modules, including educational content, a contrast dose calculator, an estimated glomerular filtration rate calculator, package inserts for gadolinium-based contrast agents available in Brazil, frequently asked questions, and quick-reference materials. This modular structure was adopted to facilitate navigation, content organization, maintenance, and future updates. The application was developed using the Next.js framework, based on React, and published on the Vercel platform. Data storage, authentication, and file management were implemented using Firebase resources, including Firestore, Realtime Database, Firebase Authentication, and File Storage. Firebase Authentication was incorporated as an access-control mechanism. The educational and operational content was organized based on national and international guidelines, technical documents, and package inserts for gadolinium-based contrast agents available in Brazil. Because recommendations regarding gadolinium-based contrast agents may change over time and may differ among scientific societies, regulatory agencies, manufacturers, and local institutional policies, the prototype was conceived as an educational and rapid consultation resource, not as a substitute for institutional protocols or clinical judgment. To support the long-term reliability of the educational material, future updates of guideline-based content will require source identification, version control, dated revisions, periodic content review, and specialist verification before incorporation into the application. The dose and estimated glomerular filtration rate calculators were designed to operate without collecting or storing patient-identifying information. Input values, such as weight, height, age, sex, and serum creatinine, are used transiently for calculation purposes and are automatically discarded after use, without generating patient records in the

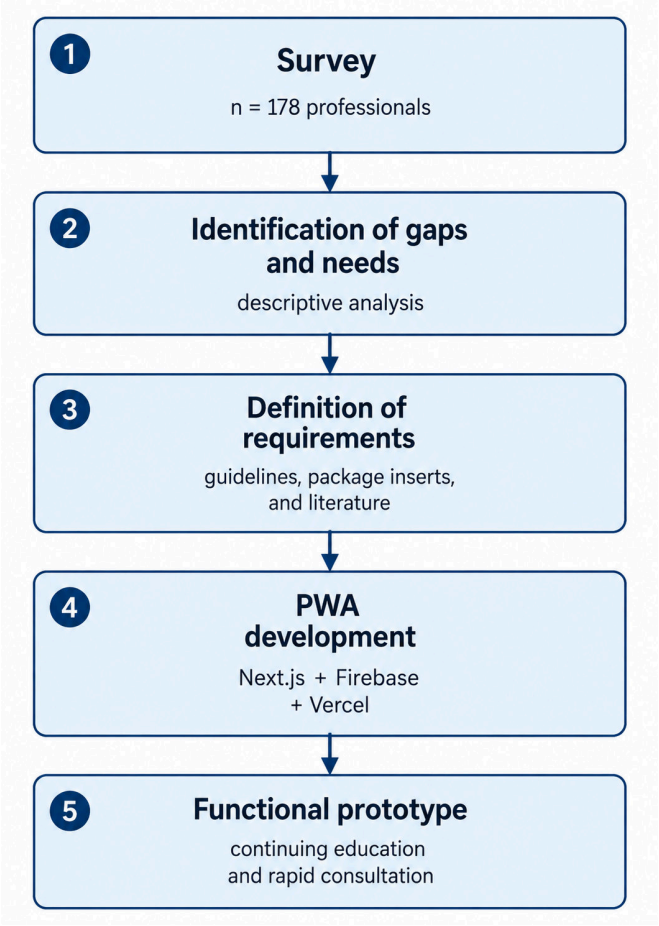

Fig. 1. Digital tool development process, from the survey with MRI professionals to the structuring of the application for continuing education and rapid consultation.

database. This design was adopted to minimize the processing of personal and sensitive health data.

The development process prioritized accessibility, ease of navigation, and information availability during contrast-enhanced MRI examinations. Fig. 1 presents the digital tool development process.

E. Ethical Aspects

The project was approved by a Research Ethics Committee under approval no. 8.468.925. Participation was voluntary and occurred after electronic informed consent was obtained. Data were collected anonymously and analyzed in aggregate form to preserve the confidentiality of the information.

III. Results

A. Needs Assessment

Among the 178 respondents, 37.6% were radiologic technologists, 37.6% were radiology technicians, 24.2% were biomedical professionals, and 0.6% had other professional backgrounds. Regarding professional experience, 47.8% had less than five years of MRI experience. The professional characteristics of the participants are presented in Table I.

TABLE I
Professional Characteristics of the Participants (n = 178)

Characteristic	n	%
Professional background		
Radiologic technologist	67	37.6
Radiology technician	67	37.6
Biomedical professional	43	24.2
Other	1	0.6
Experience in MRI		
Less than 5 years	85	47.8
5 to 10 years	34	19.1
10 to 15 years	25	14.0
More than 15 years	34	19.1
Institutional training on gadolinium		
Yes	67	37.6
No	111	62.4

Most participants considered the coverage of gadolinium-based contrast agents during their professional training to be insufficient. Additionally, 62.4% reported never having received specific institutional training on the topic. When starting their activities in MRI, 78.1% of the participants reported not feeling confident in guiding teams and patients regarding the use of these contrast agents. The main gaps identified involved use in pediatric populations, chemical aspects, agent classification, and patient care for adverse reactions related to gadolinium. Among participants, 70.2% were unable to identify ANVISA-authorized contrast agents for use in children under two years of age, 37.1% reported not being able to explain the concept of a chelate, and 36.5% stated that they did not know the differences between linear and macrocyclic contrast agents. Participants also reported difficulties related to clinical practice. Only 55.6% of participants stated that they could identify patients at higher risk of extravasation, whereas 47.8% reported not knowing or only partially knowing the recommended care following this event. When asked about their ability to guide teams and patients regarding the mechanism of action of contrast agents, dosage, contraindications, renal impairment, and adverse reactions, only 33.7% reported feeling fully prepared. Fig. 2 presents the main knowledge gaps identified among participants.

Exploratory analyses showed that previous workplace training was associated with greater self-reported preparedness to guide teams and patients regarding contrast agents. Preparedness was reported by 44.8% of participants with previous training and 27.0% of those without training (OR = 2.19; 95% CI: 1.16–4.14; $p = 0.015$). Previous workplace training was also associated with knowledge of linear and macrocyclic contrast agents, reported by 58.2% of trained participants and 27.9% of untrained participants (OR = 3.59; 95% CI: 1.90–6.81; $p < 0.001$), and with knowledge of gadolinium-based contrast agents authorized by ANVISA for use in children younger than 2 years, reported by 49.3% and 18.0% of participants, respectively (OR = 4.42; 95% CI: 2.24–8.73; $p < 0.001$). These findings are summarized in Table II.

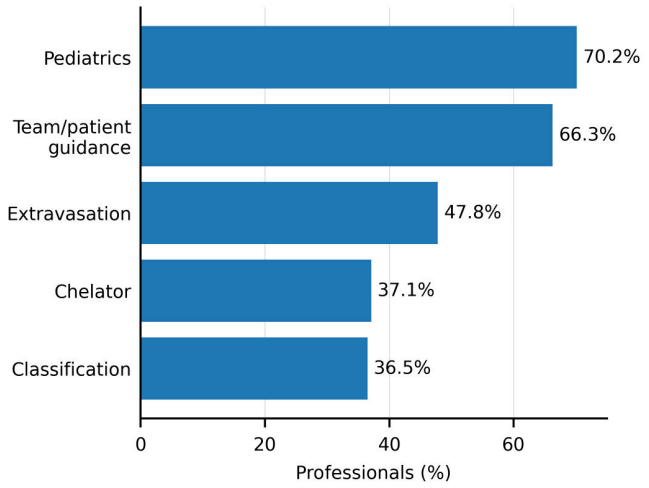

Fig. 2. Main knowledge gaps identified among participants, expressed as the percentage reporting inadequate or partial knowledge or preparedness in each domain.

TABLE II
EXPLORATORY ASSOCIATIONS BETWEEN PREVIOUS WORKPLACE TRAINING AND SELECTED OUTCOMES

Outcome	With training	Without training	OR 95% CI	p
Preparedness to guide teams/patients	30/67 (44.8%)	30/111 (27.0%)	2.19 (1.16–4.14)	0.015
Knowledge of linear/macrocyclic agents	39/67 (58.2%)	31/111 (27.9%)	3.59 (1.90–6.81)	< 0.001
Knowledge of agents authorized for children < 2 years	33/67 (49.3%)	20/111 (18.0%)	4.42 (2.24–8.73)	< 0.001

Note. Values are presented as n/N and percentage. OR: odds ratio; CI: confidence interval.

B. Digital Prototype

Based on the identified needs, a functional prototype in PWA format was developed. The functionalities were structured to address the main demands identified among participants, especially those related to patient-safety practices, guidance for teams and patients, special populations, evaluation of renal function, calculation of doses, extravasation, and classification of contrast agents. Participants showed a strong intention to use the proposed tool, with 96.1% reporting that they would use a mobile application to quickly access information on the use of gadolinium-based contrast agents in their professional routines. Fig. 3 presents examples of the interfaces developed to access educational content, calculators, and quick-reference materials.

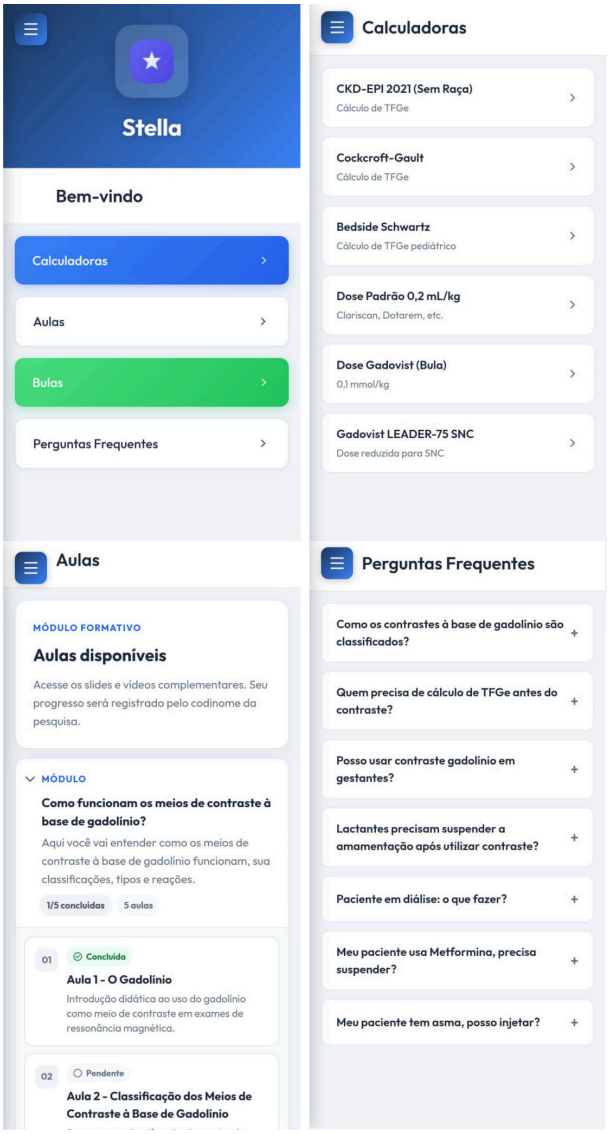

Fig. 3. Interface of the developed digital tool, presenting the main navigation modules, calculators, frequently asked questions, and package inserts.

IV. DISCUSSION

The results of the national survey revealed relevant knowledge gaps related to the use of gadolinium-based contrast agents among professionals working in magnetic resonance imaging. Although these agents are widely used in clinical practice and have favorable safety profiles, their administration involves decisions that depend on technical knowledge regarding indications, dosage, renal function assessment, recognition of risk factors, and management of adverse events. In this context, the insufficient training reported by participants may represent a barrier to more consistent professional practices and adequate guidance for teams and patients [3], [4].

The greatest difficulties identified involved topics directly related to patient safety, including the use of contrast agents in pediatric populations, understanding the differences between linear and macrocyclic agents, and care related to extravasation. These findings are relevant because they correspond to aspects frequently addressed in current guidelines, especially regarding risk stratification, selection of the contrast agent, and management of adverse situations [3], [4]. Therefore, the results suggest that the existence of technical recommendations alone does not ensure their uniform incorporation into

professional practice.

The exploratory analyses reinforce this interpretation, showing that previous workplace training was associated with greater self-reported preparedness to guide teams and patients and with better recognition of selected technical aspects, including the classification of contrast agents as linear or macrocyclic and the identification of agents authorized by ANVISA for use in children younger than 2 years. These findings suggest that institutional training may be related to specific knowledge domains relevant to MRI practice. However, these associations should be interpreted with caution, as the cross-sectional design, convenience sampling strategy, and questionnaire-based measures do not allow causal inference.

Identifying these gaps reinforces the importance of continuing education strategies that provide updated content in an accessible, objective, and workflow-integrated manner. In areas characterized by frequent guideline updates, continuing education is essential to reduce the gap between available knowledge and its application in clinical routines [7]–[10]. The high proportion of participants who reported an intention to use a mobile application suggests their receptiveness to incorporating digital technologies as a resource to support professional practice. Digital solutions for health education may expand access to knowledge, favor autonomous learning, and organize evidence-based information in formats more applicable to professional workflow [7]–[10].

Based on the identified needs, the prototype was structured to integrate educational and operational resources into a single platform. The application brings together organized content, frequently asked questions, contrast dose calculators, and tools for estimating glomerular filtration rate, seeking to facilitate access to relevant information during contrast-enhanced MRI examinations. The alignment between the gaps identified in the survey and the implemented functionalities represents a distinctive feature of the proposal, as it links technological development to the identified needs of the target audience [8].

This study has some limitations. The sample was obtained through online dissemination in professional groups and communication channels in the field, which may have favored the participation of professionals with greater interest in the topic. In addition, the data were self-reported and questionnaire-based, and the results should not be interpreted as a generalizable estimate of knowledge among all MRI professionals in Brazil. The current contribution should therefore be interpreted as a needs-informed functional prototype, rather than as a validated clinical decision-support system. Although the calculators were designed not to store patient-identifying information, future stages should include formal assessment of access permissions, logging, retention policies, deletion procedures, and compliance with the Brazilian General Data Protection Law.

The questionnaire was developed based on guideline-related topics and professional practice demands; however, it did not undergo formal psychometric validation. In addition, no formal pilot testing or structured expert review of the instrument was conducted before data collection, which should be considered when interpreting the survey findings. The complete questionnaire is available from the corresponding author upon reasonable request.

Although the application was designed to organize educational content and operational resources, it has not yet undergone technical validation, formal usability assessment, or evaluation of its impact on professional knowledge, task accuracy, clinical behavior, or patient safety outcomes.

As a continuation of this research, the tool will be evaluated through a quasi-experimental study with pre- and post-intervention measures, aiming to analyze its influence on knowledge, perceived safety, and practices related to the use of gadolinium-based contrast agents in magnetic resonance imaging. Future stages should also include technical validation of the contrast dose and estimated glomerular filtration rate calculators, including verification of formulas, units, rounding criteria, age and population restrictions, contrast agent concentration, maximum recommended doses, contraindications, and pediatric-use rules against current guidelines and package inserts. This validation should include test vectors, boundary-value tests, unit-error tests, and independent specialist review. In addition, specialist review of the educational content, version control of guideline-based information, dated updates, periodic content review, and assessment of data protection requirements should be incorporated before broader implementation. Future development may also explore non-identifiable user analytics and possible integration with institutional information systems, provided that technical validation, data protection requirements, and local governance policies are previously established. Thus, the results presented constitute the initial stage in the development of an educational technology aimed at supporting continuing education and patient-safety-oriented professional practice in MRI.

V. Conclusion

This study identified educational and operational needs related to the use of gadolinium-based contrast agents among magnetic resonance imaging professionals, especially regarding patient safety, renal function assessment, contrast agent classification, use in special populations, and management of adverse situations. Based on these findings, a needs-informed digital prototype in PWA format was developed, bringing together educational content, calculators, package inserts, frequently asked questions, and quick-reference materials. The current contribution should be understood as the development of a functional prototype for continuing education and rapid consultation, rather than as a validated clinical decision-support system. As part of the continuation of this research, technical validation, usability evaluation, specialist review, data protection assessment, and analysis of the impact of the tool on professional knowledge, perceived safety, and practices will be conducted.

Development of a Mobile Application with NFC Wristbands for Secure Patient Identification in Hospital Settings

***Abstract*—Incorrect patient identification is a relevant patient-safety problem in hospital environments, acting as the initiating event of a chain of failures related to medication errors, procedures performed on the wrong person, and communication breakdowns. Conventional identification wristbands are subject to fading, detachment, and low durability, which reinforces the need for more reliable identification methods. This work presents the development of a mobile application integrated with a Near Field Communication (NFC) wristband for the secure identification of hospitalized patients, together with a preliminary usability evaluation. The system was developed following the Interdisciplinary Method for the Development of Health Technologies, using Flutter for the front end, a RESTful API in ASP.NET Core with C# for the back end, and a SQL Server relational database. The application enables NFC-based patient identification, consultation and editing of clinical records, and registration of vital signs, medications, and procedures. Its usability was assessed in a controlled environment with ten participants using the System Usability Scale, yielding a mean score of 63.75 points. The result indicates that the application is usable but still requires refinement, mainly regarding navigation fluidity and interface intuitiveness. The proposed solution shows potential to strengthen patient safety and care traceability, and future work includes evaluation with health professionals and validation under real assistance conditions.**

***Index Terms*—Patient Safety, Patient Identification, Health Technology, Near Field Communication, Mobile Application**

I. Introduction

Patient safety is an essential component of healthcare quality, particularly in hospital environments, where the complexity of care, high assistance demand, and patient turnover increase the risk of incidents and adverse events, also strengthening institutional responsibility and the legal security of health services [1]. Among potentially preventable adverse events, patient identification errors are especially relevant, since they are directly related to incorrect medication administration, procedures performed on the wrong person, and communication breakdowns among multiprofessional teams [1].

Beyond organizational aspects, it is noteworthy that the nursing team plays a central role in the implementation of patient safety strategies, as it remains continuously at the patient's side throughout the entire care process. Nursing is responsible for hospital admission, safe identification, medication administration, specimen collection, clinical monitoring, performance of procedures, and communication among the different professionals of the multidisciplinary team. Consequently, failures in patient identification have a direct impact on nursing clinical practice, increasing the risk of preventable adverse events, particularly those related to medication administration, blood transfusions, and invasive procedures [2], [3].

International studies demonstrate that digital technologies designed for safe identification achieve clinical impact only when they are incorporated into the nursing workflow and accompanied by continuing training, standardized institutional protocols, and an organizational culture oriented toward safety. In this context, mobile solutions capable of supporting clinical decision-making, reducing professionals' cognitive load, and facilitating double-checking contribute significantly to the reduction of care-related errors and to the strengthening of care quality [2], [4], [5].

In routine hospital practice, especially under high-demand and emergency conditions, recurrent problems are observed in the use of conventional identification wristbands, such as low-quality materials, information that fades on contact with fluids, and frequent detachment, which may leave hospitalized patients without any reliable form of identification. These failures represent concrete risks, potentially leading to medication errors and interventions on the wrong patient, and reinforce the need to improve the identification methods adopted in healthcare institutions.

Technological devices have been increasingly regarded as tools to support safer, more reliable, and more effective healthcare for both patients and professionals. Among these, automated identification systems contribute directly to safety in hospital environments by reducing human failures and increasing the reliability of clinical information . However, the mere availability of technology does not ensure safe care; its effectiveness also depends on team integration, professional training, and institutional support. For this reason, recent studies recommend that mobile health (mHealth) applications undergo systematic usability assessment, mHealth-specific heuristics, and validation by specialists and potential users [4], [6], [7].

In recent years, digital transformation has driven substantial changes in nursing practice, fostering the development of so-called Digital Nursing. This approach encompasses the integrated use of electronic health records, mobile devices, clinical decision support systems, artificial intelligence, and automatic identification technologies to enhance care and improve patient safety. However, recent evidence indicates that the success of these technologies depends not only on their technical robustness but also on acceptance by professionals, ease of

Identify applicable funding agency here. If none, delete this.

use, interoperability among systems, and integration with the clinical processes conducted by the nursing team [5], [8], [9].

Furthermore, international organizations such as the World Health Organization and the International Council of Nurses emphasize that nurses play a strategic role in the digital transformation of health systems, acting as key agents in the implementation of technologies capable of improving care quality, reducing adverse events, and supporting evidence-based clinical decisions. Thus, the development of technologies aimed at safe identification must take into account the informational needs of nursing and support clinical reasoning during care delivery [2], [10].

Among automatic identification technologies, barcodes, Radio Frequency Identification (RFID), biometrics, and hybrid models have been used to reduce mismatches between patient, clinical information, and assistance intervention [5]. Near Field Connection (NFC), an evolution of RFID, enables fast and secure short-range data exchange between devices, and has shown potential for process automation, traceability, and improved accuracy in patient identification, optimizing workflow and reducing human error.

Despite advances in the use of barcodes and RFID, the application of NFC in hospital contexts is still limited, particularly regarding integration with mobile systems and usability validation by health professionals. In addition, there is a scarcity of national studies evaluating the practical applicability of these technologies in the Brazilian hospital setting, which characterizes a relevant gap in the development of accessible and secure solutions adapted to real care flows.

In this context, this work presents the development of a mobile application integrated with an NFC wristband for the secure identification of hospitalized patients, together with a preliminary evaluation of its usability. The specific objectives are: (a) to produce a technological solution that couples NFC reading with clinical functionalities for physicians, nurses, and nursing technicians; (b) to design an intuitive and secure interface for the consultation, recording, and editing of clinical and care information; and (c) to assess the application's usability through tests in a controlled environment in order to identify improvement points in its interface and functionality.

Although different automatic identification technologies have been described in the literature, studies investigating their use while simultaneously addressing the technological, care-related, and organizational aspects associated with nursing practice remain scarce. Recent reviews indicate that most research focuses on the technical validation of devices, with less scientific production concerning their influence on nurses' workload, among many other responsibilities. This gap highlights the need for studies that integrate biomedical engineering, health informatics, and nursing science to develop technologies that can be effectively incorporated into everyday hospital practice [11]–[14].

The remainder of this paper is organized as follows. Section II presents the theoretical background on patient safety, NFC, and usability. Section III describes the materials and methods. Section IV details the developed mobile application, and Section V reports its usability evaluation. Section VI discusses the findings and limitations, and Section VII concludes the paper.

II. Theoretical Background

A. Patient Safety and Correct Patient Identification

According to the World Health Organization (WHO), patient safety is defined as the reduction, to an acceptable minimum, of the risk of unnecessary harm associated with healthcare, and is directly related to the capacity of health systems to prevent errors and adverse events through safe practices, care protocols, and risk-management strategies [15]. The Global Patient Safety Action Plan 2021–2030 guides countries and institutions to eliminate avoidable harm, strengthen evidence-based practices, and broaden the participation of professionals, managers, users, and family members in building safer care systems [2]. In Brazil, this agenda was reinforced by the National Patient Safety Program (PNSP), established in 2013, which emphasizes standardized protocols and continuous surveillance for harm prevention [16]. Basic protocols, in turn, address practices such as correct patient identification, hand hygiene, surgical safety, and safe medication use [17].

Correct patient identification is recognized as a central safety goal because it precedes procedures, medication administration, transfusions, specimen collection, intra-hospital transport, surgeries, and clinical recording. It is also the first of the international patient safety goals defined by the Joint Commission International (JCI). Best practices recommend the use of at least two independent identifiers, such as full name and date of birth, avoiding variable data such as bed or room number, which may change during hospitalization. This verification should occur at the first contact with the patient and be repeated at critical moments of care, such as shift changes, exams, procedures, and medication administration. Within this process, nursing plays a strategic role, as it continuously participates in admission, double checking, medication administration, and clinical monitoring; therefore, identification technologies must be designed to support, rather than replace, professional judgment.

Contemporary literature shows that nursing constitutes the main link between safe identification technologies and the effective prevention of adverse events, owing to nurses' continuous presence at the patient's side throughout the 24 hours of hospitalization. Beyond correct identification, nurses coordinate care processes related to the safe administration of medications, collection of biological samples, blood transfusions, invasive procedures, clinical monitoring, and communication among the different members of the multidisciplinary team. Accordingly, the adoption of technologies such as smart wristbands, RFID, and NFC should be understood as a strategy to support nursing clinical reasoning and decision-making, strengthening the safety barriers established by institutional protocols and reducing the likelihood of errors arising from human failures. International studies demonstrate that incorporating digital systems into the nursing workflow promotes greater traceability of interventions, improves the quality of clinical

documentation, reduces medication administration errors, and supports continuity of care, provided that it is accompanied by continuing training, high usability, interoperability among systems, and an organizational culture oriented toward patient safety [3], [11], [14], [18].

From the perspective of Nursing Science, digital technologies intended for patient identification should be conceived as tools to support the Nursing Process rather than as substitutes for clinical judgment. International organizations emphasize that digital transformation in nursing requires user-centered solutions capable of integrating real-time clinical data, reducing professionals' cognitive load, and supporting rapid decisions in highly complex care environments. In this context, the use of mobile devices integrated with NFC technologies presents the potential to enhance patient safety, increase operational efficiency, and strengthen clinical governance, contributing simultaneously to better care outcomes and to the consolidation of an evidence-based safety culture [2], [8], [10], [14].

B. NFC and Traceability in Hospital Care

Digital health technologies include electronic health records, mobile applications, clinical decision support systems, wearable devices, sensors, barcodes, RFID, and NFC. When articulated with institutional protocols, these technologies can improve information management, reduce communication failures, and support decision-making at the point of care. The WHO global digital health strategy emphasizes that such systems must be secure, interoperable, people-centered, and integrated into care processes [8].

NFC enables short-range wireless communication between a reader device and a compatible tag or chip. In the proposed system, the NFC wristband acts as a physical identifier linked to the mobile application, providing access to previously registered information essential for care, such as patient identification, allergies, medications in use, comorbidities, and vital signs. The short reading distance can be regarded as a security advantage, since it requires the professional's intentional approximation to the patient. NFC was developed in 2002 by Sony and Philips and gained wider adoption from 2004 with the creation of the NFC Forum [19]. According to Ozdenizci [20], NFC applications can be organized into three operational modes: Reader/Writer, Card Emulation, and Peer-to-Peer, as illustrated in Fig. 1.

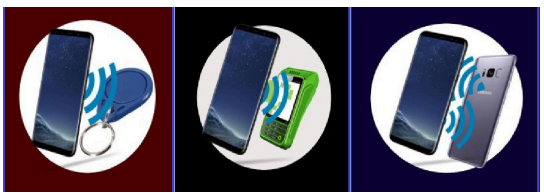

Fig. 1. NFC operational modes. Adapted from GTA/UFRJ (2018)

A recent scoping review on unique-identifier technologies showed that healthcare identification solutions rely on linear codes, two-dimensional codes, RFID, and NFC, indicating their potential to qualify the correspondence between patient and care [5]. The authors, however, stress that adoption must consider interoperability, standardization, data protection, costs, training, and implementation risks. Accordingly, the NFC wristband should be understood as a component of a socio-technical system, dependent on protocols, professional training, and institutional governance.

C. Usability and Information Security in Mobile Health

Usability is decisive for the adoption of health technologies, since clarity and ease of interaction directly affect patient safety and clinical decision-making. Poorly designed mobile systems can generate new barriers, cognitive overload, and inappropriate-use risks, which justifies the use of mHealth-specific heuristics and validation with potential users [6], [7]. A widely used instrument for this purpose is the System Usability Scale (SUS), composed of ten items rated on a five-point scale, whose scoring yields a value from 0 to 100, with results around 70 points commonly adopted as the threshold for satisfactory usability. In addition, because the application handles sensitive clinical data, privacy and information security are essential requirements, in compliance with the Brazilian General Data Protection Law (LGPD) [21].

III. Materials and Methods

A. Study Design

This is a methodological technology-development study guided by the Interdisciplinary Method for the Development of Health Technologies (MIDTS), which structures the technology-creation process into articulated, participatory, and iterative phases [22], as shown in Figure 2.

Methodological studies are suitable when the goal is to build, adapt, evaluate, or validate instruments, protocols, products, or technologies intended for professional practice. The development was organized into the following phases: (i) immersion in the problem context; (ii) elicitation of needs and requirements; (iii) design of potential solutions; (iv) Prototypingn; and (v) usability evaluation. The first phase comprised a literature review and analysis of the care problem, guided by the question of which clinical, technological, and security requirements should compose a mobile system integrated with an NFC wristband to support the secure identification of hospitalized patients.

B. Requirements Specification

The needs and requirements were defined through brainstorming sessions involving the interdisciplinary team of the project, composed of professionals from health, design, and engineering, based on the obstacles experienced in hospital routine, especially those related to patient safety. The functional requirements include the reading of NFC wristbands for patient recognition, the consultation of clinical information such as allergies and diagnoses, the updating of record data, and the management of permissions according to the user profile (nurse, physician, or nursing technician). The non-functional requirements comprise an intuitive and easy-to-navigate interface, quick access to essential resources, protection of the stored information, and compatibility with different

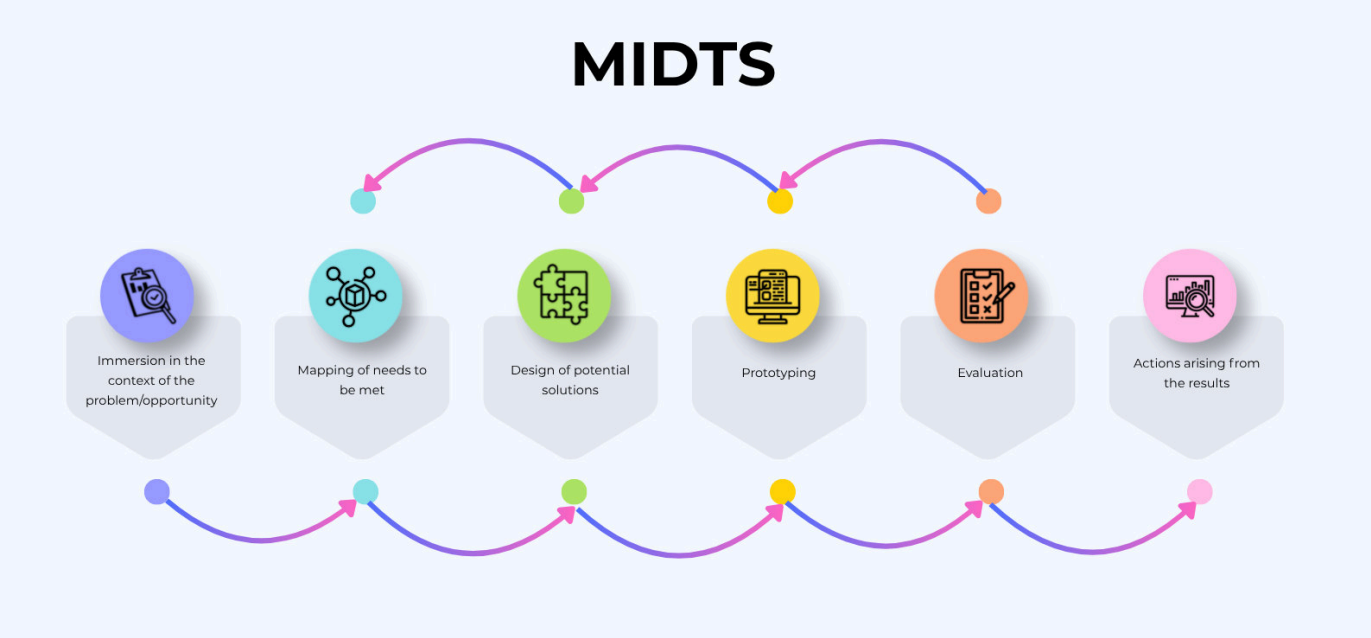

Fig. 2. MIDTS Phases. Adaptaded from [22]

digital platforms. The requirements were systematized in a descriptive table containing the identification code, description, priority level, and corresponding category, which subsidized the modeling, interface design, and implementation stages.

C. Design, Prototyping, and Development

Prototyping was carried out at two levels. Low-fidelity prototypes were produced through paper sketches to represent navigation flows, screens, and initial functionalities, allowing fast and low-cost adjustments. The high-fidelity prototype was elaborated in an interface design tool (Figma) and subsequently converted into a functional version of the application. The visual identity prioritized adequate contrast, legibility, icon consistency, information hierarchy, objective language, and error prevention, adopting the Lato typeface and a color palette organized into primary, secondary, and neutral groups.

For the implementation, the technologies were selected considering the hospital application context, the user profiles, and the target devices (smartphones and tablets). The Flutter framework was adopted for the front end, as it is an open-source framework that enables the creation of native Android and iOS applications from a single codebase and provides integration with native device resources, such as NFC, which is central to reading the patient identification wristbands. The back end was implemented with the C# language and the ASP.NET Core framework, chosen for the development of secure RESTful APIs, its modular structure, high performance, scalability, and the possibility of implementing secure authentication and profile-based permission control. Patient data were stored in a relational SQL Server database, selected for its reliability, performance, and security resources, including access control, encryption of sensitive data, and transaction auditing. The components were integrated through a RESTful API acting as an intermediary layer between the mobile application and the database. The NFC wristband consisted of a silicone bracelet with a compatible NFC chip linked to a simulated unique patient identifier. The resulting system architecture is detailed in Section IV.

D. Usability Assessment Instrument

The usability of the application was assessed through SUS [23], applied after the participants interacted with the system in a controlled, simulated scenario. The instrument comprises ten statements, alternating positive and negative wording, rated on a five-point scale ranging from 1 (“strongly disagree”) to 5 (“strongly agree”). The score is computed as follows: for odd-numbered items, one point is subtracted from the value assigned by the participant; for even-numbered items, the value assigned is subtracted from five; the resulting values are summed and multiplied by 2.5. This procedure yields a final score ranging from 0 to 100, in which higher values indicate better usability, and a score around 70 points is adopted as the threshold for satisfactory usability.

E. Ethical Aspects

The study was submitted to the Research Ethics Committee of the University of Fortaleza, in accordance with the Brazilian National Health Council Resolutions No. 466/2012 and No. 510/2016, when applicable, and with the General Data Protection Law (LGPD) [21]. As the ethical approval was pending, the entire usability evaluation was carried out using fictitious cases and simulated identifiers during the application-refinement tests, ensuring that no real patient data were used.

IV. Mobile Application

The final product of this study is a mobile application designed to support the secure and fast identification of patients in the hospital environment through NFC wristbands. The application aims to reduce failures associated with incorrect patient identification, strengthening care safety and the traceability of clinical information and of the care delivered. Its main functionalities are: NFC wristband reading with automatic display of patient data; consultation and editing of clinical records; registration of clinical information and events; and secure data storage.

A. System Architecture

The system was structured following a layered separation of responsibilities, composed of a client application developed in Flutter, a RESTful API implemented in ASP.NET Core with C# on the back end, and a relational SQL Server database. This organization favors structural clarity, scalability, and ease of maintenance, allowing the system to be extended in the future and its modules to be updated independently. The RESTful API, acting as an intermediary layer between the mobile application and the database, increases security in the traffic of sensitive information, enables service reuse across platforms (web, mobile, and desktop), and standardizes the communication among the system components, while supporting authentication and access control, which are indispensable in systems handling health data. The interaction among these components, as well as the request-and-response flow between the application layers, is shown in Fig. 3.

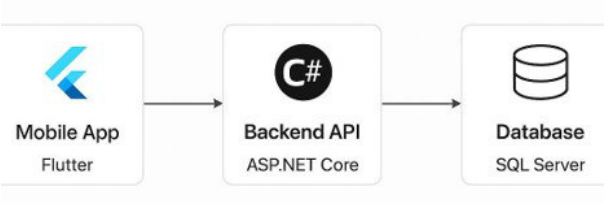

Fig. 3. System architecture: Flutter client application, ASP.NET Core RESTful API, and SQL Server database.

B. NFC Identification Flow

Patient identification is performed by approximating the smartphone or tablet to the patient's NFC wristband. This procedure enables the reading of the NFC tag and the automatic association of the patient information with the corresponding electronic record, providing greater traceability, agility, and security in the identification process. Because the reading requires intentional short-range approximation between the device and the wristband, the interaction acts as an active verification mechanism at the point of care, reducing the dependence on memory or manual checking by professionals. The functional requirements were defined considering the nursing care workflow during medication administration, vital sign measurement, recording of interventions, allergy checking, and patient identification prior to the performance of procedures.

C. Main Features and Interfaces

The home screen displays recently accessed patients, each accompanied by a color-coded risk level (green, yellow, and red), as well as a section listing patients with upcoming care activities. This organization provides a quick and systematized overview of the patients' clinical condition and enables direct access to the individual record. After identification, the application allows the importation of the patient record from a PDF file: the system provides a preview of the document and, upon confirmation, automatically extracts and fills basic patient data such as name, age, diagnosis, and allergies, which can be edited when necessary. This preview-and-confirmation step works as a double-check that reduces transcription errors and inconsistencies.

The individual patient screen centralizes essential clinical information, such as age, main diagnosis, allergies, and risk classification, and allows the consultation and recording of care activities, including vital signs, medication administration, and executed procedures. Dedicated screens support the structured registration and scheduling of vital signs (e.g., blood pressure, temperature, and oxygen saturation), medications (including dose, frequency, and administration time), and procedures, contributing to continuous monitoring and to the organized management of the care plan. The permanent display of allergies on the main screen facilitates immediate verification prior to medication administration, reducing the risk of medication-related adverse events. The structured recording of vital signs facilitates the longitudinal monitoring of the patient and may support future implementations of early warning algorithms for clinical deterioration. Finally, the recording of prescriptions could in the future be integrated with the verification of the "nine rights" of medication administration, strengthening the safety barriers established for nursing practice.

Representative interfaces of the application are presented in Fig. 4.

V. Evaluation

The usability of the application was assessed in a controlled environment using the System Usability Scale described in Section III. The evaluation involved ten participants from different academic backgrounds, including engineering, journalism, advertising, and law, in order to obtain a more diversified appraisal of the tool. During the tests, the participants interacted with the system in a simulated scenario, which made it possible to observe their interaction with the interface and with the available functionalities, after which they answered the SUS questionnaire.

The application achieved a mean SUS score of 63.75 points, a result below the reference value commonly considered satisfactory, which is around 70 points. Although the system demonstrated adequate functioning, improvement opportunities were identified, mainly related to the fluidity of navigation and the intuitiveness of the interface. According to the adopted interpretation, scores below the threshold suggest usability fragilities that require adjustments, whereas the obtained value

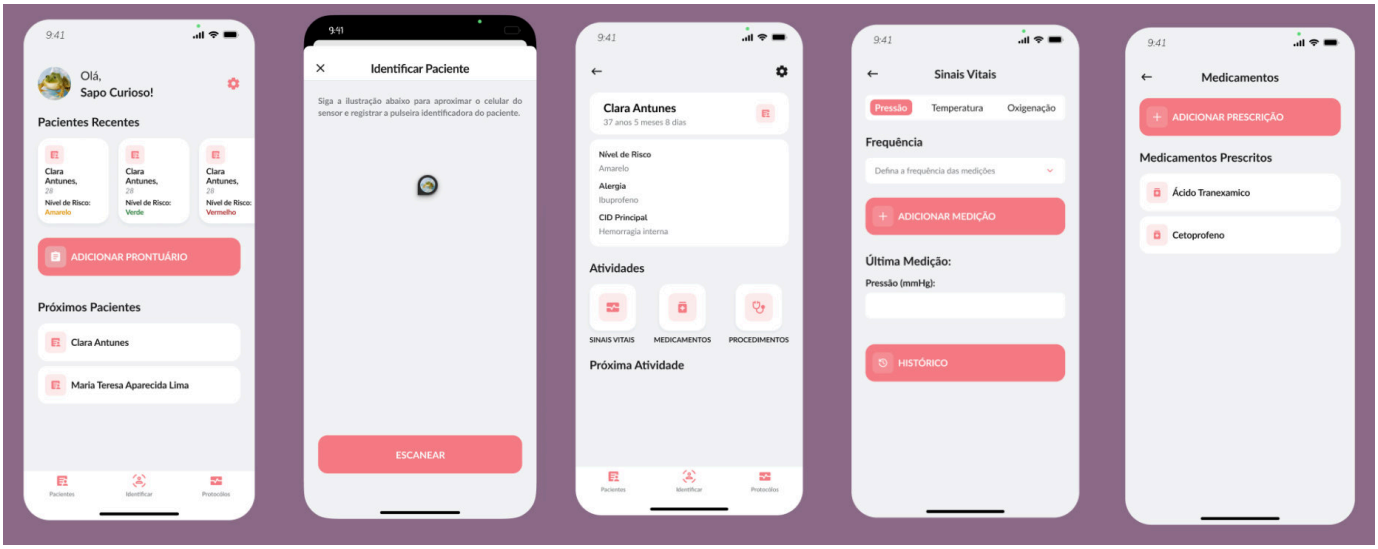

Fig. 4. Representative interfaces of the application: (a) home screen with color-coded risk levels; (b) NFC reading; (c) individual patient screen; (d) vital signs registration; and (e) medication prescription.

TABLE I
IMPROVEMENT DIRECTIONS IDENTIFIED FROM THE USABILITY EVALUATION

Dimension	Improvement direction
User interface (UI)	Redesign for greater intuitiveness, accessibility, and ease of navigation through layout reorganization and interaction simplification.
Interoperability	Integration with legacy hospital systems, such as electronic prescription, bed management, and medication stock control.
Evaluation	Longitudinal usability studies with a larger sample, prioritizing health professionals.
Functionality	Advanced features such as automatic risk alerts (e.g., drug allergies) and integration with remote monitoring.
Security	Full compliance with the LGPD, including encryption, secure authentication, and cybersecurity measures.

indicates that the application can be considered usable but still presents limitations to be addressed in order to provide a more satisfactory and efficient user experience.

Based on the evaluation, a set of improvement directions was defined to make the system more efficient and adequate to the care context, as summarized in Table I. These directions guide the subsequent refinement of the application and are further examined in the Discussion section.

VI. DISCUSSION

Patient safety has been widely discussed in the national and international literature as one of the main indicators of healthcare quality, and the correct identification of the patient is recognized by the World Health Organization as one of the priority goals for reducing harm during care [24]. Failures in patient identification are associated with medication errors, procedures performed on the wrong patient, mix-ups of laboratory exams, and disruptions in the continuity of care; the absence of standardized protocols and ineffective communication among professionals further increase assistance risks, especially in high-complexity settings such as intensive care and emergency services [25]. In this scenario, the literature highlights that identification wristbands, active checking of patient data, and technologies such as barcodes and biometrics contribute significantly to reducing identification errors, provided that they are associated with an organizational safety culture and continuous team training [26].

The functionalities of the developed application were designed as safety mechanisms incorporated into the care process rather than as merely operational resources. The NFC-based identification acts as an active verification barrier at the point of care, favoring the correct correspondence among patient, intervention, and clinical record. The home screen, by presenting recently accessed patients classified by color-coded risk levels, supports situational awareness and the early identification of potentially unstable patients in environments characterized by high workload and frequent interruptions. The importation and preview of clinical records, followed by data confirmation, function as a double-check that reduces transcription errors and documentation inconsistencies, while the permanent visualization of allergies supports safer prescription and administration decisions.

The relevance of these features is consistent with the literature on the electronic health record (EHR). The adoption of the EHR has brought important advances to care quality and service organization, favoring integration among professionals, improving the continuity of care, and reducing problems related to the illegibility of manual prescriptions, in addition to enabling traceability of clinical information and greater legal security for institutions and professionals [27]. Computerized systems can also issue automatic alerts related to allergies, drug interactions, inadequate doses, and clinical

risks, contributing to the reduction of adverse events [28]. More recently, the use of artificial intelligence and predictive analytics integrated with the EHR has been explored for the early identification of clinical risks and decision support, although such tools demand continuous monitoring, scientific validation, and professional training [29].

Despite these benefits, the literature also points to challenges in the implementation and use of electronic health systems. Usability failures, excess of automatic alerts, lack of interoperability among systems, and insufficient training may compromise the effectiveness of the EHR and even generate new assistance risks [30]. The protection of patient data is another critical aspect: the growing computerization of health services increases the need for investments in digital security policies, access control, and confidentiality of clinical information, which must be understood as an integral part of patient safety [31]. Overall, the literature converges on the understanding that secure patient identification and the EHR are fundamental strategies for preventing adverse events, but their effectiveness depends not only on technological implementation but also on institutional protocols, permanent education, an organizational safety culture, and the active participation of health professionals [8].

With regard to active participation, it is worth noting that, from the perspective of good nursing practices, the developed application has the potential to strengthen different stages of the Nursing Process by promoting correct patient identification, structured documentation of interventions, and traceability of care actions performed at the bedside. These functionalities align directly with international recommendations that identify the computerization of care as a strategy to reduce variability in clinical practice, increase adherence to care protocols, and promote evidence-based decisions. Moreover, the integration of NFC-based identification, electronic recording of interventions, and immediate visualization of critical information such as allergies and risk classification may contribute to compliance with the principles of the ”nine rights” of medication administration, strengthen communication among professionals, and enhance safety throughout all stages of care. Recent studies demonstrate that digital technologies centered on the nursing workflow improve the quality of clinical documentation, reduce recording omissions, increase compliance with safety protocols, and foster an organizational culture oriented toward the continuous improvement of care quality, particularly when combined with continuing education and evidence-based clinical governance [2], [3], [12], [14], [18].

A. Limitations

This study has limitations that should be considered when interpreting its findings. The usability evaluation was preliminary and conducted in a controlled environment, using fictitious cases and simulated identifiers, without testing in a real clinical setting. The sample comprised ten participants from non-clinical academic backgrounds, which limits the representativeness of the results for the intended end users. Moreover, the mean SUS score of 63.75 points, below the satisfactory threshold, indicates that the interface still requires refinement, particularly regarding navigation fluidity and intuitiveness. These limitations point to the need for subsequent evaluations with a larger sample of health professionals and for validation of the application under real assistance conditions.

VII. Conclusion

This work presented the development of a mobile application integrated with NFC wristbands for the identification and traceability of hospitalized patients, which proved to be a promising alternative to strengthen safety in the hospital environment. Through the automated reading of NFC wristbands, the system enables more accurate patient identification, contributing to the reduction of failures related to medication administration and to other events arising from incorrect identification. The integration with electronic records, associated with the possibility of updating the patient's clinical information, favors a more organized, agile, and reliable care flow.

Even though the system was not tested in a real environment, the preliminary usability evaluation conducted in a controlled setting with fictitious cases showed that the application presents adequate functionality, although it still demands improvements, especially regarding interface intuitiveness and ease of navigation. The mean score of 63.75 points indicates that the application can be considered usable but still presents limitations that need to be adjusted to provide a more satisfactory and efficient user experience.

These refinement points are relevant to broaden the adoption of the application in hospital institutions. As future work, the following are foreseen: redesign of the user interface to improve intuitiveness and navigability; integration with legacy hospital systems; incorporation of advanced features, such as automatic risk alerts; full compliance with data-protection requirements; and new usability evaluations with a larger sample, prioritizing health professionals, as well as validation of the application under real assistance conditions.

***Abstract*—**The timely communication of critical laboratory results is a recognized component of patient safety. This study presents the development of a Portuguese-language web prototype for structured notification of critical laboratory results, designed for future use in Brazilian hospital settings. The prototype includes prior selection of recipient professionals, notification generation, individualized reading traceability, patient-status management, and feedback to the laboratory regarding the patient pathway. Functional validation was performed in a simulated environment using fictitious data and browser local storage. The present study therefore evaluates interface-level functionality and workflow coherence only; it does not establish clinical effectiveness, delivery reliability, cybersecurity compliance, interoperability, or reduction in communication failures. A secure back-end, persistent audit logging, encryption, escalation mechanisms, integration with laboratory and electronic health-record systems, and clinical validation remain future stages. The prototype demonstrates the feasibility of a traceable notification workflow that can support subsequent technical, usability, and clinical evaluation in the Brazilian context.

Index Terms*—critical laboratory results, health communication, medical informatics, patient safety, traceability, Unified Health System*

I. INTRODUCTION

Critical laboratory results are values that may reflect pathophysiological conditions requiring urgent clinical assessment and timely communication to the professional responsible for the patient [1], [2]. Effective communication of these results is therefore an important component of patient-safety processes in hospital care.

The relevance of the topic is supported by national and international standards and guidelines. In Brazil, Resolution RDC No. 302/2005 of the Brazilian Health Regulatory Agency (ANVISA) requires clinical laboratories to maintain documented procedures for the immediate communication of results that demand urgent medical decisions, while Resolution RDC No. 36/2013 establishes patient-safety actions in health services [3], [4]. The National Patient Safety Program also emphasizes effective communication and correct patient identification. International guidance recommends that communication of critical results be timely, clear, secure, and traceable [1].

Failures in the communication of critical results remain a recognized patient-safety concern [2], [5]. In many services, communication still depends on telephone calls, messaging applications, electronic mail, or other channels that may provide limited traceability regarding who received the information and when. Published technological approaches include text-message alerts and systems designed according to closed-loop communication principles [6], [7].

Within the scope of the literature reviewed for this study, the authors did not identify a Portuguese-language solution in the Brazilian context that combined, in a single proposed workflow, prior recipient definition, individualized reading traceability, patient-status management, and laboratory-side visibility of the patient pathway. The contribution of the present work is therefore the development of a traceable Portuguese-language prototype adapted to this workflow. It is not intended to demonstrate clinical benefit at the present stage.

Accordingly, the objective of this study was to design and functionally validate, in a simulated environment, a web-based prototype for notification of critical laboratory results. The study assessed the coherence of the implemented workflow and interface functions and defined requirements for subsequent secure deployment, interoperability, usability testing, and clinical evaluation.

II. MATERIALS AND METHODS

A. Study Design

This was an exploratory, applied technological-development study focused on the design and implementation of a computerized prototype for notification of critical laboratory results in a hospital workflow. The study was limited to software prototyping and simulated functional validation; no hospital deployment, clinical intervention, or real-patient evaluation was performed.

B. Requirements Elicitation and User Roles

Requirements were elicited from the communication flow represented by the laboratory and care-team roles. For the laboratory role, the prototype considered registration of a critical result, patient identification and location, complementary observations, identification of the issuing professional, and prior selection of recipient professionals. For the care-team role, represented by physicians and nursing staff, the prototype considered receipt and visualization of the notification, individualized reading traceability, and registration of patient-status changes. Laboratory critical limits were defined according to established references such as CLSI GP47 [1]. Table I presents examples used to structure the simulated workflow.

TABLE I
EXAMPLES OF LABORATORY EXAMS, CRITICAL LIMITS, AND POTENTIAL CLINICAL CONSEQUENCES WITHOUT IMMEDIATE INTERVENTION

Exam	Critical limit	Clinical consequence
Potassium (K+)	<2.5 or >6.0 mEq/L	Arrhythmia, cardiac arrest
Sodium (Na+)	<120 or >160 mEq/L	Cerebral edema, seizures
Glucose	<50 or >400 mg/dL	Coma, ketoacidosis
Hemoglobin	<7.0 g/dL	Severe hypoxia, shock
Platelets	<20,000/mm³	Spontaneous hemorrhage
INR	>5.0	Severe hemorrhage
Leukocytes	<1,000 or >30,000/mm³	Sepsis, immunosuppression
Troponin	>99th percentile	Acute myocardial infarction

Source: prepared based on CLSI GP47 [1].

C. Workflow States and Prototype Scope

The simulated workflow comprises the following states: critical-result registration by the laboratory; recipient selection; notification generation; notification visualization by a registered care professional; recording of the reading event; and update of the patient pathway when discharge, death, or ward transfer is registered. In the current prototype, a reading event indicates that the notification was opened by a user; it does not demonstrate clinical acknowledgment or subsequent clinical action. For this reason, the prototype should be interpreted as a traceable notification workflow inspired by closed-loop communication principles, rather than as a clinically validated closed-loop system.

Individualized access is represented at the interface level by user profiles for laboratory, physicians, and nursing staff. The prototype does not include a production-grade identity and access management service, multi-factor authentication, server-

side audit logs, encrypted credential storage, or formal authorization testing. These functions were specified as requirements for future implementation before clinical deployment.

D. Modeling, Development, and Planned Architecture

The system was modeled with Unified Modeling Language (UML) diagrams, including use-case, activity, and sequence representations, to describe interactions between the laboratory and care team. Fig. 1 illustrates the use-case structure from critical-result entry to notification reading confirmation.

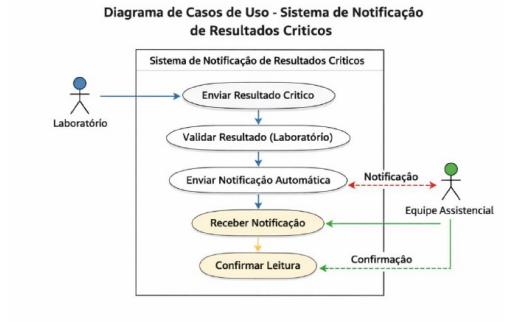

Fig. 1. Use-case diagram of the critical-results notification prototype.

Development employed HTML5 and CSS3 for interface structure and presentation and JavaScript and Python for application logic. Functional validation was performed locally with fictitious data, and visualization events were recorded in browser LocalStorage. Consequently, the current implementation does not provide a secure persistent back-end, transactional database, server-side audit trail, guaranteed message delivery, automatic retry, or downtime recovery.

For future hospital deployment, the planned architecture must include encrypted communication in transit, protected data storage at rest, secure credential management, role-based authorization, immutable or otherwise protected audit logging, message persistence and retry, explicit escalation rules for unavailable recipients or unacknowledged alerts, and documented downtime procedures. Integration with laboratory information systems (LIS) and electronic health records (EHR) was not implemented in this prototype; future interoperability should use standards supported by the participating institutions, including HL7/FHIR-based interfaces where applicable.

E. Simulated Functional Validation

The prototype was exercised with fictitious patients and professionals to verify the sequence of implemented interface functions: result registration, recipient selection, notification generation, visualization, reading traceability, and patient-status update. The present validation was designed to assess functional coherence rather than performance, reliability, cybersecurity, or clinical effectiveness.

The current study did not experimentally evaluate duplicate alerts, unavailable recipients, acknowledgment without clinical action, incorrect patient matching, or network failure. These scenarios were incorporated into the prospective validation plan because they represent safety-relevant failure modes that require controlled testing after implementation of the secure back-end and message-delivery infrastructure.

F. Ethical Aspects

The study involved technological development and simulated testing only. No real patients, identifiable clinical data, or interventions involving human beings were included, and all test information was fictitious. Under this scope, the study did not involve human-subject research. Any subsequent usability or clinical workflow validation involving laboratory professionals, nurses, physicians, patients, or identifiable health information should be submitted to the appropriate Research Ethics Committee before data collection, in accordance with applicable Brazilian requirements.

III. RESULTS AND DISCUSSION

A. Implemented Front-End Functions

The prototype provides browser-based interfaces for the laboratory, physicians, and nursing staff using individualized user profiles. At this stage, these profiles demonstrate the intended separation of user roles and traceability logic at the application interface; they should not be interpreted as evidence of production-level access control or cybersecurity compliance.

From the laboratory module, a professional can select a patient, enter the critical result, add observations, and define the professionals intended to receive the notification (Fig. 2). The simulated notification includes patient identification and location fields, such as name, date of birth, hospital registration number, ward, room, and bed. These fields are intended to support correct routing and patient identification; however, their effectiveness in preventing patient-matching errors was not evaluated in the present study.

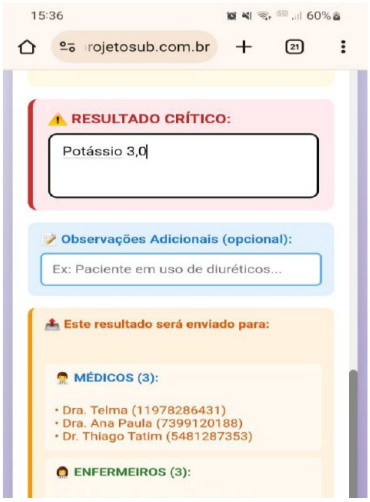

Fig. 2. Critical-result registration screen and prior selection of recipient professionals.

B. Notification Visualization and Reading Traceability

The interface reproduces the intended behavior of a push-based alert presented to registered professionals. In the simulated prototype, this demonstrates the notification workflow at the interface level only. End-to-end delivery guarantees, server-side persistence, retry policies, offline behavior, and network-failure recovery were not implemented or measured.

A central implemented function is individualized reading traceability. The system records the order in which simulated users open the notification and identifies users who have not yet generated a reading event. Fig. 3 also shows identification of the issuing professional, including professional registration information in the interface. These functions support traceability of the notification path, but a recorded reading event must not be interpreted as confirmation that an appropriate clinical action occurred.

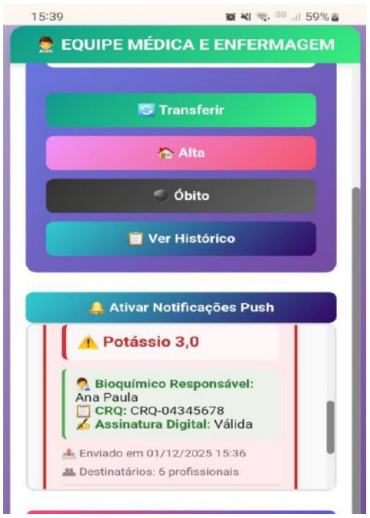

Fig. 3. Care-team interface and identification of the issuing professional in the simulated workflow.

Accordingly, the present prototype implements part of the information cycle described in closed-loop communication literature [6], [7], specifically notification presentation and reading traceability. A clinically closed loop would additionally require verification of receipt, acknowledgment, appropriate clinical action, and completion or escalation of the communication process. These outcomes were beyond the scope of the current simulated study.

C. Care-Team Management and Patient Pathway

The care-team module allows simulated registration of hospital discharge, death, and ward transfer. These updates are displayed to the laboratory module to maintain visibility of the patient's pathway within the institution. In a future integrated environment, this function may reduce the risk of directing notifications to an outdated location, but this effect was not measured in the current study.

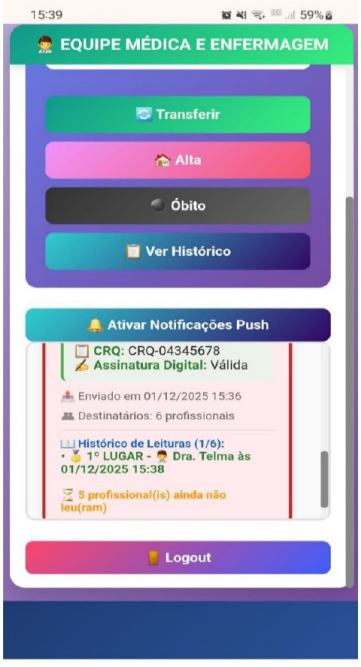

Fig. 4. Reading traceability showing viewing history and users without a recorded reading event.

D. Applicability and Innovation in the Brazilian Context

The main contribution of the proposed solution is the organization of a Portuguese-language, traceable workflow designed around communication of critical laboratory results in the Brazilian hospital context. The prototype can be accessed through commonly available web-enabled devices and does not depend, at the interface level, on proprietary hardware. These characteristics may favor future deployment in institutions with heterogeneous infrastructure, including public and philanthropic hospitals.

Nevertheless, claims of low deployment cost, high replicability, regulatory compliance, scalability, or cost-effectiveness cannot be established from the present prototype alone. Such claims require evaluation of the final architecture, infrastructure requirements, cybersecurity controls, institutional integration, maintenance burden, and performance under routine clinical load.

E. Limitations and Prespecified Future Validation Outcomes

The principal limitation is the absence of deployment in a real hospital environment. No objective performance indicators were collected for notification delivery time, acknowledgment rate, communication-failure reduction, user acceptance, or clinical response time. Interoperability with LIS/EHR platforms, scalability under concurrent routine use, cybersecurity mechanisms, and resilience to network or service failure were also not experimentally assessed.

The next validation stage should therefore combine technical testing and human-factors evaluation. Safety-relevant test cases should include duplicate notifications, unavailable recipients, notifications read without subsequent action, incorrect patient matching, interrupted connectivity, and recovery after downtime. Usability and workflow validation should include laboratory staff, nurses, and physicians under ethics oversight.

For prospective clinical evaluation, notification-to-read time and notification-to-action time should be defined as primary outcomes. Secondary outcomes should include delivery success rate, acknowledgment rate, proportion of alerts requiring escalation, communication-failure rate, user acceptance/usability measures, and frequency of workflow deviations. These outcomes should be prespecified before hospital deployment and analyzed using a secure, auditable back-end capable of recording reliable timestamps and action events.

TABLE II
IMPLEMENTATION STATUS OF KEY REQUIREMENTS IDENTIFIED DURING REVIEW

Requirement	Current status
Role-specific interfaces	Implemented in prototype
Critical-result registration	Implemented in prototype
Recipient selection	Implemented in prototype
Reading traceability	Implemented in simulated environment
Patient-pathway update	Implemented in prototype
Secure identity/access management	Planned
Encryption and protected storage	Planned
Server-side audit logs	Planned
Delivery persistence/retry	Planned
Escalation and downtime rules	Planned
LIS/EHR interoperability	Planned
Clinical usability/effectiveness	Not yet evaluated

IV. CONCLUSION

This study presents the development and simulated functional validation of a Portuguese-language web prototype for notification of critical laboratory results. The implemented functions include critical-result registration, prior recipient selection, individualized reading traceability, patient-status management, and laboratory visibility of the patient pathway. These results demonstrate the feasibility of the proposed interface and workflow logic, but they do not demonstrate improved communication, prevention of harm, reduced clinical response time, or a clinically validated closed-loop process.

Before hospital deployment, the prototype requires a secure persistent back-end, robust identity and access control, encryption, auditable server-side logging, message-delivery and retry mechanisms, escalation and downtime procedures, interoperability with institutional LIS/EHR systems, and formal cybersecurity assessment. Subsequent validation should include safety-relevant failure scenarios, usability studies with

laboratory professionals, nurses, and physicians, and prospective measurement of notification-to-read and notification-to-action times together with delivery, acknowledgment, communication-failure, and user-acceptance indicators. The present work therefore establishes a technological basis for future clinical validation rather than evidence of clinical effectiveness.

***Abstract*—This study conducted a technical-comparative documentary characterization of two Brazilian mammography databases—BancoWeb/LAPIMO-USP and BR-UNIFESP—with respect to technical, clinical, documentary, and access-related characteristics potentially relevant to explainable artificial intelligence (XAI) research. A documentary, descriptive, and comparative study was conducted based on the original publications describing the databases, subsequent updates related to BancoWeb, and Brazilian technical documents and studies on mammography. The documentary design was adopted to characterize properties explicitly reported in the sources and their evolution, rather than to perform a technical audit of the files currently made available. The comparison criteria included dataset composition and unit of count, acquisition modality, formats, metadata, clinical and diagnostic information, spatial annotations, retrieval mechanisms, and access conditions. Sources from 2018 and 2022 documented BancoWeb with approximately 1,900 real mammographic images derived from digitized films and DR systems, in addition to approximately 600 phantom images. BR-UNIFESP is described as containing 941 images from 100 anonymized cases, with tomosynthesis in 62% of the cases. During the review, registration was completed on the BR-UNIFESP platform; however, after 72 hours, access to the examinations had not yet been authorized, preventing direct inspection of the images, DICOM files, and metadata. The documented resources show distinct potential correspondences with XAI investigation modalities: BancoWeb provides tools for selecting regions of interest and phantom images associated with templates of known location, whereas BR-UNIFESP provides structured search based on clinical, radiological, and anatomopathological descriptors and includes tomosynthesis. Patients, cases, clinical images, and phantom images were treated as distinct documentary units. The findings do not establish overall superiority of either database and do not constitute experimental validation of XAI techniques; rather, they organize documentary criteria that may support the preliminary selection of resources according to the type of explanation to be investigated.**

***Index Terms*—mammography, databases, artificial intelligence, explainable artificial intelligence, medical imaging**

I. Introduction

Breast cancer is a major public health problem in Brazil. Excluding non-melanoma skin tumors, it is the most common cancer in the Brazilian female population. For each year of the 2026–2028 triennium, the Brazilian National Cancer Institute estimates 78,610 new cases, corresponding to an estimated risk of 71.57 cases per 100,000 women [1]. Its heterogeneous regional distribution and mortality burden reinforce the importance of improving early detection, diagnosis, and organization of care.

Early detection includes the diagnosis of individuals with suspicious signs or symptoms and the screening of asymptomatic individuals [2]. In this context, mammography produces not only images but also clinical, radiological, and technical information related to image acquisition, BI-RADS classification, characteristics of findings, and, in certain cases, anatomopathological confirmation. The structure and availability of this information may influence data preparation, computational model development, and the procedures used for model evaluation.

The suitability of a database for artificial intelligence research does not depend exclusively on the nominal number of images. Acquisition modality, resolution, format, metadata structure, reports, diagnostic references, regions of interest, spatial annotations, and case-retrieval mechanisms may play different roles in model preparation and evaluation. In the context of explainable artificial intelligence, spatial annotations may provide references for localization analyses; radiological descriptors and reports may support semantic analyses; anatomopathological information, when available and correctly linked, may contribute to the definition of diagnostic references; and structured metadata may support contextual analyses or the retrieval of similar cases [8], [9].

Among the documented Brazilian initiatives, BancoWeb/LAPIMO-USP was developed to support the development and comparison of computer-aided diagnosis systems. Its original publication described approximately 1,400 images from about 320 patients [3]. Later sources documented expansion and restructuring of the platform. In 2018, 1,703 images derived from digitized mammographic films and 196 images from DR systems were reported, in addition to 611 phantom images [13]. In 2022, approximately 1,700 files from digitized films, about 200 DR images, and approximately 600 phantom images were described, together with specific tools for storage, search, and retrieval [14].

BR-UNIFESP, published in 2024, was developed from digital

images acquired between 2019 and 2023. The publication describes 941 images from 100 anonymized cases, acquired using a GE Senographe Pristina 3D system, with tomosynthesis present in 62% of the cases, online visualization, and the possibility of obtaining examinations in DICOM format [4]. The platform is also described as providing search mechanisms based on numerous clinical, radiological, and anatomopathological descriptors.

The consulted publications do not provide a standardized comparison between the two databases from the perspective of documentary resources related to different explainability modalities. Therefore, the following research question was formulated: which technical, clinical, documentary, and access-related characteristics are reported for BancoWeb/LAPIMO-USP and BR-UNIFESP, and what potential correspondences can be established between these resources and different modalities of XAI investigation?

The objective of this study was to conduct a technical-comparative documentary characterization of the two databases, considering composition, acquisition modality, formats, metadata, diagnostic references, annotations, search mechanisms, access conditions, and the potential correspondence between documented resources and different explainability modalities.

II. Theoretical Background

A. Mammography, Image Quality, and Artificial Intelligence

Mammography is used for screening asymptomatic women and for the diagnostic investigation of patients with signs or symptoms. Its effectiveness depends on the technical quality of the image, interpretation, and continuity of the diagnostic workup for abnormal examinations [2], [5]. Brazilian technical documents use BI-RADS to standardize radiological findings and guide clinical management [6].

Image quality is related to the acquisition chain, including positioning, compression, exposure, contrast, spatial resolution, noise, and artifacts [5]. Differences in modality, equipment, digitization, and format may also interfere with model training and evaluation. In mammography, AI has been studied for detection, classification, malignancy estimation, case prioritization, and interpretation support. Its results may vary according to database composition, reference standard, disease prevalence, and type of validation and are not automatically generalizable to other populations or contexts [7].

B. Brazilian Databases and Explainability

Mammography databases provide infrastructure for the development and comparison of AI systems. Their potential usefulness depends not only on volume but also on modality, format, clinical metadata, reports, annotations, and diagnostic confirmation [3], [4], [13], [14].

BancoWeb/LAPIMO-USP predominantly contains digitized mammographic films, although later sources also document images derived from DR systems and a specific set of phantom images [13], [14]. BR-UNIFESP contains natively digital images and cases initially selected partly for teaching purposes [4]. None of these characteristics, considered in isolation, demonstrates that the respective datasets are representative of the Brazilian population.

In XAI applied to health care, it is necessary to distinguish the existence of elements that may potentially be used as references from the actual validation of an explanation. Regions of interest or templates with known locations may provide references for spatial analyses; BI-RADS descriptors and reports may support semantic comparisons; anatomopathological information, when available, complete, and correctly linked, may contribute to the definition of diagnostic references; and cases retrievable by attributes may provide resources for example-based approaches.

However, saliency maps, similarity measures, or apparent agreement between an explanation and a given image region do not, by themselves, guarantee fidelity to the model's decision-making mechanism, causality, or clinical utility [8], [9]. Consequently, a database is not "explainable" by itself; it may provide resources that can be used in protocols for developing and evaluating explanations, whose validity depends on previously defined experimental criteria.

III. Method

A documentary, descriptive, and comparative study was conducted, with quantitative and qualitative analysis of the characteristics explicitly declared in the sources. The units of analysis were BancoWeb/LAPIMO-USP and BR-UNIFESP.

The documentary design was adopted because the primary objective of this stage was the systematic characterization of the properties reported for the two databases and, in the case of BancoWeb, their documentary evolution, rather than a technical audit of the files currently hosted or experimental validation of artificial intelligence models.

For BancoWeb/LAPIMO-USP, the original publication by Matheus and Schiabel [3] and two subsequent sources directly related to the platform's evolution were analyzed: the dissertation by Rodrigues [13] and the study by Schiabel, Matheus, and Cardoso [14]. For BR-UNIFESP, its presentation and characterization publication was used [4].

Brazilian technical documents on mammographic acquisition and quality [5], [6] and studies based on the Brazilian Cancer Information System (SISCAN) [10]–[12] were used exclusively for technical, clinical, and health-care contextualization and were not treated as image databases included in the comparison.

Sources referring to the two databases were selected when they presented information directly related to at least one of the following criteria: dataset composition and unit of count; acquisition modality or equipment; acquisition period; format, resolution, and bit depth; presence of two-dimensional mammography or tomosynthesis; clinical, BI-RADS, or anatomopathological information; reports; spatial annotations or regions of interest; search and retrieval mechanisms; anonymization; registration, authorization, and download conditions; and documentary resources potentially related to XAI investigation protocols.

When different BancoWeb publications presented different quantitative values, the values were organized chronologically

and linked to the respective documentary period, without assuming that they represented the same state of the platform. Mammographic images derived from patients and phantom images were maintained as separate categories, and their counts were not added for the purpose of comparing dataset size with BR-UNIFESP.

Units of count were preserved according to the terminology employed by the sources. "Patient" designated the clinical unit declared for BancoWeb/LAPIMO-USP, whereas "case" designated the unit used for BR-UNIFESP. In the absence of sufficient documentary definition, no assumption was made that a case necessarily corresponded to one patient, one examination, one breast, or one diagnostic episode.

Likewise, quantities referred to as "images" were reproduced as presented in the sources, without assuming complete equivalence among two-dimensional mammographic images, DICOM objects, or tomosynthesis-related content. Therefore, patients, cases, clinical images, and phantom images were considered distinct documentary units.

To organize the analysis from an XAI perspective, the documented resources were classified according to the potential function they could perform in an experimental protocol. Previously demarcated regions, regions of interest, or templates with known locations were considered potential documentary references for spatial analyses; reports and BI-RADS descriptors for semantic or concept-based analyses; anatomopathological information, when complete and correctly linked, for defining diagnostic references; clinical metadata for contextual analyses; attribute-based search mechanisms for case retrieval in example-based approaches; tomosynthesis for investigations involving three-dimensional data; and phantoms with known locations of simulated structures for controlled detection or localization experiments.

This classification represents a preliminary analytical correspondence between documented resources and possible experimental functions and does not constitute a demonstration of database suitability or a test of explanation fidelity, robustness, causality, or clinical utility [8], [9].

During revision of the study, an operational attempt to access BR-UNIFESP was made for the specific purpose of verifying the access condition described in the publication. Registration on the platform was completed; however, after 72 hours, authorization to access the examinations had not yet been granted.

Consequently, no dataset download, image inspection, DICOM-file evaluation, header reading, metadata-completeness assessment, or annotation validation was performed. This observation corresponds to a single registration request and was not used to classify the platform as unavailable.

BancoWeb/LAPIMO-USP files were likewise not directly inspected. Therefore, it was not possible to verify whether the content currently hosted fully corresponds to the state described in the 2018 and 2022 publications.

Thus, except for the operational observation concerning the BR-UNIFESP registration process, the results correspond to characteristics explicitly documented in the sources and do not constitute a technical audit of the platforms in their current configurations. Characteristics not described were classified as "not documented in the consulted sources," without inferring that they do not exist.

No model training, performance-metric calculation, testing of XAI techniques, quality scoring, interoperability assessment, or establishment of an overall hierarchy between the databases was performed.

IV. Results

A. Technical Characteristics and Access Conditions

BancoWeb/LAPIMO-USP was described in its original publication as containing approximately 1,400 images from about 320 patients [3]. Later sources documented expansion of the dataset.

In 2018, Rodrigues reported 1,703 images from laser-digitized films, with 12-bit contrast resolution and spatial resolution of 0.085 or 0.150 mm, in addition to 196 images from DR mammography systems [13]. The same source recorded approximately 1,900 real mammographic images made available online at that time and 611 phantom images.

In 2022, Schiabel et al. documented approximately equivalent values: about 1,700 images from digitized films, approximately 200 images from DR systems, and about 600 phantom images [14]. These 2018 and 2022 records represent later stages in the documentary evolution of the platform compared with the approximately 1,400 images described in 2011, but, without direct inspection, they do not allow the conclusion that these values fully correspond to the content currently available.

The phantom images constitute a dataset documented separately from mammograms obtained from patients. Therefore, their number was not added to the number of clinical images for comparison with BR-UNIFESP. The sources describe specific information associated with the phantoms, including the equipment used, exposure parameters, layer configuration, type of simulated structure, and templates containing the positions of inserted structures [13], [14].

BR-UNIFESP was described as containing 941 images from 100 anonymized cases selected among examinations performed between 2019 and 2023. According to the publication, the examinations were acquired using a GE Senographe Pristina 3D system, and 62% of the cases included tomosynthesis [4]. The source also reports examination visualization through a web browser and the possibility of downloading individual examinations or customized sets in DICOM format.

Because "patient" and "case" have no demonstrated documentary equivalence, the quantities of approximately 320 patients and 100 cases were kept separate and were not used to compare the number of individuals in the databases. Image counts were also not used to establish a size hierarchy because the sources describe different modalities, development periods, and possible counting criteria.

An internal inconsistency was identified in the BR-UNIFESP publication regarding the number of available variables. The abstract and results section report 169 clinical and imaging variables, whereas the section dedicated to platform selection

and customization mentions 113 variables [4]. Because the publication does not provide sufficient information to resolve this discrepancy, neither value was adopted in isolation as a quantitative comparative measure.

The sources describe both platforms as freely accessible subject to registration. For BancoWeb, the 2018 and 2022 sources report registration authorized by an administrator [13], [14]. For BR-UNIFESP, registration is subject to administrative approval and requires professional identification [4]. In the attempt conducted during revision of the present study, registration on BR-UNIFESP was completed, but access to the examinations had not yet been authorized after 72 hours. This result does not allow a conclusion of general unavailability of the platform; it only records that the specific request analyzed did not result in effective access within that interval.

Table I summarizes the documented characteristics of the two databases according to the criteria defined in the method. Quantitative values are presented according to the units used by the respective sources and do not assume equivalence among patients, cases, clinical images, tomosynthesis-related content, or phantom images.

B. Clinical Information and Documented Resources With Potential Correspondence to XAI

For BancoWeb/LAPIMO-USP, the publications document associations among images, reports, BI-RADS, patient characteristics, examinations, and findings, as well as mechanisms for searching, cropping, and selecting regions of interest [3], [13]. However, the existence of a cropping or marking tool does not imply the availability of previously produced spatial annotations for all clinical images.

The phantom dataset adds a distinct documentary resource. The images may contain simulated nodules or clusters of microcalcifications and include information on configuration, acquisition, and location of the structures of interest. The system is described as being able to retrieve the template corresponding to the image, containing a reference to the positions of the simulated structures [13], [14]. This resource constitutes a potential spatial reference for controlled detection or localization experiments without, by itself, representing validation of XAI techniques.

For BR-UNIFESP, the publication describes a broad set of BI-RADS descriptors and clinical, anatomopathological, and immunohistochemical information. According to the authors, image characteristics were extracted from hospital reports interpreted by trained physicians, with manual curation and organization of the data [4].

The platform is described as being capable of combining multiple attributes when retrieving cases. However, the consulted publication does not document complete segmentation masks or bounding boxes for all lesions, and the lack of direct access to the files prevented verification of the coverage and completeness of the available fields.

Considering the possible experimental functions of these resources, previously defined regions or templates with known locations show a direct correspondence with spatial-analysis protocols. Reports, BI-RADS, and anatomopathological information have potential correspondence with semantic or concept-based approaches. Multi-attribute search mechanisms may provide resources for case retrieval in example-based approaches. The presence of tomosynthesis, in turn, represents a specific characteristic of BR-UNIFESP that may be relevant to investigations using three-dimensional data.

These correspondences represent documentary possibilities for the design of future studies. They do not demonstrate experimental suitability, model performance, explanation quality, fidelity, robustness, or superiority of one database over the other.

V. Discussion

This study conducted a technical-comparative documentary characterization of BancoWeb/LAPIMO-USP and BR-UNIFESP by applying common criteria to information explicitly reported in the sources. Inclusion of the 2018 and 2022 publications related to BancoWeb prevented its characterization from being restricted to the state documented in 2011, whereas analysis of the BR-UNIFESP publication enabled examination of its technical and clinical resources and identification of relevant documentary limitations.

The contribution of the study lies in organizing documented resources according to their possible function in different XAI experimental designs without using nominal numbers of images, patients, cases, or variables as isolated measures of suitability. The interpretation was structured by considering technical heterogeneity, clinical structuring, representativeness, and the availability of references compatible with specific analysis modalities.

A. Technical Heterogeneity and Interoperability Potential

The 2018 and 2022 sources document approximately 1,900 real mammographic images for BancoWeb at those times, whereas BR-UNIFESP is described as containing 941 images from 100 cases [4], [13], [14]. These quantities do not allow the conclusion that one database is larger in terms of individuals, examinations, or information volume because “patient,” “case,” and “image” are not necessarily equivalent units.

Differences in acquisition are also documented. A predominant portion of BancoWeb is derived from digitized mammographic films, although later sources include approximately 200 images from DR equipment [13], [14]. BR-UNIFESP is described as containing images acquired digitally using a GE Senographe Pristina 3D system and includes tomosynthesis in 62% of cases [4].

These differences may imply distinct needs regarding preprocessing, resolution, file structure, and metadata use. Therefore, any integration of the two sources would likely require some degree of technical harmonization. This consideration is a methodological inference based on documented differences and not the result of an interoperability test performed in this study.

In addition, because BancoWeb files were not directly inspected, it is not possible to state that the collection currently

TABLE I
DOCUMENTED CHARACTERISTICS OF THE BRAZILIAN MAMMOGRAPHY DATABASES

Characteristic	BancoWeb/LAPIMO-USP	BR-UNIFESP
Composition and units of count		
Institution	USP/EESC – LAPIMO	UNIFESP/Hospital São Paulo
Clinical unit declared by the source	Patient in the original publication	Case
Quantity according to the declared clinical unit	Approximately 320 patients in the 2011 publication	100 anonymized cases
Number of images as reported by the sources	Approx. 1,400 in 2011; in 2018, 1,703 digitized + 196 DR; in 2022, approx. 1,700 digitized + 200 DR	941 images
Phantom images	611 in 2018; approximately 600 in 2022	Not documented in the consulted sources
Acquisition, period, and formats		
Acquisition period	Different periods; not presented as a single comparable interval in the sources used	2019–2023
Declared acquisition	Digitized films and images from DR systems	Digital mammography; GE Senographe Pristina 3D
Documented formats	TIFF and DICOM described in the updates	DICOM; other formats also described in the publication
Bit depth/resolution	12 bits; 0.085 or 0.150 mm for the digitized set	Not documented in an equivalent manner in the consulted publication
Tomosynthesis	Not documented as a component of the clinical dataset	Present in 62% of cases
Clinical information and resources potentially related to XAI		
Clinical/radiological information	Reports, BI-RADS, findings, and patient, examination, and image information	BI-RADS descriptors; clinical, anatomopathological, and immunohistochemical information
Number of searchable variables	Not presented as a single equivalent count	169 in the abstract/results; 113 in a later section of the same publication
ROI/cropping tool	Available	Not documented in an equivalent manner
Clinical spatial annotations	Few previously demarcated regions in the original publication	Complete masks or bounding boxes for all lesions not documented
Localization template	Available for phantom images, with information on type and location of simulated structures	Not documented
Structured search	Search by different characteristics and a specific phantom module	Combinatorial search using multiple clinical and radiological attributes
Access conditions and observation		
Declared access condition	Free upon registration authorized by the administrator, according to the consulted sources	Free upon registration and administrative approval
Observation in this study	Files not directly inspected; current state of the collection not audited	Registration completed; access to examinations not granted after 72 hours

Source: Matheus and Schiabel [3], Cordeiro et al. [4], Rodrigues [13], and Schiabel et al. [14]. Quantities from different years represent documentary records of distinct stages in the evolution of the platforms. Patient, case, and image values are presented according to the units declared by the sources and do not assume quantitative equivalence between the databases. "Not documented" does not mean nonexistent. Patient, case, clinical image, tomosynthesis-associated content, and phantom image represent distinct documentary units.

available fully reproduces the state described by the 2018 and 2022 sources.

The attempt to access BR-UNIFESP added a limited operational observation to the analysis. The publication characterizes the platform as freely accessible after registration and approval [4]. In the request made during this review, access was still unavailable after 72 hours. This occurrence does not demonstrate general unavailability and does not allow estimation of the frequency of delays or denials, but it indicates that "free access upon registration" should not be interpreted as synonymous with immediate access.

B. Clinical Structuring and Limits of Representativeness

BancoWeb is described as associating images with reports, findings, and information on examinations and patients and as providing mechanisms for searching by specific characteristics [3], [13]. BR-UNIFESP presents a structure based on numerous clinical, radiological, and anatomopathological descriptors and allows combinatorial retrieval of cases [4].

These characteristics suggest informational richness but do not demonstrate population representativeness. BR-UNIFESP initially selected 100 cases prioritizing didactic representations of typical findings [4]. For BancoWeb, the images were obtained over different periods and from different institutions [3], [13]. The analyzed sources do not demonstrate that the distribution of characteristics in either database reproduces the distribution of mammographic examinations performed in the Brazilian population.

Studies based on SISCAN show that variables such as age, region, clinical indication, high-risk status, and BI-RADS classification can be used to characterize mammography production in Brazil [10]–[12]. These studies were used exclusively for health-care and epidemiological contextualization and not as a quantitative standard for establishing representativeness of the two analyzed databases.

The discrepancy between 169 and 113 variables in the BR-UNIFESP publication also demonstrates that a nominal count of fields should not automatically be interpreted as a measure of coverage or completeness. Without direct inspection of the data, it was not possible to determine how many variables are populated in each case, their degree of completeness, or their individual correspondence with each image or lesion.

C. Annotations, Diagnostic References, and Explainable Artificial Intelligence

The documentary analysis allowed identification of potential correspondences between certain available resources and different modalities of XAI investigation without experimentally demonstrating that such resources improve explanation quality.

For spatial-analysis protocols, BancoWeb presents potentially relevant documentary resources. Clinical images may be submitted to region-of-interest selection, although this tool does not represent a reference annotation previously available for the entire database [3], [13]. In the phantom dataset, simulated structures have known locations through templates associated with the images [13], [14].

This resource allows the design of experiments in which a region identified by a computational method is compared with a previously known position. However, spatial agreement between an explanation and a region of interest does not, by itself, demonstrate fidelity of the explanation to the model's decision-making mechanism [8], [9]. Furthermore, results obtained with phantoms do not replace validation on clinical images.

For semantic or concept-based approaches, BR-UNIFESP provides documentary resources such as BI-RADS descriptors and clinical, anatomopathological, and immunohistochemical information [4]. These elements may provide references for investigating associations between documented concepts and model predictions. Their experimental use, however, will depend on the completeness, quality, and effective linkage of these fields to the corresponding images, aspects not verified in this study.

For example-based approaches, the combinatorial search described for BR-UNIFESP constitutes a potential documentary resource for retrieving cases with similar clinical or radiological characteristics. This does not, by itself, mean that the platform validates example-based explanations because the quality of such explanations will also depend on the model, similarity metrics, and experimental criteria used.

For investigations involving three-dimensional data, the documented presence of tomosynthesis in 62% of cases constitutes a specific characteristic of BR-UNIFESP [4]. The quantity, structure, and effective linkage of these three-dimensional data, however, could not be directly audited.

Therefore, the results do not support an overall classification of one database as superior to the other. BancoWeb documents references potentially usable in certain localization analyses and controlled phantom experiments, whereas BR-UNIFESP documents clinical, radiological, anatomopathological, attribute-based retrieval, and tomosynthesis resources potentially applicable to other experimental designs. The effective suitability of any of these resources depends on direct inspection and experimental validation.

D. Summary of the Contribution

In summary, the analysis identifies four documentary dimensions useful for preliminary selection of databases intended for XAI research: technical acquisition and storage characteristics; availability and structure of clinical metadata; presence of diagnostic references; and existence of annotations or other elements compatible with the type of explanation being investigated.

This framework is analytical and organizational in nature and does not constitute a validated instrument for database assessment, nor does it demonstrate operational compatibility or superiority of any of the analyzed datasets.

VI. Conclusion

This study conducted a technical-comparative documentary characterization of BancoWeb/LAPIMO-USP and BR-UNIFESP considering composition, acquisition modality, formats, clinical information, diagnostic references, annotations, search mechanisms, and access conditions.

Inclusion of the 2018 and 2022 sources related to BancoWeb complemented the original 2011 publication and represented its documentary evolution. These records describe approximately 1,900 real mammographic images derived from digitized films and DR systems, in addition to approximately 600 phantom images. However, because the files were not directly inspected, these quantitative values should be interpreted as characteristics documented in the respective sources and not as an audit of the collection currently available.

BR-UNIFESP is described as containing 941 images from 100 cases, digital acquisition, DICOM format, tomosynthesis in 62% of cases, and numerous clinical, radiological, and anatomopathological descriptors. An internal discrepancy was identified in the publication itself regarding the number of searchable variables, reported as 169 in some sections and 113 in another, making it impossible to establish a definitive number exclusively from the source.

Patients, cases, clinical images, and phantom images were treated as distinct documentary units. Consequently, their quantitative values do not allow a direct comparison of the clinical size of the databases or the establishment of an overall hierarchy between them.

Direct inspection of the datasets was also not possible. For BR-UNIFESP, registration was completed during revision of this study, but access to the examinations had not yet been authorized after 72 hours. This isolated occurrence does not allow a conclusion of general unavailability of the platform. BancoWeb files were also not directly audited.

The findings suggest that, in the preliminary selection of a database for XAI research, the type of explanation being investigated and the reference required for its evaluation should be considered jointly, rather than relying solely on the nominal number of images or variables.

BancoWeb documents resources with potential correspondence to localization protocols and controlled experiments using phantoms, whereas BR-UNIFESP documents resources potentially applicable to semantic, contextual, concept-based, example-retrieval, and tomosynthesis investigations. These correspondences represent documentary potential and do not constitute validation of explanation fidelity, robustness, causality, performance, or clinical utility.

Future studies should obtain direct access to the datasets, verify file integrity and structure, clarify units of count, evaluate metadata coverage and completeness, confirm correspondence between clinical information and images, examine the quality and scope of spatial annotations, and experimentally test XAI techniques using previously defined criteria for fidelity, robustness, spatial agreement, and clinical utility.

***Abstract*—Breast cancer represents one of the most significant public health challenges in Brazil, with 64,437 diagnosed cases and approximately 21,000 deaths recorded in 2024. Mammography is the primary technique used to screen for the disease; however, its interpretation is subject to human limitations, such as fatigue, interpretative variability, and varying levels of clinical experience. In this context, the present study utilized 2,796 mammographic images from the public IRMA database, which were subjected to feature extraction using the EfficientNet-B0 deep learning network. The extracted features were provided as input to the following machine learning classifiers: Naive Bayes, BayesNet, Random Tree, Random Forest, SVM, and MLP. These were evaluated in two scenarios: Dataset 1, comprising the full set of 1,280 features, and Dataset 2, comprising 444 features selected by the Particle Swarm Optimization (PSO) algorithm. The Random Forest model with 500 trees achieved the best performance, reaching an accuracy of 76.82% and a kappa index of 0.65 in Dataset 1, and an accuracy of 75.40% with a kappa of 0.63 in Dataset 2, with an AUC of 0.88 in both cases. The results demonstrated that a reduction of approximately 65% in the number of features preserved the predictive performance of the models, indicating the efficacy of PSO in reducing dimensionality and computational cost. Furthermore, the confusion matrices demonstrated the system's robust ability to distinguish healthy individuals from those with benign or malignant breast tumors, highlighting the potential of the proposed approach as an auxiliary tool in screening, triage, and clinical prioritization strategies.**

***Index Terms*—breast cancer, mammography, artificial intelligence, classification.**

I. Introduction

Breast cancer represents a major public health challenge due to its high incidence and mortality rates. Excluding non-melanoma skin cancer, it is the most frequently diagnosed neoplasm among women and constitutes one of the leading causes of cancer-related mortality in the female population. In Brazil, data from the Department of Informatics of the Unified Health System (DATASUS) indicate that in 2024, 64,437 cases of the disease were recorded, of which 63,360 occurred in women and 1,077 in men [1]. Furthermore, the National Cancer Institute (INCA) recorded approximately 21,000 deaths associated with breast cancer during the same period [2].

Breast cancer is characterized by the uncontrolled proliferation of abnormal cells in the breast tissue. The disease can be classified as *in situ*, when it remains confined to its site of origin, or invasive, when it is capable of infiltrating adjacent tissues and spreading to other organs. Its development is

associated with genetic, hormonal, environmental, and lifestyle factors. The primary clinical signs include the presence of a breast nodule, progressive enlargement of the breast, and axillary lymphadenopathy [3].

Early detection of this disease is imperative to mitigate cancer progression and reduce mortality. Among the primary detection techniques, mammography stands out as an imaging modality that utilizes low-dose X-rays to visualize the internal structure of the breast. It is considered the gold standard for breast cancer screening due to its ability to detect microcalcifications and non-palpable nodules [4].

Although mammography is the most reliable non-invasive method currently utilized in clinical practice, the analysis of mammographic images remains a task that relies directly on the radiologist's interpretation. Consequently, subtle patterns within the images and external factors, such as fatigue, heavy workloads, interobserver variability, and limitations related to clinical experience, can influence the diagnostic outcome. In light of these limitations, advances in Artificial Intelligence and deep learning techniques have emerged as a promising strategy to assist radiologists in establishing a diagnosis, as these methods can identify patterns in the examinations that might otherwise go unnoticed by the evaluator, accelerate the analysis process, automate triage steps, and highlight suspicious regions within the images, particularly in contexts characterized by a shortage of specialists [5], [6].

In this context, the present study proposes comparing various mammographic image classification techniques leveraging artificial intelligence, with the objective of identifying the highest-performing approach for breast cancer diagnosis and contributing to the development of more efficient and accessible screening systems. To this end, mammographic images from the public IRMA database were utilized and subjected to feature extraction via the pre-trained deep neural network EfficientNet-B0, followed by the application of machine learning classifiers and the Particle Swarm Optimization (PSO) feature selection algorithm.

II. Related Work

Wang [7] presented a comprehensive review of deep learning applications in mammography for breast cancer detection and classification. The analyzed studies highlight the predominance of convolutional architectures, such as U-Net, ResNet, VGG, Inception, and Faster R-CNN. In detection and classification tasks, accuracies exceeding 95% were reported on public datasets, including DDSM, INbreast, CBIS-DDSM, and BCDR. However, many studies lack complementary metrics, such as sensitivity and specificity, hindering a more comprehensive evaluation of model performance. Furthermore, the review highlights the use of transfer learning, attention mechanisms, and ensemble strategies, which have contributed to the reduction of false positives and the enhancement of diagnostic sensitivity.

Despite their promising performance, Wang [7] highlights significant challenges regarding the clinical adoption of these approaches. Among the primary limitations are the reliance on large volumes of annotated data, the scarcity of multicenter and heterogeneous datasets, the high computational costs associated with training deep learning models, and the difficulties in generalizing across different institutions and imaging equipment. Furthermore, issues related to model interpretability, data privacy, and the standardization of acquisition protocols continue to represent barriers to the routine integration of deep learning-based systems into breast cancer screening and diagnosis.

Prodan et al. [8] investigated the application of various deep learning architectures for mammographic image analysis, including convolutional models such as ResNet and EfficientNet, as well as vision transformer-based architectures like MaxViT. The study utilized the RSNA dataset, which is characterized by severe class imbalance, and evaluated preprocessing strategies, transfer learning, and data augmentation through the generation of synthetic images using StyleGAN-XL. The results demonstrated that the artificial augmentation of the minority class yielded substantial improvements in the Area Under the Receiver Operating Characteristic Curve (AUC-ROC), sensitivity, and F1-score metrics, even when accuracy exhibited slight reductions. Furthermore, relatively simple models, such as ResNet18, achieved performance comparable to that of more complex architectures, demonstrating that appropriate preprocessing and class balancing strategies can exert a greater influence on overall performance than merely increasing classifier complexity.

The authors emphasized, however, that the high accuracy observed in certain scenarios must be interpreted with caution, particularly in highly imbalanced datasets. In several experiments, models achieving accuracies approaching 95% exhibited low precision, sensitivity, and F1-score values, indicating limitations in the identification of positive cases. Consequently, relying solely on accuracy can lead to overly optimistic interpretations of model performance, masking the difficulties associated with detecting the minority class. Notable limitations include the individual classification of mammograms without considering multiple views of the same patient, as well as the generation of synthetic images exclusively for the positive class; these factors may restrict the generalizability of the models in real-world clinical applications [8].

Manigrasso et al. [9] investigated deep learning architectures for mammogram classification, exploring convolutional models, graph-based architectures, and vision transformers in a weakly supervised learning scenario. The study evaluated strategies capable of simultaneously integrating the four standard mammographic views, corresponding to the craniocaudal (CC) and mediolateral oblique (MLO) projections of both breasts. The results demonstrated that transformer-based architectures exhibited superior performance, achieving AUC values of up to 80.3% for cancer detection, while the convolutional and graph-based architectures achieved AUCs of approximately 74.9%. The authors also observed that different architectures exhibit distinct sensitivities to specific mammographic features, indicating that combined approaches can yield more robust results than individual classifiers. Fur-

thermore, the study highlighted that transformers rely on appropriate pre-training strategies and tend to benefit from larger datasets, whereas graph-based models exhibited high sensitivity to the initialization process and image preprocessing. Additionally, the validation was conducted at a single institution, underscoring the need for multicenter studies to evaluate the generalizability of the models.

In light of the limitations observed in the literature, this study proposes a hybrid approach based on the use of a pre-trained EfficientNet-B0 as an automatic feature extractor, combined with shallow classifiers. This strategy aims to reduce the computational cost associated with training deep architectures from scratch while simultaneously leveraging the feature representation capabilities of pre-trained models. Additionally, feature selection techniques are investigated to reduce the dimensionality of the feature space, mitigate the effects of the curse of dimensionality, and potentially enhance the generalization capability of the classifiers. The use of shallow models also enhances decision interpretability, a crucial aspect for healthcare applications and for the development of more transparent clinical decision support systems. Finally, the experimental evaluation is conducted using multiple performance metrics—including accuracy, sensitivity, specificity, precision, F1-score, and AUC—to ensure a more comprehensive and robust analysis of model behavior, particularly in scenarios characterized by class imbalance.

III. Methodology

A. Proposal

This study proposes a hybrid approach for breast cancer diagnostic support using mammographic images from the public IRMA database. The methodology comprises the utilization of a pre-trained EfficientNet-B0 architecture for automated feature extraction, followed by the application of machine learning classifiers. Additionally, the impact of feature selection via PSO algorithm was investigated, aiming to reduce data dimensionality and identify subsets of the most relevant features for classification. Model evaluation was conducted using multiple performance metrics, including accuracy, sensitivity, specificity, precision, F1-score, and AUC-ROC. The complete methodological workflow, from the acquisition of images from the public IRMA database to the comparative analysis of the results, is presented in Figure1. The following subsections detail each step of the methodology employed in this study.

B. Database

This study utilized images from the IRMA database, which were sourced from multimodal public databases (DDSM, MIAS, LLNL, and the RWTH dataset) acquired during routine clinical practice. All images were consistently encoded using the IRMA ontology, a mono-hierarchical and multiaxial classification system. This encoding scheme employs four primary axes to describe the imaging technique (modality and resolution), projection (CC or ML views), anatomy (right or left breast), and biosystem (ACR tissue density, BI-RADS

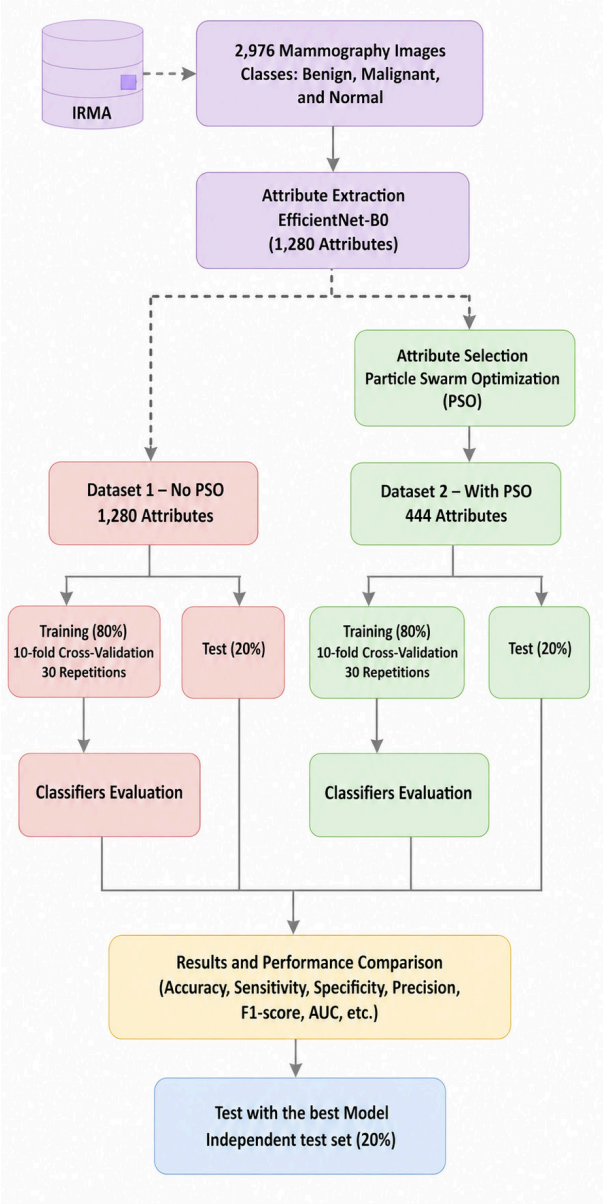

Fig. 1. Proposed method.

tumor stage, and lesion type) [10], [11]. Following integration, the reference database comprised a total of 10,509 images. For the present study, only mammographic images were selected, totaling 2,796, which were distributed across three balanced classes: benign, malignant, and normal.

C. Feature extraction

Initially, the images underwent a feature extraction process using the EfficientNet-B0 deep neural network as a feature extractor, implemented in Weka software version 3.8.6. This step utilized a transfer learning strategy, leveraging the features previously learned by the network during its pre-training on the ImageNet dataset. The network was configured to process input images resized to 28×28 pixels in a single channel (grayscale), followed by average pooling (AVR). Conse-

quently, EfficientNet-B0 served as the feature extractor for the IRMA mammographic images, generating 1,280-dimensional feature vectors that were utilized in the subsequent feature selection and classification stages.

D. Feature selection

Subsequently, the application of the PSO algorithm for feature selection was evaluated to reduce dimensionality and identify the most relevant features for the task. This algorithm addresses the optimization problem by generating a population of candidate solutions that navigate the search space, inspired by the movement of animal swarms, in pursuit of the optimal solution [12]. The application of PSO resulted in the selection of 444 features, corresponding to a 65% reduction relative to the original feature set.

E. Classification

Accordingly, the experiments were conducted using two datasets: Dataset 1, containing the complete set of extracted features (2,796 images or instances and 1,280 features), and Dataset 2, comprising only the features selected by PSO (444 features). Each dataset was then randomly partitioned into training (80%) and testing (20%) sets without overlap, utilizing the Resample filter in Weka. The following classifiers were applied to the training set: Naive Bayes, BayesNet, Multilayer Perceptron (MLP) with one hidden layer of 50 neurons, Random Tree (RT), Random Forest (RF) with 100, 300, and 500 trees, and Support Vector Machine (SVM), varying the kernel used (polynomial of degree 1, degree 2, and RBF). Each classifier was evaluated using 10-fold cross-validation with 30 repetitions.

During the training phase, each classifier configuration was evaluated using the following metrics: Accuracy, Kappa index, Sensitivity, Specificity, and AUC-ROC. Finally, the best-performing classifier was selected for the independent testing phase, where the remaining 20% of instances were classified. During this stage, a confusion matrix was generated to facilitate a more comprehensive evaluation.

IV. Results and Discussion

Tables I and II present the mean values and standard deviations obtained from the experiments conducted on the training sets of Dataset 1 and Dataset 2, respectively, utilizing 10-fold cross-validation with 30 repetitions. In both scenarios, the Random Forest classifier with 500 trees achieved the highest mean accuracy and Kappa index values, reaching $73.20 \pm 2.39\%$ and 0.60 ± 0.04 for Dataset 1, and $73.14 \pm 2.49\%$ and 0.60 ± 0.04 for Dataset 2. Furthermore, this model also yielded the highest mean specificity of 0.87, alongside competitive performance in sensitivity and AUC-ROC. The similarity between the results obtained across the two datasets demonstrates that the approximately 65% reduction in the number of features did not lead to significant performance degradation, reinforcing the potential of PSO as a strategy for mitigating the curse of dimensionality and reducing computational costs in breast cancer diagnostic support systems.

Note: ★ = Best performance; SD = Standard Deviation

TABLE II
EVALUATION METRICS FOR BASE 2 DURING THE TRAINING STAGE.

Table 2 – Evaluation metrics: Base 2 (444 attributes, with PSO)					
Classifier	**Accuracy (%)** Mean ± SD	**Kappa** Mean ± SD	**Sensitivity** Mean ± SD	**Specificity** Mean ± SD	**AUC ROC** Mean ± SD
BayesNet	70.11 ± 2.52	0.55 ± 0.04	0.70 ± 0.03	0.85 ± 0.01	0.86 ± 0.02
Naive Bayes	67.64 ± 2.40	0.51 ± 0.04	0.68 ± 0.02	0.84 ± 0.01	0.85 ± 0.01
Random Tree	68.58 ± 2.67	0.53 ± 0.04	0.69 ± 0.03	0.84 ± 0.01	0.76 ± 0.02
Random Forest (100)	72.31 ± 2.58	0.58 ± 0.04	0.72 ± 0.03	0.86 ± 0.01	0.87 ± 0.01
Random Forest (300)	72.89 ± 2.81	0.59 ± 0.04	0.73 ± 0.03	0.86 ± 0.01	0.87 ± 0.03
Random Forest (500) ★	**73.14 ± 2.49**	**0.60 ± 0.04**	**0.73 ± 0.02**	**0.87 ± 0.01**	**0.88 ± 0.01**
SVM degree 1	66.27 ± 1.00	0.49 ± 0.01	0.66 ± 0.01	0.83 ± 0.00	0.83 ± 0.01
SVM degree 2	65.67 ± 1.14	0.49 ± 0.49	0.66 ± 0.66	0.83 ± 0.01	0.82 ± 0.02
SVM RBF	65.55 ± 1.11	0.48 ± 0.02	0.66 ± 0.01	0.83 ± 0.01	0.82 ± 0.01
MLP	65.77 ± 1.97	0.49 ± 0.03	0.66 ± 0.02	0.83 ± 0.01	0.83 ± 0.01

Note: ★ = Best performance; SD = Standard Deviation

This performance is likely attributable to the randomness inherent in the operation of the Random Forest algorithm. Rather than searching for the optimal feature across the entire dataset, the algorithm constructs multiple decision trees based on smaller subsets and selects the best feature from among them. This ensures that diverse feature combinations are trained independently, thereby enhancing the model's robustness against noise and overfitting.

Regardless of the kernel employed, the SVM classifiers were distinguished by their superior consistency in performance, yielding the lowest standard deviations in accuracy among all tested models. This indicates enhanced stability and predictability on this dataset, despite achieving lower mean accuracies compared to the Random Forest-based models. Such consistency is a highly desirable characteristic for clinical applications, as system reliability is as critical as mean accuracy.

Overall, sensitivity values ranged predominantly from 0.66 to 0.73, whereas specificity values ranged from 0.83 to 0.87. Sensitivity represents the model's ability to correctly identify positive instances, making it a metric of paramount importance

in healthcare applications. Low sensitivity values can indicate an increased false-negative rate, meaning that individuals affected by the condition are incorrectly classified as healthy. Conversely, the high observed specificity suggests that the model is highly effective at correctly identifying negative cases, thereby reducing false alarms that could cause undue patient anxiety.

Notably, the MLP classifier exhibited unstable and inferior performance compared to the other models in Dataset 1, achieving an accuracy of 49.65% with a standard deviation of 16.20. However, it subsequently yielded results comparable to the average of the other models in Dataset 2, with an accuracy of 65.77% and a standard deviation of 1.97%. This demonstrates that redundant features can adversely affect models that are particularly sensitive to data dimensionality, and that feature selection can serve as a regularization step to stabilize the learning process. In addition to its suboptimal performance in Dataset 1, this classifier required a significantly high processing time, a critical factor rendering it impractical for routine use.

Accuracy results, the primary metric used to determine the best-performing classifier, are also presented as boxplots in Figures 2 and 3. It is evident that the Random Forest models exhibited not only the highest median accuracy values but also relatively low dispersion, demonstrating robust stability across the multiple cross-validation runs. In particular, the Random Forest (500) model achieved a median accuracy of approximately 73% across both datasets, corroborating the mean results reported in the tables. Similarly, the BayesNet classifier demonstrated consistent performance, with its distribution concentrated around an accuracy of 70%.

Conversely, the MLP classifier exhibited distinct behavior across the two feature sets. In Dataset 1, a high dispersion of results was observed, reflected by a large interquartile range and the presence of outliers, indicating high sensitivity to the training set and the potential influence of high data dimensionality. Following the application of PSO, a significant reduction in the MLP's variability was evident, accompanied by a substantial increase in median accuracy, which rose from approximately 50% to values near 65%. This behavior suggests that the reduction in the feature space enhanced the generalization capability of this classifier, rendering it less susceptible to overfitting.

The support vector machine classifiers exhibited highly concentrated distributions across both datasets, indicating high robustness and repeatability of the results. However, their median values remained lower than those achieved by the Random Forest models, ranging between 65% and 66% accuracy.

Following the identification of the best-performing classifier during the training phase, the evaluation proceeded on the test set. The performance of the Random Forest model with 500 trees at this stage is illustrated by the confusion matrices presented in Figure 4.

In both scenarios, all mammograms belonging to the Normal class were correctly classified, demonstrating the model's high capacity to distinguish healthy tissue. Furthermore, the

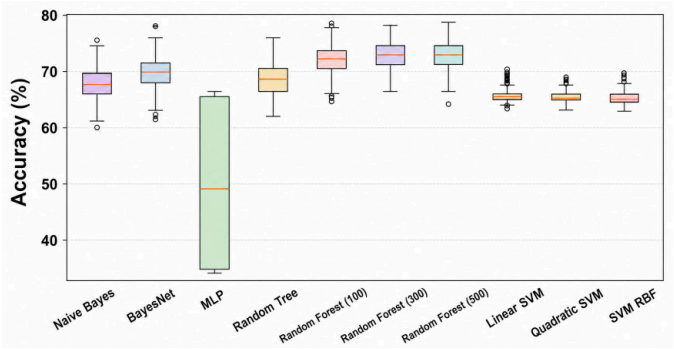

Fig. 2. Comparative boxplot of classifier accuracy on Dataset 1.

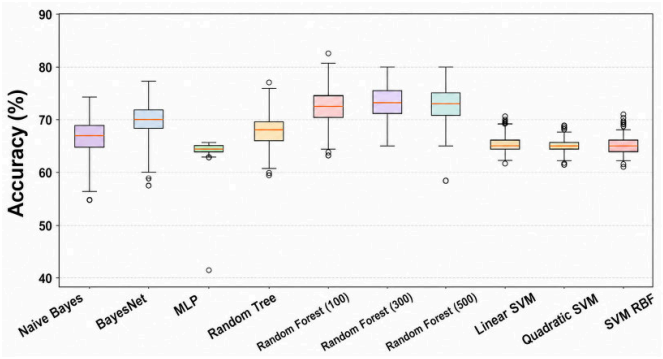

Fig. 3. Comparative boxplot of classifier accuracy on Dataset 2.

Confusion Matrix — Base 1 (without PSO) | Random Forest 500

		Predicted		
		Normal	Malignant	Benign
Actual	Normal	**187**	0	0
	Malignant	0	**116**	71
	Benign	0	59	**128**

Accuracy: 76.82% Kappa: 0.65

Confusion Matrix — Base 2 (with PSO) | Random Forest 500

		Predicted		
		Normal	Malignant	Benign
Actual	Normal	**187**	0	0
	Malignant	0	**109**	78
	Benign	0	60	**127**

Accuracy: 75.40% Kappa: 0.63

Fig. 4. Confusion matrices at the testing stage for the Random Forest classifier with 500 trees.

results obtained for Dataset 1 and Dataset 2 were highly comparable, reinforcing that feature reduction did not significantly compromise the model's performance. The primary classification challenges occurred between the Benign and Malignant classes, indicating the presence of shared mammographic features between these categories. In Dataset 1, 71 malignant cases were misclassified as benign and 59 benign cases were misclassified as malignant, resulting in an accuracy of 76.82% and a Kappa index of 0.65. In Dataset 2, the errors corresponded to 78 malignant samples misclassified as benign and 60 benign samples misclassified as malignant, yielding an accuracy of 75.40% and a Kappa index of 0.63.

Although the accuracy achieved in the independent test was lower than that reported in some studies in the literature, yielding 76.82% for Dataset 1 and 75.40% for Dataset 2, the results must be evaluated in conjunction with the other metrics. Wang [7] reviewed studies reporting accuracies exceeding 95%; however, many of these failed to report sensitivity and specificity, or presented low values for these metrics, in some cases below 0.30. This distinction is crucial, as relying solely on accuracy can mask significant limitations, particularly in imbalanced datasets. In the present study, in addition to accuracy, the Kappa index, sensitivity, specificity, and AUC-ROC were evaluated, with all metrics remaining stable above 0.60. Furthermore, the confusion matrices demonstrated that the model correctly distinguished normal cases from those presenting breast lesions, whether benign or malignant. This capability holds high clinical relevance. In screening applications, the accurate identification of patients with suspected tumors can facilitate the prioritization of complementary examinations, specialized referrals, and expedited clinical decision-making, thereby contributing to the establishment of more efficient triage workflows.

Regarding computational cost, studies such as those by Prodan et al. [8] and Manigrasso et al. [9] highlight that deep architectures, including complex CNNs, vision transformers, and multiview models, often require large volumes of data, substantial computational power, and costly training processes. The proposed methodology offers a simpler alternative by utilizing the pre-trained EfficientNet-B0 exclusively for feature extraction, followed by shallow classifiers. This strategy eliminates the need to train deep networks from scratch and facilitates deployment in scenarios with limited computational resources. Furthermore, models such as Random Forest provide greater interpretability compared to deep architectures, which may enhance their acceptance in healthcare applications. Nonetheless, the present study has limitations regarding explainability, as visual techniques, such as activation maps, were not employed to highlight the most relevant mammographic regions influencing the model's decisions.

V. Conclusion

This study aimed to investigate the use of artificial intelligence techniques for breast cancer diagnostic support based on mammographic images. To this end, a hybrid approach was proposed, relying on automatic feature extraction via the pre-trained EfficientNet-B0 architecture, followed by the application of shallow machine learning classifiers. Additionally, the impact of feature selection using the Particle Swarm Optimization algorithm was evaluated, aiming to reduce data dimensionality and enhance the computational efficiency of the system.

The results demonstrated that the Random Forest classifier with 500 trees achieved the best performance among the evaluated approaches, attaining an accuracy of 76.82%, a Kappa index of 0.65, and an AUC-ROC of 0.87 on the independent test set. Furthermore, the application of PSO was shown to reduce the number of features by approximately 65% while preserving model performance. The confusion matrices indicated the system's robust ability to distinguish healthy individuals from those with benign or malignant breast lesions. This capability is particularly relevant in screening and triage applications, where the early identification of patients requiring further investigation can facilitate clinical prioritization and optimize the healthcare workflow.

Despite the promising results, certain limitations must be acknowledged. The achieved performance remains below the level of reliability required for autonomous clinical application, underscoring that the proposed methodology should be regarded strictly as a medical decision support tool. Furthermore, the features extracted by EfficientNet-B0 exhibit limited clinical interpretability, as they lack a direct correspondence with specific anatomical characteristics or established radiological findings.

Regarding future perspectives, this study highlights the validation of the methodology on multicenter and external datasets, as well as the investigation of alternative feature selection strategies. Additionally, the exploration of hybrid architectures integrated with interpretability methods could enhance the reliability and acceptance of these tools in clinical settings, fostering the development of more transparent and efficient diagnostic support systems that are closely aligned with the demands of healthcare services.

A Comparative Study on the Use of Clinical Stratification for Predicting Hospital Length of Stay

João Victor Carneiro Faria, Nycolas Mariotto, Janderson Souza,
Luis Gustavo Modelli Andrade, Allan Felipe Fattori Alves
Universidade Estadual Paulista (UNESP)
Botucatu, SP, Brazil
joao.faria@unesp.br

***Abstract*—The length of stay in the hospital (LOS) is a key indicator of hospital resources management, influencing bed occupancy, staff size, admission planning, and care costs, in addition to being associated with complications and clinical outcomes. However, LOS prediction is challenging. LOS varies widely from patient to patient, since most hospital stays last only a few days while some extend for weeks, and this dispersion reflects quite distinct clinical profiles within the same hospital population. This work proposes dividing the hospital database into clinical groups already recognized in routine care, defined by specialists, to assess whether stratification improves LOS prediction. This clinical division is compared against an automatic division obtained through unsupervised clustering (KMeans) and against a single model that was fitted to the entire dataset. Three models were trained using electronic health records stored in the hospital database. *k-nearest neighbors* (KNN), *Random Forest*, and *XGBoost*, each with hyperparameters optimized on the complete dataset and kept fixed when segmenting the manual and automatic groups, respectively. This guarantees that only the method of dividing patients varies across approaches. Clinical division outperformed the single model ($R^2 = 0.63$) in five of the six groups, reaching R^2 values of up to 0.72, whereas automatic clustering via KMeans outperformed the single model in only one of the four groups. The results suggest that in this experiment, clinical stratification was more consistent in identifying predictively useful subgroups, although the performance of automatic stratification may vary depending on the clustering method employed. *Random Forest* and *XGBoost* performed similarly to other and better than KNN. SHAP-based interpretability analysis reinforces this result and reveals which groups remain internally heterogeneous. Subdividing by diagnostic chapter reduced the error in the surgical and elderly medical groups, with reductions of up to 19.4% in RMSE, but did not benefit every subset. The results show that specialist clinical knowledge guides the model more effectively than automatic division using KMeans, and that interpretability allows for the progressive refinement of this division.**

***Index Terms*—length of stay, machine learning, clinical stratification, clustering, interpretability, and hospital management.**

I. Introduction

Hospital length of stay (LOS) is one of the most widely used measures in hospital management. Since beds are a limited resource, LOS simultaneously functions as an indicator of occupancy, of care cost, and as an indirect indicator of complications and the degree of recovery [1], [2]. Anticipating a patient's length of stay therefore has a direct impact on staff sizing, capacity forecasting, and admission flow [3].

However, LOS prediction presents specific challenges. Its distribution is strongly right-skewed, with most hospital stays concentrated in a few days and a long tail of prolonged cases that dominates the error and penalizes models fitted to the original scale [1]. In addition, traditional statistical models, with few variables and poorly standardized data, are difficult to reproduce in the general population [4].

Given these limitations, machine learning applied to electronic health record data has become established as a promising approach for predicting complex outcomes, such as LOS [1], [5]. Among the available methods, ensemble decision-tree models, such as *Random Forest* and *XGBoost*, achieve good predictive performance and allow the contribution of the variables used by the model to be analyzed [3], [6]. This interpretability is particularly relevant in clinical applications, in which understanding the factors associated with predictions can aid in analyzing the results [4].

The literature on LOS predictions is extensive. Some studies predict only whether a stay will be long in a categorical form [2], while others predict the number of days [6], [7] across varied populations. In these comparisons, tree-based models, especially *XGBoost*, tend to show the best performance [3], [7]. However, much of this work fits a single model to the entire dataset, pooling patients with very different lengths of hospital stays. Through different approaches, other studies have investigated whether dividing the dataset before modeling improves predictive performance and which division strategy is more appropriate, whether guided by clinical knowledge [1] or obtained through automatic clustering [8]. However, a direct comparison between these two strategies under the same evaluation protocol is lacking.

This study aimed to assess whether a clinical stratification strategy for the dataset, defined by specialists, improves LOS prediction relative to (i) a single model trained on the complete dataset and (ii) an automatic stratification obtained through unsupervised clustering analysis. Three regression models were employed, two based on decision trees and one based on the distance between similar patients, applied to electronic health record data.

Table I
STUDY VARIABLES ACCORDING TO THE MOMENT OF THE HOSPITAL STAY AT WHICH THEY BECOME AVAILABLE.

Moment	Variables
1. Admission	age, sex, admission type, classification, year, month, day, and day of the week of the admission
2. Post-triage	ICD chapter*, occurrence of surgery*
3. Discharge	number of exams, number of antibiotics, patient status†

* allocation subject to the caveats discussed in the text
† excluded from all models

II. MATERIALS AND METHODS

A. Dataset and Target Variable

The target variable in this study is *Length of Stay* (LOS), defined as the patient's hospital length of stay, measured in days and obtained from institutional health records. Data were extracted from the Botucatu Medical School Hospital database and covered admissions occurring between 2015 and 2019. The dataset includes demographic information, admission characteristics, care indicators, diagnostic chapters, and temporal information associated with hospitalization.

Due to the strong positive skew observed in the length-of-stay distribution, the target variable was modeled on a logarithmic scale in order to reduce the influence of extreme values and stabilizes the data distribution. The applied The transformation is defined as

$$y' = \log(1 + y), \tag{1}$$

where y represents the original length of stay in days.

During inference, predicted values are converted back to the original scale through inverse transformation:

$$\hat{y} = e^{y'} - 1. \tag{2}$$

With this approach, the model learns on the logarithmic scale while final predictions remain expressed in days, allowing all metrics to be calculated on the original scale of the target variable.

B. Prediction Timing and Variable Availability

Information about a patient accumulates over the course of their stay, and the model's performance depends on when the prediction is made. Yang *et al.* [9] show this by comparing three stages of a hospital stay, from admission to post-treatment period. Accuracy improves as care data become available, but the useful lead time of the prediction is lost to the same extent. Therefore, the variables used in this study were organized into three moments, as presented in Table I.

The first moment is admission, comprising what is recorded upon entry without depending on the clinical assessment. The second comes after triage, when the team already knows what prompted admission. The third is discharge with closed care records.

Two variables require further consideration. Surgery is usually the second step in the management of these patients; however, in practice, this varies. In elective surgeries, the procedure is known from admission, whereas in urgent admissions, it may arise later. The diagnostic chapter, in turn, reflects a limitation of the dataset, which does not allow us to know whether the recorded code corresponds to the admission diagnosis or principal diagnosis closed at the time of discharge. This distinction is important because the divergence between the two is documented and is associated with differences in the length of stay [10]. We assumed that an equivalent diagnostic assessment was already available shortly after triage, and this simplification was explicitly stated.

The number of examinations and antibiotics was accumulated over the entire stay and belonged to the third moment. The institutional database records the prescription date of each antibiotic and the scheduling date of each exam, which allows them to be cross-referenced with the admission date and to identify how many of these records were already available on day zero, which is considered as future work.

Because it draws on information that is only consolidated over the course of care, the model evaluated here is associative in nature, rather than a predictor designed for use upon admission. Patient status at the end of the stay, recorded as death or discharge, also belonged to the third moment and was removed from all models, being retained only to describe the dataset.

C. Preprocessing

The first step was to audit the database quality and assess its consistency. Exploratory analysis showed that the original database structure generated multiple records for the same admission, creating a new entry for each stay. Records were then consolidated by admission code, such that each admission corresponded to a single row.

After this consolidation step, it was found that, over the period from 2015 to 2019, 142,575 admissions were recorded at the hospital. Records previously reserved as test patients were removed, resulting in a final total of 142,570 admissions available for analysis.

Next, the data types and proportions of missing values were examined for each variable. Records without a valid value for the target variable were removed because the absence of this information precluded supervised training. The database then underwent structural standardization, including the standardization of column names and the conversion of categorical attributes to uppercase.

From the admission date, four new temporal variables were derived corresponding to the year, month, day of the month, and day of the week. The year variable was used to represent possible long-term temporal trends, whereas the others were used to capture seasonal patterns related to admission behavior.

Within the machine learning *pipeline*, it was found that after removing records without a valid target variable, no numeric variable required imputation. Categorical variables

received constant-value imputation and *one-hot* encoding, with handling of categories not observed during training.

D. Stratification Strategies

Three modeling strategies were compared using the same protocol. The first is the *complete dataset*, in which a single model is trained on all patients and serves as a reference.

The second strategy consists of *manual clinical stratification*, in which the dataset is divided by specialists into six groups defined by objective rules based on admission type, classification, and age, with elderly patients defined as those above ≥ 60 years. The six groups were elective surgical, urgent surgical, elective medical, urgent medical, elderly surgical, and geriatric medical admissions groups.

The third strategy corresponds to *automatic stratification* via clustering. For this, the KMeans algorithm was applied in its *MiniBatch* variant, using the same set of variables employed in the supervised models, excluding the LOS. The number of clusters was fixed at four, a value defined based on four standard clustering quality indices: the elbow method inertia, silhouette coefficient, Calinski-Harabasz index, and Davies-Bouldin index.

For each group generated by the three strategies, a model was trained independently, allowing the performance of the global model to be compared directly with that of each of the two stratification methods.

E. Models, Optimization, and Evaluation

Three regression models were evaluated across all groups. The The first is the *k-nearest neighbors* (KNN), which estimates the length of stay based on the patients closest to the case being evaluated, measuring this proximity by the distance between the variables. The other two are ensemble tree models: *Random Forest* [11] combines trees trained independently on subsamples of the data, whereas *XGBoost* [12] builds them sequentially, with each new tree correcting the error left by the previous model.

The hyperparameters were fixed and identical across all modeling strategies. They were determined beforehand through global Bayesian optimization using the Optuna library, which was applied to the aggregated dataset with cross-validation on the training partition. This standardization ensured that the stratification strategy was the only experimental variable.

The evaluation was carried out using a reserved test partition corresponding to 20% of the data, defined once before any adjustment, clustering, or optimization. The partition was constructed at the patient level so that all admissions of a given patient remained entirely on the same split. No patient appeared simultaneously in the training and testing sets. The same partition was used across all three modeling strategies, ensuring that the global model, clinical groups, and *clusters* were evaluated on the same patients. The preprocessing was fitted exclusively to the training partition. The metrics used were the mean absolute error (MAE), root mean squared error (RMSE), and coefficient of determination (R^2), all calculated on the original scale in days. In the auxiliary analyses of subdivision by ICD chapter, subgroups with a number of records below the minimum threshold were discarded.

Table II
CHARACTERIZATION OF MANUALLY DEFINED CLINICAL GROUPS AND THOSE OBTAINED VIA KMEANS.

Group	N	%	Mean	Med.	p75	p90
Elective surgical	41,471	29.1	3.2	2	3	7
Urgent surgical	7,226	5.1	9.0	6	11	20
Urgent medical	81,353	57.1	6.1	3	7	14
Elective medical	12,520	8.8	9.2	4	10	22
Elderly medical	22,800	16.0	8.2	5	10	19
Elderly surgical	16,497	11.6	4.5	2	5	12
Clusters (KMeans)						
Cluster 0	29,860	20.9	11.6	6	14	27
Cluster 1	37,187	26.1	5.0	3	6	11
Cluster 2	42,434	29.8	3.0	2	3	7
Cluster 3	33,089	23.2	4.3	3	5	9

All random operations used fixed seeds. The interpretability of the tree-based models was obtained using SHAP values [13], which quantify the contribution of each variable to the prediction of each model. This is an attribution internal to the model, not a measure of the causal effect on length of stay. The columns generated by *one-hot* encoding were grouped according to the original variables they represented.

F. Nested Stratification by Diagnostic Chapter

As a complementary analysis, each clinical group was subdivided according to the diagnostic chapter, generating nested subgroups of the form *clinical group* $\times$ *diagnostic chapter*. The goal of this step was to characterize how the length of stay and predictive error varied across different diagnostic chapters within the same clinical profile, without seeking to optimize the overall performance.

This analysis was applied exclusively to the tree-based models, *Random Forest* and *XGBoost*, because they showed better overall performance and greater robustness on smaller subsets than KNN.

Within each subgroup, the diagnostic chapter was constant by definition; therefore, was removed from the set of predictors. The remaining variables, preprocessing, logarithmic transformation of the target variable, and previously optimized hyperparameters, were kept unchanged, such that the only difference relative to the previous analysis was the level of detail in the grouping.

G. Ethical Aspects

This study was approved by the Research Ethics Committee (CEP) of the Botucatu Medical School (FMB) under protocol no. 6.268.072 (CAAE 697961723.1.0000.5411).

III. RESULTS

Table II characterizes the manually defined clinical groups and those obtained through the automatic stratification.

The urgent medical group represents the largest dataset share, accounting for 81,353 admissions (57.1%), followed

by elective surgical patients, with 41,471 records (29.1%). In contrast, urgent surgical patients formed the smallest principal group, representing only 5.1%.

Regarding hospital length of stay, a marked difference was observed among the clinical profiles were evaluated. Elective surgical patients showed the shortest average length of stay, with a mean of 3.2 days and a median of 2 days, suggesting shorter and more predictable admissions. In contrast, elective medical and urgent surgical patients showed the longest average length of stay, with means of 9.2 and 9.0 days, respectively, as well as high 90th percentiles, reaching 22 and 20 days, respectively. These results indicate greater variability and a higher frequency of prolonged admissions in these groups.

The elderly group showed intermediate behavior, though consistently higher than that observed in the general surgical population. Elderly medical patients showed a mean LOS of 8.2 days and a 90th percentile of 19 days, while elderly surgical patients showed a mean LOS of 4.5 days and a median of 2 days, approaching the pattern observed for elective surgical admissions.

Automatic KMeans stratification partitioned the dataset into four *clusters* of balanced size, ranging from 29,860 to 42,434 admissions, whose sum reproduces the total dataset. Cluster 0 concentrated the longest stays, with a mean of 11.6 days and a 90th percentile of 27 days, while Cluster 2 gathered the shortest admissions, with a mean of 3.0 days.

Unlike automatic stratification, the six manually defined clinical groups were not mutually exclusive and summed to 181,867 records, exceeding the total dataset and reflecting the expected overlap between the elderly groups and medical/surgical cuts. Accordingly, every elderly surgical patient is already counted in either elective or urgent surgical, and every elderly medical patient is already counted in either urgent or elective medical category. Elderly surgical patients were distributed between elective surgical (13,656) and urgent surgical (2,841), while elderly medical patients were distributed between urgent medical (21,429) and elective medical (1,371). The four groups defined by type and classification are mutually exclusive and partition the entire dataset, which explains why the percentages sum to more than 100%.

Table III presents the R^2 values of each model by group. Across all groups, *Random Forest* and *XGBoost* showed practically equivalent performance, superior to that of KNN, with the two alternating as to which achieved the best result in each group. Manual clinical stratification outperformed the global model ($R^2 = 0.629$) in five of the six groups, while among the four *clusters* only one reached a higher level.

Complementary analyses indicated that the effect of the logarithmic transformation of the target was not uniform across the models. The transformation benefits *XGBoost*, whose sequential nature is sensitive to the skewness of LOS, and reduces the mean absolute error of all models, although it does not always increase R^2, since this metric penalizes mainly the large errors from prolonged admissions. The transformation was retained in all analyses to preserve the comparability across groups.

Table III
COEFFICIENT OF DETERMINATION (R^2) BY GROUP AND MODEL.

Group	N	KNN	RF	XGB
Complete dataset				
Complete dataset	142,570	0.592	0.625	**0.629**
Manual clinical groups				
Elective surgical	41,471	0.606	0.656	**0.665**
Urgent surgical	7,226	0.660	**0.716**	0.703
Urgent medical	81,353	0.610	0.632	**0.638**
Elective medical	12,520	0.452	**0.503**	0.499
Elderly surgical	16,497	0.632	**0.713**	0.702
Elderly medical	22,800	0.623	0.692	**0.696**
Clusters (KMeans)				
Cluster 0	29,860	0.594	**0.645**	0.643
Cluster 1	37,187	0.421	0.458	**0.463**
Cluster 2	42,434	0.418	**0.472**	0.464
Cluster 3	33,089	0.353	**0.411**	0.393

Table IV
MEAN ABSOLUTE ERROR WITH 95% CONFIDENCE INTERVAL AND ERROR RESTRICTED TO PROLONGED ADMISSIONS, IN DAYS, FOR THE MODEL WITH THE HIGHEST R^2 IN EACH GROUP.

Group	MAE (95% CI)	MAE, prolonged cases
Complete dataset	2.27 [2.21; 2.33]	9.88
Elective surgical	1.38 [1.30; 1.45]	10.22
Urgent surgical	3.11 [2.86; 3.39]	7.81
Urgent medical	2.29 [2.21; 2.38]	8.68
Elective medical	4.69 [4.34; 5.07]	15.01
Elderly medical	3.12 [3.01; 3.26]	8.12
Elderly surgical	1.79 [1.67; 1.92]	7.72

Table IV presents the mean absolute error of each group with a 95% confidence interval, obtained through *bootstrap* resampling on the test set, and the error restricted to prolonged admissions, defined as those above the 90th percentile of the complete dataset, corresponding to 13 days. In the complete dataset, the confidence intervals of *Random Forest* and *XGBoost* overlap almost entirely, whereas those of KNN do not intersect either of the other two, supporting the equivalence between the two tree models and the inferiority of KNN. Errors in prolonged admissions are two to seven times higher than the overall error of each group, and this ratio tends to be larger in groups with a shorter typical length of stay.

IV. DISCUSSION

The equivalence between *Random Forest* and *XGBoost*, both above KNN, is consistent with the LOS prediction literature, in which ensemble tree models tend to lead to [3], [6], [7]. However, the performance varied substantially by group.

Elective surgical. XGBoost shows good performance ($R^2 = 0.665$; MAE 1.38; RMSE 3.78), outperforming the global model in terms of accuracy. The pattern of shorter and more homogeneous admissions contributes to greater predictive stability.

Urgent surgical. The best result among the manual groups ($R^2 = 0.716$; RMSE 5.97) was virtually tied with elderly

surgical patients. It was also the smallest group in the study and had the greatest variability in length of stay among patients who underwent surgery, suggesting that this grouping effectively captured heterogeneity.

Urgent medical. The performance was superior to that of the global model ($R^2 = 0.638$, *XGBoost*; RMSE 5.93), with the largest sample size in the study ($N = 81,353$). The margin over the global model is the smallest among the groups that outperform it, consistent with the fact that this group accounts for more than half of the dataset and, therefore, dominates the global model itself.

Elderly surgical and elderly medical. Both maintain high performance ($R^2 = 0.713$ and 0.696; RMSE 4.05 and 5.49), indicating that predictive patterns are preserved under age-based stratification.

Elective medical. Shows the lowest relative performance ($R^2 = 0.503$; RMSE 10.77) and is the only group that does not outperform the global model. It showed the greatest LOS dispersion among the manual groups (mean 9.2, median 4.0, p90 22), suggesting relevant clinical heterogeneity within the data.

The four KMeans *clusters* reached R^2 values between 0.411 and 0.645, and only one outperformed the global model. This cluster, number 0, is also the one with the greatest LOS dispersion, with a mean of 11.6 days and a standard deviation of 16.8. The other three fell below the reference. It should be noted that R^2 and RMSE are not directly comparable across groups with different LOS. Elective medical patients had an RMSE of 10.8 days and $R^2 = 0.50$, while elective surgical patients had an RMSE of 3.8 and $R^2 = 0.67$, not because one model was worse than the other, but because the groups differed in the variance of LOS. The appropriate reading is to compare each group with the equivalent global model and clustering results, rather than comparing groups with each other in absolute terms.

The performance obtained corroborates the LOS regression literature, although a direct comparison is limited by differences in datasets and available variables, as well as the LOS scale. Mansoori *et al.* [7], in an internal medicine service, report a mean The absolute error was approximately 1.5 days with the optimized *XGBoost*. Slavu *et al.* [6] confirmed the advantage of *Random Forest* over linear regression in predicting post-surgical LOS, and the evaluation of ensemble tree models indicated *XGBoost* as a benchmark for performance and interpretability [3]. The values obtained here, RMSE between 3.8 and 6.0 days in the surgical groups and R^2 up to 0.72, fall within this range, reinforcing that the central contribution lies not in the model itself, but in the clinical stratification of the dataset.

These results support the central argument of this study. Specialist clinical knowledge, by defining the groups, guides machine learning more effectively than segmentation based on data alone. Since the models and hyperparameters are identical across the three sources, the advantage of manual stratification, present in five of the six groups, does not come from the algorithm, but from the grouping itself. The specialist

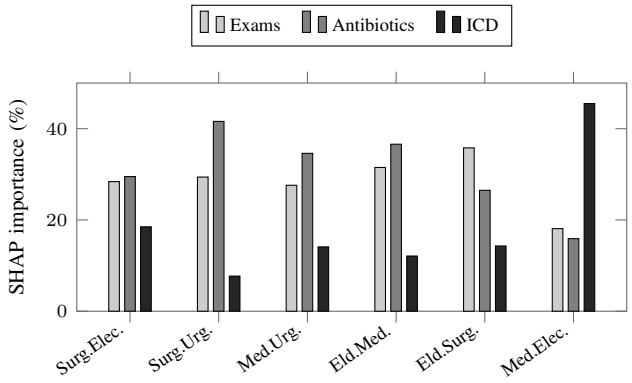

Figure 1. SHAP importance (%) of the three variables with the greatest contribution to model predictions, by clinical group (*Random Forest*). The values reflect model attribution, not a causal relationship with LOS. The ICD chapter dominates only in elective medical patients.

directly translates into rules distinctions that distance-based clustering fails to recover from the raw variables, such as the separation between surgical and medical admissions, between elective and urgent admissions, and by age group. Rather than replacing specialists, the tool establishes a collaborative cycle with them. The clinician proposes the groups, the model predicts, and the interpretability provides evidence on which groups were well captured and which require revision.

Figure 1 makes this cycle concrete. It shows the three variables with the greatest contribution per group, calculated using *Random Forest*, which is equivalent to the best model for all the groups. In the five groups where stratification outperformed the global model, importance was dominated by care-process markers (number of exams and antibiotics), while the ICD chapter always ranked third, with a modest weight (between 7.7% and 18.5%). In the only group that does not outperform the baseline, elective medical patients, this pattern reverses, and the ICD chapter takes first place, with 45.5%, more than double its weight in any other group. Interpretability thus signals where the specialist-defined grouping brings together heterogeneous diagnostic populations and points to the next step, which subdivides elective medical patients by diagnostic chapters.

Table V compares the error of each clinical group to the aggregated error, weighted by N, of its subgroups by the ICD chapter. Subgroups were considered eligible if they had at least 300 total records and at least 100 distinct patients in the test partition, the latter being the decisive criterion, since the effective sample size depends on the number of patients, not admissions; the chapter with missing code was excluded as it does not represent an actual diagnosis. Subdivision consistently reduced the error in the three groups, with drops of 19.4% in elective surgery, 16.9% in elderly surgical patients, and 7.8% in elderly medical patients. In the remaining three groups, the effect is neutral or slightly unfavorable, between $+1.8\%$ and $+11.8\%$, since fragmentation reduces the number of observations per model without sufficiently separating the populations. Coverage of the eligible subgroups relative to

Table V
ERROR OF THE CLINICAL GROUP (BEST MODEL) *versus* AGGREGATED ERROR, WEIGHTED BY N, OF ITS SUBGROUPS BY ICD CHAPTER.

Group	RMSE, group	RMSE, nested	Change
Elective surgical	3.78	**3.05**	-19.4%
Elderly surgical	4.05	**3.36**	-16.9%
Elderly medical	5.49	**5.07**	-7.8%
Urgent surgical	5.97	6.08	$+1.8\%$
Urgent medical	5.93	6.26	$+5.6\%$
Elective medical	10.77	12.04	$+11.8\%$

Table VI
THE NINE DIAGNOSTIC CHAPTERS THAT CONTRIBUTE MOST TO THE TOTAL ERROR OF THE GLOBAL MODEL, RANKED BY THE FRACTION OF ERROR THEY ACCOUNT FOR.

ICD Chapter	% cases	% error	MAE	Mean LOS
Circulatory	11.2	14.8	3.00	7.7
Mental	**3.1**	**13.8**	**10.13**	**15.5**
Infection	5.6	9.6	3.85	12.1
Neoplasm	9.0	8.0	2.02	5.3
Injury	7.7	7.7	2.27	5.6
Respiratory	7.7	7.5	2.20	5.9
Digestive	8.6	6.5	1.73	4.2
Genitourinary	8.1	5.7	1.60	4.6
Pregnancy and childbirth	11.5	5.6	1.10	3.0

each group's test set ranged from 58.8%, in elective medical patients, to 80.2%, in urgent medical patients, which qualifies the reading of the former in particular.

Table VI decomposes the error of the global model by diagnostic chapter. The mental disorder chapter accounts for 3.1% of admissions and 13.8% of the total accumulated error, with a mean absolute error of 10.1 days versus 2 3 days for most other chapters. Within it, 44.3% of admissions exceeded the prolonged-stay threshold, compared with 9.7% in the complete dataset.

The contrast between mental disorders and pregnancy and childbirth defines these two extremes. Pregnancy and childbirth accounted for 11.5% of admissions and only 5.6% of the error, with a mean absolute error of 1.1 days, a result convergent with that obtained by Jain *et al.* [1] when isolating newborns from an independent dataset. Isolating the mental disorder chapter, on the other hand, does not make it predictable, which explains why subdividing elective medical patients did not reduce the aggregated error. Interpretability correctly identified the heterogeneity of the group, but subdivision by diagnostic chapter was not sufficient to capture it when the difficulty lay in the internal variability of a specific chapter.

These results refine the central thesis of this study. The ideal level of detail is not the same for all groups. Going down to the diagnosis level pays off when the grouping brings together populations with distinct length-of-stay patterns, as in the surgical groups and elderly medical patients, and is neutral when the group is already relatively homogeneous. When the difficulty stems from the unpredictability of a specific chapter, as with mental disorders, isolating it does not resolve the issue, because the problem was not the mixing of different chapters, but the nature of that isolated chapter itself.

The care profile of each institution shapes both the groupings that make clinical sense and the length of stay within them. Statewide public datasets, such as SPARCS, make this variation observable, as they bring together hospitals with different missions under the same data structure, allowing a comparison of how length of stay is distributed across them. Predominantly psychiatric facilities, for example, show longer admissions, and the hospital's profile influences the length of stay [14], which would likely lead to different groupings than those adopted here. Institutions with a profile similar to the one studied, on the other hand, may converge toward similar groups.

Before defining the groups and choosing the models, it is necessary to understand the dataset in depth, which involves both consulting the care team, whose experience indicates which clinical distinctions are relevant in that service, and quantitative analysis of the dataset itself, which sizes each candidate group and checks whether the proposed groupings hold up in terms of size and LOS behavior. This preliminary step tends to receive little attention in the literature, even though it shapes all the subsequent decisions.

The results obtained on other datasets point in the same direction. Jain *et al.* [1], working with 2.3 million admissions from SPARCS, separated newborns from other patients and obtained markedly different performances between the two groups, and when restricting the analysis to a single diagnosis type, the performance increased from 0.43 to 0.62. None of these groupings coincide with the ones adopted here, and the variables available in the two datasets also differ, which reinforces the argument that the gain does not come from a particular list of groups, but from the practice of dividing the population according to clinically interpretable criteria and verifying whether the division improves prediction.

Clinical knowledge is not the only path for defining groupings, but it can guide the search and reduce the number of alternatives to be tested. Our group has been comparing different unsupervised clustering algorithms to verify whether this choice affects the ability to outperform the segmentation obtained through statistical methods. This is not a trivial question, since the relative performance of clustering algorithms varies according to the characteristics of the dataset [8], which recommends evaluating them explicitly rather than adopting a method by convention.

The main contributions of this study are twofold. The first is a fair comparison protocol, in which the global model, clinical stratification, and automatic stratification shared exactly the same hyperparameters, fixed per model, isolating stratification as the sole variable. Second, the models were interpreted using SHAP values, identifying the variables with the greatest contribution to predictions within each subdivision.

As a next step, we intend to evaluate a model restricted to the variables of the first moment, which will allow us to quantify how much of the performance is derived from the information accumulated during care. Institutional databases

record the dates of prescription, scheduling, and completion of exams and antibiotic administration, making it possible to reconstruct these indicators within a time window counted from admission, whose width is a parameter to be defined in future work. Depending on this width, exams and antibiotics would move from the third moment to an intermediate point between the second and third, shifting the prediction to before discharge without discarding any process variables.

V. Conclusion

This work assessed whether clinical stratification of the dataset can improved the prediction of hospital length of stay compared with a global model and an automatic clustering-based stratification strategy. Since the models and hyperparameters were kept identical across the three approaches, the comparison allowed the effect of the segmentation strategy to be isolated.

The results showed that specialist-defined stratification outperformed the global model in five of the six groups, whereas automatic stratification based on K-means outperformed it in only one group. These findings support the central argument that specialist clinical knowledge, by defining groups that are more representative of care practice, guides machine learning more effectively than segmentation based solely on data.

Interpretability was demonstrated where performance was lower, and diagnosis played a predominant role in the model's attributions, indicating high internal heterogeneity. Subdivision by diagnostic chapter proved beneficial, with reductions of up to 19.4% in RMSE in three of the six groups, but insufficient for elective medical patients. Decomposing the error by chapter clarified this limitation, revealing that a substantial error share was concentrated in the mental disorders chapter, which accounted for 3.1% of admissions and 13.8% of the total error. In this case, the difficulty stems from the internal variability of the chapter rather than from mixing across chapters.

Thus, this study suggests that predictive models applied to hospital settings can benefit significantly from incorporating specialist knowledge not only as a source of interpretation but also as an active element in defining the modeling strategy. Among the algorithms evaluated, *Random Forest* and *XGBoost* showed equivalent performance, with overlapping confidence intervals, and consistently outperformed KNN. The effect of the logarithmic transformation of the target variable proved to depend on the model and the metric considered, being beneficial for *XGBoost* and the mean absolute error of all models.

***Abstract*—Non-invasive blood glucose (BG) monitoring using photoplethysmography (PPG) represents a promising frontier in diabetes management, yet the true clinical viability of these methods relies on their ability to generalize across distinct data recordings. This work presents an evaluation of the generalization capacity of an analytical method proposed by Nakazawa et al. (2024), which is based on the phase delay between near-infrared spectroscopy (NIRS) signals derived from dual-wavelength PPG. We carried out this evaluation by collecting paired PPG and reference BG data from eight subjects under four distinct profiles of induced BG fluctuations. The analytical method was then calibrated to each subject and evaluated using three distinct data partitioning approaches. The first configuration replicated the original validation scheme by calibrating and validating the method over the same data cohort, generating optimistic performance metrics: a mean absolute relative difference (MARD) of 10.67% and a root mean squared error (RMSE) of 12.36 mg/dL. The second approach evaluated the generalizability of the method by partitioning the data into distinct calibration and validation cohorts, which resulted in a relevant performance decrease, achieving a MARD of 25.13% and an RMSE of 33.08 mg/dL. A third validation approach involved testing the calibration curve fitted on the first approach over the same validation data subset employed in the second, achieving considerably lower error rates (MARD of 9.68%, RMSE of 10.72 mg/dL). Our findings underline a key limitation in the method's performance when tested on unseen data, highlighting the importance of evaluating non-invasive BG estimation techniques over partitioned data to assess their generalization capacity and assess their clinical reliability under real-world scenarios.**

***Index Terms*—photoplethysmography, glucose, spectroscopy, diabetes**

I. Introduction

Diabetes mellitus is a condition affecting approximately one out of ten adults globally [1]. When left untreated, it leads to a chronically elevated blood glucose (BG) concentration, causing several long-term complications such as retinopathy, cardiovascular diseases, and kidney failure [2]. Current methods for monitoring BG levels include self-monitoring blood glucose (SMBG) devices, which measure glucose through finger-prick capillary tests, and continuous glucose monitors (CGMs), devices that read glucose concentration from the interstitial fluid with an intradermal sensor.

The financial burden and invasive nature of these monitoring techniques impose a significant strain on healthcare systems and lower patient quality of life due to physical discomfort, ultimately limiting treatment adherence [1], [3]–[5]. Consequently, non-invasive and continuous alternatives for BG monitoring using optical techniques like photoplethysmography (PPG) have become a major research focus due to limitations of current monitoring methods [6], [7].

PPG is a low-cost optical technique used to detect localized blood volume variations within vascularized tissue. The signal is acquired by emitting light into the tissue and measuring the intensity of the reflected or transmitted light, which fluctuates over time due to the pulsatile nature of blood flow driven by cardiac activity. The resulting PPG waveform consists of a pulsatile (AC) component reflecting the cardiac cycle, and a low-frequency (DC) component shaped by tissue vascularizа-

tion, respiration, and blood composition [8]. Since variations in the concentration of blood constituents alter its optical absorption characteristics, multi-wavelength PPG signals have emerged as a potential method for non-invasive blood glucose estimation [9]. So far, most studies have employed machine learning (ML)-based techniques to extract relevant BG-related information from multi-wavelength signals [9]–[11].

For instance, [12] proposed a wearable ring to collect multi-channel PPG data paired with a wavelet transform framework to decompose PPG waveforms into derivative signals. Features extracted from PPG data collected from 47 subjects alongside SMBG readings were used to train a linear support vector regression model, achieving a root mean squared error (RMSE) of 16.02 mg/dL and a coefficient of determination (R^2) of 0.8. Similarly, by combining 1D-ResNet models with a self-attention mechanism, [13] achieved an RMSE of 19.24 ± 1.13 mg/dL using 6-wavelength PPG signals collected from 254 individuals, coupled with demographic profiles and local environmental parameters such as humidity and temperature. Furthermore, [11] explored the relationship among PPG data collected the in red (655 nm), infrared (940 nm), and green (520 nm) wavelengths. Using a dataset of 92 subjects annotated with SMBG references, they trained a Lasso regression model on amplitude-ratio features, yielding an RMSE of 7.18 ± 5.66 mg/dL.

Recently, Nakazawa *et al.* [14] introduced a purely analytical technique for blood glucose estimation that circumvents ML complexities and computational demands. Their method estimates blood glucose using phase delay and amplitude variations between oxyhemoglobin (HbO_2) and deoxyhemoglobin (Hb) near-infrared spectroscopy (NIRS) signals, derived from dual-wavelength PPG, to compute a novel metric named the Metabolic Index (MI). Although the authors reported a strong correlation ($r = 0.73$) and an RMSE of 19.7 mg/dL, their evaluation was confined to a single subject ($n = 1$) and lacked a data split strategy that calibrates and validates the method on distinct signals.

This study aims to implement and evaluate the analytical BG estimation method proposed in [14] using a comprehensive, multi-subject dataset constructed through a similar acquisition protocol. Our dataset consists of 8 individuals who underwent four distinct beverage-based interventions. These interventions were designed not only to induce blood glucose variability but also to evaluate the impact of caffeine on the MI and provide a baseline control. Furthermore, three evaluation strategies are implemented: first, using the entire data collected from a given subject to fit the calibration curve exactly as proposed in [14]; second, partitioning each individual's data into distinct calibration and validation subsets; and third, using the method calibrated on the first approach and evaluating it on the validation data subset of the second, allowing a direct comparison between methods fitted on distinct data cohorts. These partitioning strategies allowed us to evaluate the analytical method's performance on different data subsets, providing an assessment that may reflect a performance closer to a real-world application.

II. Methodology

This section describes the methodology used in our work. The acquisition protocol for database construction is outlined, as well as the analytical method for BG estimation and its evaluation approaches. The methodology proposed by [14] to estimate the Metabolic Index is summarized in the diagram shown in Fig. 1.

A. Acquisition Protocol

A dedicated database was built using the Analog Devices MAXREFDES104 wearable development platform to collect synchronized PPG signals at a sampling rate of 125 Hz across two wavelengths: red (655 nm) and infrared (940 nm). Although configured as a smartband, the sensor was adapted to perform fingertip acquisition to maximize the signal-to-noise ratio [15]. Reference BG values were collected using an Abbott FreeStyle Libre CGM, which provides automatic readings every 15 minutes. The CGM was installed at least 48 hours prior to PPG data collection to mitigate the higher measurement errors typically reported at the beginning of the sensor's lifespan [16].

PPG signals and paired BG measurements were acquired during individual acquisition sessions lasting approximately 60 minutes. Before starting each session, volunteers were required to fast for at least 2 hours to minimize BG variations caused by external dietary factors. During data collection, participants were instructed to remain comfortably seated, resting both arms on a table with the PPG sensor positioned on the index finger of the non-dominant hand. Volunteers were also advised to avoid talking and moving throughout the acquisition to reduce motion artifacts in the PPG signal.

The first 10 minutes of each session served as a baseline PPG data collection, immediately followed by an intervention characterized by the intake of a specific beverage. Each volunteer participated in 4 sessions with an interval of at least 24 hours between sessions. The beverage's composition was session-specific, alternating sugar and caffeine content according to a predetermined order: the beverage in the session **I** contained sugar and caffeine; session **II** contained only caffeine; session **III** only sugar; and **IV** plain water. Fig. 2 illustrates the acquisition session order, beverage contents and data collecting protocol.

In total, 8 non-diabetic volunteers completed all four acquisition sessions, yielding 32 distinct recordings with duration of approximately 60 minutes each. The cohort included one female and seven male participants, aged between 27 and 52 years (mean age of 39.1 ± 10.3 years). The reference BG measurements recorded across all sessions ranged from 57 to 165 mg/dL, with a mean and standard deviation of 97.9 ± 16.1 mg/dL.

This clinical experiment fully adheres to all pertinent ethical regulations and was approved by the Institutional Review Board (IRB) under the registration SDC 5248/21/023.

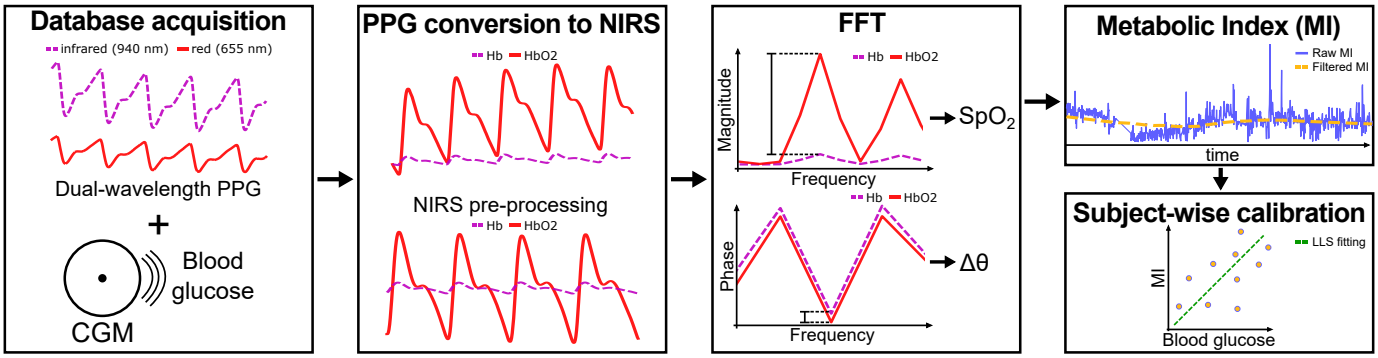

Fig. 1. Representation of the analytical methodology for blood glucose estimation. The magnitude spectrum derived from the FFT allows the estimation of the oxygen saturation (SpO_2). $\Delta\theta$ denotes the phase difference between HbO_2 and Hb NIRS signals. The MI computed by this method is used to estimate the BG by fitting a calibration curve.

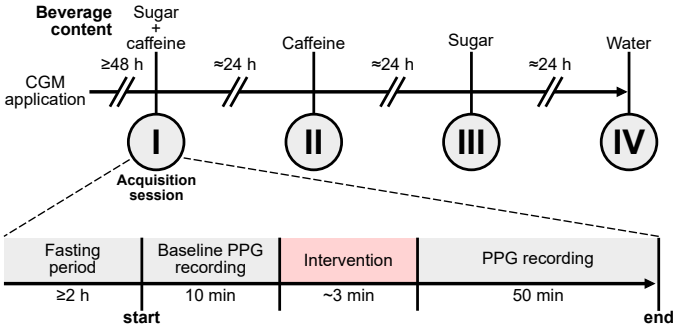

Fig. 2. Schematic representation of the sequence of acquisition sessions and beverage content of each session. Blood glucose measurements are performed automatically by the CGM every 15 minutes.

B. Analytical Method for BG Estimation

The first step of the analytical method proposed in [14] involves converting the raw PPG signals into HbO_2 and Hb NIRS signals, which represent changes in the concentration of these substances over time.

1) PPG Conversion to NIRS: Converting PPG waveforms to NIRS signals depends on the specific extinction coefficients of Hb and HbO_2 at the selected wavelengths (655 and 940 nm), which were sourced from [17]. These NIRS signals can be estimated by solving (1), a matrix formulation derived from the modified Beer-Lambert Law [18]:

$$\begin{bmatrix} N_{HbO_2}(t) \\ N_{Hb}(t) \end{bmatrix} = \begin{bmatrix} \varepsilon_{HbO_2}(\lambda_1) & \varepsilon_{Hb}(\lambda_1) \\ \varepsilon_{HbO_2}(\lambda_2) & \varepsilon_{Hb}(\lambda_2) \end{bmatrix}^{-1} \begin{bmatrix} \Delta OD(\lambda_1, t) \\ \Delta OD(\lambda_2, t) \end{bmatrix}, \quad (1)$$

where $N_{HbO_2}(t)$ and $N_{Hb}(t)$ represent the time-varying NIRS signals for HbO_2 and Hb, respectively. The parameters $\varepsilon_{HbO_2}(\lambda)$ and $\varepsilon_{Hb}(\lambda)$ denote the specific molar extinction coefficients of oxyhemoglobin and deoxyhemoglobin at a given wavelength λ. The term $\Delta OD(\lambda, t)$ represents the incremental optical density change between the baseline instant t_0 and a given time t for the wavelength λ, which is defined as:

$$\Delta OD(\lambda, t) = log_{10}\left(\frac{I_{\text{out}}(\lambda, t_0)}{I_{\text{out}}(\lambda, t)}\right), \quad (2)$$

where $I_{\text{out}}(\lambda, t_0)$ and $I_{\text{out}}(\lambda, t)$ correspond to the reflected light (PPG samples) detected at the wavelength λ at time instants t_0 and t, respectively.

2) NIRS Processing: In order to remove high-frequency noise and low-frequency baseline oscillations, the reconstructed NIRS signals are filtered using a second-order band-pass Butterworth filter with cutoff frequencies set at 0.8 and 10 Hz.

The filtered NIRS waveforms are subsequently segmented into windows spanning exactly 4 cardiac cycles, trimming the boundaries so that each segment aligns from the first cycle onset to the last one completion. To maximize the computational efficiency of the subsequent Fast Fourier Transform (FFT) and prevent spectral leakage, each segment is resampled to increase its length to the nearest power of two and multiplied by a Hamming window.

The FFT is then applied to each windowed segment to isolate the main frequency, which represents the fundamental heart rate frequency, and extract spectral information from the signals. The AC amplitudes of the synchronized HbO_2 and Hb NIRS segments are extracted from the magnitude spectrum at this dominant frequency, denoted by $A_{HbO_2}(t)$ and $A_{Hb}(t)$, respectively. These amplitudes are then used to estimate the continuous oxygen saturation (SpO_2) over time, computed as follows:

$$SpO_2(t) = \frac{A_{HbO_2}(t)}{A_{HbO_2}(t) + A_{Hb}(t)} \quad (3)$$

The resulting SpO_2 is subsequently used for estimating the Metabolic Index.

3) Estimating the Metabolic Index: The MI estimation method was formulated by assuming a slight and slow-varying phase difference, denoted as $\Delta\theta(t)$, between the synchronized N_{HbO_2} and N_{Hb} segments at the fundamental heart rate frequency [14]. By coupling the phase delay with the instantaneous oxygen saturation ($SpO_2(t)$), the time-dependent metabolic index is derived as follows:

$$MI(t) = SpO_2(t) \cdot [1 - SpO_2(t)] \cdot \Delta\theta(t) \quad (4)$$

The resulting MI values are subsequently grouped into 1-minute non-overlapping windows. Any outliers within each window are then identified and removed before averaging the remaining valid entries of a same window into an individual sample. Finally, the sequence of mean MI values is smoothed using a Savitzky-Golay filter with a first-order polynomial and a window length of 29 points to yield a stable MI series.

C. Proposed Evaluation Methods

After smoothing the resulting MI values, a calibration curve is mapped for each subject by linear least square (LLS) fitting between the estimated MI values and the reference BG measurements. Consequently, each calibration curve is specifically adjusted for one single individual. In [14], the authors use all computed MI values of one subject to fit a calibration curve with the known reference BG concentrations.

Since, in our experiment, glucose measurements were recorded with a 15-minute interval, linear interpolation was applied to BG readings in order to pair a reference BG value to each MI data point. To avoid extrapolating BG values, CGM measurements acquired immediately prior to and following PPG data collection were also used to interpolate the reference BG values, resulting in 4364 ± 456 samples per subject across all acquisition sessions. From the fitted calibration curve, any subsequently calculated MI sample can be mapped directly to a BG level estimation.

Blood glucose estimation methods, however, typically enforce an independent validation strategy by partitioning the dataset [11]–[13]. This approach ensures that the mathematical model is calibrated (or trained, in the case of ML-based methodologies) using one specific data subset and subsequently evaluated on entirely unseen data.

This partitioning technique is critical for objectively analyzing a model's generalization capacity, which cannot be reliably assessed when training and testing on overlapping temporal data of a single subject. Evaluating performance on unseen data is relevant to demonstrate that the model does not simply overfit over calibration/training data [19].

Therefore, in addition to employing the original partitioning scheme on [14], we implemented a validation strategy that partitions each subject's data into separate calibration and validation cohorts, where the data for each cohort were gathered from distinct acquisition sessions. Data within the calibration cohort were used exclusively to fit the calibration curve specific for each subject, while data from the validation cohort were subsequently used to evaluate the generalization capacity of the fitted curve on unseen segments.

The calibration set was composed of data collected during sessions **I** and **IV** of a given subject, which employed, respectively, an intervention consisting of a sugary and caffeinated beverage, and a baseline intervention of plain water. The validation set comprised the remaining two sessions (**II** and **III**), which involved beverages containing either sugar or caffeine alone.

This specific data partitioning scheme ensured that both the calibration and validation cohorts contained a balanced distribution of experimental conditions. Specifically, each cohort included a sugar-driven intervention to induce BG variations (sessions **I** and **III**) alongside a caffeinated beverage intervention (sessions **I** and **II**), thereby mitigating potential confounding effects of caffeine on the estimated MI values.

To allow a direct comparison between the described data partitioning schemes, a third approach was implemented. This approach involves taking the calibration curve fitted on all acquisition sessions of a given subject from the first approach and evaluating it on the data subset used for validation in the second approach. This configuration allows a direct comparison between the distinct calibration curves fitted in first two approaches by evaluating them on a same validation data cohort.

The data partitioning is summarized as follows:

- Approach 1: The calibration curve for each subject was fitted and evaluated using the data collected across all four acquisition sessions, mirroring the method described in [14].
- Approach 2: The calibration curve was fitted using data from sessions **I** (sugar+caffeine) and **IV** (water), and validated using the data from the remaining sessions **II** (caffeine) and **III** (sugar).
- Approach 3: The calibration curve derived in approach 1 was evaluated on the same validation data subset utilized in approach 2 (**II** and **III**).

Given the independence of individual acquisition sessions, time-dependent factors were not considered in the evaluation analysis. Fig. 3 summarizes these distinct evaluation approaches.

D. Evaluation

The BG estimation error was quantified using the Mean Absolute Relative Difference (MARD), which computes the error as a percentage of the reference and is broadly used for evaluating glucometers [4]. Additionally, we computed the RMSE, which penalizes larger errors due to its quadratic

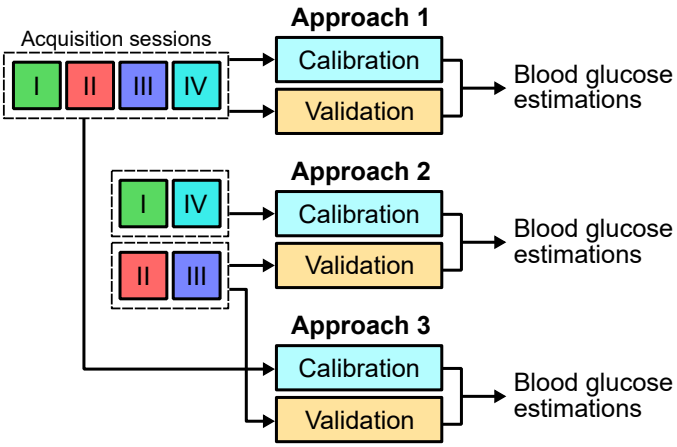

Fig. 3. Data partitioning according to each evaluation approach. A calibration curve is generated for each subject.

formulation. The Pearson correlation coefficient (r) was calculated to assess how effectively the estimated BG values tracked reference BG variations.

To assess whether the observed performance differences between the evaluation approaches 2 and 3 were statistically significant, paired Wilcoxon signed-rank tests were performed on the subject-wise performance metrics (MARD, RMSE, and r) across all eight subjects. Effect sizes were evaluated using the matched-pairs rank-biserial correlation coefficient (r_{rb}), and estimation precision was quantified using 95% confidence intervals (CIs) for the median paired differences. A non-parametric test was selected due to the cohort size ($N = 8$). Statistical significance was initially set at $\alpha = 0.05$. To account for multiple comparisons across the three evaluated metrics, a Bonferroni correction was applied, resulting in an adjusted significance of $\alpha_{\text{adjusted}} = 0.0167$. To assess for the effect of caffeine on the MI estimations, the Wilcoxon signed-rank test was also employed to estimate statistically significant differences between median MI values estimated per subject between sessions **I** (sugar+caffeine) and **III** (sugar), and between sessions **II** (caffeine) and **IV** (water).

The clinical impact of the estimations was evaluated using the Clarke Error Grid (CEG), a standard tool that categorizes glucose predictions into five zones (A through E) based on their influence on patient treatment decisions [20]. Estimates within zones A and B represent clinically acceptable outcomes that do not lead to inappropriate medical interventions.

Finally, method sensitivity to CGM lag compared to actual BG was assessed by shifting the reference CGM measurements from 1 to 15 minutes and re-evaluating all performance metrics (RMSE, MARD, r).

III. Results

This section details the performance evaluation of the analytical method proposed in [14] over a multi-subject dataset, using the three validation approaches outlined in Section II-C. Since the calibration curves were individually fitted for each subject, the evaluation metrics were computed for each individual and subsequently averaged. Their mean values and standard deviations are summarized in Table I.

The paired Wilcoxon signed-rank test indicated statistically significant differences between approaches 2 and 3 for RMSE ($W = 0.0$, $p = 0.0078$, $r_{\text{rb}} = 1.0$, 95% CI: $[-44.65, -1.16]$ mg/dL) and MARD ($W = 1.0$, $p = 0.0156$, $r_{\text{rb}} = 0.94$, 95% CI: $[-34.99, -0.21]$%), but revealed no significant difference for the correlation coefficient r ($W = 7.0$, $p = 0.2719$, $r_{\text{rb}} = -0.5$, 95% CI: $[-0.00, 0.00]$).

TABLE I
Validation Metrics

	Approach 1	Approach 2	Approach 3
MARD (%)	10.67 ± 2.37	25.13 ± 18.42	9.68 ± 2.47
RMSE (mg/dL)	12.36 ± 3.61	33.08 ± 30.57	10.72 ± 2.72
r	0.28 ± 0.16	0.28 ± 0.37	0.40 ± 0.22

No statistically significant differences were found between the MI values estimated in sessions containing caffeine and their counterparts without caffeine, as indicated by the Wilcoxon signed-rank test between sessions **I** and **III** ($W = 10.0$, $p = 0.3125$, $r_{\text{rb}} = 0.44$), and between sessions **II** and **IV** ($W = 3.0$, $p = 0.0391$, $r_{\text{rb}} = 0.83$).

The CEG generated for the approach 1, employing data from all acquisition sessions for both calibration and validation, is shown in Fig. 4.

Analysis of the CEG shown in Fig. 4 indicates that 98.5% of the estimations fell within the clinically acceptable zones A and B (with 90.8% in zone A and 7.7% in zone B). The remaining 1.5% of the predictions fell into zone D. In this scenario, these errors indicate a failure to detect hypoglycemia (BG concentrations below 70 mg/dL), which could lead to dangerous treatment omissions for the patient.

The CEG containing predictions estimated on the validation cohort of approach 2 is presented in Fig. 5.

As illustrated in Fig. 5, 96.2% of the estimations fell within zones A and B (60.1% in zone A and 36.1% in zone B). The remaining 3.9% fell into zone C, which could lead to unnecessary or inappropriate medical interventions; specifically, these errors falsely indicate hyperglycemia (BG levels over 180 mg/dL) when the true BG concentration is actually closer to a 100 mg/dL baseline.

The CEG containing validation predictions evaluated under the data partitioning scheme of approach 3 is presented in Fig. 6. For this approach, 100.0% of the estimations fell within the clinically acceptable zones A and B, with 95.1% of the predictions located in zone A and 4.9% in zone B.

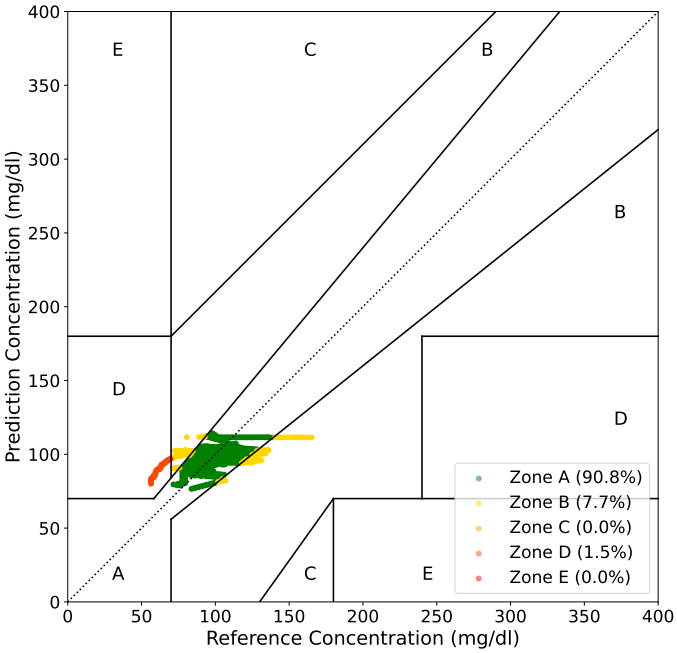

Fig. 4. Clarke Error Grid generated using the validation dataset for approach 1. This configuration replicates the evaluation method proposed in [14], where data from all acquisition sessions are utilized for both calibration and validation.

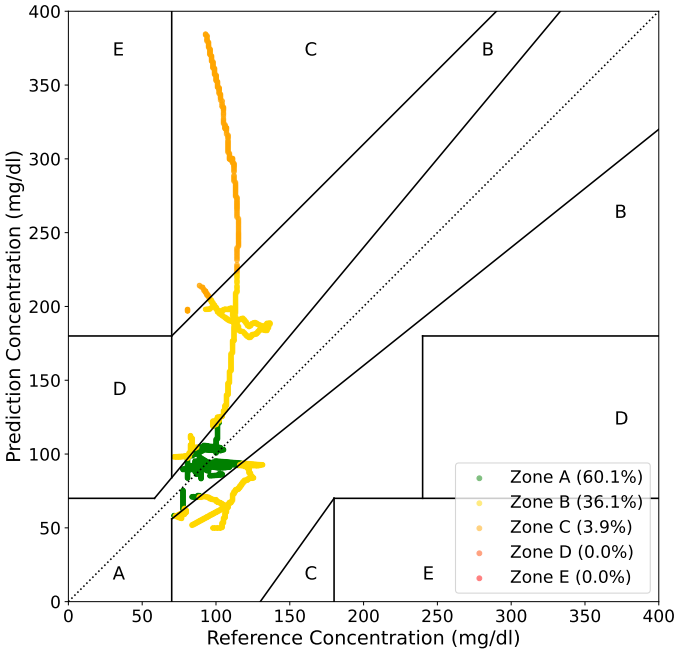

Fig. 5. Clarke Error Grid generated with estimations performed using a calibration curve fitted and validated over distinct data cohorts (approach 2). This strategy utilizes data from two acquisition sessions (**I** and **IV**) to calibrate the method for a single subject, while the validation is performed using data from the remaining sessions (**II** and **III**).

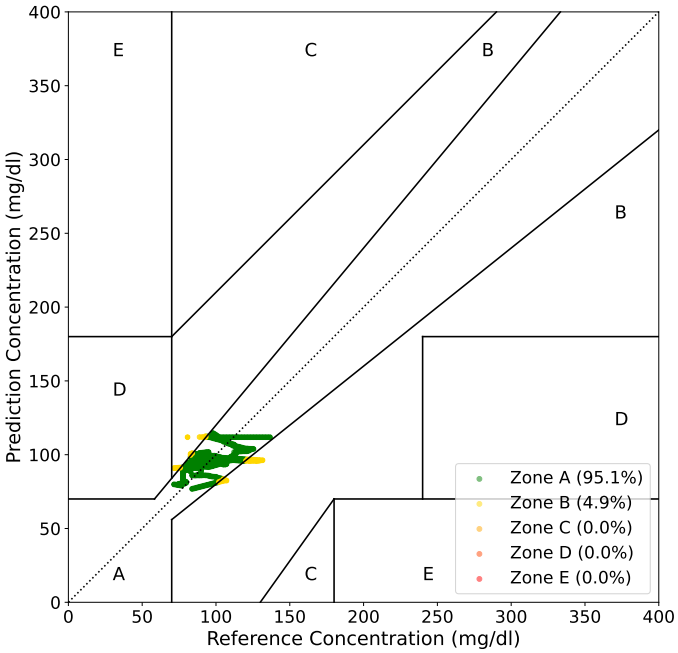

Fig. 6. Clarke Error Grid generated using estimations from the method calibrated with data from all acquisition sessions and validated on a subset cohort composed of data from sessions **II** and **III** (approach 3).

Lastly, simulating CGM response delays from 1 to 15 minutes resulted in a consistent reduction in performance across all approaches. At the 15-minute delay, RMSE increased to 12.91 mg/dL, 36.22 mg/dL, and 11.49 mg/dL, MARD reached 11.00%, 28.21%, and 10.14%, and r dropped to 0.16, 0.04, and 0.14 for approaches 1, 2, and 3, respectively.

IV. Discussion

The comparative analysis across the three distinct evaluation approaches using data gathered from eight subjects suggests a significant limitation regarding the generalization capabilities of the analytical method proposed by [14] when evaluated on a multi-subject dataset.

Approach 1 mirrored the strategy employed in [14] by fitting and validating the calibration curve of the proposed method over a single data cohort. This strategy achieved a mean MARD of $10.67 \pm 2.37\%$ and an RMSE of 12.36 ± 3.61 mg/dL, with 98.5% of estimations clustered within the clinically acceptable zones A and B. The lack of validation on a distinct data cohort, however, masks the real performance of the method on unseen data.

The importance of a separate validation cohort becomes evident when examining the results of approach 2, where the data partitioning scheme fits and evaluates the method on data from entirely distinct acquisition sessions. Under this approach, the mean MARD increases to $25.13 \pm 18.42\%$ and the RMSE rises to 33.08 ± 30.57 mg/dL. The standard deviations increase significantly, highlighting a lack of stability across different subjects. This instability is reinforced by the estimation distribution in the CEG shown in Fig. 5, where 3.9% of the data points fell into zone C, which could lead to unnecessary clinical interventions. Although the remaining 96.2% of the predictions fell within zones A and B, the wide dispersion of the data points suggests a major underlying uncertainty in the method and does not necessarily indicate clinical applicability.

Approach 3 achieved the highest overall accuracy among the other evaluation strategies, reaching a MARD of $9.68 \pm 2.47\%$ and an RMSE of 10.72 ± 2.72 mg/dL, alongside an improved correlation coefficient ($r = 0.40 \pm 0.22$). Furthermore, 100.0% of its CEG data points fell within zones A and B, which would normally indicate an optimal performance profile for a blood glucose estimation method. This approach, however, served primarily as a control strategy to allow a direct comparison between the calibration curves fitted for approaches 1 and 2. Approach 3 represents an optimistic upper bound, since the calibration model was fitted using information originating from the validation sessions, similarly to was was observed to approach 1. By comparing the results of a calibration curve fitted with data from all sessions and a curve fitted with a data subset against a same validation cohort, we isolated the impact of both calibration strategies and provided a direct comparison between both configurations.

The discrepancy in results between approaches 2 and 3, both evaluated on the exact same validation cohort, indicates that this limitation is not merely an artifact of the dataset itself. Approach 3 demonstrated a statistically significant reduction in both RMSE and MARD compared to approach 2. However, wide 95% confidence intervals were observed for both metrics, spanning 43.49 mg/dL for RMSE and 34.78% for

MARD. While the entirely negative bounds confirm a consistent reduction in prediction error for approach 3, the span of these intervals indicates high inter-subject variability, which is further influenced by the limited cohort size of 8 subjects. No statistically significant difference and a 95% confidence interval spanning zero were observed for r between approaches 2 and 3. This outcome is explained by the properties of the LLS calibration model, which is invariant to linear scale and shift transformations for a given dataset. Consequently, LLS recalibration preserves the magnitude of r, allowing only for a sign inversion if a positive or negative correlation is identified between MI values and BG measurements across approaches.

While accounting for the dataset limitations, the resulting comparison of approaches 2 and 3 suggests that the calibration partition in approach 2 provided insufficient information for generalization, or that the analytical model failed to encapsulate the necessary physiological features to track blood glucose fluctuations over time. This limitation is also reflected in the low correlation coefficients observed across all configurations (mean $r = 0.28$ for approaches 1 and 2, and $r = 0.40$ for approach 3). The similarity between the metrics achieved by the method evaluated across our multi-subject dataset and the single-subject results originally reported in [14], detailed in Table II, further reinforces these structural limitations.

As shown in Table II, evaluating the analytical method over a multi-subject dataset ($n = 8$) by calibrating and validating within an identical data cohort improved almost all performance metrics relative to those reported for the single-subject implementation. The sole metric that did not show an improvement was the correlation coefficient, r. Additionally, the expected clinical utility improved, as evidenced by the increased proportion of estimations falling within the clinically acceptable CEG zones A and B.

However, this overall improvement relative to the original work is absent when the method is calibrated and validated using separate data cohorts, as demonstrated by approach 2. This limitation is evidenced by the error increases reported through RMSE and MARD, alongside a decrease in the correlation coefficient, r. Moreover, the proportion of estimations falling within the CEG zones A and B showed a difference of less than 10%. Therefore, the comparison of our finding with the results reported in [14] highlights that the generalization capacity of this method must be carefully evaluated before considering its implementation in real-world applications.

TABLE II
COMPARISON OF METRICS ACHIEVED IN THIS WORK WITH [14]

	This work		**[14]**[2]
	Approach 1	**Approach 2**	
MARD	10.7%[1]	25.1%[1]	17.5%
RMSE	12.4 mg/dL[1]	33.1 mg/dL[1]	24.1 mg/dL
r	0.28[1]	0.28[1]	0.66
CEG zone A	90.8%	60.1%	69.2%
CEG zone B	7.7%	36.1%	30.8%
Subjects (n)	8	8	1

[1]Mean value.

[2]Results reported without α-correction.

The importance of evaluating BG estimation methods using complementary statistical metrics (RMSE, r, and MARD) alongside clinical impact assessment tools, such as the CEG analysis, is reinforced by these findings. The poor performance indicated by the relatively high RMSE and low r achieved in approach 2 is not reflected in the clinical utility measured by the CEG, which placed 96.2% of predictions in the clinically acceptable zones A and B. This divergence occurs primarily due to the high prevalence of reference BG values within the normal range: namely, measurements outside the hypoglycemic (below 70 mg/dL) or hyperglycemic (above 180 mg/dL) intervals, even when accounting for sugar-driven interventions. Increasing the proportion of diabetic subjects in the dataset would potentially expand the range of reference blood glucose values, enabling a more accurate and reliable assessment of the clinical viability of the method.

Therefore, factors such as the relatively small dataset (8 subjects), the low prevalence of diabetic subjects, the concentration of BG measurements within the normal range, imbalanced sex distribution, and the fixed order of interventions described in our study can be considered limitations to the evaluation of the method proposed in [14].

In terms of practical implementation, this method presents a relevant limitation due to its reliance on subject-wise calibration. Although calibrating individual models reduces inter-subject variability, requiring a personalized fitting procedure for every user substantially limits the method's clinical applicability.

Our results demonstrated no measurable effect of caffeine on the MI, as indicated by the paired Wilcoxon signed-rank tests performed between sessions **I** and **III**, and between sessions **II** and **IV**, where both yielded $p > \alpha_{\text{adjusted}}$, revealing no statistically significant differences attributable to the presence of caffeine.

Besides the evaluation on different datasets, specific variations between our data collection protocol and that reported in [14] may have contributed to the divergence in results. In this work, due to subject time constraints, we acquired approximately one hour of data per session, whereas the authors in [14] reported collecting approximately 90 minutes.

In [14], the authors captured PPG data using wavelengths of 650 and 930 nm, which is slightly different from the 655 and 940 nm employed in our work. Additionally, they reported collecting PPG signals via a smartphone-based camera. The impact of these hardware and wavelength variations is likely minimal, as we utilized the exact molar extinction coefficients of HbO_2 and Hb corresponding specifically to our active operating wavelengths.

The authors in [14] also performed a post-processing adjustment that incorporates an α-correction factor into the MI estimation method, which was tuned based on its direct impact on the resulting r. This factor was not implemented in our

work, and all comparisons with [14] were conducted using their reported metrics that excluded the α-correction.

Lastly, the CGM measures glucose concentrations in the interstitial fluid, where levels fluctuate with an intrinsic lag relative to blood glucose levels [21]. However, applying delay corrections spanning shifts from 1 to 15 minutes to the reference CGM measurements failed to improve overall performance, suggesting the presence of intrinsic method limitations rather than uncorrected reference lag.

V. Conclusion

This work evaluated the generalization capacity of an analytical method for non-invasive blood glucose estimation originally proposed in [14]. This assessment was conducted by collecting PPG and blood glucose data from 8 subjects and employing this dataset to calibrate and validate the model under three distinct validation approaches. Calibrating and validating the method within the same data cohort for each subject yielded optimistic metrics. However, while this approach mirrors the validation scheme performed in [14], it restricts the evaluation of the true generalization capacity of the method, since it is not evaluated on unseen data. The second approach, which employed s data partitioning scheme based on distinct acquisition sessions, demonstrated a relevant performance decrease, suggesting a key limitation in the method's ability to generalize. Validating the full-session calibration model on the same data subset as the second approach reinforced this limitation on a direct comparison. Limitations were also observed regarding the clinical applicability of the method, as an individual calibration procedure is required for each new user.

Therefore, our findings suggest that the analytical method proposed in [14] must be thoroughly evaluated across independent cohorts with a larger sample size and a broader glucose range to establish a reliable correlation between the Metabolic Index and blood glucose fluctuations. Moreover, this work highlights the need of testing non-invasive BG estimation methods on entirely unseen data to assess their clinical reliability on a real-world scenario.

Abstract— Brazil's Unified Health System (SUS) has advanced interoperability through the National Health Data Network (RNDS) and HL7 FHIR; however, traceability remains fragmented: prescriptions, lab orders, reports, appointments, referrals, and dispensing events still lack complete audit trails, and custody often remains implicit. This study proposes a traceable sanitary object, an architectural pattern that endows each care object with seven invariant properties: a global identifier (UUID), immutability after issuance, an append-only ledger, explicit and granular custody, a finite state machine, a canonical document with a cryptographic hash, and ownership from creation. Heterogeneous clinical objects share this core, dispensing is modeled as an act within the prescription flow, and derived objects are linked through referential lineage, mirroring Brazil's Pix payment rails. A reference implementation (Python/FastAPI, PostgreSQL/SQLite, AGPL) yields a tamper-evident audit trail and neutral public endpoints under the Brazilian General Data Protection Law (LGPD). Reproducible checks verify the pattern: the state machines are exhaustively checked for structural invariants, the canonical document's digest is deterministic and changes with any of its fields, all authorization scenarios pass on PostgreSQL, and no public endpoint exposes a clinical field; an independent pass reproduced the reported results. The proof of concept implements server-side ICP-Brasil signing of issued PDFs; client-side signing and an external event-publishing layer are left for future work.

Keywords: append-only ledger, audit trail, chain of custody, electronic prescription, health information interoperability.

I. Introduction

Brazil's Unified Health System (SUS) has invested heavily in the digital exchange of health data. The National Health Data Network (RNDS) adopts the HL7 FHIR standard to consolidate records from heterogeneous institutions into a distributed national interoperability layer [1]– [3]. However, empirical assessments show that integration across national health information systems is still partial and fragmented [4], [5], and reviews of electronic health records (EHR) in Brazil repeatedly identify interoperability and security as the dominant open problems [6], [7]. These initiatives focus on the exchange of clinical data rather than the traceability of the clinical objects involved in the provision of care.

A prescription, lab order, report, appointment, referral, counter-referral, diagnostic circulation, or dispensing event is more than just data. It is an artifact. Someone issues it. Someone transfers it. Someone holds it. Someone acts on it. Someone closes it. Without end-to-end traceability and explicit custody, accountability is weakened [8]. We cannot easily determine who issued the object, who held it at each moment, what happened to it, or whether anyone altered its content. These questions are important for clinical safety and also for regulation. The Brazilian Federal Council of Medicine Resolution CFM 2.299/2021 requires ICP-Brasil signatures for digitally issued medical documents. These signatures guarantee authorship, integrity, and authenticity [9].

Brazil offers a striking precedent already in the public domain. Pix, the instant-payment system operated by the Central Bank, was designed from the outset as an open public infrastructure with standardized APIs, common rules, and equal access for banks, fintechs, governments, and new entrants. In Pix, the object (the transfer) is global and neutral, addressed by a portable key, while the regulated settlement rails are the shared substrate on which any participant operates. The model has drawn international attention as an example of payments treated as public infrastructure [10], [11]. We argue that the public health system lacks equivalent open rails for its own objects: there is no shared, neutral substrate on which a sanitary object can be issued once and then traced, audited, and acted upon across institutions.

This study proposes a traceable sanitary object as an architectural pattern that supplies such a substrate at the application-architecture level. The pattern defines an object that carries its own identity, immutability, ledger, custody

chain, state machine, canonical document, and ownership independent of any single institution.

Our contribution is the pattern itself (the core), not the product. We demonstrate it through an open-source reference implementation, PicSaúde (*Plataforma de Integração do Cuidado em Saúde* in Portuguese), available at https://github.com/Tonaco-13/PicSaude. We do not merely demonstrate this; we verify it through reproducible robustness checks: exhaustive state-machine verification over 78 states and 99 transitions, 96/96 authorization scenarios, 13/13 tamper-evident document fields, and zero clinical leakage on public endpoints. An independent process was used to reproduce the reported figures. PicSaúde is a proof-of-concept, not a system deployed at a clinical scale.

The remainder of this paper is organized as follows. Section II reviews the literature. Section III defines the conceptual model and its seven properties. Section IV details the architecture of the traceable sanitary object. Section V demonstrates the generalization across clinical objects. Section VI describes the implementation and guarantees of the model. Section VII reports the reproducible robustness checks that verify these guarantees. Section VIII discusses the trade-offs, ethics, and limitations of the study, and Section IX concludes the paper.

II. Related Literature

A. National health-data infrastructure

The dominant line of work in Brazil concerns the semantic and syntactic interoperability of clinical information. The RNDS standardizes exchanges using HL7 FHIR resources and controlled terminologies [1], [2]. Studies of the e-SUS Primary Care strategy have quantified how national information systems remain only partially integrated, with persistent fragmentation across the care and surveillance domains [4]. Broader reviews of Electronic Health Records (EHR) development in Brazil conclude that interoperability is considered essential by most authors, while also flagging access control and data security gaps [6]. Comparative analyses across Latin America emphasize governance continuity as a recurring weakness [7]. This body of work is centered on moving data between systems, not on providing each clinical artifact with an auditable lifecycle.

B. Electronic prescription and digital signature

Resolution CFM 2.299/2021 and related norms govern the digital issuance of medical documents. They mandate the signing of the ICP-Brasil to guarantee authorship, integrity, and authenticity [9]. However, they specify only what a valid signed document must contain—not how to trace the object after issuance or how to transfer custody between actors.

C. Event sourcing and append-only ledgers

Outside healthcare, event sourcing is an established pattern in which state changes are captured as immutable events in an append-only store that doubles as a complete audit trail [12]. We adopt this pattern internally as the ledger property of the proposed sanitary object.

D. Track-and-trace and chain of custody

In the pharmaceutical supply chain, blockchain-based and serialization-based approaches provide a tamper-evident chain of custody from the manufacturer to the dispensing point, often motivated by regulations such as the U.S. DSCSA and EU FMD [13]– [15]. These approaches trace physical product units across different organizations. The proposed pattern traces clinical objects (and their items) across clinical roles and does not require a distributed ledger or a shared consensus.

E. Positioning and Comparative Analysis

Prior studies separately addressed data interoperability, signed-document compliance, generic event sourcing, and supply chain track-and-trace. To bridge these gaps, the main contribution of this study proposes a unifying domain pattern for heterogeneous clinical objects. This pattern combines seven invariant properties: global identity, immutability with referential lineage, an append-only ledger, explicit and granular custody, a finite state machine, a canonical document with a cryptographic hash, and ownership from the creation. Because it is expressed at the application architecture level, it can be seamlessly instantiated in a conventional relational infrastructure. To demonstrate the architectural contribution of this study, we distinguished traceable sanitary objects from four established technical paradigms:

a) Data Interoperability Frameworks (HL7 FHIR/RNDS): Efforts such as the RNDS concentrate on semantic and syntactic standardization of the information being exchanged. However, they lack strict enforcement of a deterministic life cycle or a verifiable chain of custody (tracking the current holder and object state). The proposed pattern serves as a structural complement to FHIR; where FHIR supplies the vocabulary for clinical data, this architecture establishes the state machine and custody management layer. The same boundary applies to openEHR archetypes and IHE integration profiles, which standardize clinical content models and cross-enterprise document sharing but likewise leave lifecycle enforcement and custody to each implementation.

b) Distributed Ledger Technologies (Blockchain): While recent studies favor blockchain for establishing trust in decentralized settings, a national health system possesses an inherent central anchor in the state. Consequently, the pattern adopts an append-only relational ledger combined with cryptographic hashing to achieve tamper evidence. This approach avoids the significant computational costs and latency associated with the distributed consensus mechanisms.

c) Proprietary Electronic Prescription Platforms: Existing commercial solutions often trap custody within proprietary silos, leading to vendor lock-in, where private firms control the clinical history. By defining the sanitary object as a neutral, AGPL-licensed public rail, this architecture protects citizen sovereignty and prohibits the monetization of health records, operating as an open infrastructure, rather than a closed ecosystem.

d) Healthcare Traceability Frameworks (DSCSA/EU FMD): Regulatory track-and-trace regimes such as the U.S.

DSCSA and the EU Falsified Medicines Directive mandate the serialization and verification of physical drug packages across the supply chain [13]-[15]. These frameworks locate a unit of product; they do not record who holds a clinical decision or in what state it stands. The proposed pattern operates at this clinical-object layer and is complementary to them: a dispensing event recorded under this architecture can anchor the care-level endpoint of such product-level chain.

III. The Traceable Sanitary Object

We define a traceable sanitary object as any artifact of care that has its own clinical identity and an auditable lifecycle. This pattern is characterized by seven invariant properties (Fig. 1).

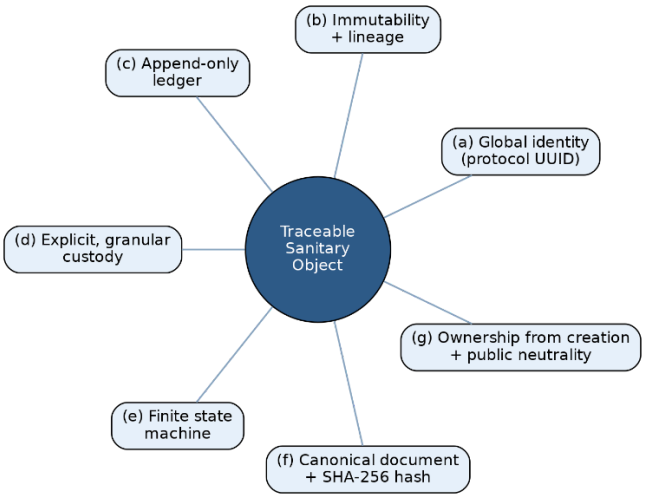

Fig. 1. The traceable sanitary object and its seven invariant properties (a)–(g): global identity, immutability with lineage, an append-only ledger, explicit and granular custody, a finite state machine, a canonical document with hash, and ownership from creation.

a) **Global identity:** Every object carries a protocol (a UUID) that is unique, immutable, and independent of any institution: the primary handle through which the object is referenced, audited, and shared, in direct analogy to a portable Pix key.

b) **Immutability with lineage:** An object is never edited after issuance. Any correction, renewal, or re-issuance produces a new derived object that points back to its predecessor through an origin reference, forming an explicit lineage chain. Therefore, audits never lose their history.

c) **Append-only ledger:** Every business-relevant event is recorded as an insertion into an events table that never receives updates or deletions. This internal event-sourcing log is the backbone of the auditability.

d) **Explicit granular custody:** Each object has a single custodian at every moment, and every transfer is recorded in a custody chain. Custody can be held over an entire object or over an individual item, which is what makes partial flows (e.g., partial dispensing) traceable. *Uniqueness of custody is enforced at the database level by partial unique indexes in both supported dialects, rather than by application convention.*

e) **Finite state machine:** Each object type has an explicit set of states and valid transitions, with terminal states distinguished by clinical meaning.

A digital flow is kept separate from a purely physical flow (paper issuance that never enters the digital cycle), avoiding category errors between, for instance, a clinical revocation and a paper-only closure.

f) **Canonical document with hash:** The object is serialized deterministically into a canonical document from which a SHA-256 digest is computed—the integrity anchor and the basis for ICP-Brasil signing under the PAdES profile; in the current proof-of-concept, server-side ICP-Brasil PAdES-B signing of issued PDF documents is fully implemented, while client-side signing of the canonical document remains future work (Section VIII).

g) **Ownership from creation and public neutrality:** Access control and inline identity assertion are enforced on every private endpoint from the moment the object is created. Public endpoints are kept neutral (carrying no clinical data) so that verification can be offered without exposing sensitive information, consistent with the LGPD Art. 11 [16].

IV. Architecture

The architecture materializes the seven properties on a conventional relational stack. Fig. 2 shows the prescription life-cycle state machine, and Fig. 3 shows the custody chain and derivation lineage.

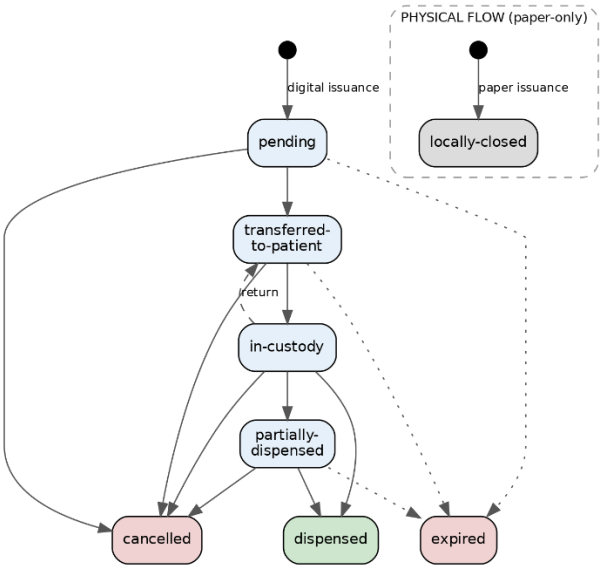

Fig. 2. Prescription life-cycle state machine. A digital flow (pending through dispensed, with cancellation and expiry) is kept disjoint from a physical, paper-only flow whose single terminal state is locally-closed, preventing a clinical cancellation from being conflated with a paper-only closure.

A. Immutable ledger

Each object family has a table of events which admits only insertions. A controlled vocabulary of events—issuance, renewal, correction, custody transfer, dispensing, partial dispensing, and item return—is recorded with the actor, timestamp, and payload. Because no update

or deletion is permitted, the ledger provides a non-destructive, append-only history that underpins all audit queries.

Because the ledger is the source of truth, a regulatory report is not a separate stateful artifact but a deterministic projection of that ledger, and two properties of this projection are already enforced and verified. Reproducibility: recomputing a closed period yields a byte-identical result, because each line reflects the running balance as of its own movement date, so events recorded after the period boundary never alter earlier lines. Identifier uniqueness: each movement—a dispensing or a reversal—appears exactly once, a property we treat as a falsifiable fraud invariant and enforce with a permanent guard-rail check in the continuous-integration gate; accordingly, every sanitary-object mutation is idempotent and protected against double submission by a row-level lock. Two further rules are adopted as invariants with implementation underway: every derived object resolves to a visible root protocol through the origin-reference chain, and external surveillance identifiers (for example, a medication's ANVISA registry number) are snapshotted onto the movement at write time rather than fetched live on the clinical path.

B. Granular custody

A custody table records the current holder and all transitions. Valid transitions are declared explicitly (e.g., prescriber to patient on digital issuance, patient to dispenser on presentation at the counter, and dispenser to patient on return). Custody may be recorded for an entire object or for individual items.

C. Finite state machine

The allowed states and transitions are declared in a single domain module that serves as the source of truth, which is mirrored in the database schema. Digital states (pending, transferred-to-patient, in-custody, partially dispensed, dispensed, and cancelled) are separated from the physical terminal state used for paper-only issuance.

D. Canonical document and integrity

A dedicated module produces canonical serialization and its SHA-256 digest. The digest is stored with the object and exposed through a document-integrity endpoint, allowing any holder to verify that the content has not changed and is the intended input for ICP-Brasil PAdES signing.

E. Ownership, RBAC and public neutrality

Every private endpoint enforces role-based access control and an inline identity assertion so that ownership is checked at creation and at each subsequent act. Public endpoints expose only non-clinical confirmation data [16].

F. Institutional scope

Operations are made contextual through optional organization and unit identifiers. The clinical object remains global and neutral—identified by its protocol—while these identifiers act as query scope, access filter, and operational context, never as the primary key. A NULL value denotes the absence of an institutional link (not a sentinel), and the fields are rolled out incrementally only when a real use case requires them. Where an organization identifier is present, queries in an institutional context must include it as a filter, enforced as an architectural guardrail.

V. Generalization of the Core

The pattern is a core, not an exception: the same seven properties instantiate multiple clinical objects (Table I).

Dispensing is not a standalone object but an act within the prescription flow, governed by the invariant "sum of dispensed quantities does not exceed the prescribed quantity." Its hospital variant follows prescriber → hospital pharmacy → (nursing unit) → patient.

TABLE I. *Instances of the Traceable-Sanitary-Object Core*

Object	***Typical states (digital flow)***	***Terminal states***	***Custody chain***
Prescription	pending → transferred-to-patient → in-custody → partially-dispensed → dispensed	dispensed; cancelled; expired; locally-closed (physical)	prescriber → patient → dispenser → (patient | prescriber)
Lab order	issued → scheduled → collected → under-analysis → result-available → closed	closed; cancelled; expired; physically-closed	prescriber → patient → lab provider → patient
Report	in-production → signed → released → acknowledged (patient/prescriber) → closed	closed; cancelled; expired; physically-closed	lab provider → (patient | prescriber)
Appointment	created → confirmed → carried-out	carried-out; cancelled; no-show	none (bilateral commitment; documented exception)
Diagnostic circulation	selected → sent-to-lab → proposal-received → patient-confirmed → performed	performed; patient-unmarked; lab-unmarked; lab-archived; expired	patient → lab (token-mediated)

Referral	issued → (under-regulation) → scheduled → attended → counter-referred → closed	closed; cancelled; expired; denied; physically-closed	prescriber (origin) → patient → prescriber (destination) → patient
Counter-referral (derived)	Registered	Cancelled	destination → origin (origin-referral reference)

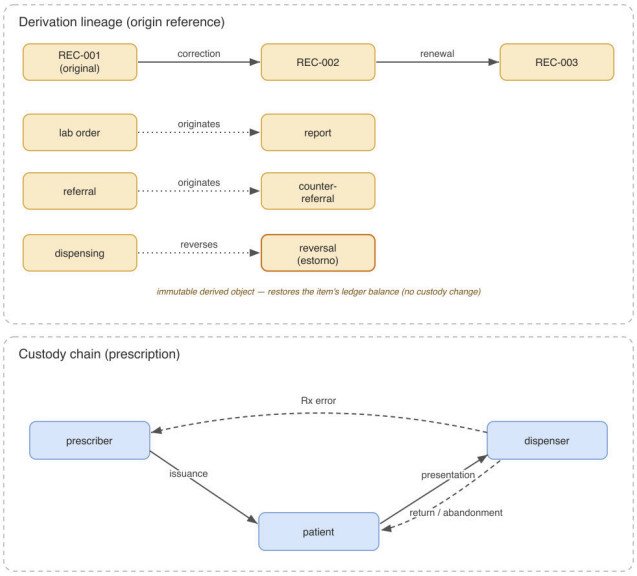

Fig. 3. Custody chain (a single custodian at each moment, with explicitly declared transitions) and derivation lineage (corrections and renewals chained by an origin reference, and cross-object derivations such as report-from-lab-order and counter-referral-from-referral).

A. *Derived objects*

The derivation generalizes beyond corrections and renewals. A report is a derived object of a lab order, and a counter-referral is a derived object of a referral. Each derivation has a distinct author, its own canonical document and hash, and a referential link to its origin. Thus, the lineage chain spans not only versions of one artifact but also causally related artifacts across the care pathway.

B. *Documented exceptions*

Some objects intentionally relax one property, and recording the exception is part of the discipline. Appointments are lightweight objects with identity, states, and a ledger but no custody chain because they represent a bilateral commitment rather than a held artifact. Acknowledgement of a report operates at the level of the entire report rather than per item. Diagnostic circulation authorizes the act through a presentation token, rather than a custody transfer. Naming these exceptions explicitly is what keeps the core coherent and stable.

VI. Implementation and Guarantees

This section describes the reference implementation of the traceable sanitary object and the guarantees the pattern entails.

A. *Stack and scale*

The reference implementation uses Python with FastAPI for the API layer and a relational store that runs on PostgreSQL in production and SQLite in development, under a single Alembic-managed schema. It comprises approximately 36,142 lines of application code across 33 routers and 47 ORM models, exposing 156 endpoints over 20 schema migrations. Seven sanitary-object families each carry their own finite state machine; across object- and item-level machines, they declare 78 states and 99 valid transitions in single source-of-truth modules, and a unified ledger helper records the controlled event vocabulary for all subdomains. Seven of these families maintain their own append-only event ledgers (alongside an internal publication outbox), and five maintain explicit custody chains. The test suite comprises 1,557 test functions across 103 files; a continuous-integration gate, the unit suite together with a selected integration subset executed against an ephemeral PostgreSQL instance, runs on every change and gates merges. All implementation figures above are as of commit babc264, Aug. 24, 2026.

B. *Dual-database test gate*

A dual-database gate executes the suite against ephemeral PostgreSQL instances in addition to SQLite. This is not redundant: SQLite's permissive typing (e.g., accepting an integer literal for a Boolean column or lax NULL handling) silently masks defects that surface only under PostgreSQL's strict typing. In our development, this gate repeatedly caught latent defects invisible on SQLite; for instance, a Boolean column written with an integer literal passed every SQLite test yet raised a type-mismatch error on PostgreSQL, meaning that a code path that appeared fully tested was in fact broken under production-equivalent conditions. The methodological claim is narrow but practical: for dual-database clinical systems, the production database must be inside the test gate—a green bar on the development database is necessary but insufficient.

C. *Guarantees from the model*

Several safety properties follow directly from the pattern rather than from ad-hoc checks. Partial dispensing cannot exceed the prescription because the sum of dispensed quantities for an item is constrained to not exceed the prescribed quantity. An item that cannot be paid for simply returns to a pending state and remains dispensable elsewhere without cancelling the prescription. Immutability, together with the append-only ledger, yields a tamper-evident audit trail: history is never overwritten, only extended; non-repudiation of issued documents is already anchored in server-side ICP-Brasil PAdES-B signing recorded in the ledger, while end-to-end non-repudiation of the canonical document follows once client-side signing is integrated. Terminal-state semantics are kept distinct; therefore, a clinical cancellation is never conflated with a paper-only closure. Access control is enforced from creation, and public endpoints are neutral by construction; functional checks found no clinical field exposed on any public endpoint (Section VII); these are functional checks, not a security audit, and adversarial testing remains future work. Table II maps each guarantee to the mechanism that enforces it and a representative test from the suite that exercises it.

TABLE II. MODEL GUARANTEES, ENFORCING MECHANISM, AND A REPRESENTATIVE TEST

Guarantee	*Enforcing mechanism*	*Representative test*
`Dispensed ≤ prescribed`	per-item balance check before insert	test_supera_saldo (HTTP 422)
Append-only audit trail	insert-only event ledger (no update/delete)	test_retorna_eventos_inseridos
Immutability with lineage	correction issues a new derived object	test_correcao_aceita_novos_campos
Valid transitions only	single source-of-truth transition tables	test_transicao_invalida (HTTP 409)
Ownership from creation	inline RBAC + identity assertion	test_dispensador_sem_custodia (HTTP 403)
Public neutrality	public endpoint projects no clinical field	test_publico_neutro

D. Regulatory and licensing posture

The design targets compliance with ANVISA RDC 1.000/2025, which governs the electronic prescription of medications under special control, emphasizing traceability, mandatory digital signature, and integration with the National Controlled-Prescription System (SNCR), which amends Ordinance SVS/MS 344/98 and CFM 2.299/2021 [9], [17]. The reference implementation was released as open source under the AGPL, on the principle that the infrastructure for a public health system should be public. The architecture is the subject of a Brazilian INPI filing (BR 51 2026 002267-3).

VII. ROBUSTNESS EVALUATION

This section discusses the claims made by the proposed pattern. The evaluation was architectural rather than clinical; a real-setting study is required in the future. Therefore, we subject each invariant property to a structural or behavioral robustness check and ask whether it holds in the implementation, not only in the design. Every check is scripted, seeded, and released with the open-source code, so each number below is reproducible; the headline figures were additionally re-derived by an independent verification pass that reproduced 14 of 15 and caught one author measurement error, since corrected to the 13/13 reported here. Table III summarizes the results.

A. Formal verification of the state machines

The seven families comprised 11 object- and item-level machines (78 states and 99 transitions). We exhaustively checked four structural properties: every transition target is a declared state, the terminal set is a subset of the states, no non-terminal state is a dead end, and terminal states are absorbing. The first three are universally applicable. The absorbing-terminal check surfaced two terminal states with a declared outgoing transition—a dispensed item that may be reversed, and an item with an available result that may be explicitly closed—revealing a tension between "terminal as clinically complete" and "terminal as absorbing." Instead of concealing it, we report it as a finding that is currently being refined. For the dispensing case in particular, the reversal is modeled as an immutable derived object that restores the effective ledger balance of the item rather than mutating the terminal item. Therefore, dispensability follows from the ledger balance rather than from the state label, while the declared dispensed-to-reversed transition remains dormant scaffolding that the check correctly surfaces. Surfacing such cases is precisely the benefit of treating the state machine as a verifiable artifact.

A guard-rail check confirmed that no movement identifier recurred in the dispensing report, and a concurrency test shows that two simultaneous identical dispensings each recorded a single movement, exercising the idempotency invariant under a race.

B. Document integrity (tamper-evidence)

For the canonical document, the SHA-256 digest was identical across 1,000 recomputations of the same input (determinism), and a single-field mutation altered the digest for all 13 document fields (eight headers and five per item); that is, any content change is tamper evident.

C. Authorization and anti-leak

Across nine authorization suites, 96 scenarios were executed against PostgreSQL, and all passed, each exercising the ordering 404 (not found), 403 (not owner), and 409 (state conflict) that prevents disclosure of an object's existence or state to a non-owner. These are functional checks of the intended access-control behavior, not a security audit; adversarial and penetration testing remain future work.

D. Dual-database divergence

The dual-database gate-caught defects are invisible on SQLite: in two concrete instances, a Boolean column written with an integer literal passed every SQLite test yet raised a type-mismatch error on PostgreSQL—a defect

class that example-based testing on the development database alone does not reveal.

E. Public-endpoint neutrality (LGPD)

A static audit of all six public endpoints confirmed that none projected a clinical field (only protocol, status, issuance type, and per-item order/status), and tests confirmed that no seeded clinical values appeared in any public response.

TABLE III. ROBUSTNESS EVALUATION RESULTS

Check	***Result***
State-machine verification	11 machines, 78 states, 99 transitions; 3/4 properties universal; 2 non-absorbing terminals found and tracked
Hash tamper-evidence	deterministic over 1,000 runs; 13/13 fields alter the digest
Authorization / anti-leak	96/96 scenarios pass on PostgreSQL (404→403→409)96/96 scenarios pass on PostgreSQL
Dual-database gate	2 boolean-as-integer defects caught on PostgreSQL, invisible on SQLite
Public neutrality (LGPD)	0/6 public endpoints project a clinical field

VIII. DISCUSSION, LIMITATIONS, AND ETHICS

A. Trade-offs

Physical (paper-only) issuance uses a fire-and-forget call: the front-end prints without waiting for the back end to confirm persistence. This favors the availability of the clinical act over guaranteed central registration—if the back end is offline, printing still succeeds, and the record may remain only on the client. The trade-off is accepted and documented; full traceability requires the back end to be reachable. Similarly, a mathematically invalid sentinel identifier is reserved for unidentified patients in paper flows and must be excluded from analytics, and the institutional scope is rolled out incrementally rather than imposed on every table at once.

B. Ethics

A non-negotiable goal of the project is that patient health data are never monetized. The aim is citizen sovereignty over health objects through auditable grants of access, never the sale of data. This principle is treated as a design constraint, rather than a policy statement.

C. Limitations and Challenges for Large-Scale Adoption

This work is currently a proof-of-concept and has not yet been deployed at clinical scale. Moving from an architectural core to a national or municipal deployment introduces several practical challenges that must be addressed:

a) External Integration and Interoperability: While the system is event-sourced internally, it is not yet event-driven externally. Because there is currently no event-publishing layer, external adapters (such as legacy HIS, TISS, HL7, and e-SUS) lack a native integration point. Real-world adoption will require developing these robust interfaces to orchestrate workflows without demanding the complete replacement of existing hospital and pharmacy systems. The planned mitigation is an event-publishing layer over the append-only ledger—cursor-based polling endpoints scoped by organization, per-organization webhook registration, and a canonical external event format—so that adapters consume official endpoints and never write directly to clinical tables, enabling incremental coexistence with legacy hospital information systems rather than wholesale replacement.

b) Cryptographic Implementation and Ledger Security: Server-side ICP-Brasil PAdES-B signing is fully implemented for issued PDF documents (e.g., prescription forms and lab orders). The PDF is signed with a certificate held in an encrypted server-side vault, and each signing act is recorded in the ledger. However, client-side signing of the object's canonical document remains future work, as it requires a deterministic serialization that is identical across client and server implementations. Furthermore, the append-only ledger is currently enforced as an application-level invariant; implementing cryptographic hash-chaining or external anchoring to make the ledger tamper-evident—even against a privileged database actor—is a necessary next step.

c) Performance under Real Clinical Workflows: Operating at the scale of the SUS means tracing millions of daily objects and their derivations. This poses significant database growth and query-performance challenges, which will require advanced data engineering (e.g., database sharding, asynchronous queues, and cold-storage archiving for physically closed objects) to maintain low latency during peak clinical hours. The relational design admits horizontal partitioning of the event and custody tables by time or organization, read replicas serving deterministic projections, and archival of terminally closed objects to cold storage; the absence of distributed consensus removes a major latency source by construction.

d) Governance and Orchestration: The Pix analogy raises a fundamental governance question beyond this paper's architectural scope. Just as Pix depends on the Central Bank as a central operator, shared health rails would require a designated public operator (such as the Ministry of Health or DATASUS) and a robust governance model to manage credentialing, access control, and cross-jurisdictional coordination. A federated operating model—central specification and auditing combined with regionally operated instances—could balance national consistency with local autonomy, but operator accreditation and dispute resolution across jurisdictions remain open institutional questions.

IX. CONCLUSION AND FUTURE WORK

We have argued that the objects of care—prescription, lab order, report, appointment, referral, counter-referral, diagnostic circulation, and dispensing—share a single architectural contract, which was formalized as the traceable sanitary object: a pattern defined by global identity, immutability with lineage, an append-only ledger, explicit and granular custody, a finite state machine, a canonical document with hash, and ownership from creation. Treating these artifacts as instances of one core is what yields traceability, auditability, and the basis for cross-institution interoperability. Crucially, this contract is not merely proposed but verifiable and verified: its state machines, canonical hashing, authorization ordering, and

public-endpoint neutrality are all exercised by reproducible, seeded scripts shipped with the AGPL-licensed code, and the reported figures were reproduced by an independent pass—so the architecture's claims can be re-audited rather than taken on trust. The same discipline keeps us honest, having surfaced two real state-machine inconsistencies that we report rather than hide. Future work includes client-side ICP-Brasil signing of the canonical document, an event-publishing layer with webhooks to enable external adapters, a municipal pilot, and empirical validation in a real care setting.

***Abstract*—Clinical information in discharge summaries is often recorded as free text, limiting its reuse in interoperable healthcare systems. This paper presents a preliminary feasibility study of transforming hospital discharge medication text into HL7 FHIR *MedicationRequest* resources using large open-weight language models. Based on MIMIC-IV-Note, MIMIC-IV, and MIMIC-IV on FHIR, we constructed a paired dataset linking discharge medication sections to structured medication references. The task was formulated as structured generation and evaluated using Gemma 4 E2B-it and E4B-it under zero-shot, few-shot, and supervised LoRA fine-tuning settings. Evaluation considered both clinical extraction quality, including medication, dosage instruction, route, and frequency, and structural quality, including JSON validity, FHIR conformance, minimum completeness, and Bundle completeness. Preliminary results indicate that prompt-based strategies were insufficient for this task, whereas LoRA fine-tuning substantially improved extraction performance, particularly for the larger E4B-it variant. However, structural validity and Bundle completeness remained lower than extraction metrics, showing that generating interoperable FHIR resources requires more than accurate entity extraction. These findings suggest that open-weight LLMs are a feasible starting point for clinical text-to-FHIR transformation, while highlighting the need for validation, correction mechanisms, and hybrid pipelines.**

***Index Terms*—Large language models, clinical information extraction, HL7 FHIR, MedicationRequest, discharge medications, healthcare interoperability.**

I. Introduction

The adoption of electronic health records, together with the digital transformation of care processes, has expanded the availability of clinical data for care delivery, management, research, and technological development. However, a substantial share of clinical information remains recorded as free text, with variations in style, abbreviations, omissions, idiosyncratic expressions, and different levels of completeness. In many health information systems, documentation is primarily produced to support the care workflow, record clinical decisions, and meet legal requirements, rather than to facilitate interoperability, automated analysis, or systematic reuse in research and innovation *pipelines* [1]–[4].

In the medication domain, information on drugs, dose, unit, route of administration, frequency, duration, dispensed quantity, and refills is directly related to patient safety and continuity of care. In hospital discharge notes, these elements may appear abbreviated, distributed along the same line, expressed partially or implicitly, or combined in heterogeneous textual patterns. The challenge increases when there are multiple medications in sequence, prescriptions with limited duration, tapering regimens, "*as needed*" instructions, and dispensing or refill fields.

Thus, the problem involves a linguistic stage, aimed at understanding clinical text, and a structural stage, aimed at correctly representing the extracted content in a computable format, at a critical moment of care transition, in which discrepancies, omissions, or incorrect interpretations of prescriptions may contribute to adverse events that could otherwise be avoided. Therefore, transforming medication instructions recorded in natural language into structured, traceable, and interoperable representations is a practical requirement to support medication reconciliation, communication between services, clinical auditing, decision support, and secondary data reuse [2], [5].

The literature has explored various strategies for this type of problem, including manual rules, dictionary-based systems, supervised sequence labeling models, neural architectures, and, more recently, Large Language Models (LLMs). Shared challenges, such as n2c2 2018, have contributed to consolidating medication and attribute extraction tasks in clinical texts, providing methodological foundations for comparing approaches [13]. These studies show that the problem is not purely lexical; it depends on context, terminological normalization, and the relational interpretation between entities.

At the interoperability level, the HL7 FHIR (*Fast Healthcare Interoperability Resources*) standard provides a modular, resource-oriented model for clinical data exchange. FHIR is strongly associated with RESTful API-based architectures, in which transactions are performed directly on resources through HTTP requests [11]. In the medication domain, the *MedicationRequest* resource represents a medication order or prescription, including both the supply and administration instructions for the patient [10].

In this scenario, LLMs emerge as an alternative for clinical information extraction and structuring tasks, since they combine contextual understanding, instruction-following, and structured-output generation capabilities. In this paradigm, the model receives the clinical text and a specification of the expected output format, and may directly return an intermediate structure, such as JSON, or a standardized resource, such as FHIR. Its main advantage lies in the ability to specify the task in natural language, combining instructions, examples, constraints, and output schemas.

Recent studies indicate that LLMs may be useful for clinical extraction tasks, but also show that results vary substantially according to the model, domain, language, prompt type, output structure, and the presence or absence of fine-tuning [16]–[22]. Overall, these studies reinforce that LLMs can reduce manual engineering effort, but do not eliminate the need for careful evaluation, post-processing, structural validation, and error analysis. Their use must be evaluated with caution, since clinical applications require not only aggregate performance, but also analysis of compliance, traceability, safety, hallucination, omissions, and semantic consistency [6]–[8].

In the specific context of FHIR, transforming free text into interoperable resources is even more demanding. In addition to correctly extracting the clinical content, the model must respect the resource structure, fill in required fields, avoid incompatible elements, maintain attribute consistency, and produce valid JSON. Recent work on converting clinical reports into FHIR has shown that the prompt strategy may be as important as, or even more important than, the choice of model, especially when the task involves generating a FHIR *Bundle* and validation using tools such as HAPI FHIR [23]. *Benchmarks* focused on assessing FHIR knowledge and generation also suggest that language models can adequately answer questions about the standard or recognize resource types, but still face substantial difficulties in the more complex task of reconstructing FHIR resources from unstructured clinical notes [24].

In this context, this article presents a preliminary feasibility study using Google/Gemma 4 as a proof-of-concept model to transform hospital discharge medication prescription texts into FHIR resources of type *MedicationRequest*. The study aims to evaluate whether the model is able to: (i) correctly identify the medications present in the text; (ii) recover prescription attributes, such as drug, dose, route, and frequency; (iii) organize these elements into FHIR *MedicationRequest* resources; and (iv) produce outputs that are syntactically valid and semantically consistent with the original content. The main contributions of this work are: the proposal of a pragmatic formulation for the problem of transforming hospital discharge medication text into FHIR resources; the presentation of a design for evaluating LLMs in a task that combines clinical extraction and structural compliance; and the evaluation of Gemma 4 as an open model, considering its applicability in scenarios in which local execution, infrastructure control, and reduced dependence on proprietary APIs are business requirements.

II. Materials and Methods

The task was formulated as a structured generation problem, in which the input corresponds to the textual discharge medication section extracted from clinical reports and the output corresponds to a set of FHIR resources of type *MedicationRequest*. The experimental design includes three main evaluation strategies: *zero-shot* inference, *few-shot* inference, and supervised model fine-tuning. The evaluation considers both the quality of clinical extraction and the structural compliance of the generated output.

A. Data Sources

The data source used in this study is the MIMIC-IV database from the PhysioNet platform. MIMIC-IV is a public and de-identified electronic health record database, built from patient clinical data and organized in a modular manner to support retrospective health analyses [1].

The MIMIC-IV-Note module was used as the source of natural-language clinical texts [25]. For this study, hospital discharge reports containing the prescribed medication section were considered. As a structured reference for comparing and validating the generated medication resources, MIMIC-IV on FHIR was used, which provides a representation of MIMIC-IV data in the HL7 FHIR standard [26].

The integration between the databases was performed through shared de-identified identifiers, especially *subject_id* and *hadm_id*. The *subject_id* enables de-identified patient identification, whereas the *hadm_id* represents the hospital admission. In this study, *hadm_id* was adopted as the primary unit of analysis to relate the discharge report, the structured prescription records, and the corresponding FHIR resources within the same care context.

B. Cohort Construction

The experimental cohort was built by matching hospital discharge reports from MIMIC-IV-Note with structured medication records available in MIMIC-IV and MIMIC-IV on FHIR. Only discharge reports associated with a valid *hadm_id* and explicitly containing a discharge medication section identifiable through textual patterns were included. The purpose of this selection was to ensure that each example used in the study presented clear textual evidence of the prescription and a structured reference associated with the same encounter.

Reports containing the *Discharge Medications* section, with the list of medications prescribed or recommended for therapeutic continuation after hospitalization, were considered eligible. Reports without valid textual content, documents in which the medication section could not be reliably located, records with predominant textual noise, and cases without adequate linkage between the discharge text and the corresponding structured medication records were excluded.

The training set for the fine-tuned models was constructed as an input-output pair. The input consists of the text from the *Discharge Medications* section combined with a fixed instruction *template*. The output corresponds to the expected structured representation, expressed in JSON and compliant

with the minimum schema for FHIR *MedicationRequest* resources. Thus, each supervised example represents a direct transformation between free clinical text and an interoperable structure.

C. Extraction of the Discharge Medication Section

The extraction of the discharge medication section was performed through a deterministic pipeline based on regular expressions. This pipeline was implemented in Python and executed on a private server running Ubuntu, with an Intel i7-14700K processor, 64 GB of RAM, and an NVIDIA RTX 4080 GPU.

The pipeline was developed following an exploratory manual inspection of clinical documents. At this stage, 250 discharge reports were randomly selected from the full set for analysis of formatting patterns in the medication section. Based on this analysis, heuristics were defined to locate the section's beginning, delimit its end, normalize the text, and segment the listed medications.

Identification of the target section was based on the literal header *Discharge Medications*. The end of the section was preferably identified by the subsequent header *Discharge Disposition*. When this end marker was not found, the pipeline applied a contingency strategy, capturing the content until the end of the document. This approach was adopted to reduce losses caused by incomplete formatting, missing headers, or partial text degradation.

After locating the section, the content underwent text normalization steps. Excess spaces, redundant line breaks, and superficial formatting variations were removed. Next, medication items were segmented based on numbered lists, a pattern frequently observed in discharge reports. Each numbered item was treated as a candidate prescription unit, preserving the original textual line in normalized format.

The pipeline output was stored in JSON format, organized by *hadm_id*. For each hospital admission, the resulting file contains the list of medication items extracted from the discharge section, the marker of the source section, and, when available, the structured medication record associated with the same encounter. This structure enables each textual line to be traced back to its clinical context and to the structured reference used in the evaluation.

D. MedicationRequest Generation Task

The central task of the study was to transform a textual discharge medication section into a set of HL7 FHIR resources of type *MedicationRequest*. The *MedicationRequest* resource was selected as the target resource because it represents a medication order or request for a patient.

Each model execution receives as input a prompt containing explicit instructions about the task and the text of the *Discharge Medications* section. The model must identify all medications described in the excerpt and generate structured JSON output in the form of a FHIR *Bundle* containing one *MedicationRequest* instance for each identified medication.

The choice of using a FHIR *Bundle* is associated with the need to represent multiple resources in a single response. Since the discharge section generally includes a list of medications, each item must be represented as an independent resource, enabling individual evaluation of each medication and its attributes.

To reduce output variability and make model comparisons fairer, a minimum field schema was defined for each *MedicationRequest*. The core fields include the medication name, route of administration, frequency, and dose. Thus, the task does not only evaluate whether the model correctly recognizes the medication, but also whether it can associate dosage attributes with the correct medication and serialize this information into a FHIR-compatible structure.

E. Gemma 4 LLM Model

Gemma 4 is a family of generative AI models developed by Google DeepMind and released with open weights in different sizes and architectures, including E2B and E4B variants [9].

For the problem investigated, some characteristics of Gemma 4 are relevant:

- the existence of smaller and medium-sized variants, favoring experiments in hardware-constrained environments and bringing the study closer to local or institutional execution scenarios;
- support for *instruction-tuned* models, facilitating task specification through *prompts* in preliminary structured extraction experiments;
- the possibility of fine-tuning or subsequent adaptation, making the model an interesting foundation for further development of the study, should preliminary results indicate limitations in purely *prompt*-based scenarios.

The experiments were conducted with the instruction-tuned variants Gemma 4 E2B-it and Gemma 4 E4B-it, obtained from Google's official HuggingFace repositories. The *zero-shot*, *few-shot*, and post-fine-tuning inference trials were designed to be executed with the same local configuration as the extraction pipeline.

- *zero-shot* – the model receives only the task instruction, the expected output schema, and the text of the discharge medication section.
- *few-shot* – the prompt includes 5 short input-output examples, demonstrating how medications and their attributes should be mapped to *MedicationRequest* resources, in order to induce greater adherence to the FHIR format, reduce serialization variations, and improve the handling of frequent prescription abbreviations, such as *PO*, *BID*, *TID*, *Q6H*, and *PRN*.
- *supervised fine-tuning* – performed on Google Cloud Platform / Google Colab infrastructure, using an NVIDIA H100 GPU, with the PEFT/LoRA strategy.

The hyperparameters used were defined separately for each variant. For Gemma 4 E2B-it, the following were used: (r=32), ($\alpha = 64$), *dropout* $= 0.05$, learning rate (1×10^{-4}), 3 epochs, effective batch size of 32, and maximum sequence length of

4096 tokens. For Gemma 4 E4B-it, the following were used: (r=16), ($\alpha = 32$), *dropout* $= 0.05$, learning rate (5×10^{-5}), 2 epochs, effective batch size of 32, and maximum sequence length of 4096 tokens.

F. Evaluation Metrics

The evaluation was conducted according to two complementary dimensions. The first concerns the quality of the clinical information extracted from the discharge medication text, measuring whether the model correctly identified medications and their associated attributes. The second concerns the structural quality of the interoperable output, measuring whether the generated resources were valid, consistent, minimally complete, and conformant to the HL7 FHIR specification.

For clinical content extraction, precision, recall, and *F1-score* were calculated independently for medication name, dosage instruction, route of administration, and frequency. The comparison was performed between the items generated by the model and the corresponding reference items in the dataset. For these calculations, the following definitions were adopted:

- True positives (TP) correspond to medications or medication attributes correctly extracted by the model according to the reference data. At the attribute level, a value was considered a true positive only when it was both correctly extracted and associated with the corresponding medication.
- False positives (FP) correspond to medications or attributes generated by the model that were not present in the reference data or were not supported by the source text. An attribute extracted with an incorrect value or associated with the wrong medication was also counted as a false positive.
- False negatives (FN) correspond to medications or attributes present in the reference data but omitted by the model. An expected attribute generated with an incorrect value or not correctly associated with its medication was also considered a false negative for the corresponding reference item.

Consequently, an incorrect attribute prediction may contribute simultaneously to the false-positive count, because an unsupported value was generated, and to the false-negative count, because the correct reference value was not recovered. This evaluation criterion is relevant to the present task because correctly recognizing a medication does not necessarily imply that its dose, route, frequency, or dosage instruction was correctly extracted or linked.

The structural evaluation was performed after verifying that the generated output was valid and parseable JSON. This preliminary validation checked whether the response could be processed by a standard JSON parser, whether the expected top-level structure was present, and whether at least one medication item was generated when medication evidence was present in the source text. Outputs containing malformed syntax, inconsistent quotation marks, invalid separators, additional text outside the JSON structure, or an unexpected top-level representation were considered syntactically invalid and were not eligible for subsequent FHIR validation.

The next evaluation layer assessed whether each generated *MedicationRequest* resource conformed to the HL7 FHIR specification. This validation considered whether the output contained only permitted elements, whether the generated values respected the expected FHIR data types and cardinalities, and whether the internal organization of the resource was structurally consistent. In particular, the evaluation considered the representation of the medication and its relationship with the corresponding dosage instructions.

The FHIR validation rate was defined as:

$$\mathrm{FHIRValidRate} = \frac{N_{\mathrm{valid}}}{N_{\mathrm{total}}} \tag{1}$$

where:

- N_{valid} is the number of generated *MedicationRequest* resources that passed the FHIR validation process;
- N_{total} is the total number of generated *MedicationRequest* resources submitted to FHIR validation.

A resource contributed to N_{valid} only when it satisfied the structural rules evaluated by the FHIR validation process. Therefore, a clinically plausible resource could still be classified as invalid when it contained an unsupported element, an incorrect data type, an invalid cardinality, or an inconsistent resource structure.

Structural validity alone, however, does not guarantee that the generated resource contains sufficient clinical information for the proposed task. A *MedicationRequest* may be structurally valid while containing only a medication name and no usable dosage information. Therefore, a minimum-completeness criterion was defined for each generated resource.

For each resource i, the binary minimum-completeness indicator was defined as:

$$C_i = 1\Big(M_i \wedge (D_i \vee T_i)\Big) \tag{2}$$

where:

- C_i is the minimum-completeness indicator for resource i, assuming the value 1 when the resource satisfies the defined criterion and 0 otherwise;
- M_i represents the condition that the medication is present in resource i, for example through a populated medication representation such as *medicationCodeableConcept.text*;
- D_i represents the condition that structured dose information is present, for example through the corresponding dose value and unit in the dosage representation;
- T_i represents the condition that a textual dosage instruction is present, for example through a populated *dosageInstruction.text* element;
- $\wedge$ denotes the logical *AND* operator;
- $\vee$ denotes the logical *OR* operator.

According to this expression, a resource is considered minimally complete only when the medication is identified and at least one form of dosage information is available. The

expression $D_i \vee T_i$ means that either a structured dose or a textual dosage instruction is sufficient to satisfy the dosage-information component of the criterion. However, because this expression is connected to M_i through the logical operator $\wedge$, dosage information alone is not sufficient when the medication itself has not been identified.

For example, when $M_i = 1$ and $D_i = 1$, the resource is considered minimally complete regardless of the value of T_i. Similarly, when $M_i = 1$, $D_i = 0$, and $T_i = 1$, the resource is also considered minimally complete. Conversely, when $M_i = 0$, the indicator is equal to zero even if dose or textual instruction information is present, because that information cannot be reliably associated with an identified medication.

The overall minimum completeness rate was calculated as:

$$\mathrm{MinCompletenessRate} = \frac{1}{N}\sum_{i=1}^{N} C_i \tag{3}$$

where:

- N is the total number of generated resources evaluated for minimum completeness;
- i identifies each individual resource in the evaluated set;
- C_i is the binary minimum-completeness indicator calculated for resource i;
- $\sum_{i=1}^{N} C_i$ is the number of resources that satisfied the minimum-completeness criterion.

Because C_i is binary, the summation counts the number of minimally complete resources. Dividing this count by N produces the proportion of evaluated resources containing an identified medication and either a structured dose or a textual dosage instruction.

Finally, because each discharge medication section may contain multiple medications, the output was generated as a FHIR *Bundle*. The complete *Bundle* rate was used to assess the model's ability to produce a structurally consistent response containing the expected set of medication resources.

The metric was defined as:

$$\mathrm{BundleCompleteRate} = \frac{B_{\mathrm{valid}}}{B_{\mathrm{total}}} \tag{4}$$

where:

- B_{valid} is the number of generated *Bundles* whose set of resources was valid and structurally consistent;
- B_{total} is the total number of generated *Bundles* evaluated.

For a *Bundle* to contribute to B_{valid}, its top-level structure and entries had to be consistent with the expected FHIR representation. In addition, the generated set had to contain the expected medication resources without structural failures that compromised the response as an interoperable exchange unit. Therefore, a *Bundle* containing some valid individual resources could still be considered incomplete when one or more expected medications were omitted, when unsupported or duplicated medication resources were generated, or when structural inconsistencies affected the complete response.

All structural metrics were calculated as proportions and reported as percentages. The separation among FHIR validation, minimum completeness, and complete *Bundle* evaluation is necessary because these metrics capture different aspects of structured generation. A resource may pass FHIR validation while remaining clinically incomplete, and a *Bundle* may contain individually valid resources while failing to represent the complete set of medications described in the source text.

III. Results

This section presents the results obtained from dataset construction, execution of the discharge medication section extraction pipeline, and the first experiments with the LLMs.

A. Dataset and Pipeline Results

The pipeline was fully executed on the set of hospital discharge reports from MIMIC-IV-Note. Of the total processed documents, 323,917 contained an identifiable *Discharge Medications* section, corresponding to 97.6% of the analyzed set. Subsequently, 311,814 documents presented a valid structure for segmentation, that is, they contained numbered items compatible with the pipeline's heuristic, representing 94.0% of the processed documents.

Despite the high coverage in the section localization and text segmentation stages, only 55,118 documents were successfully processed through all stages, including the deterministic linkage between each extracted textual line and the structured medication records associated with the same encounter. This subset accounts for 16.6% of the documents initially processed.

The total number of extracted and linked medications was 361,428, with an average of 6.56 medications per valid document. The main bottleneck of the pipeline lies in the deterministic matching stage between free text and structured records, which requires full correspondence between the items reported and the records for the same *hadm_id*. This constraint increases the reliability of the paired examples but substantially reduces the final dataset coverage.

Processing failures were mainly due to incomplete medication matching identified in the discharge report, accounting for 153,598 cases, or 46.3% of the total processed documents. This error occurs when at least one textual line extracted from the medication section fails to match any structured record in the encounter, invalidating the entire document. A total of 103,098 execution exceptions were also observed, corresponding to 31.1%, in addition to 12,103 cases of invalid structure, 7,233 cases of absence of the medication section, and 643 cases of absence of a structured prescription file.

From the final subset of 55,118 discharge documents, 1,853 unique medications were identified, with a highly imbalanced distribution. To mitigate imbalance between training and testing, medications were grouped into six frequency classes, following a stratified approach [27], namely: *very_frequent*, *frequent*, *moderate*, *rare*, *very_rare*, and *singleton*. Most entities were concentrated in the most frequent classes, with 216,944 instances in *very_frequent* and 83,633 in *frequent*. The

remaining classes had 35,542 instances in *moderate*, 18,592 in *rare*, 5,358 in *very_rare*, and 271 in *singleton*.

The train/test split followed a 90/10 ratio and, after this process, proportional preservation of the frequency classes was observed between the subsets, indicating that the resulting partition maintained adequate representativeness of the different medication strata.

B. Medication Extraction Results

Table I presents the results of the Gemma 4 E2B-it and Gemma 4 E4B-it models in the *zero-shot*, *few-shot*, and LoRA scenarios. Four extraction dimensions were evaluated: medication, dosage instruction, route of administration, and frequency. For each dimension, precision, recall, and *F1-score* were calculated.

The results indicate that the *zero-shot* scenarios did not yield useful extractions for either of the two evaluated models, with metrics equal to zero across all dimensions.

In the *few-shot* scenario, a slight improvement was observed in both models when compared with *zero-shot*. However, the values obtained remained low, suggesting that simply including examples in the *prompt* was insufficient to capture the task's complexity.

The LoRA fine-tuning scenario showed substantial improvement in both models, in contrast to the results obtained in the *zero-shot* and *few-shot* scenarios. This behavior indicates that supervised adaptation was decisive in enabling the models to learn domain- and task-specific patterns, including the clinical vocabulary of discharge prescriptions, the relationships between medications and dosage attributes, and the expected format of the structured FHIR output.

Considering only the LoRA fine-tuned models, Gemma 4 E4B-it outperformed E2B-it across all evaluated dimensions. The difference was particularly expressive for *Medication*, with an absolute gain of 25.29 *F1-score* points, and for *Freq*, with a gain of 22.16 points.

C. Validity of JSON and Structured Output

In the *zero-shot* and *few-shot* scenarios, both models yielded null values for the global metrics, indicating that the lack of adaptation or examples made it infeasible to generate useful structured outputs in the expected format. After LoRA fine-tuning, substantial improvements were observed in the global metrics.

D. Validity of FHIR MedicationRequest

The FHIR validity evaluation shows that generating *MedicationRequest* involves not only the correct extraction of clinical content but also adherence to the resource's formal structure, including expected fields, data types, and cardinalities. Thus, even clinically plausible outputs may be considered invalid when they contain structural inconsistencies.

In the scenarios without fine-tuning, the models produced virtually no valid FHIR resources. After LoRA fine-tuning, a substantial improvement was observed, especially for Gemma 4 E4B-it, which reached a *FHIRVRate* of 58.08. However, the low *BundleCRate* indicates that generating valid individual resources does not guarantee compliance with the complete response, which is composed of multiple medications. These results suggest that the fine-tuned Gemma 4 E4B-it presents initial feasibility as a proof of concept, but still requires complementary strategies, such as post-generation validation, automatic JSON/FHIR correction, and eventual deterministic serialization from an intermediate extraction.

E. Error Analysis

The error analysis indicated three main sources of failure. The first is related to clinical extraction, including medication omissions, partial identification of the drug name, and incorrect association of attributes such as dose, route, and frequency. These errors persisted in the fine-tuned models across more complex prescriptions, such as those with multiple instructions, dose ranges, conditional use, or limited duration.

The second source of error is associated with the generation of structural output. Even when the clinical content was correctly identified, invalid JSON, misplaced FHIR fields, elements not present in the specification, or inadequate cardinalities were observed. This behavior explains the difference between the extraction results and the global FHIR validity metrics.

The third source of error refers to *Bundle* completeness. In documents with multiple medications, the models may still omit items, duplicate resources, or generate individually plausible resources that do not preserve the global consistency of the response. In summary, LoRA fine-tuning considerably improved performance, but FHIR validity and *Bundle* completeness remain the main bottlenecks for operational use.

IV. Discussion

The results indicate that transforming hospital discharge medication texts into FHIR *MedicationRequest* resources is feasible as an experimental task, especially when the model is fine-tuned with supervised data. The comparison between the evaluated scenarios shows that strategies based only on *prompting*, particularly *zero-shot* and *few-shot*, were insufficient to simultaneously handle clinical extraction and structured generation. In contrast, LoRA fine-tuning improved the extraction metrics, suggesting that adaptation to the domain and output format was decisive for the observed performance.

The main evidence of feasibility lies in the performance of the fine-tuned Gemma 4 E4B-it, which achieved an *F1-score* of 86.00 for medication, 92.15 for dosage instruction, 93.88 for route of administration, and 87.37 for frequency. These results indicate that the model learned relevant patterns of the task, including the clinical vocabulary in discharge prescriptions and the association between medications and dosage attributes. However, the global structuring metrics remained lower than the extraction metrics, especially *BundleCRate*, indicating that generating a complete and validatable FHIR response is still more challenging than the isolated identification of entities and attributes.

TABLE I
RESULTS OF THE GEMMA 4 E2B-IT AND E4B-IT MODELS IN THE ZERO-SHOT, FEW-SHOT, AND LORA SCENARIOS.

Model	Strategy	Medication			Dosage Instruction			Route			Frequency			Global Metrics		
		P	R	F1	P	R	F1	P	R	F1	P	R	F1	MinCRate	FHIRVRate	BundleCRate
Gemma 4 E2B-it	zero-shot	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00
	few-shot	6.23	3.27	4.29	15.91	8.81	11.34	12.20	6.87	8.79	6.18	3.58	4.53	0.00	0.04	0.00
	LoRA	57.75	63.98	60.71	85.18	86.00	85.58	84.82	85.95	85.38	61.04	69.99	65.21	20.40	23.97	2.72
Gemma 4 E4B-it	zero-shot	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00
	few-shot	9.10	6.56	7.62	11.58	13.91	12.64	16.45	10.07	12.49	33.48	10.46	15.94	0.02	0.10	0.00
	LoRA	84.79	87.24	86.00	92.74	91.56	92.15	97.93	90.14	93.88	88.75	86.04	87.37	51.13	58.08	12.55

Note: P = precision; R = recall; F1 = F1-score; Medication = medication; DoseInst = dosage instruction; Route = route of administration; Freq = frequency; MinCRate = minimum completeness rate; FHIRVRate = FHIR validation rate; BundleCRate = complete Bundle rate.

A. Interpretation of LLM Results

The comparison between the E2B-it and E4B-it variants suggests that increased capacity within the same model family improved performance on the task. Gemma 4 E4B-it outperformed E2B-it across all evaluated dimensions after fine-tuning, with larger gains in medication identification and frequency extraction. This behavior suggests that the larger variant showed better generalization capacity for more variable textual patterns, such as medication names, abbreviations, and frequency expressions.

Even so, the results show that high extraction performance does not necessarily imply full structural compliance. The fine-tuned Gemma 4 E4B-it obtained a *FHIRVRate* of 58.08 and a *BundleCRate* of 12.55, values lower than the *F1-scores* observed in the extraction dimensions. This difference reinforces that the task has two distinct layers: the first related to understanding and extracting clinical content; and the second related to correctly serializing this content into an interoperable artifact. Thus, generating *MedicationRequest* from free text should be understood as a composite task that combines information extraction, attribute linking, and compliance with a formal data model.

The results obtained play an important methodological role within the broader research. First, they demonstrate that the problem formulation is operationalizable at scale using MIMIC-IV-Note. Second, they indicate that supervised fine-tuning is more suitable than direct use of *prompting* for this specific task. Third, they show that the evaluation must separate clinical extraction metrics from structural validity metrics, since both capture distinct dimensions of the problem. Finally, the findings guide the next experiments with other open model families, allowing investigation of whether the patterns observed in Gemma 4 hold across different architectures and models with different sizes, vocabularies, alignment strategies, and computational costs.

V. CONCLUSION

This article presented a study using Gemma 4 as a proof-of-concept to transform hospital discharge medication prescription texts into FHIR *MedicationRequest* resources. Based on a dataset built from MIMIC-IV-Note, MIMIC-IV, and MIMIC-IV on FHIR, the ability of the Gemma 4 E2B-it and E4B-it models was evaluated in three experimental scenarios: *zero-shot*, *few-shot*, and LoRA fine-tuning.

The results show that strategies based only on *prompting* were insufficient for the task, whereas supervised fine-tuning produced substantial gains in extraction metrics. The fine-tuned Gemma 4 E4B-it showed the best overall performance, especially in extracting medication names, dosage instructions, routes of administration, and frequencies. However, the FHIR validity and *Bundle* completeness metrics remained lower than the extraction metrics, indicating that generating complete, structurally valid, and interoperable resources remains a relevant challenge.

As a contribution, this work demonstrates the initial feasibility of using relatively low-complexity open models to support the transformation of free clinical text into FHIR representations. In addition, it proposes an experimental formulation that distinguishes the evaluation of clinical extraction from that of structural compliance, an essential aspect for health interoperability applications.

Although the results are promising, this evaluation should be interpreted as a proof-of-concept based on a single model family. Two Gemma 4 variants were evaluated, but both share similar architectural characteristics, training strategies, and instructional behavior. Therefore, the results do not allow the conclusion that the observed performance is representative of other open-weight models or other LLM families. Another limitation concerns the scope of the task. The study focused on the *Discharge Medications* section and on a minimum subset of attributes associated with *MedicationRequest*, especially medication, dose, route, and frequency. Additional fields, such as duration, dispensed quantity, refill, clinical intent, status, references to the patient and encounter, and standardized terminological coding, were not fully explored. In addition, semantic validation was conducted based on an operational reference derived from MIMIC-IV and MIMIC-IV on FHIR, rather than from an exhaustive manual clinical review of each generated resource.

***Abstract*—The Brazilian General Data Protection Law (LGPD) requires that clinical records be anonymized without destroying their clinical utility before secondary use. We present H-Q-MAS (Hierarchical Quantum Multi-Agent System), a LangGraph pipeline that combines a deterministic structured layer, a statistical recognizer (spaCy and BERTimbau with a LoRA adapter), a clinical-utility shield, and a two-qubit variational quantum circuit (VQC) for per-entity decisions. On 50 synthetic Brazilian clinical texts across eight specialties (148 spans of personally identifiable information, PII; 355 clinical terms), the system leaks 0 of 148 PII spans (privacy recall $= 1.0$; one-sided 95% lower bound ≥ 0.980) and retains 251 of 355 clinical terms (lexical preservation 0.7070 pooled, 0.6979 macro). The main contribution is a per-detector ablation showing where the result comes from. Privacy is produced by the structured layer (without it, recall falls to 0.4392) and preservation by the shield (without it, 0.5154). spaCy is the sole detector of 10 name spans but also the main source of clinical loss: removing it leaks those 10 spans and raises preservation to 0.9311. The BERTimbau component, as deployed, has an effectively untrained classification head and detects nothing on its own. Replacing the VQC by a fixed threshold has no measurable effect (Mann-Whitney $p = 0.97$). Free-text names remain weak: an inline first name is redacted in only 18 of 48 external texts (recall 0.375). Presidio with Brazilian regex recognizers leaks 21 of 148 gold spans (preservation 0.6789). The results support a deterministic-first design in which learned components must earn their place by per-component ablation.**

***Index Terms*—clinical text anonymization, LGPD, multi-agent systems, LangGraph, privacy recall, ablation, variational quantum circuits**

I. Introduction

Electronic clinical records concentrate sensitive personal data: patient names, the Brazilian individual taxpayer registry (CPF), the national health card (CNS), professional council numbers (CRM and others), addresses, and contact details. Brazil's General Data Protection Law (LGPD, Lei 13.709/2018) [1] conditions secondary use of such data on effective anonymization, and its Article 12 ties the legal status of anonymized data to whether re-identification is reasonably prevented. A Brazilian hospital faces two practical constraints. Anonymization must recognize country-specific identifiers (CPF, CNS, council numbers) that fall outside the HIPAA categories targeted by English-language de-identification systems [2]. Processing should also run on-premises. That is not only a deployment choice: it is a question of health-data sovereignty, keeping sensitive records of Brazilian patients on local infrastructure under national law instead of exporting raw data to external jurisdictions. The concern is concrete in the public health system (SUS), where patient records are produced at scale under public stewardship and jurisdiction over the data is itself a matter of public interest [3].

Aggressive redaction removes identifiers but also strips the measurements, drug names and findings that give a record secondary value; conservative redaction keeps that utility at the cost of residual leakage. A usable system therefore needs both high-recall identifier removal and an explicit mechanism to retain clinically meaningful terms.

This paper does not argue that a single clever model solves the problem. Its main contribution is methodological: we build a multi-agent pipeline and then measure, by ablation, which of its parts actually carry the result. Specifically, we contribute: (i) a component-level evaluation on a manually annotated gold standard showing that privacy recall is produced by the structured layer and clinical preservation by the clinical-utility shield; (ii) three results that limit the role of the learned components, reported rather than omitted: a two-qubit quantum consensus statistically equivalent to a fixed threshold, a spaCy recognizer that is the sole detector for only 10 of 148 PII spans (6.8%) while causing most of the clinical loss, and a BERTimbau component that, as deployed, contributes no detection because its classification head is effectively untrained; (iii) a same-corpus comparison with Microsoft Presidio under identical metrics; and (iv) H-Q-MAS itself, a LangGraph anonymizer with a residual-PII audit gate that runs on commodity CPU, which is the artifact on which these measurements were taken.

II. Related Work

Automatic de-identification has been driven by shared tasks and annotated corpora, notably the 2014 i2b2/UTHealth challenge [4], on which neural sequence models reached high recall [2]; that line targets English HIPAA categories, whereas our setting is Brazilian Portuguese under the LGPD, with country-specific identifiers (CPF, CNS, council numbers) and an explicit clinical-utility constraint. Recent work targets this Brazilian Portuguese setting directly: rule-based de-identification of real hospital records [5], NER- and LLM-based anonymization with a dedicated annotated corpus [6], and a recent benchmark of modern models for Portuguese clinical NER [7], building on Portuguese clinical NLP resources such as the SemClinBr corpus [8] and the BioBERTpt model [9]. In the multi-agent space, EPEAgent embeds privacy-enhancing agents to limit information flow between agents [10], MedPAO structures clinical reports through a plan-act-observe loop [11], and role-specialized agents have simulated multidisciplinary decision making with explicit consensus [12]. On the quantum side, a hybrid classical-quantum BERT couples a qubit circuit with a transformer for text classification [13], and a recent survey maps QNLP models and their data-scale limits [14]; we include a quantum consensus component but report its effect by ablation rather than assuming an advantage.

III. Method

A. Architecture

H-Q-MAS is a directed graph of agents executed with LangGraph (Fig. 1). A broker initializes the run; a named-entity recognition (NER) agent and a context agent run in parallel; a coordinator performs fan-in, immediately classifies hard identifiers, and dispatches one decision task per remaining entity through LangGraph's Send API (dynamic fan-out); an auditor applies the anonymization, rescans the output for residual PII with the structured layer, and computes a clinical-information-loss (CIL) score. If the rescan finds residual spans, a conditional edge routes them to a gate node that force-redacts them and returns to the auditor, for at most two passes; the gate reuses the structured detector, so by construction it can only catch what that detector matches, and it did not fire on any text evaluated in this paper. After the auditor accepts the output, a *billing* node extracts ICD-10 (CID-10) codes from the anonymized text by regular expressions and a keyword dictionary, without any language model, for downstream hospital billing, and a persistence node stores the output and its audit record. Both run after anonymization, do not modify the anonymized text, and do not enter any reported metric.

B. Deterministic structured layer

The structured layer detects structured identifiers with regular expressions and checksum validation (e.g., CPF, CNS, CRM and other council numbers, RG, CEP, e-mail, phone, dates), and detects person and organization names with header-anchored patterns: a role keyword ("Paciente", "Médico",

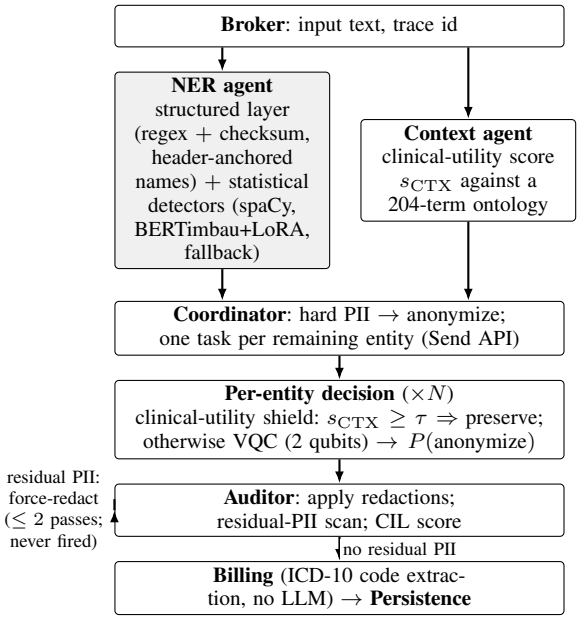

Fig. 1. H-Q-MAS agent graph. NER: named-entity recognition; PII: personally identifiable information; VQC: two-qubit variational quantum circuit; CIL: clinical-information-loss score; s_{CTX}: clinical-utility score of the context agent; τ: clinical-utility bypass threshold (Sec. III-C); billing: ICD-10 code extraction from the anonymized text. The shaded node is the NER agent, which contains the structured layer and the statistical detectors (spaCy, BERTimbau+LoRA, unsupervised fallback). Residual PII found by the auditor's rescan is force-redacted by a gate node (at most two passes) before billing and persistence; the gate never fired in our evaluation.

"Solicitante", ...) followed by a delimiter and a Title-Case multi-token name, with propagation of a matched name to its other occurrences. Identifiers in a fixed hard PII set are anonymized deterministically without consulting the quantum step.

C. Statistical recognizer and clinical-utility shield

The statistical recognizer complements the structured layer for names in free text. It merges three detectors, in priority order below the structured layer: BERTimbau [15] with a LoRA adapter [16], spaCy [17] (`pt_core_news_lg`), and an unsupervised fallback. We report a defect of the evaluated system rather than hide it: the adapter file stores a 13-label token-classification head whose weights are statistically indistinguishable from their random initialization (weight standard deviation 0.020, bias magnitude ≤ 0.0013), so as deployed the BERTimbau component emits near-uniform, essentially random candidates (mean maximum class probability 0.11 against 0.077 for a uniform output). The head is loaded from the file, not re-initialized, so its output is deterministic. It remains part of the system we measured; Sec. V-A quantifies its effect by ablation. The context agent scores each candidate token's clinical utility, $s_{\mathrm{CTX}} \in [0, 1]$, by cosine similarity against a 204-term Brazilian clinical ontology. The clinical-utility shield preserves any candidate with $s_{\mathrm{CTX}} \geq \tau$, where $\tau = 0.45$ is a fixed bypass threshold; person-name candidates

are exempt from the shield (s_{CTX} is forced to 0), and a preserved candidate never reaches the quantum step.

D. Quantum consensus (VQC)

For each entity that is neither hard PII nor preserved by the shield, the system evaluates a two-qubit circuit (PennyLane [18] `default.qubit` simulator, not quantum hardware): $R_Y(\pi\, s_{\mathrm{NER}})$ on qubit 0 and $R_Y(\pi\, s_{\mathrm{CTX}})$ on qubit 1 encode the recognizer and context scores, a CNOT entangles them, a trained rotation $R_Y\big(\pi\,(w_{\mathrm{NER}}\, s_{\mathrm{NER}} - w_{\mathrm{CTX}}\, s_{\mathrm{CTX}})\big)$ is applied to qubit 0, and measuring qubit 0 yields the probability p of anonymizing. The entity is anonymized when $p > \alpha + \beta\, s_{\mathrm{CTX}}$, i.e., the decision threshold is a fixed function of the context score: a token with higher clinical utility requires stronger evidence before it is redacted. The circuit weights (w_{NER}=0.464, w_{CTX}=0.493) were fitted by gradient descent on a synthetic set of 153 $(s_{\mathrm{NER}}, s_{\mathrm{CTX}})$ points (a 10×10 grid, 50 random points and 3 demonstration entries) labelled by a rule; the threshold parameters (α=0.50, β=0.45) were set by manual calibration. A grid search on the same synthetic set proposed α=0.575, β=0.80, but this setting was discarded because it let borderline names ($p \approx 0.57$) through, and the manual values were retained. All four values are frozen at inference and were never tuned on the gold standard. Note that β and τ coincide numerically but are distinct quantities: τ is an absolute cutoff applied before the circuit, β scales the circuit's threshold.

E. LGPD instrumentation and inference

The auditor computes a deterministic CIL score over non-PII clinical terms, used as an Article-12 utility-loss indicator. An optional local LLM (Ollama, `llama3:8b`) is queried only to emit a qualitative audit annotation; it does not alter the anonymized text or any reported metric (Sec. IV). The code is available from the authors on request.

IV. Experimental Setup

Data. The gold standard consists of 50 synthetic Brazilian clinical texts (reports, exam reports, progress notes, consultation notes, discharge summaries, prescriptions and opinions) spanning eight specialties, written and annotated by one of the authors with 148 PII spans and 355 clinical terms. Annotation was performed by a single annotator, so inter-annotator agreement is not available. The same author also designed the header-anchored name heuristic, so the annotation and the rule set are not independent. The LoRA adapter was fine-tuned on the public HAREM newswire NER corpus, not on clinical text. No real patient data were used at any stage, including model training, and the study therefore did not require ethics-committee approval. **Metrics.** *Privacy recall* (PR) is the fraction of annotated PII spans absent from the output (case-insensitive substring match). *Clinical preservation* (CP) is the fraction of annotated clinical terms still present in the output, a *lexical* retention measure by substring match, *not* a semantic equivalence judgement. We report PR and CP both pooled (micro) and macro-averaged over texts, with raw counts so that confidence intervals are well defined. **Determinism.** PR and CP are deterministic by construction: the anonymization decisions come from regular expressions, checksum validation, argmax over statistical model outputs, and a fixed-parameter VQC with a fixed threshold; the only stochastic component (the `llama3:8b` audit annotation) does not feed the anonymized text or the router. No random seed is fixed at inference; all model weights, including the BERTimbau classification head, are loaded from files rather than initialized at run time. All numbers in this paper were produced at one code state (git commit `b3a9152`); seven independent process launches of the gold-standard evaluation (each loading the models afresh), plus the originally submitted run, produced identical per-text PR and CP values ($\Delta = 0$), with latency varying as expected. **Environment.** Python 3.12 on CPU; Ollama `llama3:8b` (Q4_0); BERTimbau in PyTorch (no ONNX quantization). **Baseline.** We run Microsoft Presidio (`presidio-analyzer` 2.2.364) with the spaCy `pt_core_news_lg` model, its default recognizers, and three added pattern recognizers for Brazilian CPF, CEP and phone numbers, at score threshold 0.4, on the same 50 texts, scored with the same PR/CP code. **External setting.** For robustness we also evaluate on 48 synthetic realistic texts (40 specialty-labelled notes and 8 general records) in which *well-formed PII is injected* into a header block at known positions, plus one inline mention of the patient's first name in free text, scored separately (Sec. V-G); clinical references there are extracted automatically from the ontology, which we discuss as a measurement caveat in Sec. VI.

V. Results

A. Where performance comes from (ablation)

We disable one component at a time on the gold standard, on the same code state as the headline run (Table I). Removing the structured layer collapses privacy recall from 1.0 to 0.4392 (83 of 148 spans leak); removing the clinical-utility shield leaves privacy recall intact but drops macro preservation from 0.6979 to 0.5154 (in raw terms, retained clinical terms fall from 251 to 184 of 355; $184/355 = 0.5183$ pooled vs. 0.5154 macro). Privacy is carried by the structured layer; preservation by the clinical-utility shield. Removing the whole statistical recognizer (BERTimbau with LoRA, spaCy and the unsupervised fallback all disabled; structured layer, shield and VQC kept) leaks exactly the 10 name spans that the structured layer misses (PR 0.9324, 10 of 148, one per text in 10 texts) and raises macro preservation from 0.6979 to 0.9370 (333 of 355 terms retained).

Decomposing that ablation by detector shows where each effect lives. Disabling only spaCy reproduces the 10 leaks and almost all of the gain (CP 0.9311, 331 of 355): spaCy is the sole detector of those 10 names and the source of the clinical loss. Disabling only the BERTimbau component leaks nothing (PR 1.0) and *lowers* preservation to 0.6801 (245 of 355); disabling only the unsupervised fallback leaks nothing and moves preservation to 0.7001. The difference between 82 terms recovered without the whole recognizer and 80 without

TABLE I
COMPONENT ABLATION AND BASELINE ON THE GOLD STANDARD (N=50 TEXTS, 148 PII SPANS, 355 CLINICAL TERMS). LEAKED-SPAN COUNTS IN PARENTHESES; CP IS MACRO-AVERAGED (POOLED VALUES IN THE TEXT); Δ IN PERCENTAGE POINTS VS. THE FULL SYSTEM.

Configuration	PR	CP	Δ (pp)
H-Q-MAS, full system	1.0000 (0/148)	0.6979	—
− structured layer	0.4392 (83/148)	0.6842	PR -56.1; CP -1.4
− clinical-utility shield	1.0000 (0/148)	0.5154	CP -18.3
− statistical recognizer	0.9324 (10/148)	0.9370	PR -6.8; CP $+23.9$
− spaCy only	0.9324 (10/148)	0.9311	PR -6.8; CP $+23.3$
− BERT+LoRA only	1.0000 (0/148)	0.6801	CP -1.8
− fallback only	1.0000 (0/148)	0.7001	CP $+0.2$
VQC $\rightarrow$ fixed 0.5	1.0000 (0/148)	0.6976	CP -0.03
Presidio (pt + BR regex)	0.8581 (21/148)	0.6789	PR -14.2; CP -1.9

spaCy alone comes from two terms that the fallback detector still redacts when spaCy is off.

The 82 clinical terms recovered without the statistical recognizer are all spans that spaCy proposed with $s_{\mathrm{CTX}} < \tau$ and that the VQC step then decided to anonymize (82 of 82 carry the VQC decision reason); the fixed threshold makes the same decisions (Sec. V-F). The six additional terms lost without BERTimbau (e.g., "AAS 100mg", "índice de Lee 1") are spaCy candidates that the VQC anonymizes; in the full system the effectively untrained BERTimbau head covers the same tokens with candidates of score ≈ 0.1 that win the merge (BERT ranks above spaCy) and are kept, i.e., the defective component preempts spaCy by accident. The end-to-end metrics alone did not reveal this: only the per-detector decomposition did.

Removing the structured layer also lowers preservation slightly (0.6979 to 0.6842 macro; 251 to 246 of 355 pooled) rather than raising it, as less redaction would suggest. The mechanism is not the residual-PII gate, which never fired in any configuration (0 passes in 350 pipeline runs), but the merge order of the recognizer: spans of the structured layer, including its clinical-safe whitelist, take precedence over statistical detections and cannot be overwritten. Without it, five additional clinical strings ("FC máxima: 162 bpm", "FR 28 irpm", "Ceftriaxona 2g EV", "Esquizofrenia paranoide", "Cintilografia óssea") are tagged by the statistical detectors and redacted; no term is recovered. Note that this ablation also disables the structured detector inside the auditor's rescan, so the row measures the layer and its gate together.

Replacing the VQC by a fixed 0.5 threshold on the recognizer score leaves privacy recall at 1.0 and moves macro preservation by 0.0003 (Sec. V-F).

B. Headline anonymization

On the gold standard the full system leaks no PII: 0 of 148 spans (PR $= 1.0$; one-sided 95% lower bound ≥ 0.980, Clopper-Pearson for 0/148). Clinical preservation is 0.6979 macro-averaged and 0.7070 pooled (251 of 355 terms retained; Wilson 95% CI $[0.658, 0.752]$). Per-text latency on CPU spans 722 to 1540 ms (median 741 ms, mean 784 ms, nearest-rank p95 1174 ms), measured at commit `b3a9152` with the optional observability tracing turned off; latency is the only non-deterministic quantity and is reported as a range.

C. Comparison with Presidio

Under identical texts and scoring, Presidio with Brazilian regex recognizers leaks 21 of 148 PII spans (PR $= 0.8581$ pooled, 0.862 macro; Wilson 95% CI $[0.793, 0.905]$), affecting 20 of the 50 texts, and retains 241 of 355 clinical terms (CP $= 0.6789$ macro; the pooled value is identical). Its per-text latency has median 39 ms and nearest-rank p95 67 ms, against 741 ms and 1174 ms for H-Q-MAS. The comparison isolates what the structured layer buys: 18 of the 21 leaks are council numbers (10) and CNS numbers (8), for which Presidio has no recognizer and which the structured layer matches by pattern and checksum; the remaining three are one phone number missed by the added pattern and two header-formatted patient names (Presidio's PERSON recognizer caught the other 70 name spans). Presidio was not tuned beyond the three added patterns, so the gap partly reflects configuration effort rather than an intrinsic limit of the tool.

D. Attribution of detection (structured vs. statistical)

Cross-referencing each annotated span with the structured layer's output, 138 of 148 spans (93.2%) are detected by the structured layer, with 79 by regex/checksum (structured identifiers: CPF, CNS, council numbers, dates, e-mail, phone, CEP) and 59 names by the header-anchored heuristic, while only 10 of 148 (6.8%) rely on the statistical recognizer. Of the 72 name spans, 59 are caught by the header heuristic, 3 by other structured patterns, and 10 only by spaCy (Sec. V-A). The BERTimbau+LoRA component detects none of the 148 spans on its own: its classification head is effectively untrained (Sec. III-C), and on control sentences it emits sub-word fragments with scores around 0.1. The privacy result does not depend on it at all, and depends on spaCy for 10 spans.

E. Per-specialty preservation

CP varies by specialty (Table II); four specialties fall below the macro mean of 0.6979 (Pediatrics 0.6160, Psychiatry 0.6238, Oncology 0.6663, Cardiology 0.6686) while Pulmonology (0.8189) and Orthopedics (0.8012) are highest. The two highest are based on very small samples (n=3 and n=5) and are reported as exploratory, not as reliable point estimates.

F. Quantum consensus: a negative result

We compare the VQC decision of Sec. III-D (circuit probability against the context-dependent threshold $\alpha+\beta s_{\mathrm{CTX}}$) with a classical control in which the same entities are anonymized when $s_{\mathrm{NER}} \geq 0.5$, over the 50 texts, both runs at the same code state. The per-document F1 distributions (harmonic mean of PR and CP) are statistically indistinguishable (Mann-Whitney $U = 1244.5$, two-sided $p = 0.9724$; Cohen's $d = 0.0032$, negligible), with mean F1 0.8076 (VQC) vs. 0.8071 (fixed threshold). The circuit does exhibit measurable entanglement (Meyer-Wallach $Q = 0.2497$) [19], but this does

TABLE II
CLINICAL PRESERVATION BY SPECIALTY, GOLD STANDARD: NUMBER OF TEXTS, RETAINED/ANNOTATED CLINICAL TERMS (POOLED), AND MACRO AVERAGE OVER TEXTS.

Specialty	n	Retained/terms	CP (macro)
Pediatrics	7	28/43	0.6160
Psychiatry	5	20/32	0.6238
Oncology	5	27/40	0.6663
Cardiology	10	51/76	0.6686
Endocrinology	8	36/52	0.7007
Neurology	7	41/53	0.7684
Orthopedics	5	28/35	0.8012
Pulmonology	3	20/24	0.8189

not translate into a performance gain. The training report of the circuit shows the same picture: on its synthetic training set of 153 points (Sec. III-D), accuracy rises from 86.27% to 95.42% only when the threshold is re-optimized by grid search, and the initial and trained circuit weights yield identical accuracy under that optimized threshold, i.e., the gain is attributable to the classical threshold, not to the quantum weights; moreover, that optimized threshold is not the one deployed (Sec. III-D), and the figures are training-set accuracies on a set whose majority class alone gives 83.0%. The headline result does not rest on this component: with the VQC active or replaced by the fixed threshold, privacy recall is identical (1.0, 0 leaks) and clinical preservation moves by 0.0003 (0.6979 vs. 0.6976, 251 vs. 250 terms); the two settings differ in per-document F1 on 5 of 50 texts. It is an object of study here, not a load-bearing part of the pipeline. Note, however, that the decision step (VQC or fixed threshold) is where the clinical loss materializes: the 82 terms discussed in Sec. V-A are all anonymized by this step.

G. External robustness

On the 48 synthetic realistic texts, privacy recall over the well-formed PII injected into the header block is 1.0 with no leaks, and per-type recall on those header spans is 1.0 for every injected type (full name, CPF, RG, date, phone, e-mail, address, CEP). Because the injected names follow the same header format that the structured heuristic targets, this confirms robustness on header-formatted identifiers rather than on free-text mentions (Sec. VI). The free-text case was scored directly: each text also carries one inline mention of the patient's first name ("O(a) paciente *Ana* segue em acompanhamento"), which is not a header and not an exact repeat of the full name, so the structured layer cannot propagate to it. That mention was redacted in only 18 of 48 texts (recall 0.375); in the other 30 the first name survived in the output. All 18 redactions were spaCy candidates (label PER, score 0.95, then anonymized by the decision step); neither the BERTimbau component nor the unsupervised fallback proposed any of them, and the same first name (e.g., "José") is caught in one text and missed in another. Free-text single-token names therefore depend entirely on spaCy, and spaCy misses most of them. Clinical preservation on this set is 0.9404 (macro average over the 39 texts that contain at least one of the 274 automatically extracted reference terms; 9 texts have none). This value is not comparable with the gold-standard CP: its references are extracted automatically from the same ontology that the shield protects, which inflates it by construction (Sec. VI); the gold CP of 0.6979 remains the headline.

VI. DISCUSSION AND LIMITATIONS

Privacy is mostly deterministic. The privacy recall is carried by regular expressions, checksum validation, and the header-anchored name heuristic (138 of 148 spans); spaCy supplies the remaining 10, and BERTimbau+LoRA none. Claims of learned NER models (transformer or otherwise) driving privacy would be unsupported here.

Implications for the architecture. The per-detector ablation separates the components into four roles. The structured layer and the clinical-utility shield are load-bearing: removing either changes a headline metric by 18 to 56 pp. spaCy is a fallback with a cost: it is the only detector for 10 of 148 spans, all names missed by the header heuristic, and removing it leaks exactly those 10 (PR 0.9324); it is also the main source of clinical loss, since without it 80 more clinical terms survive (CP 0.9311). We report the two quantities side by side rather than as a trade, because a leaked name and a redacted clinical term are not commensurable under the LGPD. The BERTimbau+LoRA component is defective as deployed (effectively untrained head) and contributes no detection; its only measurable effect is accidental, preempting a few spaCy candidates in the merge (CP -1.8 pp when removed). The quantum consensus is dispensable on this task: replacing it with a fixed threshold leaves privacy unchanged and moves preservation by 0.0003. The consequence is a deterministic-first design in which rules carry privacy, a properly trained statistical fallback covers what rules cannot express, and exploratory components such as the VQC stay outside the production path until an ablation shows an effect. The multi-agent structure is useful here less for accuracy than for measurability: because each agent is a separate node and each detector a separate strategy inside the NER agent, each can be disabled and evaluated in isolation, which is what made these conclusions, including the detection of the defective component, possible.

Small evaluation set. The gold standard has 50 texts and 148 PII spans. Zero observed leaks bound the true leak rate only to at most 2.0% (one-sided 95%), so up to about three leaks per 148 spans cannot be excluded, and per-specialty estimates rest on 3 to 10 texts and are exploratory. The texts are synthetic and single-annotated, and their layout is likely more regular than that of real hospital records, which favors the header heuristic. A larger, specialty-balanced set with multiple annotators, including real de-identified records under ethics approval, is required before any deployment claim.

Name detection depends on document layout. Names are the only PII type whose detection depends on where they appear. The header heuristic captures 59 of 72 name spans, and the external set injects full names in the same header block. The one direct measurement of a free-text mention, the inline first name in the external texts, gives recall 0.375 (18 of

48): for names that are neither in a header nor an exact repeat of a header name, such as relatives or referring physicians cited in narrative, the system falls back on spaCy alone and misses most of them. The reported privacy recall of 1.0 should therefore be read as recall on a corpus dominated by header-formatted identifiers, not on free narrative.

Baseline scope. The Presidio comparison uses one configuration (default recognizers plus three Brazilian patterns) and shows where the gap comes from, not the best Presidio can do; a Presidio equipped with the full structured layer of H-Q-MAS would presumably close most of it, which is consistent with our attribution. We do not compare against the Brazilian Portuguese systems of [5], [6]: the corpus of [5] is not public, and the public part of AnonyMED-BR [6] annotates PII only, so it would support a privacy-only comparison, which we leave as future work.

Preservation is lexical, not semantic. CP counts annotated clinical strings that survive verbatim. It penalizes harmless changes, such as a term partially covered by a redaction tag, and cannot detect harmful ones that keep the string but alter its meaning, such as a removed negation or dose context. A semantic evaluation, for example an NLI-based judge validated against clinician review of a sample, is needed to show that preserved strings preserve clinical information. The external CP (0.9404) is measured against references drawn from the same ontology the shield protects, which is partly circular; the gold CP (0.6979) remains the headline.

A. Lessons Learned and Research Gaps

Lessons learned. (1) Ablation before attribution: the components that motivated the design, neural recognition and quantum consensus, were not the ones carrying the result, and without the ablation the headline would have been credited to them. (2) Country-specific identifiers are largely a rules problem: CPF, CNS, and council numbers have fixed formats and check digits, and checksum validation yields high-recall detection without training data; the Presidio gap is almost entirely these categories. (3) Privacy and utility are carried by different components and must be measured separately; a single aggregate score would hide that the shield and the statistical recognizer's candidate set determine how much clinical information survives, while the decision step (VQC or fixed threshold) merely executes those choices (Sec. V-F). (4) Negative results are results: a quantum step at parity with a threshold is a finding about the task and belongs in the paper. (5) End-to-end metrics do not certify components: a recognizer with an effectively untrained classification head ran through every evaluation with PR $= 1.0$ and was exposed only by the per-detector ablation; component-level checks (loading warnings, control inputs, single-detector ablations) belong in the evaluation protocol.

Research gaps. (1) Detection of names in free Brazilian clinical narrative, outside structured headers, is the weakest point of this system (recall 0.375 on inline first names) and needs a properly trained clinical NER model. (2) Brazilian Portuguese de-identification studies use different corpora [5], [6]; the public part of AnonyMED-BR [6] is a step toward a shared benchmark, but it does not annotate clinical terms to preserve, so a benchmark that scores privacy and utility jointly is still missing. (3) Clinical preservation lacks a semantic metric validated against clinicians. (4) Operational criteria linking the LGPD notion of reasonable re-identification effort (Art. 12) to measurable acceptance thresholds for anonymizers remain underdeveloped. (5) Whether quantum or hybrid components add value for this task at larger scale remains open; with two simulated qubits, they do not.

VII. Conclusion

H-Q-MAS leaks none of the 148 PII spans of a 50-text, eight-specialty synthetic gold standard whose names are mostly header-formatted (59 of 72 names; 0/148 leaks, 95% lower bound ≥ 0.98) and retains 0.6979 of annotated clinical terms; on inline first names in free text, however, it redacts only 18 of 48 (recall 0.375). The per-detector ablation traces privacy to the structured layer and preservation to the clinical-utility shield; spaCy is a fallback that catches 10 name spans and causes most of the clinical loss; the BERTimbau+LoRA component, as deployed, is defective and detects nothing; and the quantum consensus is equivalent to a fixed threshold. Under the same metrics, Presidio with Brazilian patterns leaks 21 of 148 spans. The most important next steps are a semantic preservation metric validated by clinicians, a properly trained statistical fallback, and an evaluation on real, multiply annotated records with free-text names.

Acknowledgment

Generative AI tools were used in preparing this paper: Claude Code (Anthropic) running the Claude Fable 5 and Claude Fable 5.1 models. They were used to edit and restructure text in all sections, draft the architecture diagram (Fig. 1) in TikZ, write evaluation and audit scripts that recomputed the reported metrics, ablations, Presidio baseline, and inline-name measurement from the authors' code and data, and check the manuscript for internal consistency and reference accuracy. No annotations, results, or references were generated by AI; all reported values were verified against the evaluation artifacts. The authors take full responsibility for the content of this paper.

Abstract*—Type 1 diabetes mellitus exposes patients to hypoglycemia, i.e. blood glucose at or below 70 mg/dL, a risk event that is especially dangerous overnight, when symptom perception is suppressed. Machine-learning alert systems built on continuous glucose monitoring (CGM) data can anticipate these events, but their viability depends on more than statistical accuracy: a high false-alarm rate erodes patient trust and high computational cost can make a model unusable on resource-constrained diabetes devices, and both are reported less consistently than discrimination metrics. This paper presents a retrospective multidimensional evaluation of five machine-learning models (Logistic Regression, Random Forest, XGBoost, LSTM, and GRU) for predicting whether hypoglycemia will occur within the next 30 minutes, trained on four public type 1 diabetes datasets (79 participants). Beyond AUPRC, AUC-ROC, and F1, we report the daily false-alarm rate and the training and inference cost as comparison axes, alongside a permutation-importance analysis of each modality and two generalization tests. Random Forest and XGBoost reached the highest AUPRC (0.887 for both, with a paired per-patient bootstrap interval crossing zero), and XGBoost trained about six times faster and produced a model hundreds of times smaller on disk. Permutation importance and ablation indicated that glucose carried most of the predictive information used by these models. Generalization to unseen patients and devices preserved risk-ranking quality while degrading the operating point, which motivates evaluating threshold recalibration per target population or device. All metrics are sample-level and all cost figures come from a single CPU environment; event-level sensitivity, time-to-warning, alarm duration, measured energy, and prospective validation are outside the scope of this benchmark and are stated as such.

***Index Terms*—hypoglycemia, continuous glucose monitoring, machine learning, type 1 diabetes, false-alarm rate, computational cost, AUPRC**

I. Introduction

Type 1 diabetes mellitus (T1D) results from autoimmune destruction of the pancreatic beta cells, eliminates endogenous insulin production, and makes the patient dependent on life-long exogenous replacement. Among the hundreds of millions of adults living with diabetes worldwide [1], [2], those with T1D face a risk tied directly to the treatment that keeps them alive: insulin therapy, although necessary for glycemic control, exposes patients to hypoglycemic episodes, clinically defined as blood glucose at or below 70 mg/dL. Unlike the non-diabetic organism, which relies on compensatory endocrine mechanisms, the T1D patient is vulnerable to abrupt, often asymptomatic glucose drops. This is a risk that peaks overnight during sleep, when symptom perception is suppressed and immediate intervention is impaired [3].

Machine learning applied to multimodal CGM time series has become the natural response to this risk, and the literature has advanced steadily in predictive accuracy. However, an alert system's viability depends on more than detecting events with sufficient sensitivity. A model that generates frequent false alarms undermines patient adherence, a phenomenon documented as alarm fatigue [4], [5], and the computational cost of inference determines whether a model can run on resource-constrained diabetes devices or companion applications. Both are usually treated as secondary rather than as design criteria; Section II-C identifies the specific gaps addressed here.

This paper compares five models predicting whether hypoglycemia will occur within the next 30 minutes, evaluated jointly across all three dimensions on four public T1D datasets. The families span the range of representational capacity and computational cost relevant to the task: Logistic Regression as a linear baseline, Random Forest [22] and XGBoost [23] as tabular ensembles, and LSTM [24] and GRU [25] recurrent networks. The contributions are:

- **Multidimensional evaluation:** beyond AUPRC, AUC-ROC, and F1, we include the daily false-alarm rate and the training and inference cost (time, memory, model size) as comparison metrics;

- **Accuracy–alarm–cost trade-off:** we quantify how models with statistically indistinguishable AUPRC differ in false alarms per day and in cost in the evaluated CPU environment;
- **Leakage-safe protocol:** a strict per-participant chronological split, without shuffling, plus generalization to unseen patients (patient-held-out) and to an unseen dataset or device (leave-one-dataset-out), with the residual boundary overlap quantified in Section III-A;
- **Multimodal ablation:** the incremental contribution of each modality (CGM, insulin, carbohydrate, activity).

The contribution is the benchmark itself, under one shared protocol. The study is retrospective and offline: no alert was presented to a patient and no treatment decision was taken from a prediction, so nothing here supports a claim of clinical utility. Section V-A states the boundary of every claim.

II. Theoretical Background

A. The Datasets

The experiments use four public type 1 diabetes datasets, 79 participants in total, harmonized to a common 5-minute grid per participant. Table I summarizes participant count, temporal coverage, native CGM sampling interval, and glucose sensor of each source. The heterogeneity of devices, populations, and durations allows assessing both average performance and generalization to unseen sources. The prediction horizon (30 min), the event definition, and the missing-data rule are common to all four sources and are stated in Section III-C.

OhioT1DM [7] is a classic reference for glucose prediction in T1D; the 2020 version covers 12 adults on insulin-pump therapy with Medtronic Enlite monitoring and is multimodal (5-min interstitial glucose, basal and bolus insulin, self-reported carbohydrate, exercise, sleep and stress events, and physiological-band signals). HUPA-UCM [19] covers 25 people with T1D (52% women, mean age 39 years, mean HbA1c 7.4%, 56% on continuous subcutaneous infusion), with 15-min FreeStyle Libre 2 glucose resampled to the 5-min grid and steps, calories, heart rate and sleep from Fitbit Ionic smartwatches. AZT1D [20] covers 25 individuals on automated insulin delivery (Tandem t:slim X2 in Control-IQ), with more than 320k Dexcom G6 Pro readings and granular bolus details (total dose, type, correction share) that are rare in public datasets. T1D-UOM [21] covers 17 participants aged 23 to 70, with glucose from multiple CGM platforms, activity from a Garmin Forerunner 45, and nutrition decomposed into carbohydrate, protein, fat, and fiber; it also has the highest fraction of missing readings (about 35%), which makes it the main data-quality challenge.

Table I
Type 1 diabetes datasets used (79 participants; unified 5-min analysis grid).

Dataset	Part.	Coverage	CGM sensor	Δt[a]
HUPA-UCM [19]	25	$\geq$ 2 weeks	FreeStyle Libre 2	15
AZT1D [20]	25	6–8 weeks	Dexcom G6 Pro	5
OhioT1DM [7]	12	8 weeks	Medtronic Enlite	5
T1D-UOM [21]	17	12 weeks	multiple[b]	5–15

[a] Native sampling interval of the source device (min); all sources are resampled to the common 5-min grid, so a 15-min source contributes one observed reading per three cells. [b] LibreView, Dexcom, Medtronic.

B. Related Work

Rather than surveying individual studies in sequence, this review is organized along the dimensions that define the present comparison: the prediction target, the input modalities, the validation regime, and the metrics reported.

Target formulation. A large share of the CGM literature addresses continuous forecasting of the glucose trajectory [8], including foundation and multimodal language models [9] and horizon-aware sequence-to-sequence Transformers with knowledge distillation [10]. A second line frames the problem as binary event classification over a future window, the formulation adopted here [11]–[14]. The two framings are not interchangeable, since event classification is evaluated under strong class imbalance and admits an explicit operating point.

Input modalities. Within the classification line, Fleischer et al. [12] use the CGM signal alone, whereas Dave et al. [11] add insulin and carbohydrate and report gains mainly at horizons longer than 30 minutes. This divergence motivates the modality ablation of Section IV-D.

Validation regime. Bergmeir and Benítez [15] document the leakage that arises in time-series cross-validation when temporal order is not preserved, which motivates the strictly temporal, per-participant split used here. Among the classification studies, generalization is assessed unevenly: Shao et al. [14] validate an LSTM across distinct populations, while the remaining studies, and related Brazilian work on biomedical time series [17], [18], report performance within a single cohort.

Reported metrics. Results in this line concentrate on discrimination (sensitivity, specificity, AUC-ROC, AUPRC). Operational quantities appear less consistently: alarm fatigue is documented as a clinical problem [4], [5], and closed-loop work [26] frames glycemic prediction as a component that must run within device computational constraints, but false alarms per day and inference cost are seldom tabulated alongside discrimination for the same models.

C. Gaps and Positioning

Two gaps emerge from the literature just reviewed. First, among the classification-framed studies [11]–[14], each reports strong discrimination, but none evaluates a linear model, a tabular ensemble, and a recurrent network under one shared protocol, so the accuracy–cost frontier across model families remains uncharacterized. Second, of these same studies only Shao et al. [14] test generalization to unseen patients, and none reports the false-alarm rate or inference cost alongside discrimination under a leakage-safe temporal protocol. This paper targets both gaps, using the datasets and protocol of Section III.

III. Methodology

A. Study Data and Experimental Design

The study data are the four public T1D datasets characterized in Section II-A (Table I).

Each participant is split *chronologically* into 60% train, 20% validation, and 20% test, without shuffling, so that the patient's future never informs the past used in training. Three evaluation scenarios are considered: (i) within-patient temporal evaluation, which measures prediction of the patient's own future; (ii) patient-held-out, in which whole patients are separated across train, validation, and test, assessing generalization to unseen individuals; and (iii) leave-one-dataset-out, in which the model trains on three datasets and is tested on the fourth, assessing transfer to an unseen device or population. Wherever generalization is claimed (scenarios ii and iii), the partitions are participant-disjoint, so no window, episode, or patient-specific statistic is shared across partitions.

Windows are built by sliding over the 5-minute grid and therefore overlap *within* a partition by construction. Under scenario (i) each participant has two contiguous cut points, and only windows spanning a cut can share readings across partitions: a window at t uses $[t-60,\, t+30]$ min, so the affected region is 90 min wide, at most 18 windows per cut and 36 per participant, i.e. about 2 800 windows across the 79 participants, against a training partition of 550 245 rows. The same bound limits episode straddling to two per participant, and only when a cut falls inside an episode; in scenarios (ii) and (iii) none is possible. This residual overlap is reported rather than removed: a 90-min embargo at each cut would eliminate it and is the recommended form of the protocol.

Cohorts combine datasets and split type. We write $\mathcal{D}_{\text{tot}}$ for the four datasets combined (79 participants) and $\mathcal{D}_{\text{uom}}$, $\mathcal{D}_{\text{azt}}$, $\mathcal{D}_{\text{ohio}}$, $\mathcal{D}_{\text{hupa}}$ for T1D-UOM, AZT1D, OhioT1DM, and HUPA-UCM alone. Cohort $\mathcal{D}_{\text{tot}}$ under temporal split is the main comparison configuration.

B. Data Pipeline

The four datasets are processed by a four-layer data lake (Fig. 1). The raw layer preserves the original files; bronze converts the heterogeneous formats (per-patient CSV, XML, per-domain CSV) to Parquet, normalizing variant headers; silver harmonizes schema, units, and timestamps, standardizing glucose to mg/dL (converting mmol/L by 18.0156 in T1D-UOM), carbohydrate to grams, and basal insulin to U/5 min, and materializes the unified 5-minute grid per participant; and gold creates the label, the tabular and sequential features, and the train-ready splits. Every transformation is deterministic and row-local: no statistic estimated from data enters this stage, so the pipeline itself cannot transport information across partitions.

C. Target Definition and Gap-Aware Coverage

Because the pipeline in III-B produces a unified 5-minute grid but does not resolve missing readings, the target and coverage rule are defined jointly, so that a future window is never built from a mostly-absent stretch of data. The task is

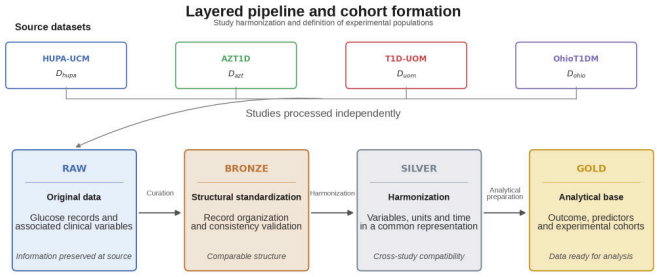

Figure 1. Layered data-lake architecture: harmonization of the four datasets into a unified 5-min grid and generation of label, features, and splits.

framed as binary classification. For each time point t on the 5-minute grid, the target is positive if the minimum glucose reading in the following 30-minute window is at most 70 mg/dL:

$$y_t = \begin{cases} 1, & \text{if } \min\limits_{1\le k\le 6} g(t+5k) \le 70 \text{ mg/dL}, \\ 0, & \text{otherwise}, \end{cases} \tag{1}$$

where $g(\cdot)$ denotes interstitial glucose and time is measured in minutes. The label therefore refers to occurrence at any point within the next 30 minutes, not to the value at $t+30$ specifically. The current glucose value $g(t)$ is excluded from the outcome window, so it is not part of the target definition; samples in which the patient is already hypoglycemic at t remain in the aggregate evaluation and are examined separately in the glucose-stratified analysis of Section IV-E.

Because sparse datasets (T1D-UOM, with about 35% null readings) would make a nominal 30-minute window span real hours, windows are computed over a gap-free grid, and a row becomes a labeled example only if it has sufficient observed coverage: at least 8 of the 12 history cells (60 min) and 3 of the 6 future cells (30 min) non-null. The minimum in (1) is taken over the observed cells only, so it may rest on as few as three readings; rows below the coverage requirement are discarded rather than imputed. The rule reduces, but does not eliminate, the possibility that an unobserved hypoglycemic reading turns a true positive into a negative label, and the residual risk differs across datasets according to their coverage. Both the horizon and the threshold follow the international continuous-monitoring consensus definition of a hypoglycemic level [6]; the rarity of these events in the continuous stream of readings imposes the class imbalance that motivates the metric choices of Section III-F.

D. Feature Engineering

With labels defined, three feature sets translate the same underlying grid into model-ready inputs at different levels of complexity. The full tabular set (17 features) gathers 60-minute glucose statistics (current, mean, min, max, standard deviation, and 5- to 60-minute deltas), cyclic time-of-day encoding, and aggregates of insulin (bolus and basal), carbohydrate, steps, and heart rate. The reduced glucose+time set (11 features) drops the insulin, carbohydrate, and activity modalities, keeping only glucose and time of day; Section IV-D reports the

AUPRC change associated with this reduction. The sequential set (9 channels) feeds the recurrent networks with the raw 12-step (60 min) series: glucose, basal, bolus, carbohydrate, steps, calories, heart rate, and the two cyclic time-of-day components. Every feature is a backward-looking function of the same participant's own history at or before t; no forward-looking, cross-participant, or full-dataset statistic is used in feature construction.

E. Evaluated Models

Five classifiers from distinct families are compared. Logistic Regression (L2 regularization, balanced classes, standardized features) is the linear baseline. Random Forest (300 trees, minimum 5 samples per leaf) and XGBoost (500 estimators, depth 4, learning rate 0.05, subsampling 0.8, `aucpr` evaluation metric, and positive-class weight computed as the negatives-to-positives ratio, near 17.6 in cohort $\mathcal{D}_{\text{tot}}$) represent the tabular ensembles. The LSTM and GRU networks share the architecture Input$(12, 9)$ followed by a 64-unit recurrent layer, 0.2 dropout, a 32-unit dense layer with ReLU activation, and a sigmoid output, trained for up to 50 epochs with early stopping on validation AUPRC. Hyperparameters were fixed a priori at these commonly used values rather than tuned by search, so no search ever observed the test partition and the comparison reflects default-configuration behavior; the class-weight ratio and the standardization scaler are estimated on the training partition only, early stopping uses validation only, and the decision threshold is selected on validation only (Section III-F). All models run on CPU in this environment. XGBoost is adopted as the reference model in the per-cohort analyses.

F. Threshold Selection and Metrics

Because hypoglycemia is the minority class (3% to 9.5% of rows depending on the dataset), accuracy is uninformative, and AUPRC, threshold-independent and more informative than AUC-ROC under strong imbalance [16], is the primary metric. The operating point is decoupled from the model: AUPRC measures risk-ranking quality, and a rule converts that ranking into a firing decision. The primary rule fixes a minimum recall of 0.80 on validation; an alternative point maximizing validation F1 is a secondary analysis (Section IV-G). Three configurations are kept distinct: the *primary comparison* (corrected pipeline, full test set, minimum-recall rule), the *complete-glucose subset* of Section IV-E, and the *alternative F1 point* of Section IV-G. Unless stated otherwise, results refer to the primary comparison.

Denominators. All reported recall, precision, and F1 are *sample-level*: the unit is one 5-minute grid row that satisfies the coverage rule of Section III-C, not one hypoglycemic episode and not one alarm. A false alarm is a test row predicted positive whose label is negative; the daily rate divides each patient's false-positive count by that patient's *observed* test days (labeled test rows divided by 288, the number of 5-minute cells in a day) and averages across patients, so unequal test durations contribute equally. We state this convention because a calendar-duration denominator would report systematically lower rates for the sparser cohorts, by up to their missing-data fraction. Event-level sensitivity, median time-to-warning, and alarm duration use different denominators and are not estimated here; Section V-A discusses what that omission costs.

AUPRC uncertainty is quantified by nonparametric bootstrap resampling at the *patient* level, preserving the intra-patient correlation that row-level resampling would ignore; two-model comparison uses the same scheme in paired form. Intervals are reported for AUPRC only; the operating-point quantities are point estimates. To separate real task difficulty, we also report AUPRC restricted to samples that are euglycemic at prediction time (current glucose ≥ 80 mg/dL), a regime in which the future event is not trivially anticipable from the current value, and we evaluate two learning-free comparators: ranking risk by current glucose ($-g_t$) and by 30-minute glucose projected by linear extrapolation ($-\hat{g}_{t+30} = -(g_t + 6\,\Delta g_5)$). Guarantees against temporal leakage (past-only features, future-only target, scaler fit on train only, threshold chosen on validation only) are verified by automated tests.

IV. Experiments

A. Experimental Setup

The primary comparison uses cohort $\mathcal{D}_{\text{tot}}$ under temporal split, with the operating point fixed by the minimum-recall-0.80 rule on validation. Cost measurements use the same cohort, with 550 245 tabular training rows and 564 951 sequential windows, on CPU: reported memory is the RAM working set and wall-clock times are single-run measurements, without repetition or dispersion (Section IV-C). Permutation importance shuffles each feature on the test set and measures the mean AUPRC drop over five repetitions.

B. Comparative Results

In the primary comparison on cohort $\mathcal{D}_{\text{tot}}$ (Table II), Random Forest and XGBoost reach the highest AUPRC (both 0.887), with Logistic Regression an AUPRC approximately 0.08 lower. In the *paired* per-patient bootstrap, the difference ΔAUPRC(RF$-$XGB) is close to zero, with a 95% confidence interval that crosses zero ($[-0.0025, +0.0053]$), so the two are statistically indistinguishable on this criterion; their similar AUPRC makes computational cost an important additional selection criterion (Section IV-C). The recurrent networks (LSTM and GRU) sit just behind the tree ensembles (0.874 and 0.878). The AUC-ROC is high and nearly saturated for all models (between 0.982 and 0.986), which supports the choice of AUPRC, more sensitive to the rare class, as the decision metric.

Two cautions apply to reading Table II as a ranking. First, the marginal intervals are wide (about ± 0.07), since there are only about 768 independent episodes across 79 patients rather than 550k independent rows; being computed independently per model, their overlap is uninformative about a within-patient difference, which the paired test estimates directly.

Table II
30-MIN HYPOGLYCEMIA CLASSIFICATION IN COHORT $\mathcal{D}_{\text{TOT}}$ (TEMPORAL SPLIT, GLUCOSE+TIME SET, OPERATING POINT AT RECALL ≥ 0.80). ALL QUANTITIES ARE SAMPLE-LEVEL (ONE 5-MIN ROW PER UNIT).

Model	AUPRC	AUC-ROC	Recall	Prec.	F1	FA/day
Log. Regression	0.804	0.982	0.807	0.738	0.771	4.05
Random Forest	**0.887**	0.985	0.798	0.802	0.800	2.80
XGBoost	**0.887**	0.986	0.801	0.796	0.798	2.91
LSTM	0.874	0.983	0.801	0.762	0.781	3.55
GRU	0.878	0.985	0.797	0.778	0.788	3.22

79 test patients, prevalence 5.62% of labeled rows. AUPRC 95% CI (patient-clustered bootstrap): LogReg [0.715, 0.859], RF [0.816, 0.922], XGB [0.814, 0.922], LSTM [0.798, 0.908], GRU [0.793, 0.913]. Paired bootstrap ΔAUPRC(RF$-$XGB) $\approx$ 0, 95% CI $[-0.0025, +0.0053]$; other pairs untested. Recall, precision, F1 and FA/day are point estimates. LSTM and GRU use the 9-channel sequential set.

Second, the paired test was applied only to the RF–XGB pair, the one on which a selection decision depends. The remaining orderings, in particular GRU above LSTM and both below the ensembles, are descriptive: they were not tested pairwise, and differences of that magnitude lie well inside the marginal intervals. No multiplicity correction is applied, since only the two pre-specified paired comparisons of this paper are reported.

C. Computational Cost Analysis

Table III and Figure 2 report cost quantities that discrimination metrics alone do not capture. With AUPRC statistically indistinguishable from Random Forest, XGBoost trained about six times faster (8.0 s versus 46.8 s), showed approximately 35-fold lower single-window latency (1.32 ms versus 46.28 ms), and produced a serialized model about 350 times smaller on disk (0.79 MB versus 274.65 MB). Relative to XGBoost, LSTM and GRU required approximately 64 and 97 times more training time, respectively, for a lower AUPRC; relative to Random Forest the corresponding training-time factors are about 11 and 17. Logistic Regression is the cheapest model but reaches an AUPRC approximately 0.08 lower. The two timing quantities are not directly comparable: single-window latency measures one prediction at a time, as in 5-minute real-time operation, whereas throughput measures batched prediction, where vectorization amortizes the fixed per-call overhead. Because Random Forest and XGBoost had indistinguishable AUPRC, computational cost became the main criterion for choosing between them in the evaluated CPU environment.

Table III deliberately reports no energy figure. An energy value obtained by multiplying training time by a fixed nominal power, as is sometimes done, is a linear transform of the first column and therefore carries no information beyond it, while ignoring idle draw, dynamic frequency scaling, and the memory subsystem. A meaningful energy comparison, particularly one supporting a claim about embedded deployment, requires wall-plug or on-board power measurement on the target hardware under a stated duty cycle, which this study does not provide.

Table III
TRAINING AND INFERENCE COST (COHORT $\mathcal{D}_{\text{TOT}}$, CPU, SINGLE RUN).

Model	Train (s)	Latency (ms/window)	Throughput (10^3 rows/s)	Train RAM (MB)	Size (MB)
Log. Regression	1.1	1.099	7 063	116	0.00
Random Forest	46.8	46.279	239	581	274.65
XGBoost	8.0	1.323	1 176	47	0.79
LSTM	514.9	50.440	15.5	429	0.28
GRU	779.0	51.243	16.6	259	0.23

Latency: one time point at a time (real-time use every 5 min). Throughput: batched prediction; the two are not comparable, since batching amortizes the fixed per-call overhead. Single-run measurements, no dispersion. Peak RAM reflects the full implementation, not the serialized model. AUPRC for the same configurations in Table II.

Table IV
PERMUTATION IMPORTANCE (MEAN AUPRC DROP) OF THE MOST RELEVANT TABULAR FEATURES.

Feature	LogReg	RF	XGBoost
glucose_current	0.3631	0.4843	0.6976
glucose_min_60min	0.6306	0.1560	0.0423
glucose_mean_60min	0.1423	0.0481	0.0193
glucose_max_60min	0.1476	0.0239	0.0077
glucose_delta_5min	0.0259	0.0524	0.0663
hour_cos	-0.0004	0.0008	0.0025

Insulin, carbohydrate and activity show drops near zero (omitted). Permutation importances are not additive; under strong correlation among the glucose features the attribution distributes unstably among them, which explains the ranking inversion across models, so the stable reading concerns the glucose block as a whole, not the internal order of its components.

D. Multimodal Ablation and Feature Importance

Permutation importance (Table IV) is concentrated in the glucose features: current glucose and the 60-minute minimum account for the largest AUPRC drops, while insulin, carbohydrate and activity features drop near zero. In the sequential models, permuting the glucose channel reduced AUPRC by about 0.83, whereas permuting all other channels reduced it by less than 0.03 in total. The ablation agrees in relative terms: reducing the classifier from 17 to 11 features (glucose+time), or to 9 (glucose-only), leaves AUPRC nearly unchanged (0.8645, 0.8636, 0.8628), a maximum absolute difference of 0.0017, stable across reruns. These absolute values come from the pre-correction pipeline (the *Original* column of Table VII), so the ablation characterizes *relative* invariance to modality removal, not the final performance level. The remaining analyses therefore adopt the glucose+time set, which is simpler and cheaper without a material AUPRC reduction.

This observation is specific to the 30-minute window, to binary ranking classification, and to these four cohorts, three of which are dominated by pump or automated-insulin-delivery therapy, with regular basal profiles and sparse self-reported carbohydrate and activity logs. An under-recorded modality cannot show importance, so a near-zero permutation drop is evidence about *these annotations*, not about the physiology. The literature reports gains from insulin and carbohydrate mainly at longer horizons [11]; the limited contribution observed here delimits the short-term regime under sparse annotation and does not rule out multimodal value in general.

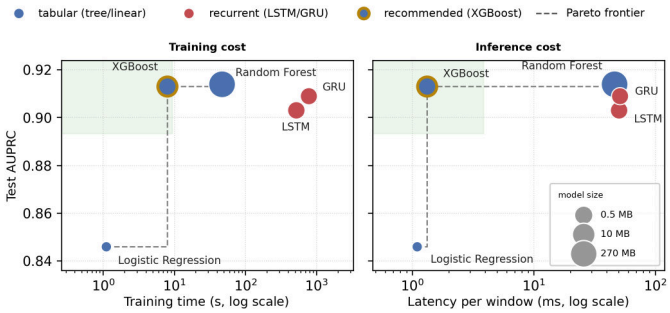

Figure 2. Computational cost versus AUPRC in cohort $\mathcal{D}_{\text{tot}}$ (CPU, single run; cf. Table II). Left: training cost; right: inference latency per window. Marker area encodes on-disk size, color encodes model family, and the dashed line is the Pareto frontier. The upper-left corner combines higher AUPRC with lower cost; Logistic Regression and XGBoost are the two non-dominated points in both panels.

Table V
COMPLETE-GLUCOSE SUBSET ANALYSIS: AUPRC OF XGBOOST VERSUS LEARNING-FREE RULES, STRATIFIED BY GLUCOSE AT PREDICTION TIME (COHORT $\mathcal{D}_{\text{TOT}}$, TEST).

Curr. glucose	n	prev.%	XGBoost	$-g_t$	$-\hat{g}_{t+30}$
all	183 419	5.70	**0.895**	0.842	0.522
≥ 80 (eugl.)	170 159	1.17	**0.321**	0.118	0.159
≥ 100	149 649	0.33	**0.135**	0.015	0.064
≥ 120	118 013	0.12	**0.056**	0.003	0.029

$-g_t$: risk ranked by current glucose. $-\hat{g}_{t+30}$: by glucose projected via linear extrapolation of the 5-min trend. Prevalence falls as the band rises, making the task progressively harder. All rows are restricted to the subset with materialized glucose; this restriction, not a change of model or pipeline, accounts for 0.895 in the *all* row versus 0.887 in Table II.

Table VI
XGBOOST GENERALIZATION (GLUCOSE+TIME): WITHIN-PATIENT TEMPORAL EVALUATION VERSUS UNSEEN PATIENTS AND DATASETS (COHORT $\mathcal{D}_{\text{TOT}}$, OPERATING POINT AT RECALL ≥ 0.80).

Scenario	AUPRC	Recall	Prec.	FA/day
Temporal (baseline)	0.887	0.799	0.798	2.87
Unseen patients	0.873	0.811	0.751	3.67
Unseen dataset	0.869	0.758	0.802	2.76

AUPRC 95% CI (per-patient bootstrap): Temporal [0.814, 0.920]; Unseen patients [0.729, 0.941] (15 test patients); Unseen dataset [0.812, 0.906]. Unseen dataset: train on three, test on the fourth (OhioT1DM holdout).

E. Real Task Difficulty and Trivial Baseline

This secondary analysis is restricted to test rows with materialized glucose at prediction time (183 419 rows), which is why the aggregate XGBoost AUPRC here is 0.895 rather than the 0.887 of Table II. Within this subset, Table V stratifies XGBoost by glucose at prediction time against two learning-free rules. In aggregate, ranking by current glucose alone already reaches 0.842 versus 0.895 for XGBoost, an aggregate influenced by samples already near the threshold, where the current value largely determines the outcome. Restricted to euglycemic samples ($\geq$ 80 mg/dL), where the drop has not begun, XGBoost falls to 0.321 and prevalence from 5.70% to 1.17%; there XGBoost exceeded the best learning-free rule (0.159) by $\Delta\text{AUPRC} = +0.162$ (95% CI $[+0.139, +0.189]$, paired per-patient bootstrap), against an aggregate margin of only 0.053. The gap between the two margins indicates that aggregate AUPRC is a poor guide to the incremental value of the learned model.

F. Generalization Analysis

Table VI contrasts within-patient temporal evaluation with generalization to unseen patients and datasets, both participant-disjoint by construction. For unseen patients, AUPRC falls from 0.887 to 0.873 while, at the same target recall, precision falls from 0.798 to 0.751 and false alarms rise from 2.87 to 3.67 per day. For a whole unseen dataset (OhioT1DM holdout), AUPRC falls comparably, to 0.869, but the operating point shifts differently: precision and false alarms are preserved, while the fixed threshold no longer sustains the target recall, which falls from 0.80 to 0.76. Risk ranking therefore transferred better than the selected operating point [14], and that point moved in opposite directions under the two shifts: toward more false alarms for new patients, toward reduced sensitivity for a new device or population. The patient-held-out interval is wide (15 test patients), so these comparisons are indicative rather than conclusive, and they motivate evaluating a threshold recalibration that this study does not test.

G. Alternative Operating Point and Data Quality

Three interventions were evaluated on XGBoost as secondary analyses: switching the threshold rule from minimum recall to F1, reducing the feature set to glucose+time, and data-quality correction (physiological clipping to 40–400 mg/dL and gap-aware windows). In Table VII the combined change in threshold and feature set increased precision while leaving aggregate AUPRC nearly unchanged; introduced in the same step, their individual effects cannot be separated. The subsequent data-quality correction was the only step in which AUPRC itself increased in every cohort, and it produced the largest AUPRC improvement among the three. The largest change appears in T1D-UOM, the cohort with the most missing data: precision rises from 0.37 to 0.78 and false alarms fall from about 18 to 1.6 per day.

V. DISCUSSION

Why the model families converged. The five architectures span a wide range of representational capacity, yet their AUPRC values fall within roughly 0.08 of each other and the two tree ensembles are statistically indistinguishable. A

Table VII
XGBOOST BY INTERVENTION (AUPRC / PRECISION / FALSE ALARMS PER DAY, ON TEST). COLUMNS ARE CUMULATIVE: EACH ADDS AN INTERVENTION TO THE PREVIOUS ONE. THE THIRD COLUMN CORRESPONDS TO THE ALTERNATIVE F1 OPERATING POINT ON THE CORRECTED PIPELINE AND IS A SECONDARY ANALYSIS, NOT THE PRIMARY COMPARISON OF TABLE II.

Cohort	Original	+ F1 thr., gluc+time	+ data corr.
$\mathcal{D}_{\text{tot}}$	0.864 / 0.756 / 4.30	0.864 / 0.854 / 2.08	**0.895 / 0.867 / 1.92**
$\mathcal{D}_{\text{uom}}$	0.676 / 0.368 / 17.9	0.680 / 0.656 / 4.09	**0.775 / 0.780 / 1.63**
$\mathcal{D}_{\text{azt}}$	0.750 / 0.497 / 7.46	0.757 / 0.705 / 2.58	**0.764 / 0.729 / 2.24**
$\mathcal{D}_{\text{ohio}}$	0.839 / 0.732 / 3.47	0.842 / 0.792 / 2.40	**0.848 / 0.877 / 1.15**
$\mathcal{D}_{\text{hupa}}$	0.948 / 0.952 / 1.18	0.951 / 0.906 / 2.63	**0.951 / 0.919 / 2.23**

Original: recall ≥ 0.80 rule, 17 features. The second column changes the threshold rule and the feature set simultaneously, so their effects cannot be separated. The third is evaluated on the subset with materialized glucose, hence 0.895 for $\mathcal{D}_{\text{tot}}$ rather than the 0.887 of Table II.

plausible explanation is that the informative structure of the 30-minute problem is largely contained in the recent glucose trajectory, which the tabular set already encodes through the 60-minute statistics and deltas; the sequential models then have little residual structure to extract, consistent with them matching but not exceeding the ensembles at one to two orders of magnitude more training cost. The ablation points the same way: removing the non-glucose modalities changed AUPRC by at most 0.0017.

What aggregate AUPRC does and does not measure. The aggregate metric is strongly influenced by samples in which the patient is already near the hypoglycemic threshold, where the current glucose value alone ranks risk almost as well as the trained model. The incremental contribution of learning becomes visible in the euglycemic subset, where prevalence is 1.17% and the margin over the best learning-free rule is $+0.162$ AUPRC. A study reporting only aggregate AUPRC therefore cannot distinguish a model that anticipates the onset of a drop from one that mostly reads the current value, and absolute values are not comparable across studies applying different inclusion criteria for current glucose.

Repeated events and effective sample size. Hypoglycemia arrives in episodes, not independent draws: consecutive 5-minute rows inside one descent share almost all of their history and carry nearly the same label, the test partition holds roughly 768 episodes across 79 patients, not 550k independent draws. Sample-level precision, recall and F1 therefore describe how many 5-minute cells are correctly flagged, and a model can score well by holding an alarm through a long episode it detected late, or by flagging one long false stretch instead of many short ones. Patient-clustered bootstrap and per-patient normalization of the false-alarm rate mitigate this, but neither converts a sample-level metric into an event-level one.

Sensor delay and what the horizon means. Features and labels both derive from interstitial CGM, which trails plasma glucose by several minutes through diffusion and sensor filtering [8]. The 30-minute horizon is therefore a horizon in *sensor time*: the physiological lead available to a patient is shorter by the sensor delay, and the margin depends on the device, which differs across the four datasets. Since the delay affects label and input alike, it does not bias the metrics reported here, but it compresses the actionable window any deployed version would provide.

Distribution shift. AUPRC was largely preserved under both tested shifts, new individuals and a new device or population, while the fixed operating point was not, moving in opposite directions in the two cases; ranking quality and calibration are separable properties. This does not establish that recalibration is sufficient: the experiments hold the threshold fixed and observe the consequence, without testing a recalibration procedure.

A. Limitations and Threats to Validity

Retrospective evidence only. Every result comes from stored recordings of four public datasets. No alert was displayed to a patient, no clinician acted on a prediction, and no downstream outcome, such as an averted episode, a carbohydrate intake, or a suspended basal delivery, was observed. This distinguishes retrospective prediction from decision support: the paper reports how well a model ranks risk on recorded data, and reports nothing about whether an alert derived from that ranking would be safe, timely, or acted upon. Prospective, multicenter evaluation across CGM platforms, with real patient interaction with the generated alerts, is required before any clinical-utility claim.

Sample-level metrics. As stated in Section III-F, recall, precision, F1, and false alarms per day are computed per 5-minute row. Event-level sensitivity (the fraction of hypoglycemic *episodes* flagged at least once before onset), median time-to-warning, alarm duration, and the number of *distinct* alarms per patient-day are the quantities a clinical reader needs, and they are not estimated here. Sample-level figures can overstate usefulness when episodes are long and alarms are held, so Table II should be read as a comparison among models under one common convention rather than as an estimate of clinical alarm burden. Confidence intervals are reported for AUPRC only.

Cost figures. Costs characterize one CPU environment, one implementation per model, and a single run per measurement, without repetition, dispersion or contention control, and no energy figure is reported (Section IV-C). Statements about suitability for resource-constrained diabetes devices are therefore extrapolations from relative cost ratios, which are more stable across environments than absolute values; no embedded target, quantized model or on-device duty cycle was evaluated.

Scope of the task. A single horizon (30 min) and a single event definition (70 mg/dL) are covered. Regression-based forecasting, level-2 hypoglycemia at 54 mg/dL, nocturnal-specific evaluation, and the longer horizons relevant to closed-loop delivery [26] are not, and neither the model ranking nor the modality result should be assumed to hold there. Adaptive threshold calibration is motivated by the generalization results but not implemented or validated, and the boundary overlap of Section III-A is bounded but not eliminated. Finally, data-quality correction is the largest gain *among the three interventions evaluated.*

VI. Conclusion

Across the five evaluated models, Random Forest and XGBoost achieved the highest AUPRC (0.887 for both), with no meaningful difference in the paired per-patient bootstrap. XGBoost required about six times less training time, roughly 35-fold lower single-window latency, and a serialized model about 350 times smaller than Random Forest in the evaluated CPU environment, so computational cost was the main criterion separating the two. Ablation and permutation analyses indicated that most of the predictive information used by these models came from recent glucose, with limited incremental contribution from insulin, carbohydrate and activity at the 30-minute window and under the annotation density of these cohorts. Ranking transferred relatively well to held-out patients and to a held-out dataset, although precision, recall and false-alarm rates changed at the fixed operating point, which supports evaluating threshold recalibration when deploying in a new population or device.

The contribution is the multidimensional benchmark under a shared protocol, and its evidence is retrospective and sample-level throughout. Future work follows from Section V-A: event-level reporting (episode sensitivity, time-to-warning, alarm duration, distinct alarms per patient-day, with intervals); measured energy and latency on embedded target hardware; prospective multicenter validation across CGM devices with real patient interaction with the alerts; adaptive per-patient and per-device recalibration, evaluated rather than proposed; and extension to longer horizons and to regression-based trajectory forecasting for closed-loop integration.

Data Availability and Ethics

This study uses four publicly available de-identified T1D datasets under their respective terms and collected no new human-subject data. OhioT1DM [7] is distributed under a Data Use Agreement restricting use to research, executed prior to access; HUPA-UCM [19] is on Mendeley Data under CC BY-NC-ND; AZT1D [20] is on Mendeley Data, its collection approved by the Mayo Clinic Institutional Review Board (#23-003065); and T1D-UOM [21] is on Zenodo under CC BY.

***Abstract*—Oral cancer and oral potentially malignant disorders (OPMDs) represent a major public health concern, with early diagnosis playing a crucial role in improving patient survival. In recent years, Deep Learning-based Artificial Intelligence (AI) models have emerged as a promising approach to support the diagnosis of these lesions. However, their development and performance depend on the availability of standardized and well-annotated clinical image datasets. This study presents the preliminary results of the development of IA Bucal Files, a platform designed for the curation, annotation, and validation of clinical images of oral lesions. To date, the database comprises 5,440 clinical images, of which 2,670 are currently undergoing annotation and 807 have already been validated by specialists. The partial analysis includes 4,232 annotations, predominantly benign lesions (3,212), followed by oral potentially malignant disorders (529) and malignant lesions (491). The most frequent conditions include Geographic Tongue (221), Secondary Syphilis Mucous Plaques (198), Leukoplakia (188), and Proliferative Verrucous Leukoplakia (163). These preliminary findings demonstrate the platform's potential to provide a robust and diverse clinical image database, supporting the training of AI models for computer-aided diagnosis and the early detection of oral lesions.**

***Index Terms*—Oral Cancer, Artificial Intelligence, Deep Learning, Image Annotation.**

I. Introduction

Oral diseases represent a major global public health problem, accounting for hundreds of thousands of new cases and deaths each year [1], [3], [7]. Various lesions can affect the oral mucosa, leading to significant clinical and epidemiological impacts, with direct consequences for patients' quality of life and survival [1], [6]. Early detection of these lesions is essential to improve prognosis, increasing survival rates from approximately 40%–50% to more than 80% when diagnosis occurs at early stages [1], [3], [6]. Conversely, delayed diagnosis limits available therapeutic options, often requiring more aggressive interventions and substantially reducing treatment success rates [7], [9].

Oral cancer rarely develops abruptly and is commonly preceded by visible clinical alterations of the oral mucosa known as Oral Potentially Malignant Disorders (OPMDs) [5]. Due to its high morbidity and mortality, oral cancer is widely recognized as a significant public health concern [2]. The main OPMDs include leukoplakia, erythroplakia, oral lichen planus, and oral submucous fibrosis [4], [6].

Leukoplakia is predominantly characterized as a white plaque of questionable risk, with pooled malignant transformation rates of approximately 9.8% [4], [7]. Erythroplakia, in turn, presents as red lesions of the oral mucosa and, although less common, exhibits a considerably higher malignant transformation potential [4], [6]. Oral lichen planus is a chronic autoimmune inflammatory disease, with estimated malignant transformation rates ranging from 1.14% to 2.28% [7]. Oral submucous fibrosis is a chronic and progressive fibrotic disorder whose malignant transformation rates range from 4.2% to 30% [6], [7]. Therefore, rigorous clinical follow-up of these conditions is essential to guide therapeutic decisions and prevent progression to invasive carcinoma [4].

Despite the easy visual accessibility of the oral cavity, the clinical diagnosis of these lesions remains a significant challenge. This is mainly due to the high visual similarity between malignant lesions, potentially malignant disorders, benign alterations, and even normal anatomical variations [1], [2].

Furthermore, oral lesions exhibit substantial clinical variability, and patients often present with diverse symptoms [1]. As a result, diagnostic accuracy depends heavily on

the examiner's experience, highlighting the importance of specialists in Oral Medicine and Oral Pathology [1], [3]. However, conventional visual examination is inherently subjective and susceptible to interobserver variability [3]. This issue is even more pronounced in regions with limited healthcare resources and infrastructure, where the shortage of specialized professionals contributes to delayed diagnosis and late patient referral [2], [3].

In this context, Artificial Intelligence (AI) has emerged as a promising strategy to support diagnosis and improve clinical assessment in medicine and dentistry [1], [8]. In particular, computer vision combined with Computer-Aided Detection (CAD) systems has introduced new approaches for medical image analysis [2]. At the core of these advances are Deep Learning models, especially Convolutional Neural Networks (CNNs), which are capable of automatically learning complex image features directly from pixel data without requiring manual feature extraction [1], [2], [8].

Recent studies have demonstrated that these algorithms can detect and classify oral lesions, distinguishing malignant lesions from benign conditions and normal tissues with accuracy, sensitivity, and specificity often comparable to or even exceeding those achieved by human specialists [1], [3], [8]. However, the performance and generalization capability of Deep Learning models in real clinical settings depend on the availability of large datasets characterized by high quality, diversity, and representativeness [1], [2].

The development of such datasets relies directly on expert annotation. Clinical images must be carefully evaluated and labeled by pathologists and specialists, frequently using histopathological biopsy results as the gold standard to ensure that algorithms learn clinically meaningful patterns [2], [3]. Nevertheless, the development of robust AI solutions is still limited by the scarcity of publicly available clinical image datasets for oral lesions. Currently, many studies continue to rely on relatively small datasets collected from single institutions, limiting the generalizability of the proposed models [1], [3].

Therefore, the development of standardized tools for the organization, annotation, and systematic management of large-scale clinical image collections is essential. Furthermore, strengthening multicenter collaborations to establish diverse clinical image repositories represents a crucial step toward advancing more robust, reliable, and clinically applicable Artificial Intelligence solutions for the early detection of oral lesions [1], [3], [8].

II. Methodology

This methodology describes the operation and use of the IA Bucal Files platform, an ecosystem designed for the creation of high-fidelity datasets intended for training Artificial Intelligence models in Oral Pathology.

A. Introduction and Workflow

The system operates through a structured workflow consisting of four main stages: image upload, technical annotation, expert review, and data export in the standardized COCO JSON format, as illustrated in Figure 1. The workflow is organized according to user roles: the Annotator is responsible for data entry and lesion annotation; the Reviewer performs the technical and diagnostic validation of the annotations; the Exporter consolidates the data for training Artificial Intelligence models; and the Administrator manages the system governance, including user and taxonomy management.

Fig. 1. Operational workflow of the annotation platform.

B. Getting Started and Navigation

The system is accessed through a web browser using authentication credentials provided by the administration. After logging in, users are presented with a dashboard displaying productivity indicators, such as the total number of projects, images, approved annotations, and pending tasks. Navigation is centralized through a side panel whose functionalities are adapted according to the user's access profile, providing access to modules such as the Reference Library, Projects, Review Queue, and User Management.

C. Projects and Datasets

Data organization begins with the creation of Projects, which serve as the main containers. Within each project, Datasets are created, where users must specify the image source (such as books, journal articles, undergraduate theses, or scanners) and reference metadata, such as the DOI.

During the upload process, the system performs automatic preprocessing to ensure dataset quality: Contrast Limited Adaptive Histogram Equalization (CLAHE) is applied to enhance image contrast, perceptual hashing is used to detect duplicate images, and a technical analysis of image sharpness and brightness is performed. The resulting gallery allows users to search by diagnosis and filter images according to annotation status.

As a fundamental quality requirement established during the literature review and data screening, 100% of the validated clinical images in the datasets possess diagnostic confirmation through histopathological examination (the gold standard). The platform preserves the explicit link between each image and its original scientific source (book, journal article, or academic thesis), enabling both annotators and reviewers to readily consult the source material within the reference library to resolve any diagnostic or anatomical doubts during curation.

D. Image Separation and Processing

In cases where a single image contains multiple pathologies or requires a specific region of interest, the Separation Workspace is used. This tool allows image duplication or precise cropping. The methodology recommends duplicating the image before cropping in order to preserve the integrity of the original image in the repository.

E. Annotation and Classification Protocol

After cropping, when necessary, the annotator selects the image (or cropped region) to be analyzed. The annotation environment provides vector drawing tools, including polygons, rectangles, circles, and ellipses, enabling the precise delineation of structures of interest. At this stage, annotations are organized into three main categories: lesions, anatomy, and exclusion zones. Figure 2 illustrates this process.

In addition to lesion delineation, the system allows the annotation of anatomical structures present in the image, such as the lips, teeth, tongue, palate, and oral mucosa, as well as exclusion zones, corresponding to regions that should not be considered during model training, such as instruments, reflections, and other irrelevant areas.

The annotator can also adjust vertices, modify polygons, and reclassify annotations whenever necessary. Once completed, the annotations are automatically forwarded to the review queue, where they await validation by Oral Health specialists.

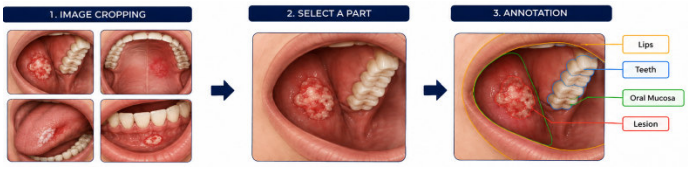

Fig. 2. Workflow of the clinical image annotation process within the platform.

F. Validation and Quality Control

The validation process is independently conducted by a panel of three dental professionals who thoroughly evaluate the accuracy of lesion contours and anatomical landmark annotations. An image is classified as 'approved' and integrated into the final dataset only upon absolute consensus (unanimous approval by all three reviewers). If one or more reviewers identify any discrepancies, the image is rejected and returned to the respective annotator's queue along with detailed technical comments. To resolve divergences, the platform features an interactive comment panel visible to both the annotator and all reviewers, enabling collaborative discussions to reach consensus on borderline cases.

G. Data Export

The final stage consists of exporting the dataset for training Artificial Intelligence models through a four-step Export Wizard. Users can select projects and datasets, filter only approved annotations, and define the patch size, ranging from the original resolution to 256 × 256 pixels. At the end of the process, the system generates a ZIP file containing the selected images and their corresponding annotations in the COCO JSON format.

III. Results and Discussion

The construction, organization, and curation of the image database resulted in the compilation of 5,440 clinical images. Of this total, the screening process enabled 2,670 images to be properly annotated and labeled. As part of the quality control stage for algorithm training, 807 of these images have already undergone rigorous validation by expert professionals, as illustrated in Fig. 3.

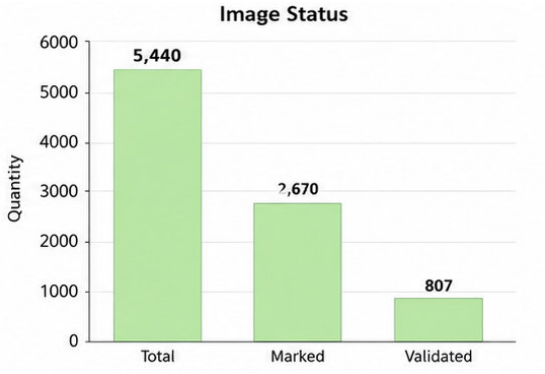

Fig. 3. Quantitative workflow of image curation, annotation, and validation within the database.

The development of Artificial Intelligence (AI) algorithms, particularly those based on Convolutional Neural Networks (CNNs), has great potential to assist in the diagnosis of oral cancer and support clinical decision-making. However, their performance and generalization capability depend directly on the quantity and quality of the data used during training [1], [2], [8].

Since this project is still under development, the results presented are preliminary. Nevertheless, the compilation of 5,440 clinical images, with 807 already validated by specialists, represents a significant advance compared with the limited dataset sizes commonly reported in the literature. Recent studies on the automatic detection of oral lesions using Deep Learning employed considerably smaller datasets, such as the study by [1], which used 518 images, and the study by [2], based on approximately 1,000 images.

The ongoing annotation and expert validation process will progressively expand a gold-standard dataset, reducing labeling bias, improving data reliability, and supporting the development of more robust models with greater clinical applicability [1], [3], [8].

Regarding the clinical and histopathological annotations (4,232 in total), benign lesions predominated (3,212 annotations), followed by 529 oral potentially malignant disorders and 491 malignant lesions, reflecting the natural distribution observed in clinical practice. The results are presented in Fig. 4.

The preliminary distribution of the categories in the database reflects the epidemiological profile commonly observed in oral medicine practice, where benign lesions (3,212 annotations) are more frequent than malignant lesions (491) and oral potentially malignant disorders (529) [1], [7]. From a computational perspective, this distribution reproduces a common challenge in Artificial Intelligence applications: class imbalance [1], [2].

It is important to emphasize that the presented results are preliminary, representing the current stage of the database

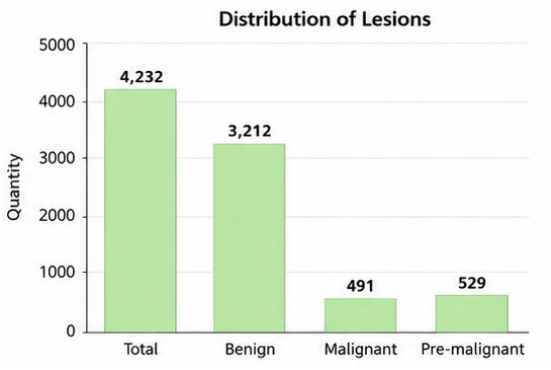

Fig. 4. Distribution of validated benign, malignant, and potentially malignant oral lesions in the database.

development. To mitigate the class imbalance naturally observed between benign, malignant, and potentially malignant lesions, the project roadmap includes targeted clinical data collection and curation focusing on minority classes. Furthermore, computational strategies such as synthetic image generation via generative models, balanced undersampling of the majority class, and weighted loss functions (e.g., Weighted Cross-Entropy or Focal Loss) will be systematically implemented prior to deep learning model training to ensure high generalization capability and prevent class bias [1], [2].

The analysis of the annotated diseases revealed a broad pathological diversity. Geographic Tongue was the most frequent condition (221 cases), followed by Secondary Syphilis Mucous Plaques (198). Among the oral potentially malignant disorders, Leukoplakia (188), Proliferative Verrucous Leukoplakia (163), and Reticular Oral Lichen Planus (103) were the most prevalent. Among the malignant lesions, Kaposi's Sarcoma accounted for 146 cases. Inflammatory, infectious, and autoimmune conditions were also identified, including Pseudomembranous Candidiasis (143), Mucocele (134), Mucous Membrane Pemphigoid (126), Pemphigus Vulgaris (112), and Melanotic Macule (107).

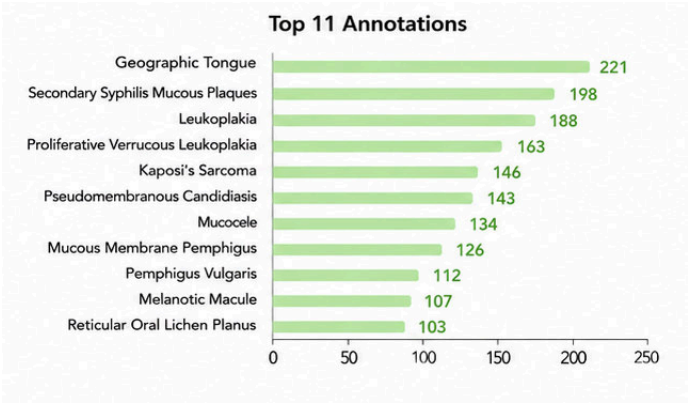

Fig. 5. Frequency of the 11 most prevalent oral diseases and lesions identified in the dataset.

The high frequency of inflammatory, infectious, and autoimmune conditions, such as Geographic Tongue (221 annotations) and Secondary Syphilis Mucous Plaques (198), represents an important characteristic for training Artificial Intelligence models. In clinical diagnosis, the main challenge is not only detecting abnormalities but also distinguishing them from benign lesions that closely resemble oral potentially malignant disorders and carcinomas [1], [7]. Therefore, the inclusion of these conditions increases the phenotypic variability of the dataset, promoting the development of models with higher specificity and lower susceptibility to misclassification [1], [3].

Another relevant aspect is the substantial representation of oral potentially malignant disorders (OPMDs), which are essential for the early diagnosis of oral cancer [4], [6]. Among them, Leukoplakia (188 annotations) and Proliferative Verrucous Leukoplakia (163), recognized for its high malignant transformation potential, stand out [4], [7]. The availability of these images enables the training of algorithms capable of identifying not only established carcinomas but also high-risk precursor lesions, contributing to early diagnosis strategies and precision medicine [6], [8].

As the annotation and expert validation stages progress, the representativeness and quality of the database are expected to increase continuously, strengthening its application in training computer vision models. This evolution may enable the development of more robust automated screening systems with greater clinical applicability, contributing to the early detection of oral lesions and reducing diagnostic delays [1], [8], [9].

Although the platform features a structured workflow, the empirical validation of its usability and clinical efficacy remains a limitation of this preliminary study and represents the next planned phase. Initially, a user experience (UX) survey will be conducted with active academic users and annotators to evaluate ease of use and the platform's learning curve.

Final Remarks

This study presented the development of IA Bucal Files, a platform designed for the curation, organization, and annotation of clinical images of oral lesions to build a database for training Artificial Intelligence models applied to the early diagnosis of oral cancer and oral potentially malignant disorders (OPMDs).

Although the project is still ongoing, the preliminary results demonstrate its potential to address an important gap in the literature. To date, 5,440 clinical images have been compiled, of which 807 have already been validated by specialists. Combined with the annotation and expert review process, this dataset contributes to the development of a high-quality database, which is essential for building more robust deep learning models with greater generalization capability [1], [2], [8].

The database encompasses a wide variety of pathologies, including benign, infectious, inflammatory, autoimmune, and oral potentially malignant lesions, promoting the learning of diverse clinical patterns and improving the differentiation between benign lesions and lesions with malignant transformation potential [1], [4], [6], [7].

As future work, the database will be continuously expanded through the inclusion of new cases and the completion of the annotation and expert validation stages. Subsequently, the dataset will be used to train and evaluate computer vision models for the automatic detection and classification of oral lesions, contributing to the development of decision-support tools for diagnosis and early patient referral, thereby reducing diagnostic delays and their impact on patient survival [1], [8], [9].

ACKNOWLEDGMENTS

The authors would like to thank the Federal University of Rio Grande do Norte (UFRN) for its institutional support and the National Council for Scientific and Technological Development (CNPq) for its financial support. They also express their sincere gratitude to Prof. Dr. Caroline Dantas Vilar for her guidance, support, and valuable contributions throughout this research. Finally, the authors thank all colleagues involved in the IA-Bucal Files project, whose dedication and collaboration were essential to the development of this work

***Abstract*—Breast cancer is the most frequently diagnosed malignancy among women in Brazil and worldwide, and its definitive diagnosis relies on histopathological analysis, a process subject to interobserver variability and scalability constraints. This work proposes an intelligent decision support system for multiclass classification of breast cancer histopathological images from the public BreakHis dataset, considering eight tumor subtypes at 100x magnification. Features were extracted using a pre-trained EfficientNet-B0 network, generating 1,280-dimensional feature vectors. The training set was balanced using SMOTE, and two feature selection methods were evaluated: Particle Swarm Optimization (PSO) and Evolutionary Search. Classifiers were trained using stratified 10-fold cross-validation with 30 repetitions. During training, the SVM with linear kernel achieved 97.15% accuracy without feature selection, while the SVM with RBF kernel reached 97.89% with PSO. On the test set, the full-feature approach achieved the best performance, with 74.70% accuracy and an AUC of 0.915, indicating that the features extracted by EfficientNet already constitute a highly discriminative representation for the proposed task. These results highlight the potential of the proposed hybrid approach for multiclass breast cancer classification and demonstrate its effectiveness in a challenging eight-class histopathological classification scenario.**

***Index Terms*—Breast cancer, Histopathological images, Hybrid models, Machine learning**

I. Introduction

Despite the diagnostic and therapeutic advances of recent decades, breast cancer remains one of the most relevant oncological challenges for women's public health [1], [2]. The disease results from a complex process of genomic instability and cellular dysregulation, in which accumulated mutations eliminate cell cycle control mechanisms and promote invasive behavior [3]. Its clinical expression is variable and influenced by genetic, hormonal, metabolic, and environmental factors, making risk prediction and treatment selection complex tasks [4], [5]. Globally, 2022 data indicated that breast cancer accounted for approximately 11.6% of all cancers diagnosed in women, placing it ahead of other types in absolute number of new cases [2]. In Brazil, this reality is equally concerning, as the geographic distribution of cases reveals regional disparities, with higher incidence concentrated in the South and Southeast of the country, reflecting differences in healthcare access, screening patterns, and socioeconomic profiles [1].

The definitive diagnosis of breast cancer necessarily involves histopathological analysis of biopsy tissue [6]. Hematoxylin and eosin staining renders visible under the microscope the cellular and nuclear organization changes that allow tumor classification by type, grade, and biological behavior, information that defines treatment and prognosis [6], [7]. The central role of histopathological examination in the oncological diagnostic workflow is widely recognized; however, it carries an inherent contradiction, as the process depends entirely on the perceptual ability and accumulated clinical expertise of the pathologist [8]. Studies document that evaluations of the same specimen by different observers, or by the same professional at different times, can yield divergent classifications, compromising report reproducibility [9]. This problem tends to worsen in high-

demand clinical settings, where the daily volume of slides to review strains sustained attention and increases the risk of interpretation errors [8], [9]. Therefore, the challenge is not conceptual, as histopathology remains the reference standard, but operational: ensuring diagnostic consistency at scale without relying exclusively on human judgment.

In this context, the demand for solutions that reduce observational dependence in histopathological diagnosis has driven, over recent decades, the development of machine learning-based computational support systems [8], [10]. Among the available architectures, Convolutional Neural Networks (CNNs) stand out for their ability to automatically and hierarchically extract visual representations of increasing complexity from images, without requiring manual feature engineering [10], [11]. The transfer learning strategy, which consists of adapting pre-trained weights from large datasets to new classification tasks, has broadened the applicability of these networks in medical contexts where labeled data are scarce [12], [13]. Furthermore, architectures such as EfficientNet, designed to balance accuracy and computational cost through systematic scaling of depth, width, and resolution, have produced relevant results in histopathological classification tasks evaluated on public reference datasets [12]. However, the use of these networks as feature extractors generates high-dimensional feature vectors that frequently include redundant or low-discriminative characteristics, which may impair model generalization and unnecessarily increase training cost [13], [14]. Feature selection thus emerges both as a computational efficiency resource and as a strategy to produce more robust, interpretable, and clinically translatable models [15].

Given this scenario, this work proposes an intelligent decision support system for breast cancer diagnosis based on multiclass classification of histopathological images from the public BreakHis dataset, considering eight tumor subtypes at 100x magnification. The approach combines feature extraction via transfer learning with EfficientNet, class balancing through SMOTE, and feature selection using bio-inspired methods, investigating the impact of dimensionality reduction on the performance of classical classifiers. The results demonstrate that it is possible to build accurate, computationally efficient models with clinical application potential, contributing to the advancement of automated tools for histopathological diagnosis support.

II. Related works

Silva et al. (2024) [16] investigated the potential of breast thermography as a complementary technique for breast cancer diagnosis by proposing a hybrid architecture that combines feature extraction through transfer learning using pre-trained CNNs with conventional machine learning classifiers. To address class imbalance, the authors employed the Synthetic Minority Over-sampling Technique (SMOTE) and compared the direct use of feature vectors with an optimized feature selection approach based on Particle Swarm Optimization (PSO). The experimental results showed that the combination of Inception V3 and an SVM with a third-degree polynomial kernel achieved the highest accuracy of 79.92%, whereas the configuration using an RBF kernel (γ = 0.25) attained 100% sensitivity and an AUC of 0.83. The application of PSO reduced both the data dimensionality and the training time by approximately 50%, while maintaining an accuracy of 78.55%. The study demonstrates the feasibility of combining breast thermography with deep learning and highlights intelligent feature selection as a key strategy for developing lightweight and computationally efficient models with potential applicability in resource-constrained clinical settings.

Following a similar research direction, Gupta and Chawla (2020) [17] proposed a two-stage model for the automatic classification of breast cancer histopathological images. The authors employed pre-trained CNN architectures as fixed feature extractors, whose activation vectors were subsequently used as input to conventional machine learning classifiers, specifically Support Vector Machine (SVM) and Logistic Regression (LR). Validated on a publicly available dataset, the study demonstrated that the combination of ResNet50 and LR achieved an accuracy of 93.27%, slightly outperforming the SVM-based configuration. Stratified analyses according to image magnification further revealed that models trained specifically on 40$\times$ and 100$\times$ images yielded superior performance, suggesting that textural patterns at intermediate magnification levels provide greater discriminative power for breast cancer classification.

Using another approach applied to breast thermography, Santana et al. (2022) [18] proposed a model based on Deep Wavelet Neural Networks (DWNNs) combined with an SVM classifier. The study employed 1,052 thermographic images distributed across four classes, with the Synthetic Minority Over-sampling Technique (SMOTE) applied to address class imbalance. Unlike conventional CNNs, the DWNN uses predefined wavelet filters, reducing computational cost and eliminating the need for intensive network training. The results, obtained through 10-fold cross-validation, achieved a mean accuracy of 99% and a Kappa coefficient of 0.99, with particularly high sensitivity for malignant and lesion-free cases. The study demonstrates that lightweight hybrid architectures based on wavelet transforms can provide highly efficient classification of thermographic images, highlighting their potential for clinical applications in resource-constrained settings.

Exploring the potential of computational pathology in precision oncology, Huang et al. (2023) [19] developed an automated feature extraction approach for whole-slide histopathological images aimed at predicting response to neoadjuvant chemotherapy in breast cancer. The proposed method integrated hematoxylin and eosin (HE) and multiplex immunohistochemistry images to characterize the tumor microenvironment through 36 interpretable features related to immune composition. LASSO-regularized logistic regression models achieved an AUC of 0.8975 for HER2-positive patients and 0.7674 for triple-negative breast cancer (TNBC), outperforming conventional approaches based on manual pathological assessment. External validation confirmed the robustness of the model for the HER2-positive subtype, although lower performance was

observed for TNBC due to its greater tumor heterogeneity. The study demonstrates that automated extraction of immune microenvironment features can support risk stratification and personalized therapeutic decision-making.

Macedo et al. (2021) [20] investigated the use of swarm intelligence techniques applied to breast thermography for the detection and classification of breast lesions. The proposed method combined shape and texture feature extraction, using Zernike moments and Haralick descriptors, with multi-objective feature selection algorithms and conventional machine learning classifiers. Validated on the MammoTherm dataset, comprising 336 thermographic images from Brazilian patients, the study demonstrated that the optimized feature selection significantly reduced computational cost without compromising diagnostic performance, achieving an accuracy of up to 87% and a Kappa coefficient of 0.80 with the MLP classifier. Furthermore, the geometric descriptors based on Zernike moments exhibited greater discriminative capability for distinguishing benign from malignant lesions, highlighting the potential of breast thermography combined with swarm intelligence-based optimization techniques as a complementary tool for breast cancer screening.

III. Materials and Methods

A. Proposed Method

The stages of the methodological workflow applied in this study are illustrated in the diagram in Figure 1. It starts with data acquisition and selection from the BreakHis dataset. The following steps are feature extraction, data splitting into training and testing sets. Morover, the next stages are class balancing and feature selection, followed by: training, validating, and testing the classification models. Each stage of the proposed methodology is described in detail in the following sections.

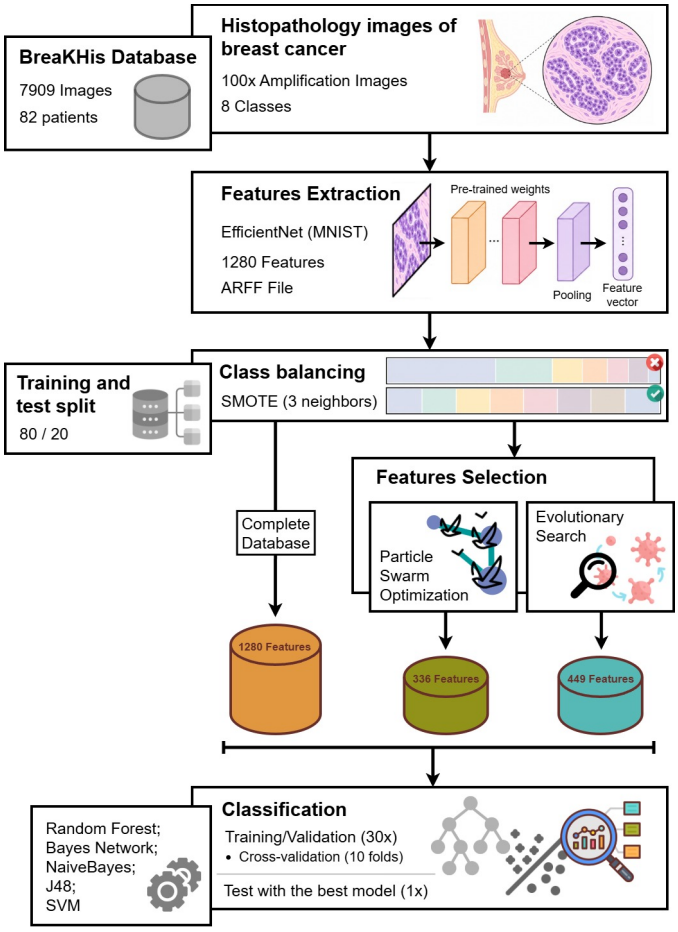

Fig. 1: Workflow of the proposed methodology, including the following stages: dataset, feature extraction, class balancing, feature selection, and classification.

B. Dataset

We used the BreakHis dataset, developed by Spanhol et al. (2016) [21] at the Research and Development Laboratory in Anatomic Pathology and Cytopathology in Paraná, Brazil. The BreakHis dataset was created to support research aimed at detecting breast cancer in histopathological images using machine learning techniques.

The dataset consists of 7,909 microscopic images of tumor tissue obtained from 72 patient's biopsies. The samples were acquired using four different microscopic magnification factors: 40x, 100x, 200x, and 400x. In total, there available 2,480 images of benign tumors, and 5,429 images of malignant tumors. The benign lesions are distributed among the following subtypes: Adenosis (A), Fibroadenoma (F), Phyllodes Tumor (PT), and Tubular Adenoma (TA). The malignant lesions are distributed among the following subtypes: Ductal Carcinoma (DC), Lobular Carcinoma (LC), Mucinous Carcinoma (MC), and Papillary Carcinoma (PC).

Although the database provides images at four levels of microscopic magnification, we used samples at 100x magnification. We chose the 100x magnification factor because it provides a more comprehensive view of the overall tissue architecture. This potentially minimizes the need for manual delineation of regions of interest. Thus, the sample used contains 2,081 images, of which 664 belong to the benign tumor class and 1,437 belong to the malignant tumor class. The images are in PNG format, with a resolution of 700 x 460 pixels, three RGB color channels, and a depth of 8 bits per channel. Fig. 2 shows an example of the images used.

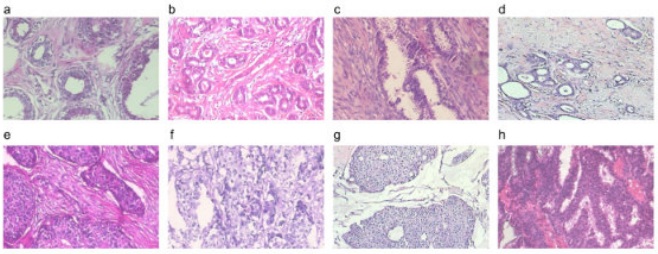

Fig. 2: Examples of histopathological images of breast cancer: a) Adenosis; b) Fibroadenoma; c) Phyllodes tumor; d) Tubular adenoma; e) Carcinoma; f) Lobular carcinoma; g) Mucinous carcinoma; h) Papillary carcinoma.

C. Feature Extraction

The feature extraction was performed using the transfer learning technique on a pre-trained EfficientNet architecture. We applied EfficientNet-B0, configured with 224 x 224 pixel input images, three color channels, a mini-batch size of 32, and frozen ImageNet-pretrained weights—leveraging the concept of transfer learning. We also used max pooling as the pooling method. All these configurations were applied using the Dl4jMlpFilter. This filter is available in the DeepLearning (DL4J) package for Weka [22]. Feature extraction was performed directly on the original images, without any prior preprocessing, including histological stain normalization. This process resulted in a dataset comprising 2,081 instances and 1,280 extracted features. It is important to note that the class attribute was preserved in the following format: A, F, PT, TA, DC, LC, MC, PC. This enabled the evaluation of the model's ability to distinguish between the eight histological subtypes observed in the dataset.

D. Classification

After the feature extraction stage, we split the dataset into training and testing sets. We used 80% of the dataset for training—comprising a total of 1,662 instances—and 20% for testing, with 419 instances. We also applied the SMOTE (Synthetic Minority Over-Sampling Technique) balancing technique to address the class imbalance within the dataset. To balance the data, we used the Weka SMOTE filter [22] with 3 nearest neighbors.

We applied the data balancing technique only to the training set. Thereby we preserved the original distribution of the test set. This strategy was adopted to ensure that performance was measured in a scenario closer to the actual data distribution.

For the classification task, we evaluated the following algorithms: Naive Bayes, Random Tree, Random Forest, and Support Vector Machine. All model training experiments were conducted in Weka, using 10-fold cross-validation with 30 repetitions for each configuration of each algorithm evaluated. For the Naive Bayes and Random Tree algorithms, the model hyperparameters remained unmodified. In contrast, the Random Forest algorithm was evaluated using 100, 200, and 300 trees. For the SVM, we evaluated configurations using a polynomial kernel of degree 1, and a RBF kernel with $\gamma = 0.5$. For both SVM configurations, the regularization hyperparameter was set to C = 1.0.

Each classifier was evaluated based on the metrics of accuracy, sensitivity, specificity, Kappa index, F-measure, and Area Under the ROC Curve (AUC). We applied the best-performing classifier to the test set described earlier in this section.

E. Feature selection

After evaluating the classifiers, we carried out an aditional step: feature selection. The goal was to reduce the datasets dimensionality, and investigate the impact of reducing the number of features on the classifiers performances. We used Weka's [22] AttributeSelection filter, and we selected two heuristic search methods: Evolutionary Search (EvSearch) and Particle Swarm Optimization (PSO).

For the Evolutionary Search algorithm, we used a population of 20 individuals over 20 generations. The selection operator was set to 1, crossover probability to 0.6, mutation probability to 0.1, and the random seed to 1. The remaining hyperparameters were left at their default Weka settings.

For the PSO algorithm, we used a population of 20 particles, 20 iterations, and a mutation rate of 0.01. Acceleration coefficients were set to 0.33 and 0.34, the reset frequency to 20, and the random seed to 1. The remaining hyperparameters were left at their default Weka settings.

We generated two subsets using the features selected by the EvSearch and PSO algorithms. These two subsets underwent training/test set splitting, class balancing, and evaluation of the classifiers applied to the training sets. The classifiers evaluated were the same as those described in Section III-D, using the same configurations. Each experiment was run 30 times using 10-fold cross-validation.

Finally, the best-performing classifiers (for each approach) were evaluated using their respective test sets. This allowed us to compare the performance of the models generated with and without the application of feature selection algorithms.

IV. Results and Discussion

A. Training Using the Complete Feature Set

Table I presents the results obtained during the training stage using the complete set of features extracted by the proposed architecture, without applying any feature selection technique. The evaluated classifiers included Naive Bayes, Bayes Network, Random Tree, Random Forest, and Support Vector Machine (SVM), each tested under different parameter configurations.

Classification with all attributes							
Classifier		Accuracy	Kappa Index	Sensitivity	Specificity	F-Score	AUC
Naive Bayes		7.031% ± 0.001	0.519 ± 0.071	0.765 ± 0.150	0.992 ± 0.011	0.834 ± 0.107	0.716 ± 0.015
Bayes Network		73.212% ± 0.002	0.694 ± 0.022	0.838 ± 0.044	0.984 ± 0.006	0.860 ± 0.031	0.983 ± 0.006
Random Tree		64.791% ± 2.139	0.598 ± 0.024	0.771 ± 0.054	0.965 ± 0.010	0.765 ± 0.043	0.868 ± 0.028
Random Forest	100 Trees	95.583% ± 0.788	0.950 ± 0.009	0.997 ± 0.006	0.996 ± 0.002	0.985 ± 0.009	1.000 ± 0.000
	200 Trees	95.963% ± 0.752	0.954 ± 0.009	0.997 ± 0.006	0.996 ± 0.002	0.986 ± 0.009	1.000 ± 0.000
	300 Trees	96.100% ± 0.729	0.955 ± 0.008	0.997 ± 0.006	0.996 ± 0.003	0.986 ± 0.009	1.000 ± 0.000
SVM	Linear	97.150% ± 0.654	0.967 ± 0.007	1.000 ± 0.001	0.998 ± 0.002	0.992 ± 0.007	0.999 ± 0.001
	RBF	78.272% ± 1.827	0.752 ± 0.021	0.751 ± 0.052	1.000 ± 0.000	0.857 ± 0.034	0.986 ± 0.008

TABLE I: Training results using the complete feature set.

The best performances were achieved by the Random Forest and SVM classifiers, whereas Naive Bayes, Bayes Network, and Random Tree yielded inferior results across all evaluated metrics. These findings indicate that the features extracted by the neural network possess high discriminative power, favoring classifiers capable of capturing complex relationships among the extracted features.

The best overall performance was obtained by the SVM with a linear kernel, which achieved an accuracy of 97.15%, a Kappa coefficient of 0.967, and an AUC of 0.999. Consequently, this model was selected for the testing stage. The Random Forest models also demonstrated consistent performance, with accuracies exceeding 95% across all evaluated configurations, indicating robustness regardless of the number of trees employed.

B. Training with PSO-Based Feature Selection

Table II presents the results obtained after applying feature selection using the Particle Swarm Optimization (PSO) algorithm. The PSO algorithm reduced the number of features from 1,280 to 336, corresponding to a dimensionality reduction of 73.77%. Despite this substantial reduction, the high performance of the leading classifiers was preserved compared with the training stage using the complete feature set, with Random Forest and SVM remaining the best-performing methods.

Classification Performance with PSO-Selected Features							
Classifier		Accuracy	Kappa Index	Sensitivity	Specificity	F-Score	AUC
Naive Bayes		60.766% ± 1.972	0.552 ± 0.023	0.697 ± 0.054	0.979 ± 0.006	0.757 ± 0.039	0.956 ± 0.012
Bayes Network		71.781% ± 1.889	0.677 ± 0.022	0.811 ± 0.046	0.977 ± 0.007	0.824 ± 0.031	0.979 ± 0.007
Random Tree		64.628% ± 1.991	0.596 ± 0.023	0.777 ± 0.051	0.966 ± 0.009	0.771 ± 0.040	0.872 ± 0.026
Random Forest	100 Trees	95.350% ± 0.850	0.947 ± 0.010	0.998 ± 0.006	0.996 ± 0.003	0.985 ± 0.010	1.000 ± 0.000
	200 Trees	95.793% ± 0.789	0.952 ± 0.009	0.998 ± 0.005	0.996 ± 0.003	0.987 ± 0.009	1.000 ± 0.000
	300 Trees	95.913% ± 0.787	0.953 ± 0.009	0.998 ± 0.005	0.997 ± 0.003	0.987 ± 0.009	1.000 ± 0.000
SVM	Linear	93.594% ± 0.960	0.927 ± 0.011	0.997 ± 0.007	0.996 ± 0.003	0.985 ± 0.010	0.999 ± 0.001
	RBF	97.887% ± 0.620	0.976 ± 0.007	0.997 ± 0.007	0.999 ± 0.001	0.996 ± 0.005	1.000 ± 0.001

TABLE II: Training Results Using PSO-Based Feature Selection.

In this case, the best performance was achieved by the SVM with an RBF kernel ($\gamma = 0.5$), which attained an accuracy of 97.89%, a Kappa coefficient of 0.976, and an AUC of 1.000, slightly outperforming the best result obtained using the complete feature set. The Random Forest classifiers also maintained consistent performance, achieving accuracies above 95% across all evaluated configurations.

These results indicate that PSO-based feature selection was able to eliminate redundant or less informative features without compromising the model's discriminative capability. Since the SVM with an RBF kernel achieved the best overall performance in this stage, it was selected for evaluation on the independent test set.

C. Training with Evolutionary Search-Based Feature Selection

Table III presents the results obtained after applying feature selection using the Evolutionary Search (ES) algorithm. The ES algorithm reduced the number of features from 1,281 to 449, corresponding to a dimensionality reduction of 64.95%. Similar to the PSO-based approach, this reduction in data dimensionality preserved the performance of the leading classifiers, with Random Forest and SVM remaining the most effective methods.

Classification Performance with Evolutionary Search-Selected Features							
Classifier		Accuracy	Kappa Index	Sensitivity	Specificity	F-Score	AUC
Naive Bayes		59.699% ± 1.935	0.539 ± 0.022	0.659 ± 0.053	0.982 ± 0.006	0.739 ± 0.040	0.955 ± 0.013
Bayes Network		71.733% ± 1.949	0.677 ± 0.022	0.827 ± 0.048	0.978 ± 0.007	0.834 ± 0.034	0.979 ± 0.007
Random Tree		63.964% ± 2.115	0.588 ± 0.024	0.753 ± 0.058	0.964 ± 0.009	0.751 ± 0.044	0.859 ± 0.029
Random Forest	100 Trees	95.325% ± 0.844	0.947 ± 0.010	0.998 ± 0.005	0.995 ± 0.003	0.983 ± 0.010	1.000 ± 0.000
	200 Trees	95.747% ± 0.797	0.951 ± 0.009	0.999 ± 0.004	0.996 ± 0.003	0.984 ± 0.010	1.000 ± 0.000
	300 Trees	95.884% ± 0.760	0.953 ± 0.009	0.999 ± 0.004	0.996 ± 0.003	0.985 ± 0.010	1.000 ± 0.000
SVM	Linear	95.087% ± 0.791	0.944 ± 0.009	1.000 ± 0.001	0.996 ± 0.003	0.986 ± 0.009	0.999 ± 0.001
	RBF	96.910% ± 0.808	0.965 ± 0.009	0.977 ± 0.018	1.000 ± 0.001	0.988 ± 0.010	0.999 ± 0.001

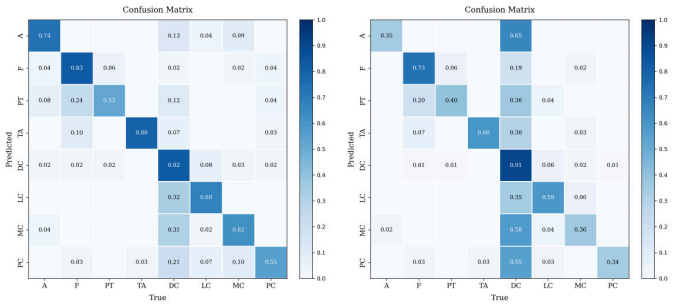

TABLE III: Training Results Using Evolutionary Search-Based Feature Selection.

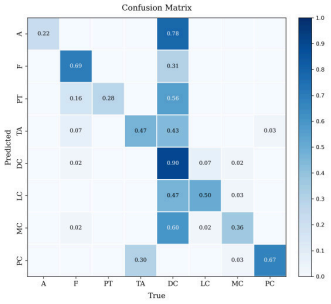
The best performance was achieved by the SVM with an RBF kernel ($\gamma = 0.5$), which attained an accuracy of 96.91%, a Kappa coefficient of 0.965, and an AUC of 0.999. The Random Forest models also demonstrated consistent performance, achieving accuracies above 95% across all evaluated configurations, indicating that feature selection did not significantly compromise the classification capability.

Although the results were slightly inferior to those obtained with PSO-based feature selection, Evolutionary Search maintained high performance while using a reduced subset of features. Therefore, the SVM with an RBF kernel was selected for evaluation on the independent test set.



D. Test Set Results

After selecting the best-performing classifier for each feature representation strategy, the models were evaluated on the independent test set, which consisted of images not used during the training stage. The corresponding confusion matrices are presented in Figure 3 for the following approaches: (i) the complete feature set extracted by the proposed architecture, (ii) PSO-based feature selection, and (iii) Evolutionary Search-based feature selection.

(a) All features

(b) Features selected by PSO

(c) Features selected by Evolutionary Search

Fig. 3: Confusion matrices obtained on the test set: (A) all features; (B) features selected using PSO; and (C) features selected using Evolutionary Search.

The approach that directly utilized the features extracted by EfficientNet-B0 achieved the best overall performance, reaching an accuracy of 74.70

The confusion matrices further support these findings. Using the complete feature set (Figure 3(A)), a well-defined main diagonal can be observed, indicating high correct classification rates for most histopathological subclasses. Notably, Fibroadenoma (83%), Tubular Adenoma (80%), and Ductal Carcinoma (82%) exhibited the highest recognition rates. In contrast, Phyllodes

Tumor (52%), Mucinous Carcinoma (62%), and Papillary Carcinoma (55%) showed the highest levels of misclassification. In particular, a considerable proportion of Lobular Carcinoma, Mucinous Carcinoma, and Papillary Carcinoma samples were misclassified as Ductal Carcinoma, whereas Phyllodes Tumor was primarily confused with Fibroadenoma.

After applying PSO-based feature selection (Figure 3(B)), the main diagonal became less pronounced compared with the model trained using the complete feature set. Although the Ductal Carcinoma (DC) class achieved a high correct classification rate (91%), misclassifications involving other subclasses increased, particularly for Adenosis (A), Phyllodes Tumor (PT), Mucinous Carcinoma (MC), and Papillary Carcinoma (PC), which were frequently classified as DC. This behavior explains the reduction in overall accuracy observed for this approach and suggests that some of the features discarded by PSO contained relevant information for distinguishing histopathological subclasses with similar visual characteristics.

Feature selection based on Evolutionary Search (Figure 3(C)) resulted in an even less pronounced main diagonal than that obtained with the complete feature set. Although Ductal Carcinoma (DC), Fibroadenoma (F), and Papillary Carcinoma (PC) maintained relatively high correct classification rates (90%, 69%, and 67%, respectively), a substantial reduction was observed in the recognition of Adenosis (A), Phyllodes Tumor (PT), Tubular Adenoma (TA), and Mucinous Carcinoma (MC). As observed with the PSO-based approach, a large proportion of these samples were misclassified as Ductal Carcinoma, indicating that the more aggressive dimensionality reduction produced a less discriminative representation of the histopathological subclasses. This behavior explains the lower overall accuracy achieved by this approach compared with the other evaluated strategies.

E. Discussions

Overall, the results indicate that the features extracted by EfficientNet-B0 provide a highly discriminative representation for the investigated multiclass classification task. This performance is consistent with the EfficientNet architecture, whose compound scaling strategy jointly optimizes network depth, width, and input resolution to improve feature representation.

Among the evaluated machine learning classifiers, SVM consistently achieved the best performance, particularly with linear and RBF kernels. This finding agrees with previous studies showing that SVMs are well suited for high-dimensional feature spaces, where they effectively exploit the complex representations generated by deep CNNs through robust decision boundaries.

Although both PSO and Evolutionary Search substantially reduced the feature dimensionality, neither approach improved the performance on the independent test set. This suggests that some of the discarded features contained complementary information that was important for distinguishing visually similar histopathological subclasses. Therefore, the original EfficientNet-B0 feature set already provided a highly informative representation for this classification problem.

These findings also indicate that the usefulness of feature selection should not be assessed exclusively in terms of classification accuracy. Although the complete EfficientNet-B0 representation achieved the best generalization performance, PSO and Evolutionary Search reduced the feature space by 73.77% and 64.95%, respectively. Such dimensionality reduction can decrease the amount of information that must be stored and processed during classification, which may be particularly relevant for embedded, edge-computing, or portable diagnostic systems with limited memory and processing resources. Therefore, the choice between the complete and reduced representations involves a trade-off between maximum predictive performance and computational efficiency. In applications where hardware resources, latency, or energy consumption are critical constraints, a reduced feature subset may still constitute a preferable solution, even at the cost of a moderate decrease in classification performance. Future studies should quantify this trade-off by directly measuring inference time, memory usage, and computational cost.

The confusion matrices further revealed a tendency for misclassified samples to be assigned to the Ductal Carcinoma (DC) class. This behavior is likely related to the original class distribution of the BreakHis dataset. While SMOTE was applied only to the training data, the test set preserved its natural imbalance, with DC representing the largest class. Consequently, the classifiers became more sensitive to its visual patterns, increasing confusion with underrepresented subclasses.

A deeper analysis of the misclassification patterns reveals that errors were not randomly distributed but primarily occurred between histopathological subclasses sharing significant morphological similarities. Specifically, substantial confusion was observed between Tubular Adenoma (TA) and Ductal Carcinoma (DC), as well as between Lobular Carcinoma (LC) and DC. In several instances, TA samples were misclassified as DC and vice versa, while LC showed a marked tendency to be confused with DC. This overlap mirrors well-documented challenges in routine clinical practice, where distinguishing between these subtypes can be difficult due to shared features such as glandular formation, cellular density, and nuclear atypia. For example, the architectural patterns of tubular adenomas can sometimes mimic well-differentiated ductal carcinomas, and lobular carcinomas may present subtle infiltrative patterns that resemble ductal variants. The fact that the model's confusion matrix reflects these clinically ambiguous boundaries suggests that the learned features capture biologically relevant morphological traits rather than arbitrary artifacts. Consequently, these misclassifications highlight the inherent difficulty of the eight-class problem and validate the model's alignment with known diagnostic pitfalls in breast histopathology.

It is also important to note that this study addressed an eight-class histopathological classification problem, whereas most previous studies considered only binary discrimination between benign and malignant tumors. Consequently, the reported accuracies should be interpreted in the context of a substantially more challenging and clinically relevant task,

requiring the discrimination of subtle morphological differences among tumor subtypes.

Overall, the findings indicate that the quality of the extracted features has a greater impact on classification performance than feature dimensionality reduction alone. Furthermore, they highlight the importance of evaluating models on independent test sets, as training performance may overestimate generalization capability. Among the investigated approaches, the combination of EfficientNet-B0 and SVM provided the most robust and effective solution for multiclass classification of breast cancer histopathological images. **However, this independence between training and test sets was only partial, since the training and test split was performed randomly at the image level, without controlling for patient identity, and the 100× subset originates from the same 72-patient cohort as the full BreakHis dataset. Furthermore, images from the same patient may have appeared in both sets, and since slides from the same patient can share staining intensity and tissue-specific patterns, this may have inflated the reported test-set accuracy. For this reason, future experiments should partition the data at the patient level.**

V. Conclusion

This study presented a hybrid decision-support approach for the multiclass classification of breast cancer histopathological images by combining feature extraction with EfficientNet-B0, class balancing using SMOTE, and feature selection through Particle Swarm Optimization (PSO) and Evolutionary Search (ES). The proposed methodology was evaluated on the BreakHis dataset (100× magnification) considering eight histopathological subclasses, representing a more challenging and clinically relevant scenario than the binary classification commonly reported in the literature.

The experimental results demonstrated that the original feature set extracted by EfficientNet-B0 provided the best generalization performance, achieving 74.70% accuracy and an AUC of 0.915 on the independent test set. Although PSO and ES substantially reduced the feature dimensionality and achieved excellent performance during training, both approaches resulted in lower test-set accuracy, indicating that some discarded features contained complementary discriminative information. Among the evaluated classifiers, SVM consistently achieved the best overall performance.

The proposed approach demonstrates the potential of hybrid deep learning and machine learning architectures for multiclass histopathological image classification while highlighting the importance of evaluating models on independent test sets. Nevertheless, this study was limited to a single image magnification level (100×) and a single feature extractor. Future work will investigate additional magnification factors, alternative deep feature extraction architectures, image-level data augmentation strategies, and explainable artificial intelligence (XAI) techniques to improve the interpretability, generalization, and clinical applicability of multiclass breast cancer classification models.

***Abstract*—The modeling of sepsis risk in intensive care units (ICUs) remains challenging because sepsis is heterogeneous, evolves over time, and is often associated with incomplete clinical information. An interpretable hybrid framework combining Structural Equation Modeling (SEM) and machine learning (ML) was developed to represent physiological information from time-indexed ICU data and evaluate its downstream utility for sepsis risk classification. Training sets A and B from the PhysioNet/Computing in Cardiology Challenge 2019 were merged, temporally ordered, and split at the patient level to prevent data leakage. An SEM model estimated a latent construct of blood pressure status from systolic, mean arterial, and diastolic blood pressure, and SEM-derived factor scores were integrated with physiological, demographic, and temporal covariates into supervised classifiers. After filtering, the dataset contained 1,407,607 records from 40,343 patients. The SEM model showed an acceptable global fit and adequate construct reliability, although the construct was strongly anchored in mean arterial pressure. In downstream classification, HistGradientBoosting achieved the best performance, with Area Under the Receiver Operating Characteristic - AUROC = 0.7669 and Area Under the Precision-Recall Curve - AUPRC = 0.0935, corresponding to a 5.09-fold lift over sepsis prevalence. Permutation importance identified ICULOS and temperature abnormality as the dominant predictors, while the SEM-derived factor contributed modestly. These findings support the SEM factor as a complementary representation of blood-pressure information rather than a major driver of predictive performance. Accordingly, this study should be interpreted as a methodological proof of concept demonstrating the feasibility of integrating a theory-driven latent physiological construct with supervised machine-learning models for sepsis risk prediction.**

***Index Terms*—sepsis risk modeling, structural equation modeling, machine learning, interpretability, intensive care, physiological modeling.**

I. Introduction

Sepsis remains a major challenge in acute and critical care because it represents the progression from infection to life-threatening organ dysfunction [1]. According to Sepsis-3, it is defined as "life-threatening organ dysfunction caused by a dysregulated host response to infection" [1]. Its global burden is substantial, with an estimated 48.9 million cases and 11.0 million sepsis-related deaths worldwide in 2017, which corresponds to 19.7% of all global deaths [2]. Early recognition is essential because sepsis is treatable, and timely targeted interventions improve outcomes [2], whereas delayed diagnosis may postpone resuscitation, antimicrobial therapy, hemodynamic reassessment, source control, monitoring, and organ-supportive care [3]. However, strict operationalization of Sepsis-3 criteria may increase specificity at the expense of sensitivity, potentially delaying recognition in middle-income or resource-limited settings [4].

The clinical concept of sepsis has shifted from Systemic Inflammatory Response Syndrome (SIRS) to organ dysfunction and dysregulated host response. Earlier definitions identified sepsis as an infection associated with at least two SIRS criteria, but these criteria had limited specificity and sensitivity [1], [4]. Sepsis-3 adopted SOFA as the main operational criterion for organ dysfunction and introduced qSOFA as a simplified bedside prompt for patients at increased risk of poor outcomes [1], [4]. Nevertheless, the Sequential Organ Failure Assessment (SOFA) depends on physiologic and laboratory variables that may be incomplete, delayed, or unavailable at the point of care, and the Quick Sequential Organ Failure Assessment (qSOFA) should not be used as a stand-alone diagnostic definition of sepsis [1], [4].

Despite these conceptual advances, sepsis risk modeling remains clinically and methodologically challenging because sepsis is heterogeneous, time-evolving, and may involve occult organ dysfunction at presentation [1]. This limits recognition based only on static bedside criteria or delayed laboratory confirmation [1]. Electronic health records can address part of this limitation by enabling longitudinal analysis of routinely collected clinical data. In the PhysioNet/Computing in Cardiology Challenge 2019, algorithms using hourly clinical data from more than 60,000 ICU patients predicted sepsis several

hours before clinical recognition, although generalizability across hospital systems remained a major challenge [5].

Machine learning models have shown promising performance for sepsis risk classification and clinical deterioration modeling. Barton et al. reported that a gradient-boosted model using six routinely collected vital signs achieved AUROC values of 0.88 at sepsis onset, 0.84 at 24 hours before onset, and 0.83 at 48 hours before onset, outperforming SIRS, Modified Early Warning Score (MEWS), SOFA, and qSOFA at onset [6]. However, methodological barriers remain, including variation in cohorts, variables, labels, prediction windows, and metrics, while AUROC may not fully capture clinical utility, false alarms, missed events, or overtreatment [5]. In addition, many ML models remain difficult to interpret at the bedside, and explainable approaches such as SHAP have been proposed to increase transparency and support patient-level explanations [7].

Structural Equation Modeling is relevant in this context because observable clinical variables may reflect underlying physiological processes rather than isolated predictors [8]. Sepsis involves dysregulated host response and organ dysfunction across multiple biological systems, including cardiovascular, respiratory, metabolic, renal, hepatic, neurologic, and coagulation pathways [1]. By integrating measurement and structural models, SEM can represent latent physiological constructs and provide an interpretable link between routinely collected clinical indicators and plausible patterns of deterioration [8].

A hybrid SEM–ML approach may therefore combine physiological representation with downstream predictive evaluation. SEM can organize correlated clinical variables into latent constructs [8], while ML classifiers can evaluate whether these representations have discriminative capacity for sepsis risk classification in the context of previous sepsis prediction studies [5], [6]. This integration addresses complementary limitations: SEM is explanatory rather than classification-oriented [8], whereas ML supports predictive risk classification in sepsis-related tasks [5], [6] but may be limited by false alarms, generalizability challenges [5], and reduced clinician trust due to black-box behavior [7].

Although the fully nested calibration analysis prevented access to the outer test set during model and calibrator fitting, the calibrated model showed only modest Brier Skill Score relative to a prevalence-based reference. Consequently, the low post-calibration Brier score should not be interpreted in isolation as evidence of strong absolute probabilistic performance. External validation of calibration remains necessary.

Therefore, the proposed work develops and evaluates an interpretable SEM-ML framework for physiological sepsis risk modeling using time-indexed clinical data from the PhysioNet/Computing in Cardiology Challenge 2019 [5]. The primary contribution is methodological: to evaluate whether a latent representation derived from routinely collected blood-pressure variables using SEM [8] can be integrated with supervised ML classifiers as a structured hemodynamic representation. Rather than assuming that the SEM-derived factor provides substantial predictive superiority over directly observed physiological variables, its incremental contribution is evaluated empirically through downstream classification and controlled analyses, in the context of previous ML-based sepsis studies [5], [6]. The supervised task is formulated as time-indexed classification of the contemporaneous SepsisLabel at the hourly record level, without a future-shifted target or a predefined prediction horizon. Accordingly, the framework should be interpreted as a methodological proof of concept for integrating an interpretable SEM-derived representation with supervised learning, rather than as a validated lead-time-specific early sepsis prediction model, while retaining an emphasis on clinically interpretable risk information [7].

II. Methods

Training sets A and B from the PhysioNet/Computing in Cardiology Challenge 2019 were used as the data source, representing a benchmark dataset for sepsis risk classification using routinely collected ICU data [5]. Original pipe-separated files were converted to comma-separated format, assigned unique patient_id values using dataset prefixes, and concatenated into a single dataset. Data integrity was assessed by checking record and patient counts, SepsisLabel distribution, Intensive Care Unit Length of Stay (ICULOS), duplicate patient-time observations, and uniqueness of patient_id-ICULOS pairs.

A. Variables and Preprocessing

The analytical dataset was restricted to variables selected for SEM-based physiological modeling: patient_id, heart rate (HR), systolic blood pressure (SBP), mean arterial pressure (MAP), diastolic blood pressure (DBP), respiratory rate (Resp), oxygen saturation (O2Sat), temperature (Temp), Age, Gender, ICULOS, and SepsisLabel. HR, SBP, MAP, DBP, Resp, O2Sat, and Temp were treated as continuous vital signs; Age, Gender, and ICULOS were retained as demographic and temporal covariates; and SepsisLabel was used as the binary outcome. The patient_id variable was used only for patient-level organization, temporal ordering, data splitting, and leakage prevention, and was not used as a predictive feature.

Initial data quality assessment quantified missingness, valid observations, zero values, and SepsisLabel distribution at record and patient levels. Records in which all selected vital signs were simultaneously missing were removed because they did not contain physiological information for SEM estimation or downstream classification. The impact of this filtering was assessed by comparing record counts, patient counts, and SepsisLabel prevalence before and after removal.

The remaining records were ordered by patient_id and ICULOS to preserve temporal structure. Temporal consistency was verified by checking monotonic ICULOS ordering within patients and the absence of duplicate patient_id-ICULOS pairs. Missing vital signs were imputed using causal forward fill within each patient trajectory, followed by residual median

imputation estimated from the training set and applied to the test set.

Patient-level train-test splitting was performed using StratifiedGroupKFold with five folds, shuffling enabled, and $\mathrm{random_state} = 42$. The grouping variable was patient_id, and stratification was based on SepsisLabel, ensuring that records from the same patient did not appear in both training and test partitions. The split was audited by reporting record counts, patient counts, SepsisLabel prevalence, and the absence of shared patient identifiers. Final SEM datasets were created from raw variables only, without derived variables or standardization at this stage.

B. Structural Equation Modeling

Structural Equation Modeling (SEM) was performed using the *semopy* package [9], [10]. The final specification, Model_D_BP_SEM, was fitted only on the training dataset after removal of patient_id, ensuring that the patient identifier was used only for data organization and leakage prevention. Model estimation used the MLW objective function implemented in *semopy*, and fit statistics, standardized estimates, factor loadings, structural paths, covariances, and residual variances were extracted after fitting. SepsisLabel was included as an observed binary endpoint in the structural SEM to characterize standardized associations. Because estimation used the MLW objective, coefficients involving SepsisLabel were interpreted only as exploratory standardized associations, not as logistic effects, odds ratios, calibrated probabilities, or causal effects. Predictive evaluation was performed separately using supervised classifiers.

The SEM measurement model defined one latent construct, Blood_Pressure_Status, as an SEM-derived representation of the shared variation among systolic blood pressure (SBP), mean arterial pressure (MAP), and diastolic blood pressure (DBP):

$$\text{Blood_Pressure_Status} =\sim \text{SBP} + \text{MAP} + \text{DBP}. \tag{1}$$

The construct was specified as a compact representation of correlated blood-pressure measurements rather than as an a priori assumption of a physiological domain independent of its observed indicators.

The structural model evaluated the association between SepsisLabel and the latent blood-pressure construct, together with observed physiological, demographic, and temporal predictors. Thus, the outcome was modeled as:

$$\begin{aligned}\text{SepsisLabel} \sim\ & \text{Blood_Pressure_Status} + \text{HR} \\ & + \text{Resp} + \text{O2Sat} + \text{Temp} + \text{Age} \\ & + \text{Gender} + \text{ICULOS}.\end{aligned} \tag{2}$$

To account for clinically plausible physiological dependencies, covariance terms were included between cardiovascular, respiratory, and temperature-related variables:

$$\begin{aligned}\text{HR} &\sim\sim \text{Blood_Pressure_Status}, \\ \text{Resp} &\sim\sim \text{O2Sat}, \\ \text{Resp} &\sim\sim \text{Temp}, \\ \text{O2Sat} &\sim\sim \text{Temp}.\end{aligned} \tag{3}$$

Estimated parameters were organized into measurement, structural, covariance, and residual components. Standardized loadings for SBP, MAP, and DBP were used to assess the contribution of each indicator to Blood_Pressure_Status. Structural paths quantified the association between SepsisLabel, the latent construct, and the observed predictors. Composite Reliability and Average Variance Extracted were calculated from standardized loadings and residual variances as descriptive summaries of the measurement structure.

Graphical analyses supported SEM interpretation by displaying standardized loadings, structural paths, and specified covariances. The estimated Blood_Pressure_Status factor score was also examined as an auxiliary latent representation, allowing comparison of score distributions across training and test sets and according to SepsisLabel.

To assess whether the binary endpoint affected the measurement structure, a sensitivity analysis fitted a measurement-only SEM containing SBP, MAP, and DBP while excluding SepsisLabel and all structural regressions. Standardized factor loadings were compared with those of the original SEM.

C. Factor-Score Extraction

After fitting Model_D_BP_SEM on the training data, SEM-derived factor scores were extracted for the latent construct Blood_Pressure_Status. Factor scores were obtained from the fitted SEM model for both training and test datasets after removing patient_id from the SEM input matrices. The test set was not used to refit the SEM model, preserving independence between SEM estimation and downstream evaluation.

The extracted factor scores were aligned with the original time-indexed records by resetting corresponding indices. Alignment was verified by confirming that the number of extracted scores matched the number of records in each partition. Final factor-score datasets contained patient_id, SepsisLabel, and Blood_Pressure_Status_factor_score, and were validated for missing values before predictive modeling.

D. Machine Learning Classification

The supervised learning task was defined as hourly record-level classification of the contemporaneous SepsisLabel. Predictors and the target corresponded to the same time-indexed observation, and the outcome was not shifted to a predefined future prediction horizon. Accordingly, the primary analysis evaluates time-indexed sepsis risk classification rather than prospective lead-time-specific prediction.

Supervised ML classifiers were trained to evaluate whether SEM-derived physiological representations could support sepsis risk classification. The final predictive feature set included Blood_Pressure_Status_factor_score_z, HR_z, Resp_z,

O2Sat_z, Temp_Abnormality_z, Age_z, Gender, and ICULOS_z. Temp_Abnormality was defined as the absolute deviation from normal body temperature, $|\mathrm{Temp} - 37.0|$, to represent systemic temperature disturbance.

The classifiers were Logistic Regression with balanced class weights, Random Forest with balanced subsampling, and HistGradientBoosting with balanced sample weights; all applicable models used $\mathrm{random_state} = 42$.

Before training, integrity checks verified that training and test sets contained no shared patient_id values, no missing values, and no non-finite numerical values in the model inputs.

E. Evaluation Metrics

Models were evaluated on the held-out test set using predicted probabilities and binary predictions at a threshold of 0.5. Because sepsis risk classification is highly imbalanced, performance was assessed using threshold-independent metrics, including AUROC, AUPRC, Brier score, and AUPRC lift relative to positive-class prevalence, and threshold-dependent metrics, including precision, recall/sensitivity, specificity, F1-score, balanced accuracy, and confusion-matrix counts.

Additional derived metrics included false-positive rate, false-negative rate, negative predictive value, predicted positive rate, and predicted negative rate. AUPRC was used as the primary ranking criterion because it is more informative than AUROC under strong class imbalance. ROC, Precision-Recall, and calibration curves were generated to visualize discrimination, performance under class imbalance, and agreement between predicted probabilities and observed event rates.

F. Complementary Evaluation of the SEM-ML Model

Complementary analyses were conducted for the SEM factor-score-based classifiers, with the best-performing model selected primarily according to AUPRC. Threshold analysis examined how probability cutoffs affected recall, specificity, precision, F1-score, and confusion-matrix counts, allowing evaluation of trade-offs between missed sepsis events and false alarms.

A controlled ablation analysis compared four feature configurations under the same patient-level split, classifier, class weighting, and hyperparameters: (1) observed SBP, MAP, and DBP plus the remaining covariates; (2) the SEM factor alone; (3) the SEM factor plus non-blood-pressure covariates; and (4) the same covariates without the SEM factor. The primary incremental comparison was between configurations 3 and 4.

To assess dependence on ICULOS, HistGradientBoosting was retrained without ICULOS_z while preserving the same split, remaining predictors, class weighting, and hyperparameters. Changes in AUROC, AUPRC, and Brier score quantified its contribution.

Model calibration was assessed through a fully nested patient-level analysis. The outer training set was divided into subtraining and calibration partitions; residual imputation, SEM estimation, factor scoring, standardization, and HistGradientBoosting training were fitted exclusively on the subtraining data. Isotonic and sigmoid calibrators were fitted only on the calibration partition, and the independent outer test set was used solely for final evaluation. Calibration performance was characterized using Brier score, log loss, AUROC, AUPRC, and mean predicted probability. Brier Skill Score used a no-skill reference based on prevalence estimated exclusively from the subtraining partition.

The relative contribution of the SEM-derived Blood_Pressure_Status factor score and the observed physiological, demographic, and temporal covariates was subsequently examined through variable-importance analysis. A complementary post hoc temporal analysis characterized the timing of threshold-based model alerts relative to the first positive SepsisLabel within individual patient trajectories. This analysis was descriptive and was not used to redefine the primary supervised task as prospective early prediction.

TABLE I
DATASET CHARACTERIZATION AFTER PREPROCESSING AND PATIENT-LEVEL SPLIT.

Dataset	Records	Patients	Sepsis prevalence (%)
Merged A+B	1,552,529	40,346	1.7987
After filtering	1,407,607	40,343	1.8400
Training set	1,125,653	32,286	1.8420
Test set	281,954	8,057	1.8350

III. RESULTS

A. Dataset Characterization

The conversion and merging audit confirmed that the PSV-to-CSV transformation preserved the original data structure, with no discrepancies in record counts, patient counts, SepsisLabel distribution, ICULOS range, or duplicate patient-time observations. After concatenating training sets A and B, the combined dataset showed strong class imbalance, with 27,925 sepsis-labeled records and 2,933 patients with at least one positive SepsisLabel.

Records in which all selected vital signs were simultaneously missing were removed before temporal imputation. This filtering removed 144,922 records and minimally changed record-level sepsis prevalence, while preserving nearly all patients. The resulting dataset and the final patient-level train-test split are summarized in Table I.

After temporal ordering by patient_id and ICULOS, no out-of-order ICULOS trajectories or duplicated patient_id-ICULOS pairs were found. Causal forward-fill imputation resolved most missing values in the selected vital signs, and residual missing values were imputed using training-set medians. The final split contained no shared patient identifiers between partitions, and no missing values remained after residual imputation.

B. SEM Model Fit and Latent Constructs

The final SEM model, Model_D_BP_SEM, was successfully fitted on the training set using the MLW objective. Because of the large sample size, model fit was interpreted primarily through approximate fit indices rather than the

TABLE II
SEM MODEL FIT AND BLOOD_PRESSURE_STATUS CONSTRUCT SUMMARY.

Measure	Value
Degrees of freedom	47
χ^2	195,613.1
CFI	0.9156
RMSEA	0.0608
Composite Reliability	0.8782
Average Variance Extracted	0.7103
SBP loading	0.7608
MAP loading	1.0000
DBP loading	0.7430
Approximate SepsisLabel R^2	0.0219

statistically significant chi-square test. The model showed acceptable but not perfect global fit, as summarized in Table II.

Within the measurement component, Blood_Pressure_Status was defined by SBP, MAP, and DBP, with all indicators showing strong standardized loadings. The construct also showed adequate internal consistency and convergent validity. However, the unit loading and approximately null standardized residual variance of MAP indicated that Blood_Pressure_Status was strongly anchored in MAP, requiring cautious interpretation.

A measurement-only sensitivity analysis excluding SepsisLabel and all structural regressions yielded virtually unchanged standardized loadings: SBP = 0.7613, MAP = 1.0000, and DBP = 0.7427, versus 0.7608, 1.0000, and 0.7430 in the original model (maximum absolute difference = 0.00054). Thus, inclusion of the binary endpoint did not materially alter the Blood_Pressure_Status measurement structure. Because this three-indicator model was just-identified (DoF = 0), its global fit indices were not interpreted.

Figure 1 presents the complete SEM specification, including the measurement component of the Blood Pressure Status construct, the structural paths to SepsisLabel, and the physiologically motivated covariance terms among cardiovascular, respiratory, and temperature-related variables.

In the structural component, ICULOS showed the largest standardized association with SepsisLabel, whereas Blood_Pressure_Status had a small negative standardized association. The estimated structural associations were generally small, and the model explained only a limited proportion of SepsisLabel variance; accordingly, these paths were interpreted exploratorily. The specified covariances were also significant, with the strongest association observed between Resp and O2Sat, supporting the physiological plausibility of respiratory compromise and systemic temperature disturbance within the SEM specification.

C. SEM-Derived Factor Scores

Factor scores for Blood_Pressure_Status were successfully extracted from the fitted SEM model for both training and test sets. The resulting factor-score datasets contained no missing values in patient_id, SepsisLabel, or Blood_Pressure_Status_factor_score.

TABLE III
PREDICTIVE PERFORMANCE OF SEM-ML CLASSIFIERS ON THE HELD-OUT TEST SET.

Model	AUROC	AUPRC	Lift
Logistic Regression	0.7247	0.0754	4.11
Random Forest	0.7581	0.0877	4.78
HistGradientBoosting	0.7669	0.0935	5.09

The distribution of Blood_Pressure_Status_factor_score was similar between training and test partitions, showing similar distributions across the patient-level train–test split. Graphical inspection according to SepsisLabel showed only modest separation between positive and negative records, with substantial overlap between classes. Thus, the latent blood-pressure domain provided interpretable physiological information, but was not sufficient alone for clear visual discrimination of sepsis events.

D. Machine Learning Performance

Predictive models were trained using the standardized SEM-derived Blood_Pressure_Status factor score together with observed physiological, demographic, and temporal covariates. Because AUPRC was used as the primary ranking criterion under strong class imbalance, HistGradientBoosting was selected as the primary predictive model, achieving the highest AUPRC and lift over test-set sepsis prevalence, as shown in Table III.

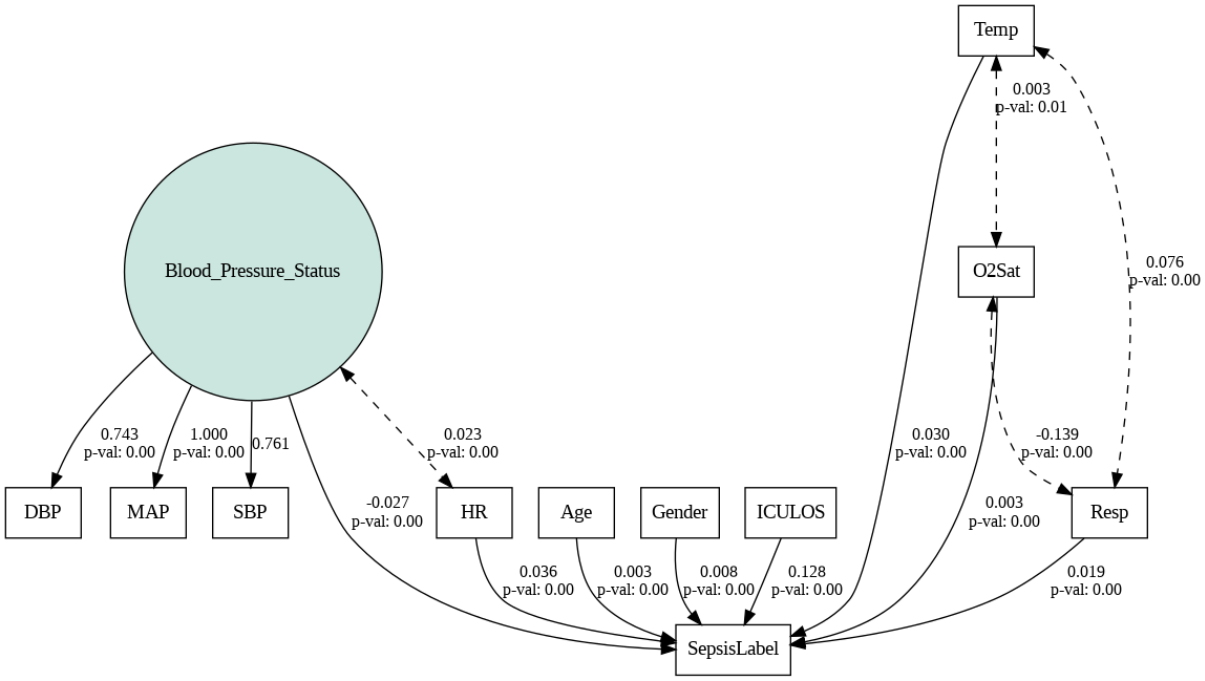
At the default threshold of 0.5, HistGradientBoosting achieved recall of 0.6015, specificity of 0.8025, precision of 0.0539, F1-score of 0.0989, balanced accuracy of 0.7020, and Brier score of 0.1632. The low precision reflects the strong class imbalance and the resulting false-positive burden in record-level sepsis risk classification.

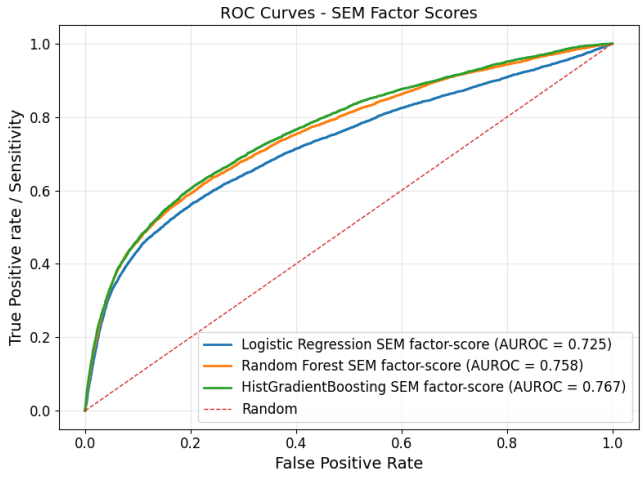
Ablation showed a modest incremental contribution of the SEM factor. SEM factor + covariates achieved AUROC = 0.7669, AUPRC = 0.0935, and Brier = 0.1632, compared with 0.7639, 0.0904, and 0.1656 without blood-pressure information. The factor alone showed limited discrimination (AUROC = 0.5254; AUPRC = 0.0207). Direct inclusion of SBP, MAP, and DBP yielded AUPRC = 0.0895 and Brier = 0.1627, supporting representational compactness but not general superiority of the SEM factor.

The ROC and Precision–Recall curves in Fig. 2 were consistent with the quantitative results reported in Table III, with HistGradientBoosting showing the strongest discrimination among the evaluated classifiers. The Precision–Recall curves further highlight the effect of class imbalance, as all models operated above the prevalence baseline but with limited positive predictive value.

E. Calibration and Model Interpretability

Graphical analysis provided a complementary representation of the estimated SEM structure. The latent Blood_Pressure_Status construct was strongly anchored in MAP, whereas the structural component showed that ICULOS had the largest standardized association with SepsisLabel.





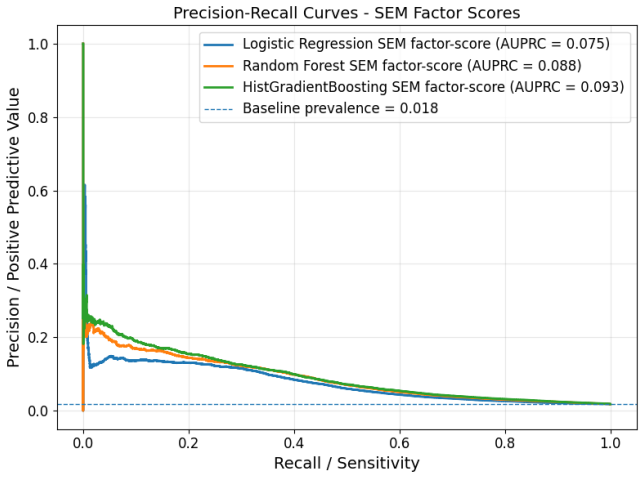


Fig. 1. Structural equation model diagram for Model_D_BP_SEM, including the latent Blood_Pressure_Status construct, observed predictors, physiologically motivated covariances, and standardized paths to SepsisLabel.

(a) ROC curves for Logistic Regression, Random Forest, and HistGradient-Boosting.

(b) Precision-Recall curves showing model behavior under strong class imbalance and the prevalence-based baseline.

Fig. 2. Discrimination performance of the evaluated SEM-ML classifiers.

The covariance structure was also physiologically plausible, particularly through the negative association between Resp and O2Sat and the positive association between Resp and Temp.

In the fully nested experiment, the uncalibrated model achieved Brier = 0.1591, AUROC = 0.7566, and AUPRC = 0.0858 on the outer test set. Sigmoid calibration reduced Brier to 0.0174 while preserving AUROC and AUPRC and was therefore preferred to isotonic calibration, which slightly reduced discrimination. The no-skill Brier was 0.01801 and sigmoid Brier Skill Score was 0.0355, indicating modest probabilistic skill beyond the prevalence baseline. Mean predicted probability decreased from 0.3502 to 0.01982 (observed prevalence = 0.01835), and no Brier degradation was observed from calibration to outer test.

Permutation importance indicated that ICULOS_z and Temp_Abnormality_z were the dominant predictors, while HR_z, Resp_z, and the SEM-derived Blood_Pressure_Status factor score had smaller but measurable contributions. As shown in Fig. 3, temporal progression and systemic temperature abnormality were the dominant predictive components,

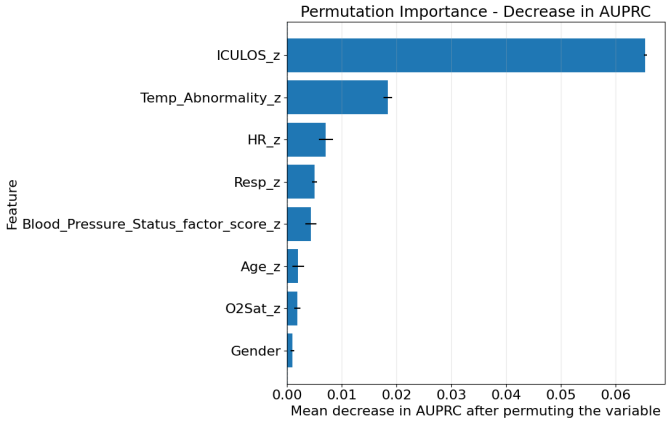

Fig. 3. Permutation importance of the HistGradientBoosting SEM factor-score model, expressed as the mean decrease in AUPRC after feature permutation. ICULOS_z and Temp_Abnormality_z were the dominant predictors, whereas the SEM-derived Blood_Pressure_Status factor score showed a smaller but measurable contribution.

while the SEM-derived factor score acted as a complementary interpretable hemodynamic feature.

IV. DISCUSSION

This study developed an interpretable SEM–ML strategy for physiological sepsis risk modeling using time-indexed ICU data from the PhysioNet/Computing in Cardiology Challenge 2019. The analysis combined a latent Blood Pressure Status construct with physiological, demographic, and temporal covariates in supervised classifiers. In this design, ML classification served as a downstream evaluation of the latent representation rather than as the sole objective of the study. HistGradientBoosting achieved the best performance according to AUPRC, although positive predictive value remained limited by the strong class imbalance.

The SEM-derived blood-pressure representation should be interpreted cautiously. MAP strongly dominated the construct, supporting its interpretation as a compact hemodynamic representation rather than a fully independent latent physiological domain. Structural associations involving SepsisLabel also require caution because the binary endpoint was modeled using the MLW objective. These coefficients represent exploratory standardized associations rather than logistic, probabilistic, or causal effects. Importantly, the measurement-only sensitivity analysis produced virtually unchanged SBP, MAP, and DBP loadings, indicating that the measurement structure was not materially driven by inclusion of SepsisLabel.

Controlled ablation confirmed that the SEM factor provided only modest incremental information: adding it increased AUPRC from 0.0904 to 0.0935, while the factor alone showed limited discrimination. Replacing SBP, MAP, and DBP with the factor preserved discrimination but did not establish predictive superiority. Thus, its value is better interpreted as compact hemodynamic representation rather than as a major performance driver.

In contrast, removing ICULOS reduced AUPRC by 58.3%, demonstrating substantial dependence on temporal position within the ICU stay. Because patient-level train-test independence was preserved, this finding does not establish leakage; ICULOS is better interpreted as an important temporal proxy within the current classification design.

Calvert et al. [11] similarly demonstrated that relationships among physiological signals can support sepsis detection, reporting AUROC = 0.92 three hours before a sustained SIRS episode. Direct comparison is limited by differences in cohort, endpoint definition, available variables, and prediction design. InSight, the machine-learning framework proposed by Calvert et al. for early sepsis prediction, incorporated higher-order interactions among physiological variables and their temporal trends. In contrast, the present framework uses SEM to explicitly represent physiological relationships before incorporating the resulting latent representation into downstream classification.

Previous studies have evaluated sepsis prediction at explicit pre-onset horizons. However, direct comparison with those systems should be made cautiously because the present study addresses contemporaneous time-indexed classification rather than fixed-horizon prospective prediction. The classifier was trained using the contemporaneous hourly SepsisLabel rather than a future-shifted outcome defined at a predefined prediction horizon. Accordingly, any retrospective temporal relationship between model alerts and the first positive SepsisLabel should be interpreted as descriptive alert timing rather than as validated early-prediction performance.

Clinically, the method relies on routinely collected ICU variables and may support risk estimation with an interpretable physiological context. Threshold analysis indicated that lower cutoffs favor sensitivity-oriented screening, whereas higher cutoffs reduce false-positive burden at the cost of missed events. Therefore, threshold selection should depend on whether the clinical objective prioritizes early sensitivity or more specific alerts linked to resource-intensive interventions.

Several limitations should be noted. The SEM was restricted to a single SEM-derived blood-pressure representation and included binary SepsisLabel while using the MLW estimation objective. Accordingly, structural coefficients involving SepsisLabel should be interpreted only as exploratory standardized associations rather than logistic or probabilistic effects. Although the measurement-only sensitivity analysis showed virtually unchanged factor loadings after removal of SepsisLabel, this does not establish MLW as the optimal estimator for binary outcomes. The Blood_Pressure_Status factor was strongly anchored in MAP, which had a standardized loading of 1.000 and an approximately null residual variance. Therefore, the factor should not be interpreted as a fully independent physiological domain. The present model was trained for contemporaneous hourly classification of SepsisLabel rather than for prediction of a future outcome at a predefined horizon. Consequently, retrospective intervals between model alerts and the first positive SepsisLabel should not be interpreted as validated early-warning lead times. The modest incremental

contribution of the SEM-derived factor has not been externally validated.

Although sigmoid calibration markedly corrected probability inflation, its Brier Skill Score relative to the prevalence baseline was only 0.0355. Thus, the low calibrated Brier score should not be interpreted alone as evidence of strong probabilistic performance. External calibration validation remains necessary.

Performance was strongly dependent on ICULOS, limiting interpretation based solely on contemporaneous physiology and motivating explicitly time-aware prospective designs.

V. CONCLUSION

The proposed SEM-ML framework demonstrates the feasibility of integrating an SEM-derived hemodynamic representation with supervised machine learning for time-indexed sepsis risk classification using ICU data from the PhysioNet/Computing in Cardiology Challenge 2019. The Blood_Pressure_Status factor provided a compact representation of SBP, MAP, and DBP and was integrated with physiological, demographic, and temporal covariates. However, the factor was strongly anchored in MAP, limiting its interpretation as an independent latent physiological domain.

In downstream classification, HistGradientBoosting achieved the best performance in terms of AUPRC. The SEM-derived blood-pressure representation showed a modest incremental contribution to discrimination, whereas ICULOS and systemic temperature abnormality were the dominant predictive components. Accordingly, the proposed framework should be interpreted primarily as a methodological proof of concept for integrating a compact SEM-derived hemodynamic representation with supervised learning rather than as evidence of substantial predictive superiority. Because the supervised task used the contemporaneous SepsisLabel at each time-indexed observation, without a future-shifted target or predefined prediction horizon, the present results should not be interpreted as validation of a lead-time-specific early sepsis prediction model. Future work should evaluate external validation, broader physiological representations, explicitly prospective prediction designs, and clinically oriented calibration and threshold strategies.

***Abstract*—Quantifying the Ki-67 marker is an essential step in evaluating cellular proliferation in tumor samples. However, it still largely relies on manual analyses that are subject to observer variability and subjectivity. In this study, an automated system was developed for detecting and quantifying Ki-67 expression in breast cancer histological images using the YOLOv8 deep learning model. The images were acquired using a smartphone camera attached to a microscope eyepiece, and training was conducted with K-fold cross-validation (80/20%) to ensure robustness and generalization. The model achieved balanced performance, with a precision of 0.88, a recall of 0.86, and an F1-score of 0.87, values comparable to those reported in the literature, even with a reduced dataset and a low-cost acquisition method. These results demonstrate the potential of YOLOv8 as an accessible and accurate tool for immunohistochemical analysis. In future work, we intend to develop a mobile application based on the proposed model, aiming to democratize access to digital pathology and expand automated diagnostic capabilities in regions with limited infrastructure.**

***Index Terms*—Breast cancer, Ki-67, Deep learning, YOLOv8, Digital pathology, Image analysis.**

I. Introduction

Breast cancer represents the second main cause of death by cancer among women worldwide [1]. According to data from the World Health Organization (WHO), in 2022 alone, approximately 2.3 million women were diagnosed with the disease [2].

Characterized as a heterogeneous disease, breast cancer constitutes a spectrum of distinct biological subtypes, which present variations in morphological, molecular, and clinical characteristics [3], [4]. This diversity reflects variations in tumor behavior, in the response patterns to different therapeutic modalities, and in clinical outcomes. Although conventional clinical factors, such as histological grade, tumor size, lymph node involvement, and surgical margins, are relevant in determining prognosis, they are not sufficient when considered in isolation [5]. Thus, prognostic and predictive definition is largely based on the identification and classification of the biological subtype of the tumor [2], [6], [7]. The distinction of these subtypes is based on the expression of hormonal receptors and on the indices of cell proliferation indicated by Ki-67 [8].

Ki-67 is a nuclear protein expressed in all active phases of the cell cycle (G1, S, G2, and M) but absent in resting cells (G0). This characteristic makes it a reliable marker to estimate the growth fraction of the neoplastic cell population [9]. Considering that the high rate of cell reproduction is one of the central characteristics of breast cancer [10], Ki-67 has been consolidated as an important prognostic marker [5], [7], [11], [12].

Traditionally, in clinical practice, the evaluation of the Ki-67 index is performed predominantly by two approaches, visual estimation (commonly referred to as *eyeballing*) and manual counting [13]. In the first, the pathologist estimates, based on his experience, the proportion of positive tumor cells, without effective counting. The manual counting, in turn, seeks to accurately quantify the percentage of positive cells in a given sample from the effective counting of positive and negative cells [14], [16]. However, both approaches present limitations, such as intra- and interobserver variability [13], [15], in addition to a long time required for manual counting, which can compromise workflow and negatively affect the quality of results, especially in scenarios of high demand or under

Partially funded by Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), National Council for Scientific and Technological Development (CNPq) and Fundo Nacional de Desenvolvimento da Educação (FNDE) - Programa de Educação Tutorial (PET)

professional fatigue, making visual evaluations subjective [13].

In recent years, several technological solutions have been developed with the objective of automating the Ki-67 proliferation index in breast cancer. The study "Artificial Intelligence-assisted interpretation of Ki-67 expression and repeatability in breast cancer" demonstrated that AI-assisted interpretation achieves high interobserver reproducibility and meets the standards established by the International Breast Cancer Working Group [13]. In the high-throughput study with tissue microarrays from the Breast Cancer Association Consortium, thousands of samples were used to develop an automated algorithm, and it demonstrated that AI-assisted interpretation achieved high interobserver reproducibility and good agreement with pathologists [16]. Recent works have advanced to tumor segmentation in whole slides and registration between HE and IHC sections, which improves precision in tumor region selection [17]. Liu et al. [18] proposed an AI-based method for segmentation of invasive carcinoma regions, allowing greater precision in the selection of relevant tumor areas.

In summary, there is a large number of studies, with relevant results, that present automated solutions aiming to estimate the Ki-67 index. However, its full implementation in clinical practice requires robust computational infrastructure, microscopes with integrated scanning systems or equipment for slide digitization, and large image storage capacity. Technologies of this scale may be associated with substantial investments, and this scenario imposes significant challenges, especially in low-income regions, where resource limitations directly impact the availability of accurate and timely diagnoses.

Considering the high mortality rate associated with breast cancer, especially in regions with lower human development index [2], the development of accessible, reliable, and scalable methods for the evaluation of the Ki-67 index constitutes a need in the context of global public health. From this perspective, we developed in this study an automated scoring system using Artificial Intelligence, based on the YOLOv8 model, to quantify cellular proliferation with Ki-67 in histological images acquired through the camera of a common smartphone coupled to the microscope eyepiece.

II. MATERIALS AND METHODS

The dataset used in this study is composed of 45 pathological studies from patients diagnosed with invasive breast cancer, acquired from the Anatomy and Pathology Laboratory of Hospital Erasto Gaertner between June and September 2022. This study was approved by the Research Ethics Committee of Hospital Erasto Gaertner – Liga Paranaense de Combate ao Câncer, under approval number 013571/2022. The tissue specimens were stained with Diaminobenzidine (DAB) and counterstained with Hematoxylin (H). The DAB staining resulted in brown nuclear labeling in Ki-67–positive cells, indicating proliferative activity, while hematoxylin provided blue coloration to the nuclei of Ki-67–negative cells. For five-fold cross-validation, the 45 patients were divided into five groups using an algorithm based on the number of Ki-67 reactive cells in each case. This strategy was adopted to improve the balance of reactive cells. From each original image, 36 patches were generated with 25% overlap between consecutive patches tto reduce the loss of relevant information at patch borders. Thus, a total of 1,620 patches were obtained, corresponding to 324 patches per fold.

A. Image Acquisition

The hotspot areas were selected by a pathologist using an Olympus CX23 microscope. After the hotspot was selected by the pathologist, a smartphone camera was attached to the microscope eyepiece to capture the images.

The configuration established for image acquisition was a spatial resolution of 1190×863 pixels, with 24-bit color depth in RGB matrices. The files resulting from the acquisition process were stored in JPG format, preserving the integrity of visual information.

B. Computacional Resources and Processing Time

All image processing and model training were performed on a workstation equipped with an Intel Core i5-12400F processor (2.5 GHz, up to 4.4 GHz Turbo, 18 MB cache), 32 GB of DDR4 3200 MHz RAM, an NVIDIA GeForce RTX 4060 Ti GPU with 8 GB of GDDR6 memory, and a 1 TB NVMe SSD. Considering the entire computational pipeline, including image patch generation, model training, and subsequent reassembly of the results, the complete processing of the 45 images required approximately 15 minutes, corresponding to an average processing time of approximately 20 seconds per image.

C. Model Selection

Deep learning models have been widely used in object detection for biomedical images, providing greater accuracy and reproducibility for analyses. In this study, we chose YOLOv8[1], a mature and widely adopted version of the YOLO (You Only Look Once) family, primarily due to the stability of its implementation and the robustness of the Ultralytics ecosystem, which provides consistent tooling, active maintenance, comprehensive documentation, and good reproducibility, in addition to its favorable balance between inference speed and detection performance. YOLOv8 includes advanced backbone and neck architectures, responsible for combining and refining features at different scales for object detection, improving the model's ability to detect objects of various sizes and shapes. These attributes motivated the model's selection, given the complexity and variability of tumor cells in histopathological images.

D. Annotation

Before the annotation process, an automatic cropping by intensity projection was applied. This step was necessary to remove the black borders resulting from the acquisition process and to segment only the relevant area for analysis. Next, manual annotation of the images was performed to identify and label the cells. This stage was conducted by a

[1]Ultralytics YOLOv8: https://github.com/ultralytics/ultralytics

professional previously trained by a pathologist with 8 years of experience, ensuring accuracy and standardization of the markings.

Annotations were carried out using the LabelMe tool[2], developed in Python, which allows the delimitation of areas through bounding boxes. Through this interface, two distinct classes were labeled, Ki-67–reactive tumor cells and Ki-67 non-reactive tumor cells.

The annotations were generated directly in YOLO format (.txt) files, containing the coordinates of the marked regions and their respective class labels. In this format, each image is associated with a corresponding text file containing the normalized box coordinates and class labels. Fig. 1 shows an example of the result obtained in the manual annotation stage, highlighting the visual difference between reactive (R) and non-reactive (NR) cells. These annotations served as a reference for training and validating the automated counting method.

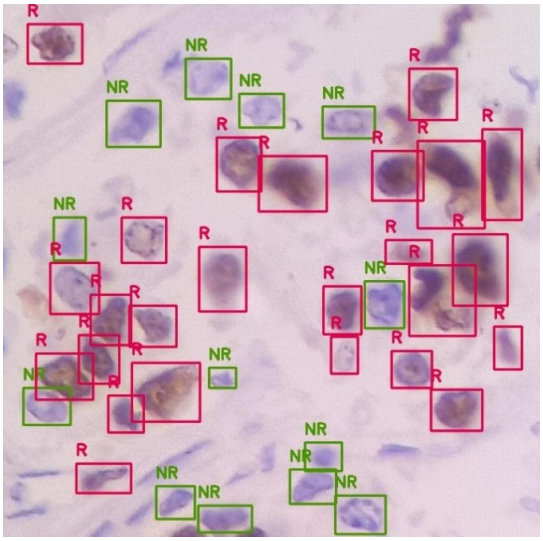

Fig. 1. Representative example of the manual annotation produced in LabelMe over a Ki-67 hotspot field. Each tumor nucleus is enclosed by a bounding box and labeled as either reactive (R, Ki-67 positive), shown in red, or non-reactive (NR, Ki-67 negative), shown in green. These annotations provided the reference used to train and validate the automated model.

E. Model Training and Validation

To ensure greater statistical robustness and reduce the risk of overfitting, the model training was conducted using the K fold cross-validation method. In this process, the dataset is divided into approximately equal subsets. In each iteration, one subset is reserved for validation while the remaining ones are used for training. This process is repeated so that all subsets are used, in different rounds, both for training and validation, as illustrated in Fig. 2.

The application of this method allows for a more reliable evaluation of the model's performance since the results are not

[2]LabelMe: https://github.com/wkentaro/labelme

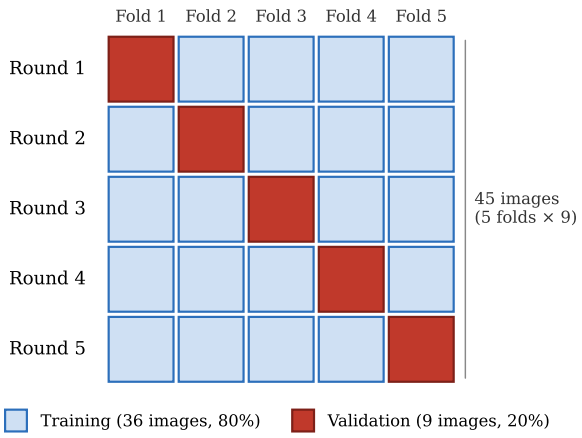

Fig. 2. Schematic of the five-fold cross-validation scheme. The 45 images were split into five folds of nine images each. In every round, four folds (36 images, 80%) were used for training and the remaining fold (9 images, 20%) for validation, so that each fold served once as the validation set.

restricted to a single data partition. In the present study, five training rounds were carried out, each containing nine images.

To avoid bias during cross-validation, each subset was created maintaining a balanced proportion between Ki-67 positive and Ki-67–negative cells, so that the model learned consistently across all training rounds, ensuring greater reliability of the obtained metrics.

The training process was conducted in YOLOv8, with parameters adjusted to balance computational performance and stability. The batch size was set to 16, allowing multiple images to be processed simultaneously and ensuring stability in weight updates. The input image size (imgsz) was set to 640×640 pixels, providing adequate resolution to capture important details without overloading processing time. The initial learning rate (lr0) was set to 0.01, with gradual adjustment during training, helping the model to learn efficiently without converging to suboptimal solutions. Training was performed for 2000 epochs, providing sufficient time for the model to converge and adjust its parameters.

Data augmentation techniques were applied to increase the diversity of the training set. Among them, the RandAugment method introduced random variations such as rotation and brightness/contrast adjustment, increasing model robustness. The Mosaic method was also evaluated in one of the K-fold subsets. However, the configuration using full images showed superior performance, which is why it was adopted as the standard method.

Throughout the entire training process, validation (val) was performed on independent subsets, allowing continuous monitoring of performance metrics (precision, recall, and F1-score) and ensuring good model generalization. This monitoring also made it possible to identify signs of validation regression, preventing overfitting. To mitigate these effects, the training process included adaptive learning rate adjustments and early stopping when no consistent improvement in validation metrics was observed. These mechanisms, combined, were

essential to optimize training and achieve high performance in the object detection task.

III. Results and Discussion

The study addresses a pratical bottleneck in Ki-67 scoring and uses low-cost image acquisition, case-level, cross-validation, and direct comparison between automated and manual proliferation indices. The model training was conducted using cross-validation with an 80/20% proportion, where 80% of the images were used for training and 20% for validation in each round. During the training process, the model showed balanced performance across the folds. Table I summarizes the detection metrics per class and overall, calculated by aggregating the predictions for all annotated cells across the cross-validation folds, rather than averaging the metrics obtained from the individual models. For the non-reactive class, the model achieved a precision of 87.29%, a recall of 84.93%, an accuracy of 75.58%, and an F1-score of 86.10%. For the reactive class, the model achieved a precision of 88.27%, a recall of 86.88%, an accuracy of 77.88%, and an F1-score of 87.57%. Considering all annotated cells jointly, the model achieved an overall precision of 87.54%, a recall of 85.44%, an accuracy of 76.17%, and an F1-score of 86.48%. These results indicate that the model distinguished Ki-67–reactive from Ki-67–non-reactive tumor cells consistently, even under the marked class imbalance between the 7,272 reactive and 21,061 non-reactive annotated cells.

TABLE I
Detection performance per class and overall, calculated from the aggregated predictions across all annotated cells from the five cross-validation folds. The last column reports the total number of annotated cells (ground truth) for each class.

Class	Precision	Recall	F1-score	Cells
Reactive (R)	0.88	0.87	0.88	7 272
Non-reactive (NR)	0.87	0.85	0.86	21 061
Overall	0.88	0.85	0.86	28 333

The learning curves presented in Figures 3, 4, and 5 illustrate the training process, showing the Precision, Recall, and F1-score, respectively. Together, they display a stable behavior throughout the epochs, with no signs of overfitting, and a gradual increase until reaching a plateau, which suggests consistent learning.

The comparison between the estimated proliferation index (YOLOv8) and the reference proliferation index (manual counting) showed high agreement between the methods. The overall means were 24.61% for the estimated index and 24.24% for the reference index, resulting in an absolute mean error of 2.66 percentage points (p.p.) and an average percentage error of 12.45%. The model presented an average error of 0.37 p.p., indicating a slight tendency to overestimate the reference index, and a stable percentage error between 10.8% and 14.2%, suggesting good reproducibility among all groups. A linear regression of the estimated index on the reference index yielded $y = 1.037\,x - 0.493$, with a slope whose 95% confidence interval $[0.971,\ 1.103]$ includes 1

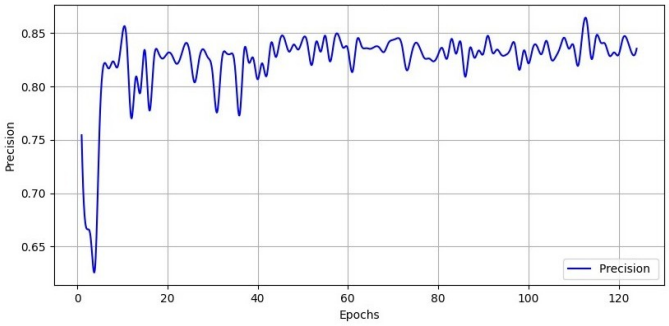

Fig. 3. Precision on the validation data as a function of the training epoch. The metric rises sharply during the first epochs and then stabilizes around a plateau, with no signs of overfitting up to the early-stopping point.

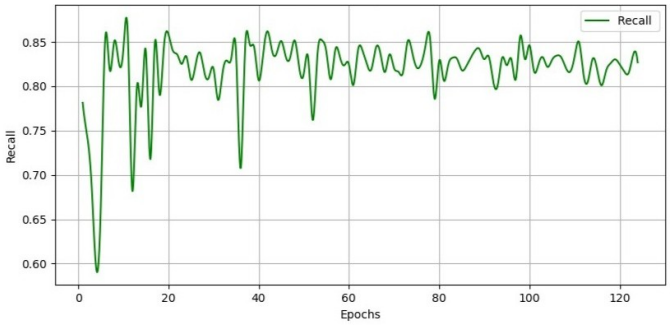

Fig. 4. Recall on the validation data as a function of the training epoch, showing the same rapid initial increase followed by a stable plateau observed for the other monitored metrics.

and an intercept whose interval $[-2.484,\ 1.498]$ includes 0, indicating the absence of statistically significant proportional or fixed bias. The two measurements were strongly correlated (Pearson $R = 0.979$, 95% CI 0.962–0.989, $R^2 = 0.959$), and the intraclass correlation coefficient for absolute agreement was excellent (ICC(2,1) $= 0.978$, 95% CI 0.960–0.988). Fig. 6 illustrates this relationship, showing the proximity between the estimated and reference values.

When compared with other studies that also use AI and deep learning to automate the immunohistochemical analysis of Ki-67, our study shows comparable results. For example,

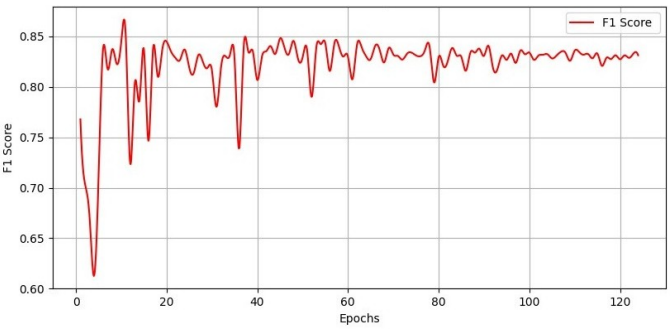

Fig. 5. F1-score on the validation data as a function of the training epoch. As the harmonic mean of precision and recall, it summarizes the joint behavior of both metrics and likewise converges to a stable plateau without overfitting.

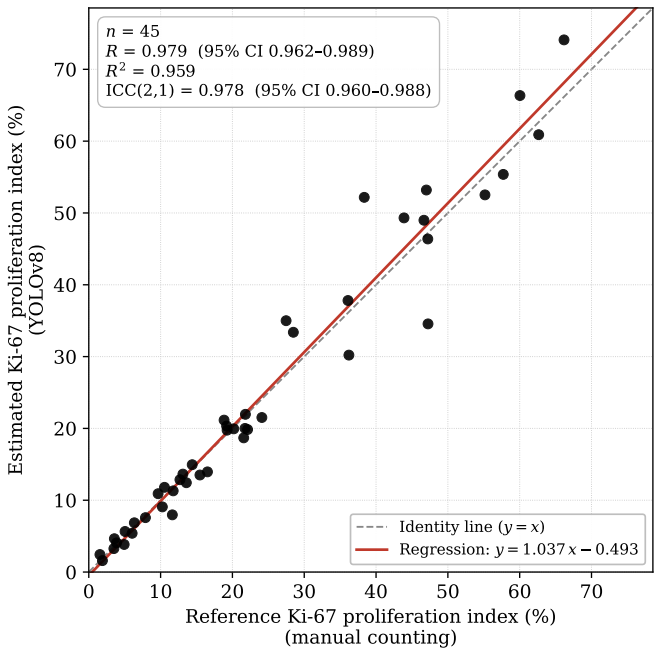

Fig. 6. Scatter plot showing the agreement between the estimated Ki-67 proliferation index (YOLOv8) and the reference Ki-67 proliferation index (manual counting) for the 45 evaluated images. The solid red line is the fitted regression ($y = 1.037\,x - 0.493$), where x is the reference index and y the estimated index. The dashed grey line is the identity line ($y = x$). The two measurements are strongly correlated (Pearson $R = 0.979$, $R^2 = 0.959$) and show excellent absolute agreement (ICC(2,1) = 0.978, 95% CI 0.960–0.988).

in [19], the proposed tool named piNET achieved an F1-score between 0.8 and 0.9 across different types of histological images, within a robust dataset containing color variations and imaging artifacts. In this context, the average F1-score of 0.87 obtained in this study shows that YOLOv8 achieved comparable performance, despite the reduced number of slides and the use of images acquired through a low-cost method.

Likewise, the study by [20] observed that the use of AI-based tools reduced the mean error from 5.9% to 2.1% and increased the Intraclass Correlation Coefficient (ICC) from 0.70 to 0.92 in cell proliferation assessment among pathologists. The present study presented an absolute mean error of 2.66 p.p. and an average error of 0.37 p.p., together with an ICC(2,1) of 0.978 (95% CI 0.960–0.988) between the estimated and reference indices. These values indicate that the automated approach achieved a level of agreement comparable to that obtained by human observers assisted by AI, whose inter-rater agreement reached an ICC of 0.92.

Furthermore, the study by Zehra et al. [21] also employed deep learning techniques for Ki-67 quantification and reported an accuracy of 95% when comparing automatic and manual counts, using images acquired by a camera coupled to the microscope, similar to the acquisition performed in this study. In the present work, the YOLOv8 model reached a precision of 0.88, a recall of 0.86, and an F1-score of 0.87 at the detection level, together with strong agreement at the index level (ICC(2,1) of 0.978 and Pearson correlation of 0.979). A direct numerical comparison with Zehra et al. is limited by the different metrics and evaluation protocols adopted, yet both studies indicate that low-cost, camera-based acquisition can support reliable automated Ki-67 quantification. Any residual difference may be attributed to the particularities of the dataset and the variations in acquisition conditions, since the images used here were captured using a smartphone attached to an optical microscope.

Even so, the closeness between the results reinforces the potential clinical applicability of the proposed model, even in scenarios with limited infrastructure.

A limitation of this study concerns the generalizability of the proposed model, as the dataset was obtained from a single institution and comprised a relatively limited numbers of cases. Although the model showed consistent performance during cross-validation, its performance may be affected by variations in staining protocols, microscopes and image acquisition conditions, which can alter tissue appearance and nuclear characteristics. Therefore, the results should be interpreted within the context of the data used in this study, and future studies should be interpreted within the context larger and more diverse datasets from different institutions and acquisition setting to further assess its robustness and generalizability.

It is worth noting that the adopted approach relies on axis-aligned bounding boxes to represent each nucleus, rather than on pixel-level (semantic or instance) segmentation. In Ki-67 evaluation, tumor nuclei frequently appear overlapped or organized in dense clusters, especially within hotspot regions of high proliferative activity. Under these conditions, the bounding boxes of adjacent nuclei may overlap considerably, which can lead to merged or suppressed detections during non-maximum suppression and, consequently, to counting errors. In the present study, the strong chromatic contrast introduced by the DAB/hematoxylin staining, combined with the automatic hotspot cropping, mitigated part of this difficulty by making reactive and non-reactive nuclei more separable. Nevertheless, the resolution of densely packed nuclei remains an intrinsic limitation of bounding-box–based detection, and future work may explore instance segmentation strategies to delineate individual nuclei more precisely in highly cellular regions.

A further limitation concerns the construction of the reference standard. Although this work is motivated by the intra- and interobserver variability that affects manual Ki-67 assessment, the annotations used here were produced by a single trained annotator, under the supervision of a pathologist. As a consequence, the reference may carry the individual criteria and potential bias of that annotator, and the inter-annotator agreement of the ground truth itself was not quantified. The agreement reported in this study should therefore be interpreted as the concordance between the automated method and one reference standard, rather than against a consensus of multiple independent experts. Future work should incorporate annotations from several specialists, together with a consensus or majority-vote reference, so that inter-annotator variability can be measured and the robustness of the automated estimates

can be assessed against it.

IV. Conclusion

This study proposed a deep learning–based framework for detecting and quantifying the expression of the Ki-67 marker in histological images using the YOLOv8 model. The developed approach demonstrated technical feasibility and clinical potential, especially by employing images captured with low-cost equipment and still achieving results consistent with those reported in the literature. In future work, it is intended to expand the dataset and develop a mobile application that integrates the proposed model, enabling automated analysis directly via smartphone. Such developments may support the broader use of automated Ki-67 analysis, particularly in settings with limited infrastructure, although their clinical applicability will require further validation.

***Abstract*—Missing healthcare data compromises predictive accuracy and introduces model bias. We evaluate Label Propagation for Missing Data Imputation (LPMD), a graph-based semi-supervised method that treats missing values as unlabeled nodes, on four real-world COVID-19 datasets. Benchmarked against MICE, kNN, SAEI, and PMIVAE, LPMD matched the downstream classification performance (AUC, Recall, Specificity) of top-tier baseline methods while achieving up to 5.2 times faster processing times than MICE. LPMD represents an alternative for high-performance clinical data imputation.**

***Index Terms*—Missing data, Imputation, Semi-supervised learning, healthcare data**

I. Introduction

COVID-19 is an infectious respiratory disease that caused the pandemic reported by the World Health Organization (WHO) in March 2020 [1]. The disease quickly spread worldwide and drew the attention of scientists from diverse areas around the world by studying disease mechanisms, prevention and treatments [2]. The pandemic ended in May 2023 [3], and unfortunately, there were more than 7 million deaths worldwide caused by COVID-19 until April 2024 [4]. However, despite its end, it left social consequences and lessons learned [5]. The acquired knowledge, including that in data science applied to medicine, must continue to improve for future adverse public health situations [6], like future pandemics, and current disease problems, such as dengue fever regional epidemics in Brazil [7].

During the pandemic, several studies were dedicated to COVID-19 data analysis and ML techniques for diagnosis and prognosis of the disease [8]. Researchers developed models ranging from rule-based scoring systems to advanced deep-learning ML models. These researches were possible because hospitals produce large amounts of data every day by collecting laboratory tests and medical records, and such data allow extraction of important insights. Although there are different types of healthcare data, the most common approach to developing ML models for healthcare decision making has been tabular data [9].

Despite the large amount of healthcare data generated,

This work was carried out with the support of the São Paulo Research Foundation (FAPESP), Brazil. Process number 2021/06870-3 and 2024/23791-8. This work was also funded by national funds through FCT – Foundation for Science and Technology, I.P., within the scope of the research units UID/00326 - Centre for Informatics and Systems of the University of Coimbra, https://doi.org/10.54499/UID/00326/2025 and UID/50014/2025 (https://doi.org/10.54499/UID/50014/2025).

Missing Data (MD) is a common problem reported in the medical domain, which can prevent reliable data analysis [10]. According to the guideline on Statistics Principles for Clinical Trials (ICH E9), MD represent a potential source of bias despite a consensus that there will almost always be MD in healthcare data. Therefore, every effort should be made to minimize the amount of MD and its effects [11].

According to García-Laencina *et al.* [12], we have three different forms to working with MD: (a) Deletion of incomplete data; (b) Model-based procedures; and (c) Imputation (the most popular approach). Imputation consists of "replacing" the missing values according to specific criteria, like statistical methods or imputation based on ML. Statistical imputation methods include techniques such as mean/mode imputation, multiple imputation, and regression imputation. In contrast, ML-based methods encompass approaches like k-nearest Neighbors (kNN), Multiple Imputation by Chained Equations (MICE) and autoencoders (AE) based imputation [13].

ML-based imputation performs various ML predictive tasks in two steps. First, the ML algorithm generates the model using complete data during the learning part. The generated model is then used to predict the missing values for MD. Over the years, several authors have studied different ML-based imputation algorithms, such as kNN, Decision Tree (DT), Random Forests (RF), and Self-Organizing Maps (SOM) imputation. However, these approaches do not always consider intrinsic information that may be related to the performance of algorithms, such as feature distribution. Matching the data distribution to the most appropriate imputation method avoids repeatedly testing many methods, providing a heuristic about the best choice for each study [14]. On the other hand, the MICE imputer, which considers the features distribution, and is considered the state of the art for imputation, does not perform well when applied to high missing rate (MR), which is the reality of healthcare data [15].

A more recent ML imputation methodology is based on autoencoders (AE-based) [15], like the Siamese Autoencoder-based Approach for Imputation (SAEI) [16] and Partial Multiple Imputation with Variational Autoencoders (PMIVAE) [17]. However, AE-based models, especially with deep architectures and customized strategies, can be more computationally intensive than statistical or neighborhood-based methods (e.g., kNN) [16]. In addition, AE-based imputer has limitations such as dependence on complete data [17].

Among the best ML imputers are kNN, and RF, which respect the paradigms of supervised ML [18], and AE-based imputation [13], which respects the unsupervised ML paradigm. The scientific literature widely explored the two most well-known ML paradigms for MD imputation. However, in ML, there is also semi-supervised learning, which has several benefits compared to the other two paradigms. It offers a way to extract maximum benefit from a scarce amount of labelled data while using relatively abundant unlabeled data, and it has been very little explored in the literature on MD imputation [19].

Previous research [20] developed a new imputation method using the Label Propagation algorithm, named Label Propagation for Missing Data Imputation (LPMD), which uses the semi-supervised learning paradigm. This research applied the method to 10 healthcare benchmark datasets and obtained results comparable to the best imputation techniques, while achieving shorter processing times. However, LPMD has not yet been applied to real-life datasets. Testing a new methodology on real-world datasets is important because these datasets present challenges such as inconsistencies, outliers, and class imbalance, which offer a significant research opportunity related to the vast amount of health data available on COVID-19.

Due to the pandemic, healthcare data repositories were created, such as the COVID-19 Data Sharing FAPESP[1] [21] and these data have a high MR [22]. As the literature demonstrates, handling MD in healthcare data is essential for reliable data analysis and ML models [12]. On the other hand, the most widely used imputation algorithms have gaps that need to be improved for practical use in medicine [14]. This study aims to apply a new approach for MD imputation with semi-supervised learning using the Label Propagation algorithm to COVID-19 real datasets and compare with the best imputation methods available on literature. To this end, four datasets were selected, obtained from the COVID-19 Data Sharing FAPESP and pre-processed in previous studies. The aim of this research was to subject real-world COVID-19 datasets to a MD imputation process using an innovative method called LPMD and to compare this method with other state-of-the-art algorithms.

II. Missing Data and Imputation concepts

MD mechanisms are broadly categorized into three distinct types: Missing Completely at Random (MCAR), Missing at Random (MAR), and Missing Not at Random (MNAR) [11]. As outlined by [23], MCAR represents the highest degree of randomness, occurring when missingness depends on neither observed nor unobserved values. Conversely, MAR allows the missingness to depend on the observed data, provided it remains independent of the missing values themselves. Lastly, MNAR arises when the probability of a value being missing is directly related to the unobserved value of that specific attribute. Importantly, valid data imputation is generally restricted to mechanisms satisfying the MCAR or MAR assumptions.

To establish the formal framework for the MD mechanisms, let X be a dataset structured as an $N \times D$ matrix, where N denotes the number of observations and D represents the number of features. Each entry in the matrix is denoted by x_{ij}, with $i = 1, \ldots, N$ and $j = 1, \ldots, D$. Furthermore, $x_{\cdot j}$ denotes the j-th feature vector, containing all observations for that feature, whereas $x_{i\cdot}$ denotes the i-th observation vector, containing all feature values for that specific instance. Each observation is associated with a target class y_i and a missingness indicator vector $\mathbf{m}i = [mi1, m_{i2}, \ldots, m_{iD}]$.

[1] https://repositoriodatasharingfapesp.uspdigital.usp.br/

Consequently, the MD indicator can be defined as a binary matrix M of size $N \times D$ [24]:

$$m_{ij} = \begin{cases} 1, & \text{if } x_{ij} \text{ is missing,} \\ 0, & \text{otherwise,} \end{cases} \qquad M = \{m_{ij}\}_{i,j=1}^{N,D} \quad (1)$$

where M explicitly maps the positions of missing values within X. Assuming the dataset X can be partitioned into observed (X_{obs}) and missing (X_{miss}) components, and letting ψ represent the parameters of the missingness model, the three classical MD mechanisms are defined as follows.

MCAR (Missing Completely at Random): Under this mechanism, the probability of a value being missing is entirely independent of both observed and unobserved data, as shown in Equation 2:

$$Pr(M = 1|X, \psi) = Pr(M = 1|\psi). \quad (2)$$

Here, the missingness probability depends solely on the parameters ψ [15]. Because MCAR represents the highest level of randomness, standard analytical and inference procedures designed for complete datasets remain valid when applied to the observed data.

MAR (Missing at Random): Missingness depends directly on the observed components of the dataset (X_{obs}), but remains independent of the unobserved values (X_{miss}). Formally, MAR satisfies Equation 3:

$$Pr(M = 1|X, \psi) = Pr(M = 1|X_{obs}, \psi). \quad (3)$$

As noted by [15], missingness correlates strictly with X_{obs}. A typical illustration is patient dropout in longitudinal studies [11]: if two patients share identical covariates and responses up to a given time step, and one drops out, the missing values are considered MAR if the statistical behavior of the dropped-out subject aligns with that of the remaining subject. Valid statistical inferences can still be drawn under MAR without explicitly modeling the missingness process.

MNAR (Missing Not at Random): This mechanism occurs when the missingness depends directly on unobserved values, violating both MCAR and MAR assumptions. Formally, it is expressed as:

$$Pr(M = 1|X, \psi). \quad (4)$$

As highlighted by [15], MNAR typically arises in two scenarios: (a) when missingness depends on the missing value itself, or (b) when it depends on unobserved covariates missing from the dataset. MNAR represents the most challenging setting; addressing it generally requires modeling the underlying reasons for missingness or performing sensitivity analyses under multiple plausible scenarios. In summary, as synthesized by Luengo *et al.* [23], MCAR exhibits complete independence from data values; MAR relies on observed data; and MNAR depends on unobserved variables. Although real-world datasets often reflect complex mixtures of MAR and MNAR, standard imputation strategies perform more reliably under MAR assumptions, whereas applying them to MNAR data can introduce significant estimation bias [25].

Properly handling MD is a crucial step in data science pipelines. In specialized domains such as healthcare, addressing missingness effectively is vital, as biased imputations can misguide clinical decision-making. However, conventional imputation techniques often ignore intrinsic data characteristics—such as feature distributions—that directly influence model performance. Tailoring the imputation strategy to the specific properties of the dataset mitigates the need for exhaustive trial-and-error testing across numerous algorithms [14].

According to [26], the performance of the imputation methods using two main approaches: (i) *imputation quality*, which directly measures reconstruction accuracy by comparing imputed values against the original complete data using metrics such as Mean Absolute Error (MAE) or Root Mean Square Error (RMSE); and (ii) *downstream predictive performance*, which evaluates the impact of the imputed datasets on predictive models using metrics like Area Under the ROC Curve (AUC) or F1-score. In a previous study [20], the LPMD was tested using complete health data (benchmark) containing missing values introduced via amputation. The present study aims to bridge this gap and evaluate downstream predictive performance using real-world data.

III. Related work

To the best of our knowledge, very few studies have addressed the topic of semi-supervised learning applied to the MD imputation process. Among these studies, we highlight the article by [19] that demonstrated the Iterative Robust Semi-Supervised based Imputation (IRSSI) method. Although IRSSI is a semi-supervised methodology, it differs from Label Propagation because while Label Propagation is of the transductive type (network-based learning), IRSSI mixes transduction with induction, which is why it is considered a hybrid algorithm.

Pan et al. (2026) [27] proposed Semi-supervised Generative Adversarial Network (SEGAN), a semi-supervised learning-based imputation method that integrates a generator, a discriminator, and a classifier to jointly exploit the data structure and the available label information. The model also incorporates a missingness hint matrix, enabling the discriminator to more effectively distinguish between observed and imputed values. Experimental results showed that SEGAN outperformed both traditional and deep learning-based imputation methods, achieving lower Root Mean Squared Error (RMSE) values, greater robustness to increasing missingness rates, and improved performance in downstream classification and regression tasks. However, its deep learning-based architecture increases the computational cost and training complexity. In contrast, the Label Propagation method proposed in the present study does not rely on deep learning, resulting in a computationally simpler and potentially more broadly applicable solution for missing data imputation.

IV. Label Propagation in Missing Data Imputation

Label propagation is a classic algorithm for transductive inference on graphs. The primary objective is to assign labels or classes to an unlabeled set of instances by leveraging the topological and semantic structure present in a smaller set of labeled data.

Formally, let $X_L = (\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)$ denote the labeled data points with corresponding labels $Y_L = \{y_1, \ldots, y_n\} \in \{1, \ldots, C\}$, where C represents the total number of classes. Let $X_U = \{\mathbf{x}_{n+1}, \ldots, \mathbf{x}_{n+m}\}$ represent the unlabeled dataset whose corresponding target values $Y_U = \{y_{n+1}, \ldots, y_{n+m}\}$ are unobserved. Typically, $n \ll m$. The joint dataset is given by $X = \{\mathbf{x}_1, \ldots, \mathbf{x}_{n+m}\} \in \mathbb{R}^D$. The goal is to estimate Y_U from X and Y_L under the smooth manifold assumption, which dictates that nearby data points are likely to share identical labels.

To capture these spatial relationships, a fully connected graph is constructed where the nodes correspond to all instances in X (both labeled and unlabeled). The edge between any two nodes i and j is assigned a weight w_{ij} inversely proportional to their distance d_{ij}. Using a Gaussian Radial Basis Function (RBF) parameterized by σ, the edge weights are computed according to Equation 5 [28]:

$$w_{ij} = \exp\left(-\frac{d_{ij}^2}{\sigma^2}\right) = \exp\left(-\frac{\sum_{d=1}^{D}(x_{id} - x_{jd})^2}{\sigma^2}\right). \quad (5)$$

The label assignment of each node propagates to adjacent nodes proportionally to their connecting edge weights; stronger connections yield greater influence during propagation. Information transmission across the graph is modeled via a transition probability matrix $T \in \mathbb{R}^{(n+m)\times(n+m)}$. Each entry T_{ij} denotes the probability of label information transferring from node j to node i, defined as follows [28]:

$$T_{ij} = \frac{w_{ij}}{\sum_{k=1}^{n+m} w_{kj}}. \quad (6)$$

Additionally, a soft-label matrix $Y \in \mathbb{R}^{(n+m)\times C}$ is defined, where the i-th row encodes the class probability distribution for observation $\mathbf{x}_i$. While the rows corresponding to labeled instances are initialized as one-hot vectors representing their ground-truth classes, the rows associated with X_U can be initialized arbitrarily without impacting the theoretical convergence of the algorithm.

The Label Propagation for Missing Data Imputation (LPMD) algorithm adapts the formulation proposed by Zhu and Ghahramani [28]. We model the datasets as proximity graphs and use the graph structure to propagate feature values between connected nodes, which can be weighted and aggregated for MD imputation. There are widespread Label Propagation algorithms capable of assigning labels to unlabeled data, even when the proportion of labeled data from which the information is propagated is relatively low. Therefore, Label Propagation can also be beneficial in MD imputation, especially in cases where one expects high MR [29].

Formally, LPMD receives a dataset represented as a matrix X of size $N \times D$, comprising N observations described by D input features. The dataset X contains missing values in either univariate or multivariate configurations. Initially, the missing values are filled arbitrarily or through a baseline imputation strategy (e.g., mean imputation), yielding a complete matrix denoted by X'. To track missing entries, a binary indicator matrix M of the same dimensions as X is defined, where $m_{ij} = 1$ if the corresponding value is missing and 0 otherwise.

Next, pairwise distances between all instances in X' are computed using a Radial Basis Function (RBF) kernel, as formulated in Equation 5, parameterized by $\gamma = \frac{1}{\sigma^2}$. By default, the hyperparameter is set to $\gamma = \frac{1}{D}$.

Based on the affinity weights w_{ij}, a transition probability matrix T_{ij} is constructed according to Equation 6. The LPMD algorithm then proceeds iteratively through the following steps:

1) **Propagation:** Update the complete matrix X' by propagating information using the transition matrix T:
$$X' = TX'. \quad (7)$$
2) **Reset Observed Data:** Restore the original observed entries from X into X', ensuring that only the missing values (indicated by M) are updated during propagation.
3) **Convergence Check:** Repeat Steps 1 and 2 until the difference between matrices from two consecutive iterations falls below a predefined convergence threshold ϵ.

The pseudocode (Algorithm 1) shows the general functioning of the LPMD algorithm [20]. Under the default initialization scheme, all missing values are set to -1.

Input: Matrix X with missing values; tolerance ϵ.
Output: Imputed matrix X'.
Initialize missing values in X, obtaining X';
Compute similarity matrix W using the RBF kernel (Eq. 5);
Compute the transition matrix (Eq. 6);
repeat
  Propagate values according to Eq. 7;
  Restore observed entries of X;
until *convergence*;
return X'

Algorithm 1: LPMD Imputation

In addition to the baseline framework, structural modifications were incorporated into LPMD, yielding an enhanced variant denoted as LPMD2. This modified version introduces a filtering mechanism prior to the label propagation stage to mitigate the propagation of noisy values and outliers. Specifically, the filtering strategy applies the Interquartile Range (IQR) rule, a computationally efficient method for outlier detection. Furthermore, LPMD2 refines the initial MD completion step by employing a class-wise mean imputation strategy, which yields a more accurate initial approximation of the missing

entries. In unsupervised or unlabeled settings, the data is first partitioned using the k-means algorithm with $k = C$ (where C is the number of clusters/classes), and missing values are subsequently initialized using the corresponding cluster-wise means.

V. Materials and Methods

The proposed method has been implemented in an open-source software package[2], which has been officially registered with the Brazilian National Institute of Industrial Property under registration number BR512026003240-7. The methodology was divided into three main stages: The (A) Data collection step includes the selection of real-life health datasets. The (B) MD imputation step was performed using different algorithms considered state-of-the-art in imputation and the LPMD. Finally, the (C) Evaluation step was performed using the processing time and classification evaluation criteria; we created models from the different imputed datasets and compared the efficiency of each model. The detailed implementation of each step is described in the subsequent subsections.

A. Datasets

We used open data available on the FAPESP COVID-19 Data Sharing/BR repository to assemble datasets for COVID-19 prognosis. Table I summarizes the information from these assembled datasets, and below, we provide more information about each one. The assembled datasets refers to patients who attended by Hospital Sírio-Libanês (HSL) and Hospital Beneficiência Portuguesa (HBP) in São Paulo-Brazil and were tested for COVID-19 during the pandemic. Although we chose open data, the Brazilian Research Ethics Committee approved the research under the "CAAE 37362220.4.0000.5505" registration. Patient consent was waived due to anonymized data being available in an open repository.

Dataset 1 refers to a study of Healthcare-Associated Infection (HCAI) among patients diagnosed with COVID-19. This dataset was assembled from patients' data at the HSL and was made available in previous research we conducted [30]. Dataset 2 deals with a study on the COVID-19 prognosis related to the worsening of the disease. This dataset was also assembled from data from HSL patients and made available in previous research we conducted [31]

Datasets 3 and 4 were assembled from data from patients at the HSL and HBP, respectively. The research deals with a data-centric perspective approach and was made available by previous research [32].

Statistical tests were applied to classify the missing data mechanism in each dataset using the missr package in R software. Little's MCAR test [33] was first employed to assess the null hypothesis that the MD mechanism are MCAR. If the mechanism were not classified as MCAR, a multivariate logistic regression [34] was fitted for each variable with missing values, considering as the response a binary indicator of missingness (0 or 1), and as predictors all other observed variables. This procedure was repeated for each variable with missing values, and the p-values of the regression coefficients were stored. If the smallest p-value was statistically significant, evidence was found that missingness depends on at least one observed variable, and the MD mechanism were classified as MAR. MD mechanism were considered MNAR if they were neither MCAR nor MAR.

[2]https://github.com/filipeloyola/LPMD-applied-COVID-19-datasets

B. Imputation

As with the benchmark datasets, in the case of real datasets, we also performed the imputation process with the Label Propagation algorithms (LPMD and LPMD2) and the state-of-the-art algorithms that served as a baseline. The hyperparameter of the LPMD and LPMD2 algorithms was ϵ equal $1e^{-32}$, representing a value that tends to zero. The baselines used to compare LPDM and LPMD2 were Mean, kNN, MICE, SAEI and PMIVAE. All strategies perform data imputation in the training subsets and use the extracted patterns to perform imputation in the test subsets, preventing data leakage.

C. Evaluation

We performed computing time and classification models evaluation. In the quality classifier evaluation, we used models produced with the Gradient boosting (GB), Random Forests (RF), and Support Vector Machine (SVM) algorithms. We evaluated each model's predictive performance based on the AUC, Recall, and Specificity metrics. RF and GB used a maximum depth of ten. The results of classification were submitted to a Friedman statistical test for multiple comparisons, with the Nemenyi post-hoc test, a nonparametric statistical test used in comparisons between multiple algorithms [35]. The procedure used SCMAMP library from the R language [36].

VI. Results and Discussion

Considering the four real datasets, the seven imputation methods, and the three classification quality metrics used, we computed 84 classification results. It is worth noting that for each result, we have the mean and standard deviation values obtained from the five cross-validation rounds. Next, we address the results of the processing time evaluation and assessments based on classification.

Time evaluation: Table II presents the sum of processing times of all imputation algorithms for each real dataset. LPMD2 was advantageous in this aspect, especially compared to SAEI, PMIVAE, and MICE. It is also possible to observe that the LPMD processing time was smaller than kNN for datasets 1, 2 and 4 and close to kNN for dataset 3, proving to be an interesting algorithm in terms of processing time.

Classification models evaluation: Figure 1 shows a compiled result, considering all models created with the GB, RF and SVM algorithms. This analysis shows the classification performance achieved from the datasets imputed by the different imputation methods (kNN, LPMD, MICE, Mean, PMIVAE and SAEI).

TABLE I: Real datasets used in the experiments.

Dataset	MR%	# Instances	# Classes	# Features	
				Cat.	Cont.
1: HSL-HCAI-INFECTION	13.5	499	2	2	36
2: HSL-COVID-PROGNOSTIC	13.2	4320	2	2	29
3: HSL-DATA-CENTRIC	6.6	1432	2	2	18
4: HBP-DATA-CENTRIC	9.0	185	2	2	18

Legend: MR - Missing rate.

TABLE II: Total processing time for each real dataset (in seconds).

Algorithm	Dataset 1	Dataset 2	Dataset 3	Dataset 4
kNN	198.0	864.7	837.2	242.7
MICE	249.7	4407.8	1531.5	248.2
PMIVAE	348.7	2165.8	2684.3	466.4
SAEI	414.9	1440.9	1562.1	408.4
LPMD	192.2	847.1	941.8	240.6
LPMD2	**186.1**	**756.3**	**749.3**	**210.4**

Legend: The lowest time value for each dataset is marked in bold.

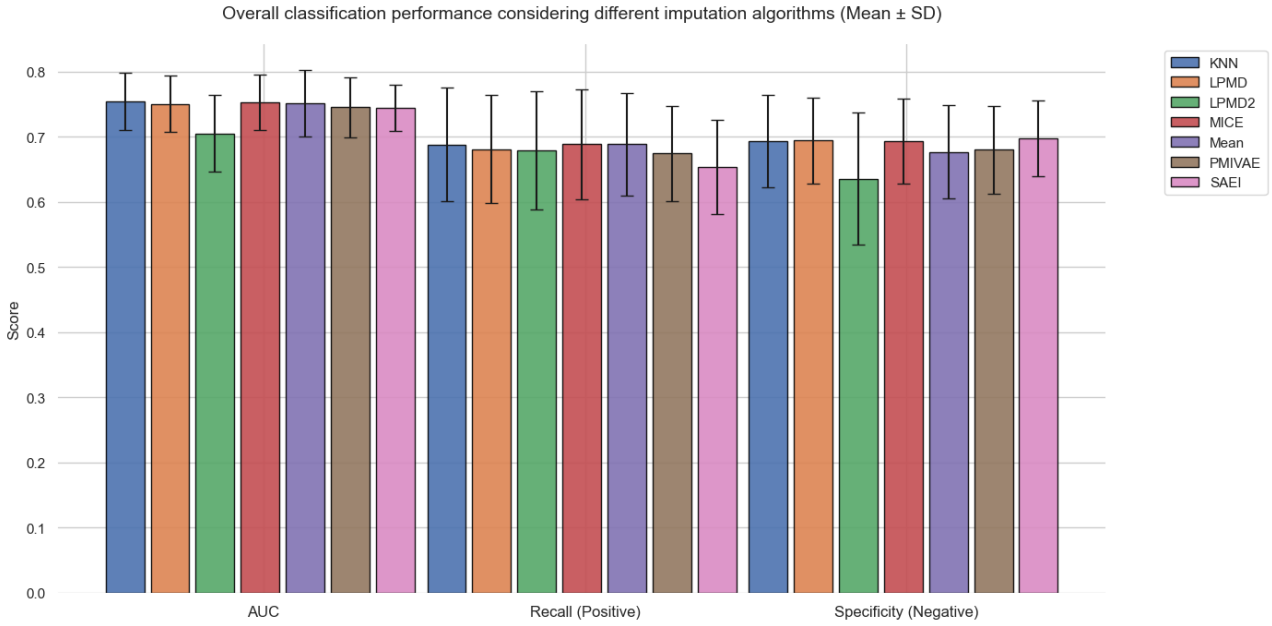

Fig. 1: Classification evaluation for all machine leaning model and all datasets, considering each imputation algorithm.

From Figure 1, it is possible to notice that the result obtained from the LPMD algorithm is comparable with the results obtained by the kNN and MICE algorithms for tree metrics. However, it is possible to observe that the result obtained from LPMD2 is inferior to the others by the AUC and Specificity metrics. It is also possible to verify a result inferior to the others in the results obtained by the SAEI algorithm considering the Recall metric.

In Figure 2, we provide a statistical analysis under an overview of the classification analysis, bringing together the results of all models, all datasets and all metrics. The statistical analysis available in Figure 2 provides a graph known as Critical Difference (CD), used to compare algorithms. This graph shows an average ranking of the algorithms, with the best ones being further to the left and the worst ones further to the right. In this evaluation, the best algorithms were MICE and LPMD. There was no statistical difference between the algorithms MICE, LPMD, kNN, Mean, SAEI and PMIVAE, as they are connected by the same horizontal bar. The worst algorithm was LPMD2 (further to the right), presenting a statistical difference in relation to the other imputers.

In this research, we applied only the time evaluation and classification models evaluation, and we did not use quality imputation evaluation since we used real datasets. Real datasets are incomplete, so they do not have reference values for calculating the imputation error. It is worth mentioning that we use three classic classification algorithms for indirect evaluation, notably RF, GB and SVM. These algorithms are known in the literature as Shallow Learning; they do not use Deep Learning. Shallow learning algorithms have some advantages, such as shorter processing time and greater interpretability of the models.

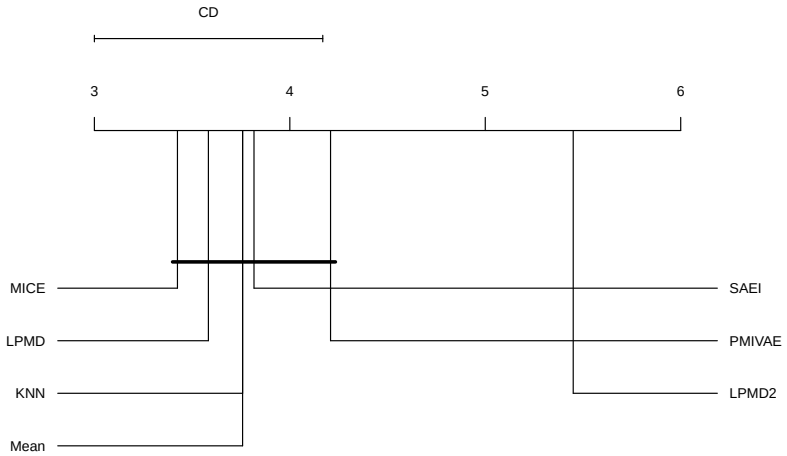

Fig. 2: Classification evaluation for all machine leaning model, all datasets, and all metrics, considering each imputation algorithm.

LPMD2 algorithm stood out significantly in time analysis, presenting a shorter processing time than the other imputation algorithms. The shortest processing time is due to using a filter in the algorithm. This filter eliminates outliers when propagation labels, allowing the propagation to converge more quickly than LPMD. However, considering the classification analysis, LPMD2 did not perform as well as expected. When performing a new time comparison without considering LPMD2, it is possible to see that LPMD obtained the best processing time for Datasets 1, 2 and 4. Only for Dataset 3 was LPMD's processing time (941 seconds) longer than kNN's (837 seconds). It is worth noting that LPMD achieved a shorter processing time (for Dataset 3) compared to the other imputation algorithms (other than kNN), while also showing promising results in the classification analysis.

The results shown in Figure 1 show an overview of the results for all datasets and an average for all classification models. This analysis shows that the average of the LPMD classification results is very close to the other imputation algorithms for AUC, Recall and Specificity, which is an exciting result. However, it is possible to observe lower values for LPMD2 for AUC and Specificity. The AUC metric is widely used in classification analyses, and it means the area under the ROC curve (AUC). It is very significant when the data have balanced classes. In the health domain, however, the existence of unbalanced classes is very common, which can be seen in the datasets used in this research. Therefore, together with AUC, it is necessary to use Recall, which verifies the hit rate of true positives and Specificity, which verifies the rate of true negatives. It is worth noting that for the medical field, values above 80% for these metrics are considered exciting.

The analysis shown in Figure 2, considering an overview of all results, shows that LMPD stood out as the second best algorithm, very close to MICE, considered the state of the art in missing data imputation. This result is very interesting considering that LPMD obtained a better processing time, up to 5.2 times shorter than MICE. In addition, the tested datasets have up to 13.5% missing data. New research will need to be carried out with higher missing data values, considering real datasets, since theory shows that LPMD tends to work better for higher MD [20].

Regarding the MD mechanism analysis, overall, the four datasets analyzed showed a predominance of the MAR mechanism, as indicated by the tests performed ($p < 0.05$). Only the "Urine Leukocytes" variable, from the HCAI-INFECTION dataset, showed evidence consistent with an MNAR mechanism. Future research may use the MD mechanism analysis methodology to evaluate the performance of different imputers for each mechanism type.

VII. Conclusions and future work

This study addresses healthcare data imputation by evaluating LPMD and its variant LPMD2, semi-supervised Label Propagation algorithms that treat missing values as unlabeled instances. Evaluated on real-world COVID-19 datasets, LPMD achieved classification performance competitive with top-performing benchmarks at low execution time, whereas LPMD2 showed limited predictive utility. LPMD offers an efficient, viable solution for clinical data imputation, though broader validation remains recommended. For future work, we plan to evaluate LPMD on larger and more diverse healthcare datasets to further assess its scalability and predictive performance. Additionally, we intend to explore alternative graph construction kernels and edge weight thresholding strategies. Finally, benchmarking LPMD against advanced imputers such as MissForest, and emerging Large Language Model (LLM)-based imputation techniques, represents a promising direction for future research.

Disclosure of Generative AI Usage

No generative AI system was used to generate experimental results, fabricate data, or perform the scientific evalua-

tion presented in this work. During the preparation of this manuscript, generative AI tools were used exclusively to assist with language refinement, grammar correction, and text clarity improvement.

***Abstract*—The detection of hallucinations in medical language models is a critical task for the safe use of artificial intelligence-based systems in healthcare. However, it is not yet clear to what extent lightweight methods, such as embedding similarity, natural language inference, and signal fusion, are capable of distinguishing factual statements from hallucinated ones in medical benchmarks. In this work, we investigate the limits of these methods on MedHal, an evaluation dataset aimed at detecting factual hallucinations in medicine. Furthermore, we enriched the dataset with medical specialty labels using a classifier trained on MedMCQA, enabling a stratified analysis by clinical domain. We evaluated approaches based on embeddings, textual inference models, hybrid methods, and an LLM-as-a-judge using Qwen2.5-7B. The results show that similarity-based methods remain close to chance, while textual inference models present modest gains. The LLM-as-a-judge achieved the best overall performance, with an AUC of 0.823, but still presented relevant limitations, especially in false negatives. The lexical analysis revealed that hallucinated statements can be closer to the source than factual statements, due to the minimal substitution mechanism present in the benchmark. In addition, the specialty analysis showed significant performance variation across medical areas. These findings indicate that medical hallucination detection must be treated as a factual verification task, rather than merely as a semantic similarity problem.**

***Index Terms*—medical hallucination detection, large language models, MedHal, lexical bias, clinical specialties, factual verification**

I. Introduction

Large language models have demonstrated increasingly impressive performance in biomedical and clinical tasks, including medical question answering, scientific text summarization, and support for health information interpretation. Recent studies indicate that these models are capable of encoding clinical knowledge and achieving competitive results on medical benchmarks, but they also emphasize that healthcare applications require rigorous evaluation of factuality, reasoning, potential harm, and bias [1]. In this context, the generation of incorrect, inaccurate, or unsupported information represents a critical problem. This phenomenon, known as hallucination, has been widely discussed in the natural language generation literature and remains one of the main challenges for the reliable use of LLMs [2].

The automatic detection of medical hallucinations thus emerges as an important step to increase the reliability of systems based on language models. However, this task is not limited to verifying whether two sentences are semantically similar. Previous work on factuality and faithfulness in text generation shows that an output can appear fluent and close to the reference text, but still contain unsupported or factually incorrect information [3]. Similarly, recent factuality evaluations argue that verification must consider whether specific claims are supported by reliable sources, and not just whether there is global textual proximity between generation and reference [4].

The MedHal benchmark was proposed to evaluate factual hallucination detection in the medical domain [5]. The dataset gathers statements derived from different types of biomedical sources, including scientific articles summarized from SumPubMed [6], medical multiple-choice questions from MedMCQA [7] and MedQA [8], as well as augmented clinical notes from the ACM dataset [9]. Other medical hallucination benchmarks have also been proposed, such as Med-HALT [18], which focuses on reasoning and memory tests derived from medical examinations, whereas MedHal is centered on factual verification through minimal substitution. This diversity makes MedHal a relevant resource for evaluating detection methods in scenarios with different textual registers, formality levels, and types of medical knowledge.

Despite its relevance, MedHal also presents important methodological challenges. In particular, some hallucinations are constructed by minimal substitutions of critical terms, preserving the original sentence's structure and altering only a single factual element. This process can make the hallucinated statement lexically very close to the source, while a factual statement may appear as a paraphrase with less word overlap. Furthermore, the dataset does not directly provide the medical specialty associated with each instance, which limits stratified analyses by clinical domain.

In this work, we investigate the limits of lightweight meth-

ods for hallucination detection in medical language models, focusing on three main questions: (i) to what extent methods based on similarity, textual inference, and signal combination can differentiate factual statements from hallucinated statements in MedHal; (ii) how the benchmark's lexical bias affects the performance of these methods; and (iii) whether the detection difficulty varies across different medical specialties. To enable this stratified analysis, we enriched MedHal with medical specialty labels using a classifier trained on MedMCQA, which contains questions annotated by medical disciplines [7].

The results show a clear performance gradient. Embedding-based methods remain close to chance, textual inference models present modest gains, and the use of an LLM as a judge achieves substantially superior performance. Still, even the best evaluated method presents relevant limitations, especially in terms of false negatives, that is, cases where a hallucination is classified as factual. Moreover, the specialty analysis reveals that detection does not have uniform difficulty across medical areas, being more favorable in domains of more canonical knowledge and more challenging in clinical and surgical areas.

The main contributions of this work are: (i) a comparative evaluation of lightweight methods and an LLM-as-a-judge for hallucination detection on MedHal; (ii) the identification and analysis of a lexical bias that favors the textual proximity of hallucinated statements to the source; (iii) the enrichment of the dataset with medical specialties for stratified analysis; and (iv) a discussion on the risks of interpreting aggregated metrics as sufficient evidence of safety in medical scenarios. With this, the study reinforces that medical hallucination detection must be treated as a factual verification problem, and not merely as a semantic similarity task.

II. Related Work

A. Hallucination and Factuality in Text Generation

Hallucination in language models, that is, the generation of fluent but incorrect or unsupported content, is recognized as one of the main obstacles to the reliable use of LLMs [2]. Works on faithfulness and factuality in abstractive summarization have shown early on that an output can be textually close to the reference and still be factually incorrect [3], which motivated metrics that evaluate the support of specific claims by reliable sources, rather than mere global textual proximity [4]. This distinction between textual proximity and factual support is central to the problem investigated in this work.

B. Hallucination Detection Methods

Approaches for automatic hallucination detection can be organized into families with distinct costs and assumptions. Methods based on embeddings and semantic similarity measure the proximity between the generation and the source in a vector space, assuming that factual content would be closer to the evidence [10], [11]. Methods based on natural language inference (NLI) treat verification as a textual entailment problem, classifying whether the source entails, contradicts, or is neutral towards the statement [12]; this formulation better captures negation and contradiction than pure similarity. More recently, the LLM-as-a-judge paradigm, in which a language model directly evaluates factual consistency, has been employed in verification tasks [13]. This paradigm, however, is a target of criticism regarding biases (position, verbosity, and self-preference biases) and limitations in reasoning and reproducibility, especially when applied to subjective quality evaluation [13], [19]. In our work, we employ the judge in a formulation that reduces some of these concerns: a binary classification verifiable against the benchmark's ground truth, with an open model and deterministic generation. However, because it is an LLM acting as an evaluator, biases cannot be entirely ruled out. We comparatively evaluate these three families, in addition to a hybrid combination, under the same protocol, which allows us to situate their relative performances in a controlled manner.

C. Evaluation of LLMs and Hallucination in the Medical Domain

In the medical domain, it has been shown that LLMs encode relevant clinical knowledge and achieve competitive results on benchmarks, but healthcare applications require rigorous evaluation of factuality, reasoning, and risk [1]. Several datasets have been proposed to evaluate medical knowledge and reasoning through multiple-choice questions, such as MedMCQA [7] and MedQA [8], but such resources were not designed for factual hallucination detection. MedHal [5] fills this gap by gathering statements from heterogeneous biomedical sources (scientific articles [6], multiple-choice questions [7], [8], and augmented clinical notes [9]) labeled for veracity. However, MedHal does not provide the medical specialty of each instance, which prevents stratified analyses by clinical domain, and its hallucination generation mechanism via minimal substitution introduces specific characteristics that motivate a dedicated analysis. Our work addresses these two points: we enrich MedHal with specialty labels, enabling stratified analysis, and we investigate the effect of the benchmark's lexical bias on detection methods.

III. Materials and Methods

A. Dataset

We used MedHal [5], a factual hallucination detection *benchmark* in medicine. Each instance consists of a medical statement (`question` field), a binary veracity label (`correct_answer`: factual or hallucinated), and a reference textual explanation (`explanation`) that justifies the label based on the source context. The statements are derived from four distinct sources, scientific articles (SumPubMed [6]), medical multiple-choice questions (MedMCQA [7] and MedQA [8]), and clinical reports (ACM [9]), providing register and domain diversity. Hallucinations in MedHal are predominantly generated by minimal substitution of entities or values: the hallucinated statement preserves the structure of the correct sentence, altering only a factually critical term (e.g., substituting "apical periodontitis" with "cervical resorption").

It should be noted that, in the evaluated subset, the explicit context field was mostly empty; therefore, we adopted the `explanation` field as the ground truth anchor for the detection methods, as it provides the textual justification associated with the factual label. This choice was necessary to enable a consistent evaluation across all instances; however, we acknowledge that using explanations instead of the original source context may influence the measured performance, since the available evidence is derived from the benchmark annotation process rather than the complete source documents.

B. Medical Specialty Enrichment

MedHal does not provide the medical specialty of the statements, which is relevant information for analyzing hallucination detection stratified by clinical domain. To bridge this gap, we trained a specialty classifier and applied it to the dataset.

Training data. We used MedMCQA [7], which contains 194 thousand questions annotated with 21 medical disciplines (`subject_name` field), used directly as the classification targets. A normalization function (conversion to lowercase, removal of accents, parentheses, and acronyms) handled spelling variations across the dataset (e.g., "Anesthesia" vs. "Anaesthesia").

Model and training. We adopted PubMedBERT [14], specifically the `abstract-fulltext` checkpoint, pretrained on PubMed *abstracts* and full texts, with a linear classification layer ($768 \rightarrow 21$) on top of `AutoModelForSequenceClassification`, from the *Transformers* library [15]. The classifier's input is exclusively the question text, without alternatives or explanations—a deliberate decision because, when applied to MedHal, only the statement is available; training with more context than what will be present at inference would artificially inflate accuracy. To mitigate the imbalance between disciplines, we applied *undersampling* with a maximum of 15,000 examples per class. The training used 3 epochs, a *batch size* of 32 (train) and 64 (evaluation), a learning rate of 2×10^{-5}, a *warmup ratio* of 0.06, a *weight decay* of 0.01, mixed precision (fp16) [16], and a fixed seed of 42. The best *checkpoint* was selected by weighted F1 on the official MedMCQA validation set.

Application and confidence filter. The classifier was applied to MedHal statements, assigning each instance a predicted specialty and a confidence score. For the specialty-stratified analysis, we retained only predictions with confidence ≥ 0.80 to reduce noise in specialty attribution. After filtering, the enriched dataset contained 9,275 statements. Areas with an insufficient number of instances after the filter (e.g., *Skin*, with only two examples) were excluded from the specialty-stratified analysis.

This confidence threshold was applied exclusively to the specialty attribution step and was not used to modify the hallucination detection task itself. However, we acknowledge that this filtering strategy may introduce selection bias in specialty-level results, as instances with uncertain specialty predictions are excluded from the stratified analysis.

C. Detection Methods

We evaluated three main families of methods and one hybrid combination strategy for the task of classifying a statement as factual or hallucinated, given the reference source. The neural models were implemented using the *Transformers* library [15].

Embedding similarity. We calculated the cosine similarity between the embeddings of the statement and the source. We tested two models: multilingual-e5-large [10] (with the recommended `query:`/`passage:` prefixes) and BGE-large-en-v1.5 [11]. The underlying hypothesis is that factual statements would be semantically closer to the source than hallucinated ones.

Natural language inference (NLI). We employed cross-encoder NLI models that receive the source as a premise and the statement as a hypothesis, producing probabilities of entailment, contradiction, and neutrality. The models are based on the DeBERTa-v3 architecture [12]. We adopted the difference $P(\text{entailment}) - P(\text{contradiction})$ as the factuality score and tested the base and large versions.

LLM-as-a-judge. We used Qwen2.5-7B-Instruct (`Qwen/Qwen2.5-7B-Instruct`) [17], loaded with 4-bit NF4 quantization using the BitsAndBytes library, as a factual consistency judge. The model receives the source and the statement through a structured medical fact-checking prompt and returns, in strict JSON format, a verdict (FACTUAL or HALLUCINATION) and a confidence degree (0–100). The generation is deterministic (`do_sample=False`), ensuring reproducibility. To obtain a continuous score suitable for AUC computation, we mapped the verdict and confidence onto a factuality probability in $[0, 1]$: a FACTUAL verdict with confidence c (normalized to $[0, 1]$) yields a score of $0.5+0.5c$, while a HALLUCINATION verdict yields $0.5 - 0.5c$. Thus, a high-confidence FACTUAL verdict approaches 1, a high-confidence HALLUCINATION verdict approaches 0, and low-confidence verdicts of either kind remain near 0.5. Unlike the use of LLM-as-a-judge for subjective quality evaluation—which is a known target of criticism regarding bias and reproducibility—our use is a binary classification verifiable against the benchmark's ground truth, with an open model and deterministic output.

Hybrid methods. We combined embedding similarity and NLI signals through logistic regression. The input features consisted of the similarity scores from multilingual-e5-large and BGE-large, together with the factuality scores from DeBERTa-v3-base and DeBERTa-v3-large. The classifier was evaluated using 5-fold cross-validation, with probability outputs used as factuality scores for AUC computation.

D. Evaluation Protocol

The primary metric is the area under the ROC curve (AUC), treating detection as a ranking problem between the factual and hallucinated classes. Confidence intervals were estimated using non-parametric bootstrap with 2,000 resamples and a fixed random seed of 42. The 95% confidence intervals were obtained from the 2.5th and 97.5th percentiles of the bootstrap distribution. For all scoring-based methods, scores

were oriented as factuality scores, where higher values indicate stronger evidence of factual consistency. For the LLM-as-a-judge, the continuous factuality score described above was used for AUC, while the discrete verdict was used for accuracy, precision, recall, and F1-score, as well as the confusion matrix. All methods were evaluated on the same set of 9,275 statements and the same ground truth, ensuring direct comparability. Additionally, we analyzed the judge's performance stratified by medical specialty and investigated the lexical overlap (Jaccard index) between the statement and the source, separated by class, to characterize the mechanism underlying the methods' performance.

IV. Results

A. Performance of Detection Methods

Table I presents the AUC of all evaluated methods on the 9,275 statements, with 95% confidence intervals estimated via bootstrap. A clear performance gradient is observed. The methods based on embedding similarity lie at the chance level: e5-large reaches an AUC of 0.504 (95% CI: 0.492–0.515), with the interval including 0.5, being statistically indistinguishable from a random classifier; BGE-large shows a marginally superior performance (0.517; 95% CI: 0.504–0.529), still very close to chance.

The NLI methods outperform pure similarity. The nli-deberta-v3-base achieves an AUC of 0.560 (95% CI: 0.548–0.571), and the large version raises the performance to 0.636 (95% CI: 0.625–0.647). The signal fusion via logistic regression (hybrid) reaches 0.646 (95% CI: 0.635–0.656), the best result among the lightweight methods—still, a modest ceiling.

The LLM-as-a-judge (Qwen2.5-7B) substantially outperforms all lightweight methods, with an AUC of 0.823 (95% CI: 0.815–0.830). The gain of approximately 18 percentage points in AUC over the best lightweight method is large and statistically unequivocal, since the confidence intervals do not overlap. Fig. 1 illustrates this gradient, highlighting the separation between similarity/entailment-based methods and the reasoning-based judge.

TABLE I
HALLUCINATION DETECTION PERFORMANCE (AUC) ON 9,275 MEDHAL STATEMENTS, WITH 95% CONFIDENCE INTERVALS ESTIMATED VIA BOOTSTRAP. METHODS ARE ORDERED BY INCREASING AUC.

Method	Type	AUC (95% CI)
Embedding e5-large	Similarity	0.504 (0.492–0.515)
Embedding BGE-large	Similarity	0.517 (0.504–0.529)
NLI DeBERTa-v3-base	NLI	0.560 (0.548–0.571)
NLI DeBERTa-v3-large	NLI	0.636 (0.625–0.647)
Hybrid (all)	Fusion	0.646 (0.635–0.656)
Judge Qwen2.5-7B	**LLM**	**0.823 (0.815–0.830)**

B. The Lexical Bias Mechanism

To understand why similarity methods fail, we investigated the lexical overlap (word Jaccard index) between each statement and its reference source, separated by class. The result is counterintuitive and reveals a structural bias in the benchmark.

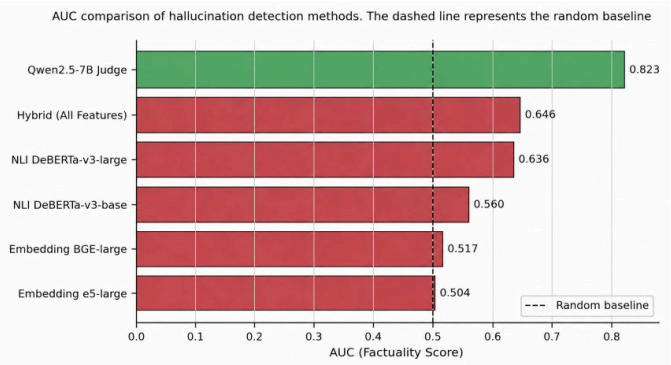

Fig. 1. Gradient of performance across different hallucination detection methods.

In short statements (up to 40 words, 8,102 instances), hallucinated statements present an average lexical overlap of 0.552 with the source, compared to only 0.137 for factual ones—the hallucinated version is about four times more lexically similar to the source than the correct one. The same pattern holds for long statements (over 40 words, 1,173 instances): 0.202 against 0.019, a ratio of approximately ten times. Table II summarizes these values, and Fig. 2 presents the Jaccard distributions by class.

This finding explains the failure of embedding similarity. Since the MedHal hallucinations are generated by minimal substitution of a critical term, the hallucinated statement preserves almost all the vocabulary of the original sentence and maintains high proximity to the source, whereas the factual statement is often a rewording with distinct vocabulary. Similarity-based measures, by rewarding superficial overlap, attribute greater proximity precisely to the hallucinations, neutralizing their discriminative power.

TABLE II
MEAN LEXICAL OVERLAP (JACCARD INDEX) BETWEEN STATEMENT AND SOURCE, BY CLASS AND BY STATEMENT LENGTH. THE HALLUCINATED CLASS IS CONSISTENTLY MORE OVERLAPPED WITH THE SOURCE.

Regime	N	Factual	Hallucinated
Short ($\leq$ 40 words)	8,102	0.137	0.552
Long ($>$ 40 words)	1,173	0.019	0.202

C. Specialty Analysis

Table III reports the performance of the LLM-as-a-judge stratified by the 21 medical specialties. The judge exhibits strong variation across domains, with the highest AUC in basic science areas—Biochemistry (0.930), Microbiology (0.912), and Physiology (0.878)—and the lowest in clinical and surgical areas—Orthopedics (0.696), Surgery (0.738), and Anesthesia (0.754).

This pattern is consistent with the nature of the statements in each domain. Basic science statements tend to express canonical and verifiable facts, which are well represented in the model's pre-training knowledge, whereas clinical statements frequently depend on case context and judgment, making

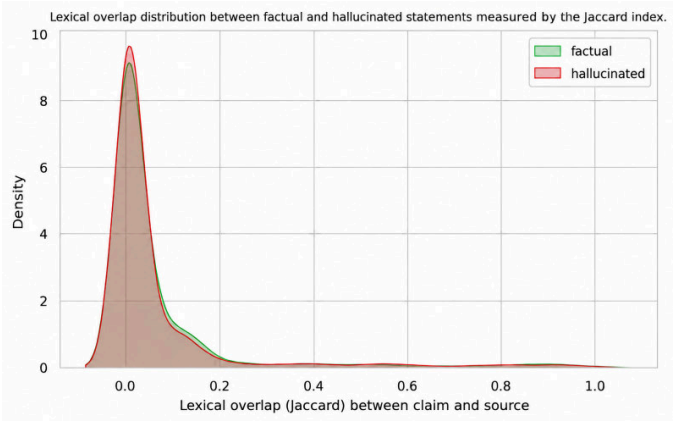

Fig. 2. Jaccard index distributions by class, demonstrating higher lexical overlap for hallucinated statements.

verification more difficult. Specialties with an insufficient number of instances after the confidence filter were excluded from this analysis.

TABLE III
PERFORMANCE OF THE LLM-AS-A-JUDGE (QWEN2.5-7B) BY MEDICAL SPECIALTY, ORDERED BY DECREASING AUC. SPECIALTIES WITH FEWER THAN 20 INSTANCES WERE OMITTED.

Specialty	N	AUC	F1
Biochemistry	500	0.930	0.900
Microbiology	500	0.912	0.883
Physiology	500	0.878	0.828
Pathology	500	0.855	0.658
Pharmacology	500	0.853	0.810
Otorhinolaryngology	500	0.845	0.792
Prev. and Social Medicine	500	0.843	0.788
Forensic Medicine	500	0.838	0.763
Ophthalmology	500	0.834	0.710
Gynecology and Obstetrics	500	0.816	0.522
Psychiatry	500	0.814	0.569
Anatomy	500	0.810	0.784
Radiology	500	0.809	0.701
Pediatrics	500	0.782	0.614
Dentistry	500	0.770	0.418
Medicine	500	0.763	0.287
Anesthesia	500	0.754	0.485
Surgery	500	0.738	0.440
Orthopedics	273	0.696	0.447

D. Error Analysis

Although the LLM-as-a-judge achieves the highest AUC, its confusion matrix (Table IV) reveals a conservative behavior. With a precision of 0.903 and a recall of 0.550 (F1-score of 0.683), the judge is highly reliable when it declares a statement as a hallucination, but it fails to detect a substantial portion of the hallucinated cases: out of the 4,489 hallucinated statements, only 2,630 were correctly identified, while 2,156 were classified as factual. Out of the 4,786 factual statements, 4,205 were correctly recognized.

This imbalance carries critical weight in the medical context, where the most dangerous error is the false negative—an undetected hallucination presented as reliable. Even though the judge represents a significant advance over lightweight methods, its recall level indicates that robust medical hallucination detection remains an open problem. Furthermore, it is observed that in some specialties the F1-score drops sharply even with a high AUC (Medicine: AUC 0.763, F1 0.287), reflecting the judge's tendency to rarely assign the hallucination label in these domains and evidencing the sensitivity of the results to the decision threshold.

TABLE IV
CONFUSION MATRIX OF THE LLM-AS-A-JUDGE (QWEN2.5-7B). ROWS: ACTUAL CLASS; COLUMNS: PREDICTION.

	Pred. Factual	Pred. Hallucinated
Actual Factual	4,205	284
Actual Hallucinated	2,156	2,630

V. DISCUSSION

The results outline a clear gradient: embedding similarity operates close to chance level, entailment via NLI offers a modest gain, and the evaluated LLM-as-a-judge approach achieves substantially superior performance. This ordering suggests that medical hallucination detection is not, in essence, a problem of semantic proximity, but of factual verification—a task that requires evaluating the relationship between statements and evidence rather than merely measuring textual similarity. Lightweight methods showed limited effectiveness for hallucination detection under the evaluated MedHal setting.

The most relevant finding of this work is the lexical bias that characterizes MedHal. Because they are generated by minimal substitution, the hallucinated statements often preserve a large portion of the vocabulary of the source sentence, remaining lexically closer to the source than the factual statements themselves—which are frequently reworded. This phenomenon inverts the premise upon which similarity methods rely and explains their chance-level performance. However, an interpretive caveat is necessary: it is unclear whether this bias is an artifact of the benchmark construction process or if it reflects a genuine property of substitution hallucinations, which indeed tend to be textually close to the correct statement. In either case, the practical implication is the same—similarity methods should not be employed in isolation to detect this type of hallucination, and detection benchmarks should report the lexical overlap between classes as a diagnostic of difficulty.

Even though the LLM-as-a-judge represents a significant advance, its asymmetry between high precision and low recall deserves particular attention in the medical domain. A detector that still presents a substantial false-negative rate, even if it rarely raises false alarms, is of limited utility in clinical applications, where the false negative—incorrect information presented as reliable—constitutes the most consequential error. This conservative behavior, coupled with the sensitivity to the decision threshold evidenced by the drop in F1-score in some specialties, indicates that the aggregated AUC performance, although favorable, does not fully capture the method's

suitability for practical use. Future work could calibrate the decision threshold to favor recall, even at the expense of precision, in line with the application's risk profile.

The stratification by specialty reveals that the detection difficulty is not uniform. The superior performance in basic sciences and inferior performance in clinical and surgical areas suggest that the verifiability of a statement depends on how canonical and decontextualized the knowledge it mobilizes is. Biochemistry or microbiology statements may correspond more frequently to canonical facts, while clinical medicine, surgery, or anesthesia statements may depend more heavily on contextual information, judgment, and exceptions. This result has methodological value: hallucination detection evaluations that report only aggregated metrics may mask weaknesses concentrated precisely in the specialties of greatest clinical complexity, and the specialty dimension—made possible here by the dataset enrichment—proves to be an informative axis of analysis.

This study presents limitations that bound the scope of its conclusions. First, the evaluation of the LLM-as-a-judge paradigm was based on a single model; although open and deterministic, it does not represent the diversity of possible behaviors among different LLMs, and known judge biases such as position, verbosity, and self-preference may still affect model-based evaluation [13], [19]. An ensemble of judges could produce more robust estimates. Second, since the explicit context field of the used subset was mostly empty, the explanation field was adopted as the reference evidence; this choice may influence methods that rely on the source. Third, the specialty labeling was obtained by an automatic classifier and filtered by confidence, so residual attribution errors cannot be entirely ruled out. Finally, the conclusions are limited to MedHal and its specific hallucination generation mechanism; benchmarks built by other processes may exhibit distinct biases.

VI. Conclusion

This work investigated the limits of lightweight methods for hallucination detection in language models applied to the medical domain, using the MedHal benchmark as an experimental basis [5]. The analysis compared approaches based on embedding similarity, natural language inference, signal combination, and a language model acting as a judge. The results indicate that medical hallucination detection cannot be treated merely as a problem of semantic proximity between a statement and its reference source.

Embedding-based methods showed near-chance performance, while textual inference models obtained only modest gains. The LLM-as-a-judge achieved substantially superior performance, suggesting that factual verification requires contextual evaluation of the relationship between evidence and statement. Still, even this method presented important limitations, especially regarding the occurrence of false negatives, where hallucinated statements were classified as factual. In a medical context, this type of error is particularly critical, as it can allow incorrect information to be interpreted as reliable.

One of the main findings of the study was the identification of a lexical bias in MedHal. Because many hallucinations are produced by minimal substitutions of critical terms, they preserve much of the original source's structure and vocabulary. This causes hallucinated statements to potentially be lexically closer to the reference than factual statements rewritten as paraphrases. This behavior weakens the premise of similarity-based methods and highlights the importance of evaluating not only the aggregated performance of detectors but also the mechanisms that explain their successes and errors.

The stratified analysis by medical specialty also showed that the detection difficulty is not uniform across clinical domains. Areas associated with more canonical and straightforward knowledge, such as basic sciences, showed better performance, while clinical and surgical specialties revealed greater difficulty. This result suggests that aggregated evaluations may hide relevant weaknesses in areas of greater contextual complexity, reinforcing the need for domain-specific analyses when evaluating healthcare hallucination detectors.

As limitations, this study evaluated only a single model in the LLM-as-a-judge configuration, used automatically obtained specialty labels, and focused on the specific characteristics of MedHal. Furthermore, the lack of explicit context in part of the dataset led to the use of the textual explanation as a reference anchor. Future work should investigate multiple judges, threshold calibration aimed at reducing false negatives, and retrieval-augmented generation approaches that may improve source grounding and transparency in healthcare settings.

In summary, the results reinforce that medical hallucination detection must be understood as a factual verification task, rather than merely a textual similarity task. Lightweight methods can be useful as auxiliary signals, but they should not be employed in isolation in high-risk scenarios. These findings highlight considerations for the development of more reliable medical AI evaluation systems.

Acknowledgment

The authors used AI-assisted tools only to support paragraph rewriting without changing the original meaning, translation from Portuguese to English, and code generation or code refinement during the development of the experiments. The methodological design, experimental setup, data analysis, results, and scientific interpretations were independently defined and conducted by the authors. AI-assisted tools were not used to generate experimental results, alter data, fabricate references, or perform statistical analyses. All assisted text, translations, and code were reviewed, validated, and approved by the authors.

Abstract*—This study aimed to evaluate the feasibility of reconstructing the functioning score of adults after a Stroke using machine learning algorithms, utilizing variables of activities of daily living and social participation in a Latin American population study. It was a cross-sectional and analytical study based on secondary data from the III National Survey on Disability and Dependency (III ENDISC). The sample consisted of 409 adults who reported a history of stroke. The dependent variable was the continuous functioning measure "des_puntaje_adult". The data were divided into training (70%) and testing (30%) sets. Based on a selection using eight independent relevance methods, the 100 most important variables were retained. Eleven supervised regression algorithms were tested, representing linear, regularized, kernel-based, ensemble, boosting, generalized linear models, and deep neural network approaches. Performance was evaluated by the Coefficient of Determination (R^2), Root Mean Squared Error (RMSE), and Mean Absolute Error (MAE). The results demonstrate that non-linear algorithms based on gradient boosting showed superior performance. XGBoost obtained the best reconstruction capacity on the test set (R^2 = 0.9827, RMSE = 3.0755, and MAE = 2.3106), followed by LightGBM and Gradient Boosting. In contrast, linear models (Linear Regression, Ridge, and Lasso) and neural networks (MLP and DNN) presented unsatisfactory performance, with a negative R^2 on the test set. The difference between the training and testing errors indicated the presence of overfitting in the highest-performing models. It is concluded that the results represent an initial proof of concept regarding the technical capacity of tree-based algorithms to reconstruct the mathematical structure of the functioning score from its constituent components. However, due to overfitting, small sample size, and cross-sectional design, the model does not have a direct clinical prediction purpose, depending on external validation and longitudinal data in future studies.

***Index Terms*—Public Health, Stroke, Machine Learning, XGBoost**

I. Introduction

Historically, mortality and morbidity indices have been used as indicators to measure individuals' health. However, population aging, coupled with the increasing burden of non-communicable diseases (NCDs), such as stroke, makes the epidemiological context more complex by contributing to the global increase in the number of years of life lost due to premature death and years lived with disability [1]. Consequently, assessing only mortality and morbidity is no longer sufficient to describe a population's health status [2]. In this scenario, the assessment of functioning acts as a complementary indicator to mortality and morbidity. This is a crucial measure for investigating the use of body functions and structures, as well as the individual's performance in daily activities and social participation, thus advancing the production of health information beyond mere morbidity and mortality outcomes [3].

Globally, it is estimated that 2.4 billion people require interventions aimed at functioning [4]. Such data drive territorial research on disability and health. The III Estudio Nacional de la Discapacidad (III ENDISC) exemplifies this by outlining the disability profile of the Chilean population.

Therefore, traditional statistical tools may lack the necessary precision to capture the non-linear interaction of variables and, consequently, may be insufficient for predictive modeling. Furthermore, Artificial Intelligence (AI), based analyses for coding information about functioning have demonstrated efficiency in optimizing human resources, as well as in supporting clinical decision-making and Public Health management [5]. It should also be noted that machine learning models incorporating Social Determinants of Health (SDOH) show superior performance to those developed solely with clinical characteristics, since functioning results from the interaction of environmental, social, and cultural factors that transcend the underlying pathology, in this case, stroke [5], [6].

In light of this, the present study aimed to evaluate, in an exploratory manner, the feasibility of reconstructing the functioning score of adults after a stroke using machine learning, utilizing variables related to activities of daily living and social participation available in a Latin American population survey.

To the Coordination for the Improvement of Higher Education Personnel (CAPES) for granting the master's scholarship.

It is, therefore, an investigation characterized as a methodological proof of concept regarding how well non-linear algorithms can reconstruct a functioning measure from its own constituent components, and to what extent social determinants of health (SDOH) contribute to this reconstruction in Latin American populations, such as that of Chile.

II. Method

A. Design and data source

This is a cross-sectional and analytical study developed using secondary data from the III ENDISC, a survey conducted in Chile in 2022 by the Servicio Nacional de la Discapacidad (SENADIS) regarding disability in the national population [7]. The survey utilized probabilistic sampling, stratified to represent urban and rural residents, and based its data collection instruments on the International Classification of Functioning, Disability and Health (ICF) to assess individuals from a biopsychosocial perspective.

B. Population and outcome variable

The population consisted of adults aged 18 years or older who reported having had a stroke. Only data from individuals who presented the minimum information necessary for the reconstruction of the continuous risk index for functioning were included; thus, the responses of 409 individuals were evaluated. The dependent variable selected for this study was *"des_puntaje_adult"*, which addresses the performance in carrying out activities in the individuals' usual environment. *"des_puntaje_adult"* was calculated in the III ENDISC from the questions recorded in module D (Performance - Desempeño), using the Rasch Partial Credit Model, which allows for the construction of a continuous scale aligned with the principles of the ICF. To prevent data leakage, the variables derived from the assessment of functioning *(cap_puntaje_adulto, cap_nivel_adulto, des_nivel_adulto, disc_grado_adulto, disc_adulto, depen_grado_adulto, depen_adulto)* were removed from the predictive space.

C. Feature selection and preprocessing

Initially, columns with numerical variables concerning mobility, self-care, domestic activities, interpersonal interactions, health conditions, caregiver availability, assistive devices and support technology, educational and labor participation, and demographic variables were selected. Columns with categorical variables, mixed data, or entirely null columns were excluded, and the remaining missing values were imputed by the mean estimated exclusively on the training set. Next, the selection was adjusted solely on the training set, after partitioning into 70% training and 30% testing (test_size=0.3, random_state=42). Subsequently, eight independent relevance assessment methods were applied, combining filter, embedded, and recursive elimination approaches, which were: Pearson and Spearman correlation (absolute value as ranking criterion), mutual information (mutual_info_regression), univariate F-statistic (f_regression), random forest importance, gradient boosting importance (100 estimators, max_depth=5), absolute coefficients of a LassoCV with 5-fold cross-validation(CV), and recursive feature elimination (RFE) with a simplified random forest (25 estimators, maximum depth 6) as the base estimator. The eight scores were combined by simple arithmetic mean and normalized to obtain a percentage score (0 to 100%), which was ordered in descending order, highlighting the 100 variables with the highest score to compose the final prediction. Thus, the database was restricted to the 100 selected variables plus the target variable, totaling 101 numerical columns and 409 observations. Preprocessing was integrated into the pipeline of each model and consisted of mean imputation, justified by the modular structure of the questionnaire and the assumption of missing approximately at random, followed by z-score standardization. Measures of means, standard deviations, and imputation parameters were estimated solely on the training set for subsequent application to the test set, preventing data leakage. Standardization was applied uniformly to all models, ensuring comparability of the training conditions.

D. Tested algorithms and model evaluation

To compare different predictive paradigms, a diverse set of eleven supervised regression algorithms representing linear, regularized linear, kernel-based, ensemble, boosting, neural networks, and generalized linear model approaches were evaluated. Specifically, the evaluated models included Linear Regression (OLS), Ridge, Lasso, Support Vector Regression (SVR), Random Forest, Gradient Boosting, XGBoost, LightGBM, Multilayer Perceptron (MLP, via MLPRegressor, with early stopping and up to 1,000 epochs), fully connected feed-forward deep neural network (DNN) implemented in TensorFlow/Keras, and GLM with Gamma distribution and logarithmic link. The network architecture included an input layer followed by three dense hidden layers with 128, 64, and 32 neurons, respectively, using Rectified Linear Unit (ReLU) activation functions. Dropout regularization (0.30 and 0.20) was applied after the first two hidden layers to reduce overfitting, and a single linear output neuron was used for continuous regression. Model optimization employed the Adam optimizer with a learning rate of 0.001 and Mean Squared Error (MSE) as the loss function. Training was performed for up to 200 epochs with a batch size of 32, using 20% of the training data for validation and an Early Stopping strategy (patience = 20) to restore the best-performing weights. The hyperparameters of each of the eleven models were individually optimized using exhaustive grid search with 5-fold cross-validation with shuffling (KFold(n_splits=5, shuffle=True, random_state=42)), fitting each pipeline $k \times C$ times, with $k = 5$ folds and C combinations per model. Model performance was evaluated using the Root Mean Squared Error (RMSE), Mean Absolute Error (MAE), and the coefficient of determination (R^2). All three metrics were calculated on both the training and test sets. The R^2 indicates the proportion of the dependent variable's variance explained by the model, ranging from 0 to 1 (and can be negative when the model generalizes worse than a mean-based reference predictor), with values closer to 1 indicating

a greater capacity for reconstructing the target variable. Final model selection was primarily based on the coefficient of determination (R^2) obtained on the test set, prioritizing generalization capacity within the reconstruction task itself over performance on the training set. Subsequently, we considered the RMSE and MAE of the test set, as well as the difference between the training and testing metrics as an indicator of overfitting.

E. Ethical Aspects

The study exclusively used public and anonymized microdata from the III ENDISC, made available by SENADIS without individual identification, with no primary collection or intervention involving human beings.

III. Results

The set of 100 variables intrinsically related to functioning included questions about the performance of activities of daily living and social participation. In this group, the ten most relevant variables refer to the level of difficulty or how problematic it has been for the individual to perform certain tasks, which are: 1ª. Maintaining sufficient energy (mean score 0.68); 2ª. Taking care of one's own health (mean score 0.61); 3ª. Getting to desired places (mean score 0.60); 4ª. Remembering important things to do (mean score 0.60); 5ª. Walking 10 blocks or one kilometer (mean score 0.55); 6ª. Using the toilet (mean score 0.53); 7ª. Taking care of one's appearance or getting dressed (mean score 0.53); 8ª. Walking or climbing stairs (mean score 0.52); 9ª. Handling all necessary tasks (mean score 0.51); 10ª. Bathing or dressing (mean score 0.47). The complete list of variables is available in the Supplementary Material [8].

Algorithms based on non-linear methods—XGBoost, LightGBM, and Gradient Boosting—showed better results than the others, given that these methods capture the mathematical relationships between the functioning variables and the global score more accurately. Table I presents the comparative performance of the algorithms in the functioning score reconstruction task. XGBoost exhibited the best performance for reconstructing the functioning score, with R^2 = 0.982799 (RMSE = 3.075570 and MAE = 2.310636) on the test set; the model accounted for explaining 98.2% of the score variance. Conversely, the Linear Regression, Ridge, and Lasso models, as well as the MLP and Deep Neural Network, presented unsatisfactory performance. The performance of the Linear Regression, Ridge, and Lasso algorithms can be explained by the fact that functioning involves a complex network of interactions among variables, and these algorithms are more accurate for treating outcomes that occur in a direct or sequential manner. In turn, MLP and Deep Neural Network work better with more voluminous datasets. Furthermore, it is believed that the high difference in RMSE values between the training and test sets indicates data overfitting, which compromises the interpretation of the values.

Figure1 demonstrates the comparative RMSE performance among the evaluated algorithms. With the image, it is possible

TABLE I
RANKING OF ALGORITHMIC MODELS IN THE TEST SET

Model	Evaluation and validation strategy				
	RMSE*	RMSE**	R^{2}*	R^{2}**	MAE
XGBoost	0.486	3.075	0.999	0.982	2.310
LightGBM	1.087	3.379	0.997	0.979	2.489
Gradient Boosting	0.495	3.701	0.999	0.975	2.661
Random Forest	1.718	5.099	0.994	0.952	3.927
SVR	6.202	8.532	0.934	0.867	5.638
GLM (Gamma + Log)	17.768	13.401	0.896	0.673	7.852
Lasso Regression	5.892	20.596	0.940	0.228	7.353
Ridge Regression	5.687	25.118	0.944	-0.147	8.394
Linear Regression	4.848	28.451	0.959	-0.472	9.762
Deep Neural Network	6.051	32.182	0.937	-0.883	12.631
MLP Neural Network	5.250	48.166	0.952	-3.218	14.607

to visually confirm the superiority of tree-based models in reconstructing a score with non-linear interactions, since they present residual errors below five. On the other hand, the linear regression, Lasso regression, and Ridge regression algorithms, as well as MLP and Deep Neural Network, presented performance limitations for the presented data.

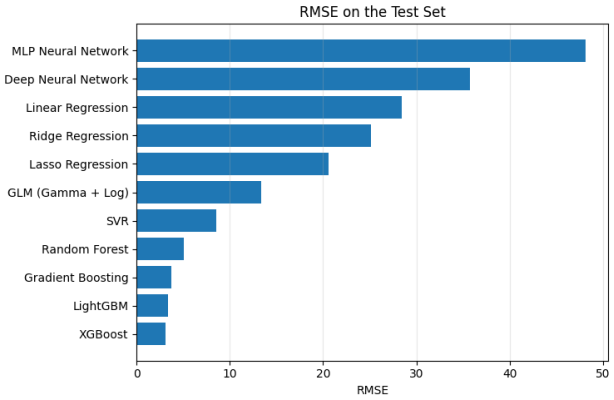

Fig. 1. Comparison of the Models on Test Set (Authors, 2026.)

Figure 2 illustrates the relationship between actual and predicted values by XGBoost, with the dispersion of points close to the reference line, indicating agreement between observed and reconstructed values. In turn, Figure 3 presents the residual plot of this model, which evidences the unsystematic pattern of distribution in relation to the predicted values, with a greater concentration of outliers between the values of -5 and +5. Thus, visual inspection may suggest homoscedasticity of the results; however, formal tests were not performed to confirm this observation.

In turn, in the histogram (Figure 4, a distribution of errors close to normality is observed; therefore, the model presents a low risk of systematic bias. However, it should be noted that the risk of overfitting, as well as the sample size, may also have interfered with the stability of the residuals presented in this graph.

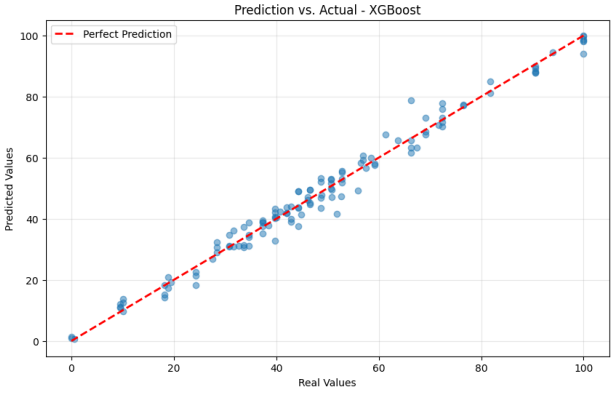

Fig. 2. Real Values x Prediction Values - XGBoost (Authors, 2026.)

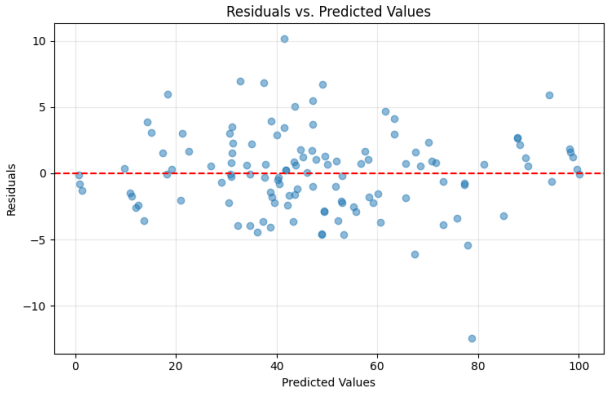

Fig. 3. Residual Plot (Authors, 2026.)

As previously mentioned, the XGBoost algorithm showed more promising results; thus, it was used for independent analyses by macro-regions (North, Central, South, and Metropolitan) and SHapley Additive exPlanations (SHAP) analysis. The algorithm's ability to capture the variance of the functioning score presented important discrepancies across the geographic strata. The model adjusted for the Central macro-region obtained the highest precision (R^2 = 0.97 on the test set; Mean Absolute Error [MAE] = 2.82). Similar predictive behavior was observed in the South macro-region (R^2 = 0.95; MAE = 3.79). In this scenario, the Metropolitan region recorded R^2= 0.92 and MAE = 4.96, while the North region had R^2= 0.91 and MAE = 5.68. The table II summarizes the metrics.

TABLE II
MODEL PERFORMANCE STRATIFIED BY MACRO-REGION

Macroregion	**Tests**			
	Test Set	**R^2**	**RMSE**	**MAE**
North	21	0.915	8.11	5.68
Center	51	0.97	3.79	2.82
South	45	0.95	4.99	3.79
Metropolitan	26	0.92	6.77	4.96

Source: Authors, 2026.

The mean absolute SHAP values were important for identifying which variables had the highest average impact on the models' predictions. The SHAP analysis shown in Table III, revealed both universal patterns and significant regional disparities in the determinants of functioning. The variable d7, which investigates the difficulty in performing daily tasks, stood out as the most important predictor in the four regions, exerting an exceptionally high impact in the Central region (mean SHAP = 6.28). Variables such as d6, d8, and d9, which respectively investigate problems with tiredness and lack of energy, memory, and carrying out household tasks, also demonstrated high overall predictive relevance.

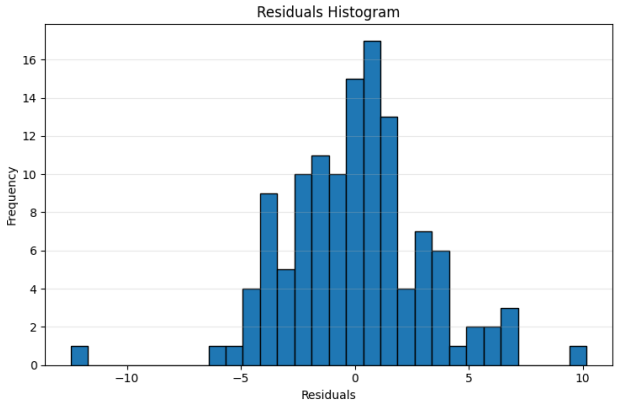

Fig. 4. Residual Distribution (Authors, 2026.)

In the Metropolitan region, the variable c4 (difficulty walking or climbing stairs) is of significant importance to the model, occupying the second position (mean SHAP = 3.12). Similarly, the model for the South region is influenced by the variable c14, which represents the difficulty in shopping or going to the doctor (mean SHAP = 2.67). The North region presented a unique profile, in which age emerged among the 10 features with the highest impact (mean SHAP = 1.19), which did not demonstrate the same level of importance in the other macro-regions.

These results suggest that, although the fundamental challenges related to functioning are shared geographically, specific regional contexts introduce distinct determinants that must be considered when carrying out localized interventions.

IV. DISCUSSION

This study aimed to evaluate the feasibility of reconstructing, through machine learning, the functioning score of adult stroke survivors using variables belonging to the same conceptual domain as the outcome. XGBoost demonstrated a good capacity for the mathematical reconstruction of the functioning score in this specific dataset (R^2 = 0.982 on the test set). However, the study demonstrates a proof of concept regarding the technical feasibility of the approach, but it does not validate it as a tool ready for predictive use in clinical contexts.The observed overfitting results from the disproportion between the sample size and the number of predictor variables (409 individuals compared to 100 predictor variables). This characteristic, as well as the cross-sectional nature of the data and

TABLE III
TOP 10 MOST IMPORTANT VARIABLES PER MACRO-REGION ACCORDING TO MEAN ABSOLUTE SHAP VALUES

Rank	Center	Metropolitan	North	South
1	d7 (6.28)	d7 (3.41)	d7 (4.29)	d7 (3.48)
2	d8 (2.96)	c4 (3.12)	d9 (3.61)	c14 (2.67)

the lack of external validation, constitute limitations for the study. In this scenario, the imbalance between individuals and variables may have compromised the training stage, since the algorithms are capable of memorizing response noise during training, thus distorting the testing phase [9].

Furthermore, the cross-sectional design prevents making inferences about patients' recovery over time; on the other hand, the absence of algorithm validation in an independent sample also limits the generalization of the results to other populations or contexts beyond the one studied.Measuring functioning after a stroke involves evaluating the complex interaction of SDOH, which encompasses clinical, socioeconomic, cultural, and environmental aspects. According to published studies, SDOH can improve the predictive capacity of algorithms [6], [10]. SDOH have also demonstrated central importance in the construction of predictive models for cognitive decline in the Mexican population; variables such as educational level, age, reading habits, maternal education, and frequency of social activity had the highest predictive importance [11].

Therefore, by aggregating clinical and social information, the III ENDISC survey becomes a rich material for assessing functioning in the Chilean population and also contributes to subsequent investigations of a predictive nature. Furthermore, it is necessary to use social, racial, and economic variables in a critical and ethical manner, because although the use of these data in computational analyses can support conclusions about inequalities, predictive analyses can also reinforce existing barriers if not properly contextualized [12].

The favorable performance of the XGBoost, LightGBM, and Gradient Boosting algorithms in this reconstruction work was likely influenced by the inclusion of SDOH-related variables. Similar results were observed in the study by Xiao et al. [10], in which there was the integration of serum globulin levels with ICF components to validate a predictive model of long-term functioning, through the development of a therapeutic decision support tool for rehabilitation plans. Moreover, models based on Gradient Boosting, such as LightGBM, are more suitable for handling tabular, smaller, and imbalanced datasets. On the other hand, Deep Learning algorithms, such as Deep Neural Networks and MLP Neural Networks, perform better with extremely large amounts of labeled data [13], [14].

Therefore, the good reconstruction performance presented in this study should be interpreted with caution due to the limitations of sample size and the risk of overfitting and they should not be used for clinical predictive purposes. The results primarily reflect the algorithm's potential to reconstruct dimensions related to functioning from variables within the same domain and do not generate a validation of predictive capacity for future and independent clinical outcomes. Although the present study does not build unprecedented predictions, its importance is reiterated in supporting future research involving the more advanced use of the tested algorithms for the development of health solutions and policies.Due to the results obtained with the algorithms applied to the Chilean population data and the observed efficiency of models in other population groups, it is recommended that future research gather clinical and sociodemographic data from the Brazilian population to test them with machine learning models aimed at predicting health situations and, if appropriate, the reconstruction of scores using Brazilian data. It is important to use Brazilian data, as algorithms trained on foreign populations, such as the Chilean one, may not produce the expected results when applied to different demographic groups. This recommendation is aligned with the assumptions established by Brazilian and international authorities, which strongly recommend the use of artificial intelligence tools, such as predictive analysis [15], [16].

However, the main challenge in conducting such research in the Brazilian context lies in the need for national surveys that incorporate information on the functioning of body structures, activities of daily living, social participation, and mental health—in other words, robust measures of functioning. The small sample size constitutes the main limitation of this study, as it can interfere with the predictive capacity of the learning models. Furthermore, the application of this approach as a predictive tool itself still depends on the use of predictor variables collected independently from the outcome, avoiding overlap of the conceptual domain; external validation in independent samples; longitudinal data that allow evaluating recovery trajectories; and tests in different populations, prior to any application in risk stratification or clinical decision support in rehabilitation. Additionally, the scarcity of Latin American studies with longitudinal data on post-stroke functioning and the need for externally validated predictive models in these populations are highlighted.

CONCLUSION

In summary, Gradient boosting algorithms, particularly XGBoost, demonstrated good performance in reconstructing the functioning measure in this dataset. These results establish an initial proof of concept regarding the feasibility of machine learning models for handling complex health outcomes in population-based studies. Furthermore, the future application of these algorithms, appropriately designed for predictive

purposes, can strengthen the use of machine learning and AI in promoting functioning and quality of life.

As machine learning is increasingly applied to predict health outcomes using large population datasets, our understanding of chronic social issues becomes clearer.It is recommended that future studies test these algorithms in longitudinal cohorts with larger population groups; use predictors conceptually independent of the outcome; and perform validations in external samples to assess generalization capacity and large-scale applicability.

***Abstract*—Dementia has a high global prevalence and high rates of underdiagnosis in Brazil (76.1% to 77%). Machine learning (ML) is emerging as a promising tool to assist with diagnostic screening. Objective: To develop, compare, and evaluate the performance of ML models for identifying dementia. Method: Data from 334 observations of 150 participants (men and women, aged 60–98) from the Open Access Series of Imaging Studies (OASIS) database were used. The Boruta algorithm identified the MMSE as the most relevant variable, followed by Sex and nWBV. These variables were selected as predictor variables. Data were cleaned and prepared to train three predictive models: Support Vector Machines (SVM), Gradient Boosting (GBM), and Multilayer Perceptron (MLP). To compare performance of these algorithms, a non-parametric Friedman test was conducted. Results: the MLP algorithm performed best overall, with 86% accuracy, 81% sensitivity, 90% specificity, and AUC-ROC of 0.90. However, the analysis of the confidence intervals for accuracy, sensitivity, specificity, and AUC-ROC of the three models shows an overlap and the Friedman test (X^2 = 1.23, p = 0.54) revealed no statistically significant differences in performance among the models. Conclusion: The developed models demonstrated good predictive performance. These algorithms represent viable alternatives for supporting clinical decision-making in high-demand scenarios or situations with time and resource constraints.**

Keywords — Machine learning. Dementia. Older adult health.

I. INTRODUCTION

It is estimated that the number of people affected by dementia worldwide increased by 117% between 1990 and 2016, largely due to the aging population [1]. In 2019, 2.46 million people were living with dementia in Brazil, and projections indicate that this number will reach 5.05 million in 2039 and 8.74 million in 2049 [2]. Despite this high prevalence of dementia, the estimated underdiagnosis rate is 76.1% to 77% in Brazil [3,4].

Machine learning (ML), a subfield of Artificial Intelligence, is a data analysis technique that uses algorithms to build predictive, identification, and decision-making models [5,6]. ML is rapidly evolving in the medical industry, encompassing everything from diagnosis to disease visualization and the study of disease transmission [6].

This study aimed: *i*) to develop supervised machine learning models for dementia identification, using magnetic resonance imaging data (normalized whole brain volume (nWBV)), parameters from the Mini-Mental State Examination (MMSE), and sex; *ii*) to compare the performance of the developed models; *iii*) to identify the importance of the predictor variables.

II. BACKGROUND

In recent years, the application of machine learning (ML) algorithms has helped to solve several complex problems in various fields. In biomedicine, these algorithms have been used for prediction, diagnosis, and identification of disease development stages. In the context of Alzheimer's disease (AD), ML algorithms have been used in various research projects, from mapping genes and biomarkers (beta-amyloid 42 (Aβ42) and tau proteins) to image analysis (magnetic resonance imaging (MRI) and positron emission tomography (PET)) and sociodemographic and clinical data. The invasive nature of lumbar puncture limits the widespread use of biomarkers such as amyloid beta-42 (Aβ42) and tau proteins. The high cost and limited availability also restrict wider applications of MRI and PET [7,8].

Recent studies have applied ML algorithms (neural networks and classical algorithms) to predict and detect AD. For instance, the study in reference [8] developed machine learning models (logistic regression with penalty (LR), support vector machine (SVM), decision trees, random forest (RF), extreme gradient boosting (XGB) and artificial neural network (ANN)) to predict AD using sociodemographic, self-reported health and blood biomarker information. Meanwhile, the study in reference [9] analyzed magnetic resonance imaging, demographic, clinical, and cognitive data using a long short-term memory (LSTM) neural network and a feedforward neural network (FNN) to detect AD early.

In this study, we use three algorithms: Support Vector Machines (SVM), Gradient Boosting (GBM) and Multilayer Perceptron (MLP) to identify dementia.

A. Support Vector Machines (SVM)

The Support Vector Machines (SVM) algorithm is a supervised machine learning model that aims to find an optimal hyperplane in an *n*- dimensional space that maximizes the margin between the classes of interest. The balance

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

between maximizing the margin and minimizing training errors is controlled by the regularization hyperparameter *C* (cost) [5,6,10].

B. Gradient Boosting (GBM)

Gradient Boosting (GBM) is a supervised machine learning technique that builds models in an additive and sequential manner. The performance of the previous model influences each new model. It combines multiple base models (weak learners) to produce a final, higher-performing model (strong learner). GBM focuses on correcting errors made by previous models. The algorithm treats training as an optimization problem within a function space. The goal is to find an approximation function that minimizes the expected value of a loss function. A loss function quantifies the impact of classification or prediction errors in the solution to a problem. Given a specific loss function, the optimal solution for a classification or prediction problem is the one that minimizes that loss. At each step *m*, a new "weak model" (a shallow decision tree) is trained to predict the negative gradient of the loss function with respect to the current model's output. The new model attempts to learn the direction and magnitude of the error accumulated by the ensemble up to that point. The final result is derived from the last tree. However, it is necessary to determine the extent to which the target variable is adjusted at each step. This is achieved using a learning rate, which ranges from 0.0 to 1.0 [11, 12].

C. Multilayer Perceptron (MLP)

A Multilayer Perceptron (MLP) network is a feedforward artificial neural network architecture characterized by the organization of neurons into multiple layers. It consists of three layers: the input layer, the hidden layers, and the output layer. Each neuron in a hidden or output layer performs a weighted sum of its inputs, plus a bias term, and submits the result to a non-linear activation function. The learning process is driven by the backpropagation algorithm, which adjusts the network weights to improve predictions by computing the gradient of the cost function with respect to the weights, updating them layer by layer [5,11].

III. METHODS

A dataset from the Open Access Series of Imaging Studies (OASIS) was used, comprising 374 observations of 150 demented and non-demented subjects (men and women), right-handed, aged from 60 to 98 years. They underwent cranial magnetic resonance imaging (MRI), and clinical and sociodemographic assessments across two or more visits spaced at least one year apart. The sample data included the following variables: class (Group), Sex, Age, socioeconomic status (SES), years of education (EDUC), Mini-Mental State Examination (MMSE), estimated total intracranial volume (eTIV), normalized whole brain volume (nWBV), and atlas scale factor (ASF) [13]. Two groups of interest were considered: demented and non-demented. Observations with inconclusive class (Group) were excluded. Missing entries were observed in two observations for the MMSE variable and seventeen for the SES variable.

A. Variables Selection

The Boruta algorithm, a variable selection method that identifies all relevant variables in a database, was implemented, using Random Forest as a basis. After expert analysis, correlation matrix, contingency tables, and Boruta results, two observations with missing entries for the variables MMSE, SES, and ASF were excluded. The SES variable showed little relevance and had missing observations. The ASF variable showed a 99% correlation with the eTIV variable.

The results of the Boruta algorithm show that MMSE is the most important predictor variable, followed by Sex and nWBV. The MMSE is a quick test (5 to 10 minutes) focused on the patient's cognitive performance at the time of the consultation. The MMSE is easy to apply in the routine of a clinic or hospital.

The variables Sex, MMSE and nWBV, along with their specific characteristics, were selected as predictor variables. The variable Group was chosen as the output (outcome) variable corresponding to the diagnosis of dementia based on the other input (predictor) variables.

After cleaning and preparing the data, a total of 334 observations from 135 participants and 4 variables were obtained (one outcome variable and three predictor variables). The data were balanced (43.1% demented and 56.9% non-demented) and there were no missing observations in any of the four variables (Table 1).

TABLE I. VARIABLES CHARACTERISTICS

Variables	Statistics/Frequency
Group	Demented: 144 (43.1%) Non-demented: 190 (56.9%)
Sex	Female: 187 (56%) Male: 147 (44%)
Age	Mean (sd[a]): 76.7 (7.6) Minimum: 60 Maximum: 98
EDUC	Mean (sd[a]): 14.5 (2.9) Minimum: 6 Maximum: 23
MMSE	Mean (sd[a]): 27.2 (3.8) Mínimo: 4 Maximum: 30
eTIV	Mean (sd[a]): 1493.3 (178.7) Minimum: 1106 Maximum: 2004
nWBV	Mean: 0.7 Minimum: 0.6 Maximum: 0.8

[a.] Standard Deviation

B. Hyperparameter adjustments

Three algorithms were implemented in the R (v. 4.5.0) [14]: Support Vector Machines (SVM), Gradient Boosting (GBM) and Multilayer Perceptron (MLP). For supervised learning, the structured dataset was split into training (70% = 234 observations from 95 participants), validation and test (30% = 100 observations from 40 participants) set by participant ID, ensuring that no data from the same individual appeared in more than one set. All models used 10-fold cross-validation as control parameters for training. The area under the ROC curve (AUC-ROC) was used to select the best model, aiming to balance between sensitivity and specificity.

SVM Linear: data were standardized (using “center” and “scale”). The regularization hyperparameter (*C*) was optimized using a grid search. The tested grid varied in powers of 10 (10^{-3} to 10^{3}). In this model, *C* optimal = 0.1.

GBM: The hyperparameters maximum depth of each tree (interaction.depth), total number of trees (n.trees), learning rate (shrinkage), and minimum number of observations at terminal nodes (n.minobsinnode) were optimized using a grid search. The tested grid ranged from 3 to 8 for interaction.depth, 50, 100, and 500 for n.trees, 0.1, 0.01 and 0.001 for shrinkage, and 10 and 15 for n.minobsinnode. In this model, the best hyperparameters were: interaction.depth = 4, n.trees = 100, shrinkage = 0.001 and n.minobsinnode = 15.

MLP: data were standardized (using "center" and "scale"). Dummies were created for categorical variables. The hyperparameters were hidden layer neurons (size) and weight decay. The decay values were optimized using a grid search. The tested grid ranged from 2, 4, 8, and 16 for size, and 0, 0.0001, 0.001, and 0.01 for weight. Decay. In this model, optimal size = 2 and optimal decay weight = 0.01.

IV. Results

The models (SVM, GBM, and MLP) achieved good accuracy and high predictive capacity (Table 2). The MLP algorithm achieved a good overall balance, with the highest accuracy (86%), sensitivity (81%), specificity (90%), and AUC-ROC (0.90). It presents an optimized architecture that required only two neurons in the hidden layer (Figure 1). However, the analysis of the confidence intervals for accuracy, sensitivity, specificity, and AUC-ROC of the three models shows an overlap. This highlights the similarity in the models' performance. The SVM algorithm stood out for its higher specificity (94%). It was the most effective model for identifying positive cases of non-dementia, with only three false positive recorded (Table 3).

TABLE II. PERFORMANCE MEASURES OF MODELS

	SVM	**GBM**	**MLP**
Accuracy [95% CI]	0.85 [0.76 0.91]	0.83 [0.74 0.90]	0.86 [0.77 0.92]
Kappa Index	0.69	0.65	0.72
Sensitivity [95% CI]	0.74 [0.61 0.85]	0.76 [0.64 0.89]	0.81 [0.70 0.91]

Non-Demented	12	50	11	47	9	48

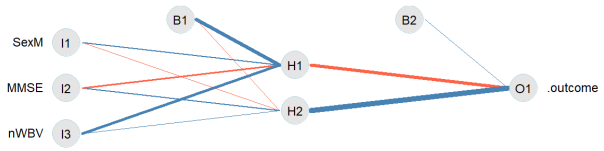

Fig. 1. MLP network architecture

To compare performance of the evaluated machine learning algorithms (SVM, GBM, and MLP) across the cross-validation folds, a non-parametric Friedman test was conducted. The analysis revealed no statistically significant differences in performance among the models (χ^2 = 1.23, p = 0.54), indicating that all three architectures achieved similar predictive capability on this dataset.

V. Discussion

Comparing the results obtained in this study with those from [8] in scenario 3 (sociodemographic variables, self-reported health information and blood biomarkers), the SVM model developed here outperformed the SVM from reference 8 in terms of accuracy (85% vs. 56%), sensitivity (74% vs. 65%) and specificity (94% vs. 89%). The performance of the GBM (accuracy = 83% and AUC-ROC = 0.88) was slightly superior to that of the XGBM (accuracy = 71% and AUC-ROC = 0.79). The MLP outperformed the ANN across all metrics: accuracy (86% vs. 65%), sensitivity (81% vs. 70%), specificity (90% vs. 84%), and AUC-ROC (0.90 vs. 0.73). This superiority suggests that including the MMSE and structural neuroimaging biomarkers (nWBV) enhances the models' discriminative capacity compared to the blood biomarkers and self-reported health data used in reference 8.

Reference [9] utilized demographic, clinical, cognitive, and MRI data. It was observed that individual architectures, such as LSTM (accuracy = 89.44%) and FNN (accuracy = 89.5%), achieved accuracy levels comparable to those of the models in this study (85%, 83%, and 86%). Employing a hybrid LSTM-FNN approach resulted in an accuracy of 99.82%. This highlights the high potential of combined deep learning models for the early detection of Alzheimer's disease when applied to large structured datasets.

VI. Conclusion

In this study, the developed ML models demonstrated strong performance in identifying dementia, with high efficiency. As demonstrated by the Boruta algorithm and the Friedman test, the integration of just three key predictors (MMSE score, nWBV, and sex) was sufficient to yield effective and statistically equivalent models in predictive capacity (p = 0.54). It suggests that these algorithms constitute effective and suitable prediction tools for application in high-demand clinical environments or with limited technical and temporal resources. Machine learning integrated with rigorous clinical protocols can be a good tool to mitigate the high rates of underdiagnosis of dementia in Brazil.

Although research on dementia detection has grown significantly over the last two decades, driven by collaboration between health and computer science, there remains a need to identify relevant characteristics that improve the predictive capacity of models. This work contributes to the advancement of this field by validating the use of machine learning approaches for diagnostic purposes and investigation of predictive variables.

The longitudinal nature of this dataset represents a significant limitation for training predictive models. Repeating observations of the same individual, even with a minimum interval of one year, can lead to inter-observational correlation, violating the assumption of sample independence. Consequently, although the results demonstrate robust performance, generalizing the models to a population of

patients with completely independent data should be interpreted with caution.

ACKNOWLEDGMENT

***Abstract*—Early diagnosis of breast cancer remains a challenge for healthcare systems, especially in resource-constrained settings, where high demand for specialized examinations can delay diagnostic investigation. In this context, this work presents Mamo.IA, a web-based Artificial Intelligence (AI) platform developed to support screening and analysis of breast images from three distinct modalities: thermography, histopathology, and mammography. Initially, an algorithmic validation stage was conducted using images from public and institutional datasets. The images were characterized using transfer learning with a pre-trained LeNet architecture and classified by different machine learning algorithms, including Random Forest, Support Vector Machine (SVM), J48, Bayes Network, and Naive Bayes. The models were evaluated using stratified 10-fold cross-validation, employing accuracy, Kappa coefficient, sensitivity, specificity, and AUC-ROC as performance metrics. The SVM with RBF kernel achieved the best performance for thermography (accuracy of 76.99% and Kappa of 0.69), while Random Forest was superior for histopathology (85.50% and Kappa of 0.71) and mammography (72.76% and Kappa of 0.59); these models were incorporated into the platform backend. The interface was implemented in Django, enabling user authentication, exam submission, automated processing, generation of diagnostic reports, and results export. The integration between predictive models and a unified web interface demonstrates the feasibility of Mamo.IA as a clinical decision support tool, with potential to contribute to screening organization, patient prioritization, and expanded access to breast cancer diagnostic support technologies**

within the Brazilian Unified Health System (SUS).

***Index Terms*—Breast cancer, AI platform, Mammography, Thermography, Histopathology**

I. Introduction

Breast cancer is the most frequently diagnosed neoplasm among women and a leading cause of cancer-related mortality in females [1]. Late diagnosis remains a significant challenge, particularly in middle-income countries, where structural limitations compromise timely access to screening examinations. Mammography remains the gold standard screening method; however, its high cost, unequal distribution of equipment, use of ionizing radiation, and reduced sensitivity in dense breast tissue motivate the search for complementary technologies. Among these alternatives, infrared thermography stands out as a non-invasive, painless, and radiation-free modality capable of detecting thermal alterations associated with tumor vascularization and metabolic activity [1].

The advancement of Artificial Intelligence (AI) and machine learning has expanded the diagnostic potential of breast thermography. Santana et al. demonstrated the viability of Extreme Learning Machines in thermographies [2], and Silva et al. highlighted feature selection by genetic algorithms and particle swarm optimization [3]. With deep learning, hybrid architectures emerged: Deep-Wavelets with convolutional neural networks [4], Deep-Wavelet with support vector machines [5], and Deep Transfer Learning [6]. Espíndola et al. analyzed thermophysical parameters of superficial breast temperature, reinforcing the scientific foundation of the method [7].

There is also the expansion of intelligent clinical decision support systems. Platforms from the same group, such as Heg.IA and IKONOS, integrated AI into care workflows of the Brazilian Unified Health System (SUS) based on laboratory tests and biomedical images [8], [9]. In this scenario, Mamo.IA is proposed as a support system for early breast cancer screening that integrates infrared thermography, mammography, histopathological analysis, digital image processing, and AI algorithms, with the potential to assist in risk stratification and the organization of healthcare waiting lists.

This perspective is relevant for the SUS, which faces high demand for specialized examinations and limited resources. Studies on AI in Brazilian public health indicate that intelligent systems can optimize screening and patient prioritization [10], [11]. Thus, this work presents Mamo.IA, an AI-based platform to support early breast cancer diagnosis, describing its interface, functional architecture, and application as support for breast cancer screening and patient prioritization in the SUS.

The platform will include efficient machine learning algorithms and a Software as a Service (SaaS) architecture to provide rapid access to analysis tools. It integrates, in a single workflow, professional registration, the capture and preprocessing of breast images, the extraction of relevant features, and the automatic risk classification through machine learning models, allowing the results to be made available quickly to healthcare teams. It is expected that the tool will be able to identify patterns suggestive of breast changes across different examination modalities (thermography, histopathology, and mammography) with accuracy comparable to that of related studies in the literature, contributing to reducing the time between clinical suspicion and referral for confirmatory exams.

To present this development, the paper is structured as follows: Section II presents the related work, discussing recent approaches of computer-aided diagnosis systems applied to breast imaging exams; Section III describes the methodology employed in the development of the Mamo.IA platform, including the algorithmic validation process and the selection of classifiers in the backend, as well as the construction of the web interface; Section IV presents and discusses the results obtained in the training and testing of the classifiers for the thermography, histopathology, and mammography datasets, in addition to the interface usage workflow; finally, Section V presents the final considerations of this work.

II. Related Studies

Within the scope of computerized thermography, Resende (2025) [13] developed a graphical user interface (GUI) in a MATLAB environment that integrates thermal image processing and a CNN architecture optimized via a Bayesian algorithm. The interface performs data augmentation and adaptive filtering tasks to reduce noise from text-based matrices, displaying real-time learning stability with a validation accuracy of 97.91% and 98.95% in the final tests. However, the operational limitations of the GUI include a strict dependence on specific file formats and risks of spectral confusion on the screen, requiring object-oriented segmentation to accurately delineate the lesions.

Freitas et al. (2022) developed an approach based on Multi-Instance Learning (MIL) integrated with a pre-trained DenseNet201 convolutional neural network [14] for the automated diagnosis of breast cancer in histopathological images from the BreakHis dataset. The system performs processing steps involving white noise removal, partitioning of the original image into 16 smaller instances, and the calculation of attention weights, identifying, during the inference phase, the regions with the highest malignant relevance, achieving an accuracy of 90% and a sensitivity of up to 98% in the binary classification between benign and malignant tumors. However, the limitations of this approach include the high computational cost resulting from the multi-input architecture and the performance degradation observed when excessively deep dense layers are employed, necessitating the use of structural optimization strategies to enhance the system's generalization capability.

Regarding thermography, Attallah (2025) [15] proposed a Computer-Aided Diagnosis (CAD) system focused on thermographic images from the public DMR-IR dataset. The study employed lightweight Convolutional Neural Networks (MobileNet, EfficientNetB0, and ShuffleNet) based on the Transfer Learning technique and applied Non-Negative Matrix Factorization (NNMF) for dimensionality reduction. The

model achieved 99.9% accuracy using only 350 final optimized parameters. The main advantage of this approach is the substantial reduction of the computational load for analysis, ensuring efficient and radiation-free screening, although it presents the limitation of evaluating only a single examination modality within a relatively small dataset.

Focusing on the confirmation stage, Atrey, Singh, and Bodhey (2023) [16] investigated the classification of tumors in histopathological images at 40× magnification, extracted from the Brazilian collaborative BreaKHis dataset. The methodology involved the extraction of texture and color features, followed by a feature selection step based on a Genetic Algorithm (GA) to select the most relevant attributes, and classification using a Long Short-Term Memory (LSTM) neural network architecture. The model achieved an accuracy of 99.85% in classifying benign and malignant lesions by combining the 192 attributes selected by the genetic filter. The system demonstrated efficiency in assisting with biopsy diagnoses, reducing inter-observer discrepancies and laboratory workload, despite relying solely on 40× magnification and addressing class imbalance within the dataset.

Regarding intelligent systems already applied to SUS diagnostic workflows, Gomes et al. (2020) [10] developed IKONOS, an application designed to support the diagnosis of COVID-19 and pneumonia using chest X-ray images. The application extracts features and classifies images into four categories: healthy patients, viral pneumonia, bacterial pneumonia, and COVID-19. They displayed accuracy, sensitivity, and specificity metrics to assist professionals in decision-making. For feature extraction, the system employed Haralick and Zernike extractors combined with classical classifiers such as Multilayer Perceptron, Support Vector Machine, Random Trees, Random Forest, Bayesian Networks, and Naive Bayes. Among these, Support Vector Machines stood out, achieving an average accuracy of 89.78%, with an average sensitivity of 0.8979 and average precision and specificity of 0.8985 and 0.9963, respectively. The tool demonstrates the feasibility of implementing low-cost, texture-based diagnostic support directly into clinical routine, reinforcing the rationale for platforms like Mamo.IA. However, its reliance on handcrafted texture and shape descriptors, rather than deep feature learning, may limit generalization when applied to the more heterogeneous imaging conditions typically found in resource-constrained healthcare environments.

III. Materials and Methods

The study aims to develop advanced algorithms for assessing medical images used in the context of breast cancer screening and diagnosis and to create an artificial intelligence SaaS platform. This initiative seeks to optimize early breast cancer diagnosis, reduce costs, contribute to the training of healthcare professionals, and drive significant advancements in the field by providing innovative models and methods for future clinical applications.

The proposed platform is projected to be used by healthcare professionals in the usage workflow proposed in Figure 1. Upon arriving at the healthcare facility, the patient undergoes screening via breast thermography; the resulting image can be sent to the system to aid in decision-making regarding the presence or absence of potential findings. If there are no indications of lesions, the patient may be discharged. Otherwise, the professional may choose to refer her for further investigation using other imaging modalities. In addition to breast thermography image analysis, the first version of this platform supports decision-making based on mammography and microscopy images within the context of histopathological analysis.

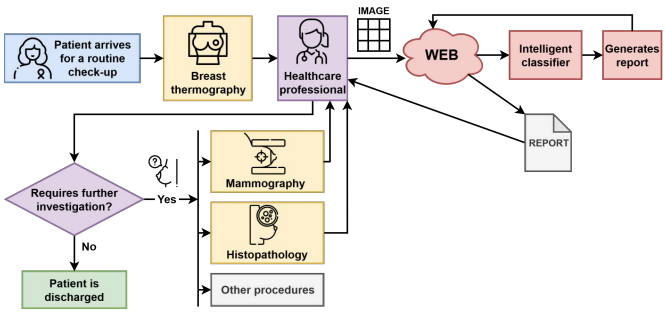

Fig. 1: Proposed workflow for using the Mamo.IA platform. The yellow blocks represent the imaging modalities implemented in the first version of the platform. In the red blocks we illustrate the processing stages based on our machine learning models.

The following sections describe the steps for developing the first version of the platform. We begin by presenting the processing infrastructure (back-end) used to support decision-making. Next, we introduce the steps taken to create the user interaction interface (front-end).

A. Backend Development

Before the development of the interface, a preliminary stage was conducted to identify the best-performing classifier for each dataset. Characterized as cross-sectional research with a quantitative approach, this stage constitutes an algorithmic validation study integrated into the development of the backend of the Mamo.IA platform.

In these experiments, the performance of different classification models was investigated for the automatic suggestion of diagnoses based on medical images of multiple modalities (thermal, histopathological, and mammographic). The central objective of this validation was to ensure the accuracy of the system in supporting the early detection of breast changes through Artificial Intelligence.

Three datasets were used, one for each modality addressed. The breast thermographic image dataset was the MammoTherm, which includes 336 images obtained from 100 patients treated at the Hospital das Clínicas of the Federal University of Pernambuco, using a FLIR S45 infrared camera [17]. For each patient, they captured eight images at different angles: frontal with hands on hips (T1), frontal with hands raised (T2), right breast (MD), left breast (ME), inner lateral right breast

(LIMD), inner lateral left breast (LIME), outer lateral right breast (LEMD), and outer lateral left breast (LEME). However, in this study, only the images in the T1 and T2 positions were used, as this view has favored classification. The images are categorized into four groups: no lesion (n = 66), benign lesion (n = 121), malignant lesion (n = 76), and cyst (n = 73).

Regarding the histopathology data, microscopy images from the BreaKHis dataset were used, which was developed by the Federal University of Paraná and contains 7,909 breast cancer histopathological images from 82 patients, acquired at different magnifications [18]. In this study, exclusively the images with 40x magnification were used, categorized as benign tumor and malignant tumor.

Finally, the mammography images used are from the IRMA (Image Retrieval in Medical Applications) dataset, which consists of fragments (patches) of digitized mammograms used to train and test AI models in the context of breast assessment based on the BI-RADS system [19]. The images were collected from widely known datasets in the related literature: DDSM: 2,479 studies, totaling 9,916 mammograms (695 healthy cases, 870 benign, and 914 malignant); MIAS: 322 mammograms; LLNL: 197 mammograms; and RWTH: 170 mammograms. The *patches* were standardized with dimensions of 128×128 pixels and classified into the categories: malignant lesion, benign lesion, and normal. In the 12er_patches configuration, 2,796 *patches* were used, equally distributed across 12 classes (233 images per class), and only the classes corresponding to the aforementioned clinical categories were selected for this research.

For all image modalities, the adopted processing was similar. Initially, image characterization from numerical data (feature extraction) was performed using the transfer learning technique with the LeNet convolutional neural network architecture, pre-trained on the MNIST dataset. Although the network was originally pre-trained on a dataset involving a substantially different image classification problem, namely handwritten digit recognition, it is important to emphasize that the pre-trained LeNet model was not directly employed to perform the classification of breast cancer images. Instead, it was used exclusively as a robust feature extractor, leveraging the capacity of convolutional neural networks to learn and represent relevant visual patterns from images. The extracted representations were subsequently provided as input to conventional machine learning classifiers, which were responsible for the final classification task. This step was performed through the Weka 3.8 software, with support from the *deeplearning4j* (DL4J) library. This feature extraction approach was adopted to simultaneously leverage the robustness of image characterization from deep neural networks and reduce computational cost, eliminating the need for hyperparameter tuning of a deep classification model, which is a relevant factor for practical application in contexts with limited computational infrastructure, such as in many SUS services.

Subsequently, the datasets were divided into training (75%) and testing (25%) sets using the random resampling method (Resample). Furthermore, considering the imbalance in the amount of data per class, the SMOTE (Synthetic Minority Over-sampling Technique) method was applied to generate synthetic samples of the minority classes in the training set and, thus, avoid bias during the training of the classifiers.

Regarding the classifiers, five supervised classification algorithms were tested: Random Forest, with variation in the number of trees (10, 20, 50, 100, 150, 200, 250, and 300); Support Vector Machine (SVM), with linear, polynomial (degree 2), and radial (RBF, $\gamma = 0.5$) kernels; J48 decision tree; Bayesian Network (Bayes Network); and Naive Bayes.

The models were evaluated using stratified cross-validation with 10 folds, repeated over 30 runs, ensuring statistical robustness. To prevent data leakage, cross-validation was performed exclusively on the training set, with each instance corresponding to an individual patient. Therefore, the stratified 10-fold cross-validation was conducted at the patient level, ensuring that no patient could simultaneously contribute samples to the training and validation folds. The performance metrics considered were: accuracy, kappa coefficient, sensitivity, specificity, and area under the ROC curve (AUC-ROC). The results were organized into CSV files for subsequent statistical analysis and comparison between algorithms.

After the identification and statistical validation of the best-performing classifier for each dataset within the Weka environment, the transition phase to the backend production environment began. Using the Python programming language, the selected models were implemented and replicated for their respective equivalent datasets, integrating specialized machine learning libraries to ensure algorithm portability. This Python stage consolidated the analytical intelligence of the platform, allowing the optimized classifiers to operate natively and integrated into the request and data processing flow of the Mamo.IA backend.

B. Interface Development

The development of the Mamo.IA platform interface was conducted with a focus on usability and efficient integration with the predictive models operating in the back-end. The web system architecture was structured using the Django framework, chosen for its structural robustness in Python and ease of integration with Artificial Intelligence libraries.

The platform focuses on expanding access to quality breast diagnosis within the context of the Brazilian Unified Health System (SUS), especially in regions lacking specialized professionals, such as mastologists and radiologists, contributing to the reduction of health inequalities.

The materials and technologies employed in the construction comprised:

- **Markup and Styling Languages:** HTML5 and CSS3, implemented to ensure a clean, responsive, and adaptable design to different resolutions, avoiding distortions in exams of varied clinical proportions.
- **Back-end Framework and Routing:** Django, responsible for view control, user session management, and strict form validation.

- **Database:** SQLite, used in the development environment to store upload histories, structured reports, and access credentials.

The development stages followed an iterative logical workflow. Initially, the authentication flow and the main dashboard were structured. Next, the dynamic exam submission form was implemented, which features database validation to categorize clinical entries (Mammography, Thermography, and Histopathology). The final stage consisted of building the results visualization interface. This screen was designed with layout security constraints to display the proportionally resized medical exam, accompanied by the respective diagnosis generated by the model, in addition to integrating PDF export and email sending functionalities.

IV. Results e Discussion

A. Training and Testing of Classifiers

The results obtained from the training of the classifiers for thermography, histopathology, and mammography are presented, respectively, in Tables I, II, and III.

The experiments demonstrated that the best-performing classifier for the thermography dataset was the SVM with RBF kernel ($\gamma = 0.5$). On the other hand, for the histopathology and mammography datasets, the Random Forest algorithm achieved the best results. Aiming to optimize computational cost, the configuration with 200 trees was selected, as this parameter ensured the maintenance of high accuracy without compromising the values of the other performance metrics.

Upon analyzing Tables I, II, and III in more detail, this superior performance on the thermography dataset (accuracy of 76.99%, Kappa of 0.69) can be associated with the capacity of this kernel to model non-linear decision boundaries, which are suitable for the strong spatial correlation between the temperatures recorded in adjacent regions of the breast. Conversely, the worst performance was observed with Naive Bayes (accuracy of 50.19%, Kappa of 0.34), closely followed by the Bayes Network. Both classifiers are based on the assumption that the attributes are independent of each other, which is not sustainable given the thermal correlation between neighboring regions of the breast.

In the histopathology dataset, Random Forest with 300 trees achieved the best result (accuracy of 85.50%, Kappa of 0.71), which is likely due to its ensemble nature, conferring greater robustness to correlated features and noise present in the data extracted via transfer learning from the LeNet network. Naive Bayes, in turn, presented the worst performance with an accuracy of 29.61%, evidencing difficulty in generalizing from these same features. Since the LeNet network was originally trained for the domain of handwritten digits (MNIST), the extracted features tend to be numerous and related to each other in a complex and non-linear manner, which contradicts the independence assumption made by the Bayesian classifier.

In the mammography dataset, Random Forest again presented the best performance, although with an accuracy lower than that obtained in the other modalities (72.76%), which is consistent with the greater visual complexity of this dataset for diagnosis. The worst performance was observed with the RBF SVM (accuracy of 66.86%, Kappa of 0.50), a result that contrasts with the good performance of this same kernel in the thermography dataset. This inversion suggests that the gamma parameter is sensitive to the scale and variability of the features of each modality, which points to the need to adjust it specifically for each domain in future work.

In the tests, the datasets obtained the metrics found in Table IV. The confusion matrices of the tests are shown in Figure 2.

TABLE IV: Table showing the database test metrics.

Database	Accuracy	Kappa	Sensitivity	Specificity	AUC-ROC
Thermography	100%	1.0	1.0	1.0	1.0
Histopathology	100%	1.0	1.0	1.0	1.0
Mammography	75.54%	0.63	0.76	0.88	0.88

b = T_malignant	111	122	0
c = T_normal	0	0	233

(c) Confusion matrix for the Mammography Database.

Fig. 2: Confusion matrices obtained by the best classifiers for each database.

The results obtained in the test with the thermography dataset, presented in Table IV and 2a, revealed an ideal performance, with perfect metrics and confusion matrix. This behavior may be associated with the reduced number of samples available in the test set, which simplified the classifier's decision boundary for this specific subset.

Analogously, the evaluation of the model on the histopathology dataset (Table IV and Figure 2b) exhibited maximum performance, evidenced by perfect metrics and a confusion matrix without incorrect classifications. This flawless result suggests a probable influence of the restricted sample size in

the test set, which tended to make the algorithm's separation boundary less complex.

Unlike the scenarios observed in the thermography and histopathology datasets, the results obtained for the mammography dataset (Table IV and Figure 2c) did not present perfect metrics. Using the Random Forest classifier, the model achieved an accuracy of 75.54% and a Kappa index of 0.63. This behavior is justified by the greater complexity and intrinsic visual variability of mammographic images, in addition to the substantially larger sample size in this dataset, which imposed a real generalization challenge for the algorithm.

B. Interface Presentation and Usage Flow

The final interface establishes the visual and interactive bridge between the screening algorithms and the healthcare professional. Figure 3 displays the main access dashboard of the Mamo.IA platform. From this screen, the user is directed to the exam submission interface (Figure 4), which enables the upload of medical files and the categorized selection of the clinical procedure performed.

C. Viewing Diagnostics and Reports

Following the algorithmic processing, the platform displays the analysis results on a stabilized interface. Figures 5 and 6 illustrate representations of reports generated by the system,

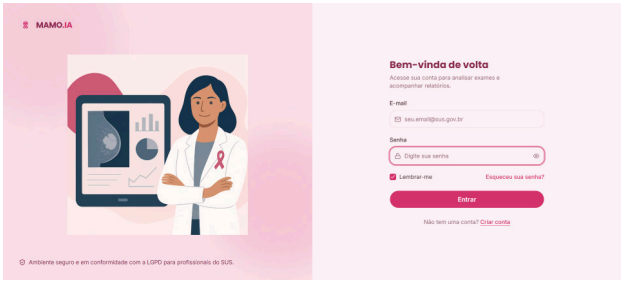

Fig. 3: Home page of the Mamo.IA platform, displaying the acess dashboard.

detailing the resized image without loss of proportion (aspect ratio) and the diagnosis issued by the AI.

Complementarily, Figures 7 and 8 demonstrate the system's flexibility in handling different types of results (positive and negative findings) for the submitted examinations. The interface layout ensures that the reading panel and action buttons remain contained within a single viewing area, eliminating the need for excessive scrolling and optimizing decision-making in the clinical environment.

V. Conclusion

The development of computational tools capable of supporting the screening and early diagnosis of breast cancer represents a promising strategy to expand access to specialized care, especially in high-demand scenarios, such as the Brazilian Unified Health System (SUS). In this context, this work presents Mamo.IA, a web platform structured as Software-as-a-Service (SaaS), developed to integrate different modalities of medical images into a single clinical decision-support environment.

Fig. 6: Visual representation of a processed report, integrated with export buttons.

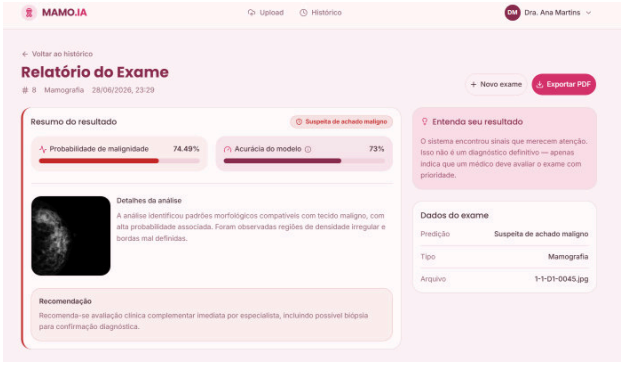

Fig. 7: Results interface detailing an analysis with positive clinical findings.

The platform was built upon the validation of machine learning algorithms applied to thermography, histopathology, and mammography datasets, followed by the implementation of the selected models in a backend developed in Python and integrated with the Django framework. Among the evaluated classifiers, the SVM with an RBF kernel achieved the best performance for the thermography dataset, while the Random Forest, configured with 200 trees, was adopted for the

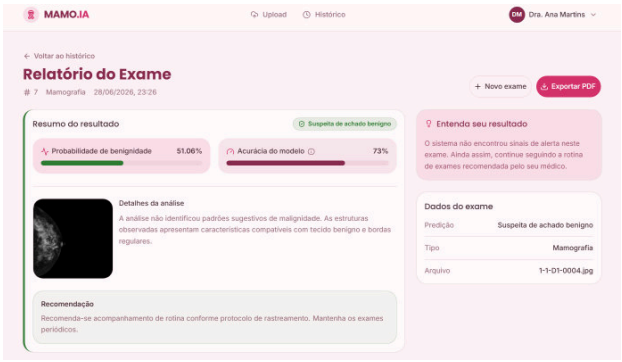

Fig. 8: Results interface detailing an analysis showing no abnormalities (negative).

histopathology and mammography datasets due to its ability to maintain high performance at a lower computational cost. The integration of these models resulted in an interface capable of handling the categorized submission of examinations, generating automated reports, and consolidating different image modalities into a single user workflow. The results obtained demonstrate the feasibility of Mamo.IA as a clinical decision-support tool, leveraging artificial intelligence throughout the diagnostic process to help prioritize patients for confirmatory examinations within the scope of the SUS.

The independent processing of each imaging modality reflects the intended clinical workflow of Mamo.IA, in which the different modalities are not necessarily acquired or analyzed simultaneously, but may be requested and incorporated at different stages according to the patient's clinical needs and the diagnostic pathway. Thus, rather than combining all modalities into a single multimodal model, the platform was designed to provide complementary decision support as additional examinations become available.

However, this study presents limitations related to the use of specific datasets, the lack of validation in real-world clinical settings, and the need for hyperparameter optimization for each image modality. Additionally, aspects concerning the platform's usability and its impact on the clinical workflow require further investigation. In this regard, future works may encompass the multicenter validation of the tool, its evaluation in real clinical scenarios, the incorporation of new examination modalities, and the refinement of the predictive models, thereby contributing to expanding its generalizability and applicability in clinical practice.

VI. Declaration of Artificial Intelligence Use

The Qwen3.6-Plus, ChatGPT4, and Claude 4.5 language models were employed for orthographic, grammatical editing of the manuscript and on the support on structuring the interface. No artificial intelligence was involved in the conception of any part of the research itself, nor in methodological design, data acquisition or analysis, interpretation of results, or generation of intellectual content. All AI-assisted processes and outputs were rigorously validated and audited by the human authors, who assume full responsibility for the accuracy, originality, and scientific integrity of this work.

Acknowledgment

***Abstract*—Administrative data preserve institutional memory, but their reuse can be distorted by counting units, linkage failures, missing territorial information, and disclosure decisions. MEADS-Health is an auditable methodology for exploring heterogeneous institutional data with language-model support restricted to analytical planning. Records remain in a protected environment. Only objectives and sanitized metadata are sent to the model. Formulas, denominators, linkage rules, and release levels remain under technical-team control. The method was examined through a qualitative, artifact-centered municipal case study and a bounded synthetic linkage stress test. The V7 planning grammar exposed 17 reusable axis templates, of which 10 were activated for the health-source configuration. Across 30 synthetic replicates per noise level, each with 5,000 identities, deterministic match recovery decreased from 100.0% without perturbation to 93.1% under 20% independent field noise, while mean precision remained 99.8%. The synthetic test evaluates only the key-matching rule; no real-data gold standard, alternative-pipeline comparison, inferential analysis, or end-to-end effectiveness assessment was performed. These results support claims about inspectability and the bounded robustness of the matching rule. They do not support population inference, operational efficiency, or a privacy guarantee.**

***Index Terms*—sensitive data, public health, persons with disabilities, exploratory data analysis, language models, record linkage, georeferencing, auditing.**

I. Introduction

Administrative datasets are produced to deliver services and document institutional activity, not to answer research questions. Their value for secondary analysis is therefore inseparable from the routines that generated them: a row may represent a person, procedure, dispensing event, program link, or administrative occurrence. If that unit is not defined before counting, the resulting indicator can change meaning rather than merely lose precision. This is why reuse of routinely collected data requires explicit reporting of provenance and analytical units [1], [2].

In health settings, this structural ambiguity coexists with sensitive content such as clinical codes, medications, procedures, addresses, and care notes protected by the Brazilian

General Data Protection Law (*Lei Geral de Proteção de Dados Pessoais*—LGPD) [3]. Analyses involving persons with disabilities must be useful for planning without turning data integration into an additional source of exposure; this concern is consistent with WHO recommendations and the Brazilian Law for the Inclusion of Persons with Disabilities [4], [5].

Data quality cannot be reduced to file cleaning. Established frameworks emphasize completeness, correctness, concordance, conformance, and plausibility [6]–[8]. A source may faithfully represent an administrative process and still be unsuitable for population inference, just as a plausible key may be insufficient to establish identity across systems. Dashboards can hide these uncertainties when duplicate handling, linkage failures, or territorial gaps disappear behind final charts [9]–[11].

LLMs can help organize questions from a sanitized schema, but that usefulness does not justify transferring identifiable records to external services. WHO and NIST guidance emphasize minimization, oversight, transparency, and risk management, while health-AI literature warns against unverified outputs and unnecessary exposure [12]–[15]. The methodological gap addressed here concerns the workflow between AI-assisted planning and record-level execution. MEADS-Health keeps these stages separate while preserving analytical units, linkage provenance, territorial failures, and the calculation path behind each product.

This paper presents MEADS-Health, an analytical-engineering methodology examined in a municipal case involving sensitive health and cross-sector records of persons with disabilities. The records remain under restricted access; the scientific object is the process used to examine, link, calculate, and release auditable aggregates. MEADS-Health separates planning, execution, and validation. The LLM proposes initial analytical axes from sanitized metadata. The technical team defines formulas, denominators, linkage rules, interpretation, and disclosure, and all calculations are performed locally. For biomedical engineering, this addresses the data-engineering and governance layer that precedes secondary analysis of sensitive health information. MEADS-Health is not a clinical decision-support system or predictive algorithm.

II. Related Work

The supporting literature was organized as a problem-oriented narrative review because MEADS-Health connects concepts that are usually discussed in separate domains [16]. For data quality and provenance, health-data frameworks show that secondary use depends on the meaning of the source, not only on missingness or format, and provenance research extends this requirement to transformations and computational workflows [7], [8], [17]–[19]. For this reason, formulas, parameters, denominators, and intermediate decisions remain inspectable alongside the dashboard.

Record linkage adds a second layer of uncertainty. Fellegi–Sunter and later data-matching work formalize identity resolution as a process of preparation, comparison, and classification rather than a simple join [20], [21]. Public-health PPRL literature likewise shows that accuracy depends on field completeness and stability, and that matching errors can propagate bias [22]–[24]. MEADS-Health does not claim a cryptographic PPRL protocol: identifiers are pseudonymized inside an authorized environment, while disclosure control remains a separate step involving aggregation, granularity, and residual reidentification risk under LGPD and NIST guidance [3], [25].

Finally, dashboards, geospatial analysis, and human–AI interaction share a governance problem: useful interfaces can still conceal incomplete coverage or uncertain transformations. Dashboard studies emphasize audience, context, and iterative validation [9]–[11]; geocoding introduces both analytical value and disclosure risk [26]; and human–AI guidance stresses limitations, correction, and oversight [12], [27]. These strands support the central design choice of MEADS-Health: define in advance what may reach the AI and keep record-level processing, validation, and release authority in the protected environment.

III. Materials and Methods

A. Study Design and Evaluation Scope

The study follows an applied, *design-science* approach [28] with a qualitative, artifact-centered evaluation. The object is the pipeline, not the population represented in the datasets; no prevalence, causal effect, healthcare effectiveness, or comparative end-performance is estimated.

The case study used pre-existing municipal sources concerning persons with disabilities, including health and other sectors, inside an authorized institutional analytical environment. There was no participant recruitment or intervention, and no person-level findings are disclosed. Under the LGPD minimization principle [3], the paper reports neither record volumes nor frequencies, coverage rates, rare categories, or extracts. These controls do not replace ethics review when required by a future study design.

Inferential statistics are not supported because the sources are administrative rather than probability samples, service contact affects inclusion, extraction periods and coding practices differ, repeated rows may be duplicates or legitimate events, missingness is workflow-dependent, identifiers can be incomplete or unstable, and complete population denominators are unavailable for some sources. Counts and coverage ratios are therefore treated only as descriptive accounting signals, without confidence intervals, hypothesis tests, or causal interpretation.

B. Analytical Units, Linkage, and Privacy

Administrative data accommodate different units of observation. A record preserves an occurrence produced by the system; a person represents the unique entity to which multiple occurrences may be associated; and a link expresses that person's presence in a particular source, service, or policy. This distinction is critical because deduplication does not have a single meaning. Removing repetitions may be

appropriate for population indicators and inappropriate for utilization analyses, in which repeated occurrences constitute the phenomenon being observed. Reporting guidelines for studies using routinely collected data reinforce the need to make the population, analytical unit, and treatment of records explicit [2].

Record linkage seeks to identify when observations from different sources or time points refer to the same entity. Deterministic strategies may rely on direct identifiers, while auxiliary keys combine normalized registration attributes when those identifiers are missing or invalid [21]. The usefulness of each alternative depends on field availability, stability, and quality. Key provenance and matching confidence are therefore part of the analytical information, not merely implementation details. Records with insufficient evidence should remain unlinked because a forced match may alter denominators and introduce associations that do not exist [24].

Pseudonymization and anonymization serve different purposes along this path. Internal codes reduce the circulation of identifiers during processing, but still allow links to be reconstructed within an authorized environment. Disclosure requires an additional control layer based on aggregation, small-group suppression, reduced granularity, and assessment of residual reidentification risk. NIST guidance for government data treats deidentification as a process tied to objectives, release models, and continuous risk management [25]. This distinction treats privacy as a workflow-level requirement that extends beyond the initial handling of the input file.

C. Computational Resources and Exploration Techniques

Python and Jupyter Notebook support profiling, normalization, pseudonymization, deduplication, linkage, aggregation, and documentation. GeoPandas and Shapely handle territorial geometry and point-in-polygon joins; HTML, CSS, and JavaScript present aggregates without embedding calculation logic in the interface. Separating analytical code from presentation supports re-execution and inspection [19].

AI assistance was restricted to planning through ChatGPT (OpenAI) using the MEADS-LLM V7 prompt/analytical grammar. Because the hosted interface was not version-pinned, the exact backend build was not recorded as an experimental factor and model updates may alter proposed axes. Input was limited to institutional objectives and a sanitized data dictionary; individual values, formulas, linkage rules, and disclosure decisions remained outside the interaction. Numerical evidence was produced by local, inspectable code.

D. Execution and Audit Artifacts

The technical notebook retains loading, transformations, and calculations in re-executable form, while a styled notebook and dashboard reorganize only approved aggregates. An execution summary records warnings; the manifest identifies the aggregates consumed by the interface; and the calculation record stores formula, filter, denominator, and unit. This separation follows reproducible notebook practice [29]. The curation matrix links each visual component to its question, reference universe, evidence, and disclosure limit, adding semantic inspection to computational reproducibility [18].

E. Evaluation Criteria

The qualitative evaluation uses four criteria: *unit integrity*, preserving distinct meanings for records, persons, and links [6]; *traceability*, connecting results to source, formula, denominator, and filter [18]; *coverage accounting*, retaining failed linkages and territorial assignments; and the *privacy boundary*, examining logical and organizational controls that reduce unnecessary exposure [25]. These criteria assess artifact inspectability, not statistical validity, linkage accuracy, user effectiveness, or reidentification resistance.

F. Synthetic Linkage Sensitivity Check

A fully synthetic stress test examined the deterministic identity rule without exposing restricted records. For each noise level, 30 deterministic replicates (base seed 8972026) generated 5,000 fictitious identities with a random 11-digit identifier, name, mother's name, and birth date; 10% formed homonym pairs sharing name and birth date. Matching used exact identifier, then normalized name–mother–birth date, then name–birth date, rejecting ambiguous keys. Independent 0%, 5%, 10%, or 20% per-field perturbation either removed a value or changed one character. Recovery, precision, and unmatched proportion were recorded. The test isolates this exact-matching rule and does not represent correlated errors, temporal drift, real identifier distributions, probabilistic linkage, or municipal-data accuracy.

IV. MEADS-Health Methodology

The MEADS-Health architecture is shown in Fig. 1. The workflow separates the institutional environment, where records are held and processed, from the LLM-support environment. Communication between them is limited to the institutional objective, sanitized schema, and preliminary axis plan. Dataset rows, identifiers, and individual values do not cross this boundary. This boundary also assigns responsibilities: the model supports analytical planning, local code performs the computation, and the responsible team controls validation and release.

A. Protected Reading and Analytical Contract

Reading begins in the protected environment. In Steps 1–3 of Fig. 1, the purpose is delimited, file structures are examined, and fields are classified by sensitivity. The initial profile includes encoding, inferred data types, missingness, cardinalities, and candidate keys. Technical field names are then replaced with understandable descriptions, such as person name, identifier, parentage, date of birth, age, address, and clinical notes. The result is a generalized data dictionary that describes the structure without exposing record contents.

Before any cross-source linkage, the request is formalized in an analytical contract. The document records the purpose, authorization, reference population, period, counting unit, required sources, and intended audience. This agreement

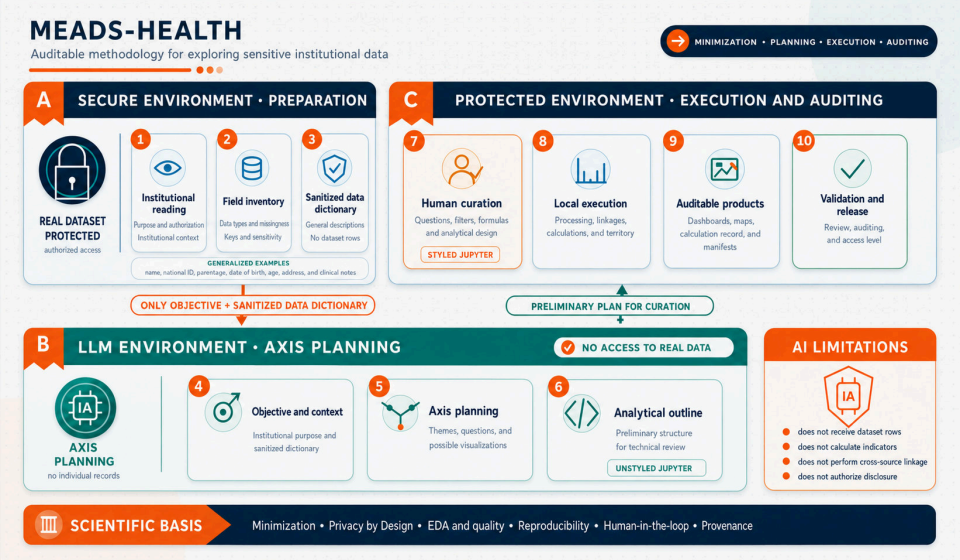

Fig. 1. MEADS-Health architecture. AI supports initial planning, while calculations, linkages, products, and release decisions remain in the protected environment.

prevents the mere technical possibility of combining files from being treated as sufficient justification for doing so. It also distinguishes population questions, which require unique persons, from healthcare-utilization questions, in which repeated occurrences may represent actual service use.

B. AI-Assisted Axis Planning

In Steps 4–6, the institutional objective and sanitized data dictionary form the LLM input. The request asks for analytical axes, guiding questions, plausible groupings, and visualization possibilities. Given the structure of a health dataset, for example, the model may suggest topics related to registration profiles, healthcare follow-up, territorial distribution, and data-entry quality. Because dataset values are not part of the input, this output contains no counts, diagnoses, or inferences about individuals.

Suggestions are organized into an analytical notebook outline. Each item states the intended question and the fields potentially required, without yet taking the form of a final indicator. Axes with no institutional value, incompatible with the schema, or excessively granular for the authorized purpose are removed during review. Only after this screening are the formula, filter, unit, denominator, and privacy rule defined. The model proposes candidate questions, and the team decides which ones are supported by the available sources and authorized purpose.

C. Curation, Execution, and Identity Control

In Step 7, analysts and domain specialists convert the outline into an executable plan. Each question is reviewed against the unit of analysis, reference universe, available fields, and disclosure level. Related axes are grouped into macro-components so that the dashboard preserves a coherent reading path rather than presenting independent charts organized only by column availability.

Step 8 returns the plan to the local environment and begins the workflow detailed in Fig. 2. Labels, dates, and characters are normalized, but original values remain in the audit trail whenever a transformation could affect matching. Invalid identifiers are explicitly flagged rather than corrected by assumption. The key strategy follows the conditions of each source, and its provenance remains associated with the resulting links.

Deduplication occurs only after the unit has been defined. Population indicators retain one internal code per individual, whereas utilization analyses preserve repeated occurrences. In cross-source analyses, the source specified in the analytical contract serves as the reference universe, while the others add information without silently changing the denominator. Coverage of source S relative to universe U is expressed as

$$C_s = \frac{N(U \cap S)}{N(U)} \times 100. \tag{1}$$

Here, C_s is an accounting flag, not a validated statistical estimator. Missing or malformed identifiers, spelling/date variation, duplicate handling, and non-overlapping extraction periods can change the numerator; strict keys may increase false nonmatches and relaxed keys false matches. Because the municipal sources have no reviewed linkage gold standard, unmatched records and key provenance are retained rather than treating C_s as population coverage. The synthetic experiment below probes only the deterministic rule under controlled perturbation and does not validate C_s on real records.

D. Territorial Enrichment

The territorial branch in Fig. 2 examines existing coordinates and addresses eligible for geocoding. Missing coordinates, reversed axes, locations outside the study boundary, and incompatibility with the area of interest produce distinct

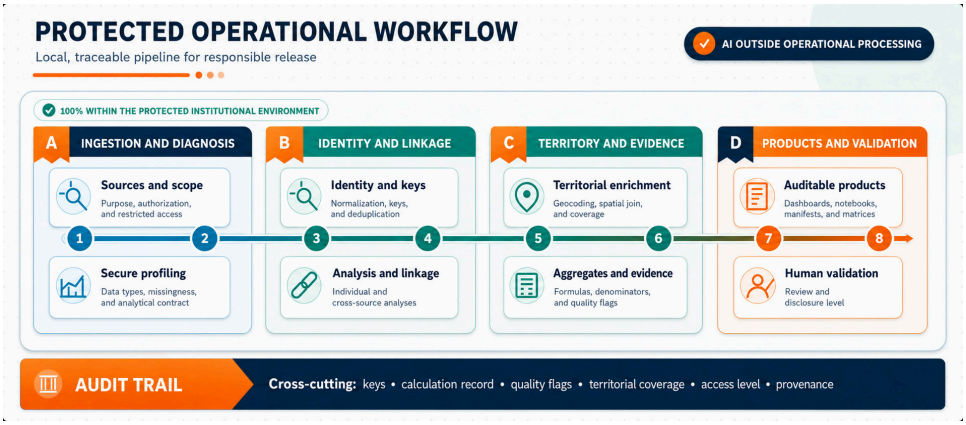

Fig. 2. Protected operational workflow. Processing, linkage, calculations, and validation are performed locally without AI participation.

flags. When a point is valid, a point-in-polygon join assigns the corresponding administrative division. Territorial coverage is calculated in the processed file itself:

$$C_g = \frac{N(\text{records with an assigned division})}{N(\text{records assessed})} \times 100. \qquad (2)$$

The ratio C_g is likewise a bookkeeping signal, not a validated spatial statistic. Missing or stale addresses, geocoding noise, coordinate errors, and polygon mismatch affect it, so it cannot establish representativeness of the mapped population.

Three situations remain separate: a valid point with an assigned area, an available point with no territorial match, and insufficient information for assignment. This distinction matters in health analysis because an apparently underrepresented territory may reflect poor registration quality rather than low demand. Point maps remain restricted to the authorized environment. Released products use area-level counts and small-group suppression whenever granularity could facilitate reidentification.

E. Products, Auditing, and Release

In Steps 9 and 10, the executed plan produces a set of complementary artifacts. The technical notebook preserves data loading, transformations, and calculations; the styled notebook reorganizes the institutional reading without replacing the computational source. The dashboard presents the macro-components, the calculation record documents formulas and denominators, the execution summary brings together warnings, and the manifest lists the aggregates consumed by the interface.

Each visual component has a corresponding entry in the curation matrix. Approval depends on agreement among the question, unit, denominator, filter, formula, and value. Human validation also determines the access level, which may be restricted, institutional aggregate, or public aggregate. Internal interfaces may query detailed files within the authorized environment, but those files are not included in the release package.

V. Results of the Methodological Application

A. Adaptation to Heterogeneous Sources

During the case study, heterogeneous sources used a common workflow without a single counting rule: person registries used individual-oriented deduplication, healthcare records retained events, and program datasets represented links. This preserved the intended unit in the artifacts, but no comparison established greater numerical accuracy than an alternative pipeline. Direct identifiers remained distinguishable from auxiliary keys, insufficient matches stayed unlinked, and key provenance followed the aggregates.

B. Analytical Axes and Products

The V7 planning grammar contained 17 reusable axis templates. For the health-source configuration, sanitized metadata activated 10 templates for the technical notebook; seven were not carried into execution because their required field roles were absent. This count describes how the planning grammar filtered the available templates and should not be interpreted as a measure of LLM quality. Human review could still remove, merge, or reorganize activated proposals before notebook development. The retained questions addressed population follow-up, healthcare records, territory, registration quality, and integration with other policies; the model defined neither final indicators nor clinical interpretations. Approved axes became dashboard macro-components linking each question to its unit, fields, filter, visualization, and interpretation warning.

C. Synthetic Linkage Sensitivity

Table I shows the bounded stress test. Recovery fell from 100.0% to 93.1% as field noise reached 20%; precision remained above 99.7%, while unmatched records rose to 6.7%. Composite fallbacks recovered some corrupted direct identifiers, but the nonzero false-link rate confirms that the rule is not noise-invariant.

Across the 30 replicates at each nonzero noise level, recovery SDs were 0.09, 0.21, and 0.33 percentage points at 5%, 10%, and 20% noise. These are simulation outputs, not institutional linkage estimates.

TABLE I
SYNTHETIC SENSITIVITY OF THE DETERMINISTIC LINKAGE RULE

Field noise	Recovery	Precision	Unmatched
0%	100.00%	100.00%	0.00%
5%	99.50%	99.98%	0.48%
10%	98.11%	99.92%	1.81%
20%	93.10%	99.78%	6.69%

TABLE II
QUALITATIVE EVALUATION: CRITERION AND OBSERVED EVIDENCE

Criterion	Observed evidence	Interpretation limit
Unit integrity	Separate record-, person-, and link-oriented paths; deduplication after unit definition.	Does not establish numerical correctness.
Traceability	Notebook, calculation record, manifest, curation matrix, and key/coordinate provenance.	Supports reconstruction, not external replication of restricted data.
Coverage accounting	Unmatched links and territorial failures retained; C_s and C_g recorded descriptively.	Not a validated completeness or coverage estimate.
Privacy boundary	Record values excluded from LLM input; release artifacts aggregated and curator-reviewed.	Reduces exposure pathways but does not eliminate residual risk.

D. Territory and Preservation of Failures

Territorial enrichment assigned administrative divisions to valid points while retaining unresolved cases in internal coverage reports. This distinguished missing geographic information from absence of an occurrence and prevented registration gaps from being attributed to the territory. Coordinate origin was also preserved, separating values present in the source, recovered from another authorized dataset, or rejected during validation. This provenance accompanies the maps and limits the claims supported by the spatial distribution.

E. Dashboard Auditability

The dashboard was accompanied by the calculation record and curation matrix. Table II maps each qualitative criterion to observed evidence and its interpretation limit.

Audit review exposed discrepancies in units, denominators, and legends that were not apparent from the interface alone; they returned to the plan before release. No error-reduction rate, review time, or final analytical accuracy was measured.

VI. DISCUSSION

MEADS-Health is an analytical-engineering methodology rather than a predictive model, and the evidence from the case study is operational. Analytical contracts framed heterogeneous sources; records, persons, and links retained distinct meanings; matches preserved provenance; territorial failures remained visible; and dashboard components were connected to audit documents. The paper therefore presents no epidemiological estimates or sector-performance comparisons. This delimitation is particularly important for health sources, where medical reports, clinical codes, medications, procedures, and care notes may encourage inferences beyond what administrative data support. Their use depends on a previously defined question, unit, and purpose.

The synthetic test adds a bounded performance observation: exact fallback keys preserved high recovery under independent perturbations, but increasing noise produced both unmatched records and false links. Generated identities and simplified errors mean that this result cannot resolve real-world linkage uncertainty.

The LLM boundary translates governance principles into an architectural decision. International guidance recommends minimization, oversight, and risk management [12], [14], [30]; here, only the sanitized data dictionary reaches the model, while records remain in local execution and curators review proposals, calculations, and aggregate evidence. AI output supports early planning but does not constitute evidence, a final formula, or authorization for use.

The results also distinguish reproducibility from auditability. Re-executing a notebook can reproduce a value, but cannot show by itself that the denominator answers the question or that the interpretation suits the audience. The curation matrix adds this semantic layer by connecting the result, unit, formula, context, and disclosure condition. This brings the dashboard closer to institutional decision-making routines [9]–[11].

A. Implications for Health and Public Management

A missing match between a registration source and a healthcare record may indicate that the event did not occur, the key failed, the periods differ, or the extraction covers only part of the system. MEADS-Health preserves this ambiguity as provenance and coverage information rather than resolving it through automatic inference. The same caution applies to territory: a spatial concentration may reflect demand, service supply, referral patterns, or more complete addresses. Reporting coverage and geographic origin reduces the risk of treating graphical precision as evidence of information completeness.

The components are candidates for transfer to comparable public-sector settings, but transferability has not been empirically tested. Keeping record values outside the AI layer reduces one potential exposure pathway, but it does not guarantee privacy. Detailed metadata, small aggregates, access-control failures, and curator errors can still create residual risk.

B. Limitations

This single-context study used a qualitative, artifact-level evaluation. No direct pipeline comparison or endpoint for analytical accuracy, efficiency, user performance, or decision quality was defined; restricted data also prevent external replication. Auxiliary-key matches lacked a reviewed gold standard, so linkage accuracy is unknown.

The synthetic sensitivity check covers only independent missingness or single-character perturbation in four identity fields. It does not reproduce correlated registration errors, legal name changes, coding drift, duplicate creation, stale addresses, geocoding error, or source-specific missingness. Real-world linkage accuracy remains unknown without a reviewed gold standard, and territorial robustness remains untested. With unstable keys or incomplete source capture, linkage and coverage

flags may still be too uncertain for cross-source interpretation. The hosted LLM was not version-pinned, so repeated planning may differ.

Privacy controls are logical and organizational barriers, not guarantees. Reversible pseudonyms, quasi-identifiers, small groups, detailed metadata, access misconfiguration, and human release decisions leave residual risk; no reidentification attack or quantitative privacy-risk assessment was performed. Future work should add direct pipeline comparisons, reviewed real-data linkage references, correlated and source-specific noise models, territorial sensitivity tests, curator agreement, privacy-risk analysis, and prospective measurement of rework and validation time.

VII. Conclusion

MEADS-Health is a preliminary methodological artifact for organizing sensitive institutional-data exploration around explicit analytical units, provenance, local computation, and human-controlled AI assistance. The municipal case study produced inspectable notebooks and audit artifacts, while a separate synthetic stress test supplied bounded evidence on the deterministic linkage rule. Under independent field perturbation, match recovery declined predictably while precision remained high; this result does not substitute for a reviewed real-data gold standard. No alternative pipeline, final analytical accuracy, operational gain, or population-level inference was tested.

The available evidence supports the architecture, audit trail, and limited robustness of the deterministic matching component. End-to-end effectiveness and generalization were not evaluated. The method may become inconclusive with incomplete source capture, correlated or systematic key errors, stale territorial data, or disclosure granularities that raise residual reidentification risk. Reviewed linkage references, direct comparisons, richer noise models, territorial sensitivity tests, privacy-risk analysis, and prospective measurement of curator agreement and rework time are needed before practical benefits can be quantified.

Acknowledgments

The authors thank the teams responsible for the governance, maintenance, and interpretation of the institutional datasets used in developing the methodology. This work preserves record confidentiality and presents only methodological aspects and audit evidence.

***Abstract*—Emergency department triage requires the integration of heterogeneous information under time and resource constraints, while class imbalance may limit the recognition of less frequent urgency categories. This study investigates modern Hopfield networks with patient-level associative memory for predicting the five-level urgency assignment recorded in the 2022 National Hospital Ambulatory Medical Care Survey Emergency Department dataset. The final unweighted cohort comprised 10,207 emergency department visits, divided into training, validation, and test sets using a fixed stratified partition. Two architectures were evaluated: a shared-memory model, in which selected training visits were stored in a single associative memory, and a class-aware model, in which the same patterns were organized into five urgency-specific memory banks. The proposed models were compared with ZeroR, proportional-odds ordinal logistic regression, k-nearest neighbors, and XGBoost. XGBoost achieved the highest test accuracy (0.5836) and the lowest ordinal mean absolute error (0.4543). In contrast, the class-aware Hopfield model obtained the highest macro-F1 (0.3861) and balanced accuracy (0.4014), while the shared-memory model achieved the highest quadratic weighted kappa (0.4514). The Hopfield architectures substantially improved recall for under-represented urgency classes, including the most urgent category, for which XGBoost obtained zero recall and the class-aware model achieved 0.19. These results indicate that class-structured associative retrieval may reduce majority-class concentration and improve coverage across urgency levels. However, this benefit was accompanied by lower overall accuracy and higher ordinal error than XGBoost, and did not reduce severe undertriage relative to the best conventional model. Modern Hopfield networks therefore provide a promising approach for class-balanced triage prediction, but require further investigation across multiple seeds, datasets, and externally separated evaluation settings.**

***Index Terms*—Modern Hopfield networks, associative memory, emergency department triage, urgency classification, machine learning.**

I. Introduction

Emergency department triage is a time-critical process in which patients are rapidly assessed and assigned an urgency level to guide prioritization, resource allocation, and timely access to care. Inaccurate triage may affect both individual patients and emergency department operations. Undertriage can delay the evaluation and treatment of patients with urgent conditions, whereas overtriage can divert limited resources from patients with greater needs and contribute to congestion in high-acuity pathways. Triage decisions are therefore not merely administrative classifications, but a central component of emergency care that influences waiting times, patient flow, and the delivery of appropriate treatment [1], [2]. In an observational study comparing nurses' initial Emergency Severity Index assignments with classifications derived from the ESI handbook, the reported overall accuracy was 67%, while undertriage and overtriage occurred in 25% and 8% of cases, respectively, illustrating that classification discrepancies remain frequent in practice [2].

Accurate triage remains challenging because urgency assessment depends on the interaction of multiple sources of information and is performed under demanding operational conditions. Presenting complaints, vital signs, visual assessment, patient history, professional experience, training, workload, interruptions, and emergency department crowding may all influence the assigned urgency level [1]. These difficulties may be particularly relevant for older adults, whose serious conditions can manifest through nonspecific complaints, atypical symptoms, or physiological measurements that do not clearly indicate deterioration. Such presentations increase the risk that an urgent patient will be assigned to a lower-priority category, potentially prolonging waiting time and delaying necessary evaluation and treatment [3]. These limitations motivate the development of decision-support methods capable of integrating heterogeneous triage information more consistently.

Machine learning provides a promising opportunity to support this process. By learning complex and potentially nonlinear relationships among routinely collected variables, including demographic characteristics, mode of arrival, chief complaints, and vital signs, machine-learning models may identify patterns that are difficult to represent using fixed rules

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES), and supported by the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq).

or conventional scoring systems. Using 135,470 adult visits from the National Hospital Ambulatory Medical Care Survey (NHAMCS), Raita et al. found that several machine-learning approaches outperformed an ESI-based reference model in predicting critical care and hospitalization outcomes. For critical care prediction, the best-performing model achieved an area under the receiver operating characteristic curve of 0.86, compared with 0.74 for the conventional model, and identified a larger proportion of critically ill patients assigned to lower-acuity ESI categories [4]. More broadly, a systematic review of 26 studies reported that artificial intelligence- and machine-learning-based triage models frequently achieved AUC values above 0.80 and often outperformed conventional triage tools, particularly when structured clinical variables were combined with textual information [5]. Nevertheless, much of the available evidence is retrospective, single-center, and characterized by limited external validation. These technologies should therefore be regarded as potential decision-support tools rather than replacements for clinical assessment [5].

Within this context, Modern Hopfield Networks have renewed interest in associative-memory models by addressing several limitations of their classical formulations. Classical Hopfield networks operate primarily with binary states and have limited storage capacity. Modern formulations introduce alternative energy functions and continuous-valued states, with theoretical results showing storage capacity that can grow exponentially with the dimension of the associative space under suitable conditions, rapid pattern retrieval, and differentiable integration into deep learning architectures [6]. Their update rule has also been shown to correspond to the key–value attention mechanism used in Transformer architectures, providing an energy-based interpretation of attention as the retrieval of either an individual stored pattern or a weighted combination of related patterns [6], [7]. Modern Hopfield Networks can consequently serve as trainable layers for memory, association, attention, prototype learning, and pooling.

The practical relevance of these properties has been demonstrated across heterogeneous learning problems. In computational biology, Hopfield-based attention has been used to retrieve informative patterns from immune repertoires containing hundreds of thousands of instances, supporting both classification and the identification of disease-associated sequence motifs [7]. Modern Hopfield Networks have also been applied to reaction-template retrieval, where learned associations between molecular and template representations improved prediction for rare and previously unseen templates [8], and to graph representation learning, where associative memories were used to encode structural prototypes for node classification and link prediction [9]. For tabular data, Hopular demonstrated that the training set can be stored as an external memory and accessed across successive layers to model sample–sample, feature–feature, and feature–target dependencies, achieving competitive performance against established gradient-boosting and deep learning methods [10]. Collectively, these studies motivate the use of Modern Hopfield Networks when predictions may benefit from content-addressable access to previously observed examples or learned prototypes.

This capability is conceptually relevant to emergency triage. Patients with similar demographic characteristics, presenting complaints, physiological measurements, and arrival conditions may exhibit related patterns of recorded urgency. A Modern Hopfield Network can encode a current patient visit, compare that representation with encoded visits from the training set, and retrieve a weighted combination of related historical cases before producing a prediction. Unlike conventional nearest-neighbor methods, for which similarity is determined by a predefined distance in the input or preprocessed feature space, the Hopfield-based approach can jointly learn the patient representation and the association mechanism used for retrieval. However, the studies reviewed above do not establish how patient-level associative-memory architectures compare with conventional ordinal, tree-based, and nearest-neighbor models for five-level classification of recorded emergency-triage urgency. In particular, the balance between overall predictive performance, recognition of underrepresented urgency classes, and errors toward lower recorded urgency remains to be characterized in this setting.

To address this gap, this study evaluates Modern Hopfield Networks with patient-level associative memory for predicting five recorded urgency levels using the 2022 NHAMCS Emergency Department dataset [11]. The memory is constructed exclusively from encoded training visits, while validation and test visits act only as queries and are never incorporated into the stored memory. For each current visit, the model retrieves representations of training cases and combines them with the visit's own representation before producing class probabilities. We evaluate both a shared-memory architecture, in which the selected training visits constitute a single associative memory, and a class-aware variant, in which stored patterns are organized according to their recorded urgency classes.

The proposed architectures are compared with complementary baselines: a majority-class ZeroR model [12], proportional-odds ordinal logistic regression [13], multiclass k-nearest neighbors [14], and multiclass XGBoost [15]. These baselines represent class-frequency-based prediction, linear ordinal modeling, conventional instance-based learning, and nonlinear tree-based classification. Performance is evaluated on a common fixed data partition using accuracy, macro-F1, balanced accuracy, ordinal mean absolute error, and quadratic weighted kappa. Because the class labels are ordered from immediate to nonurgent care, we additionally quantify undertriage and severe undertriage relative to the recorded urgency assignment. These measures describe disagreement with the recorded labels rather than independently adjudicated clinical error. A complementary analysis of the shared-memory model compares full, disabled, and uniform retrieval at inference time, with trained weights held fixed, to assess how these interventions affect predictions and performance. Accordingly, the study characterizes the predictive and ordinal trade-offs of the evaluated architectures; differences in class weighting and model capacity preclude attributing performance differences

exclusively to associative retrieval.

II. Methodology

A. Dataset and Preprocessing

This retrospective study used the 2022 Emergency Department Public Use File of the National Hospital Ambulatory Medical Care Survey (NHAMCS) [11]. The observational unit was an emergency department visit. Of the 16,025 original records, 10,207 visits with `IMMEDR` values from 1 to 5 were retained. Records coded as -9, -8, 0, or 7 were excluded because they did not contain an ordered urgency label compatible with the supervised five-class task. The target preserved the original ordering: 1 (Immediate), 2 (Emergent), 3 (Urgent), 4 (Semi-urgent), and 5 (Nonurgent), with lower values indicating higher recorded urgency. The final class counts were 139, 1,595, 5,340, 2,826, and 307, respectively, as shown in Fig. 1. The outcome was interpreted as the urgency recorded in NHAMCS rather than an independently adjudicated clinical ground truth. Survey weights and complex-sampling variables were not used; therefore, the reported results describe the retained unweighted sample and are not national estimates.

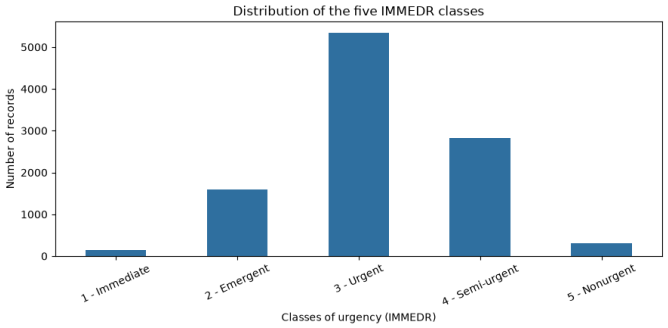

Fig. 1. Distribution of recorded urgency classes in the retained NHAMCS sample.

Twenty-six predictors designated as available at the initial triage assessment were considered. Numerical variables comprised age, temperature, pulse rate, respiratory rate, systolic and diastolic blood pressure, oxygen saturation, and pain score. Two binary indicators represented special pulse and blood-pressure measurement codes. Categorical variables included visit month and weekday, residence, sex, ethnicity, race, emergency-medical-services arrival, ambulance transfer, a previous visit within 72 hours, five coded reasons for visit, and visit episode. Arrival time was treated as a temporal variable. Identifiers, hospital codes, survey-design variables, the target, diagnoses, injury and external-cause fields, dispositions, admissions, transfer outcomes, deaths, and other post-triage information were excluded to reduce temporal and target leakage.

All preprocessing parameters were estimated exclusively from the training set and then frozen. For ordinal logistic regression, k-nearest neighbors, and the Hopfield models, missing numerical values were imputed with training medians, missingness indicators were added, and continuous variables were standardized using training means and population standard deviations. For XGBoost, numerical missing values were retained and no standardization was applied [15]. Arrival time was converted from HHMM to minutes after midnight and represented by $\sin(2\pi t/1440)$ and $\cos(2\pi t/1440)$; missing values were additionally marked by an indicator. Categorical levels occurring fewer than 100 times in the ordinal model or fewer than 10 times in the remaining feature-based models were grouped as infrequent, while blank, unknown, and not-applicable categories were preserved. After numerical and temporal processing and one-hot encoding of categorical variables, the final feature matrices contained 91 variables for ordinal logistic regression, 491 for XGBoost, and 499 for k-nearest neighbors and the Hopfield architectures.

B. Baseline Models

Four baselines represented complementary assumptions. ZeroR ignored the predictors and returned the empirical training-class distribution, with the majority class used for hard predictions [12]. Proportional-odds ordinal logistic regression modeled the cumulative probabilities of the five ordered classes using a shared coefficient vector and four thresholds [13]; the model was fitted without regularization by L-BFGS, with a maximum of 1,000 iterations [16].

Multiclass k-nearest neighbors provided a conventional instance-based comparison in the fixed preprocessed feature space [14]. A validation grid evaluated $k \in \{1, 3, 5, 7, 11, 15, 21, 31\}$, uniform or inverse-distance voting, and Manhattan or Euclidean distance. Selection minimized validation ordinal mean absolute error, with macro-F1 and log loss used as tie-breakers; the selected model used 31 neighbors, Manhattan distance, and uniform voting.

XGBoost represented a nonlinear tree-based baseline [15]. It used a five-class probabilistic objective, histogram-based trees, learning rate 0.05, maximum depth 6, minimum child weight 1, row and feature subsampling of 0.8, L2 regularization of 1, and at most 2,000 boosting rounds. Early stopping monitored validation multiclass log loss with patience of 100 rounds, selecting 351 rounds.

C. Proposed Modern Hopfield Models

Both proposed models used the same 499-dimensional input and encoded each visit into a 64-dimensional latent representation $\mathbf{z}$. The encoder followed the sequence $499 \to 128 \to 64$, with layer normalization and GELU activations after both linear layers and dropout of 0.20 after the first. Independent learned projections produced 64-dimensional queries, keys, and values. Given a projected query $\mathbf{q}$ and stored training representations $\{(\mathbf{k}_i, \mathbf{v}_i)\}_{i=1}^{N}$, where N denotes the number of stored patterns, one modern Hopfield retrieval update was computed as [6]

$$a_i = \frac{\exp\left(\beta \mathbf{q}^\top \mathbf{k}_i\right)}{\sum_{j=1}^{N} \exp\left(\beta \mathbf{q}^\top \mathbf{k}_j\right)}, \qquad \mathbf{r} = \sum_{i=1}^{N} a_i \mathbf{v}_i, \tag{1}$$

with fixed scaling $\beta = 1/\sqrt{64} = 0.125$. A single associative head and one update were used.

The memory was constructed exclusively from training visits. At most 256 visits were sampled without replacement from each recorded urgency class, while classes with fewer observations contributed all available visits. This produced 1,080 stored patterns with class counts $(97, 256, 256, 256, 215)$. The same selected visits were used in both architectures. Thus, both memories used the same class-capped sampling scheme rather than reproducing the original training-class distribution. Memory embeddings were recomputed with the current encoder during training and detached from the computational graph. Validation and test visits were never added to memory. When a training query was itself stored, its corresponding pattern was masked before the association softmax to prevent direct self-retrieval.

In the shared-memory model, all 1,080 patterns formed a single bank. The encoded current-visit representation $\mathbf{z}$ and retrieved representation $\mathbf{r}$ were concatenated and passed through a $128 \to 64 \to 5$ classification head with GELU and dropout of 0.20. The model contained 93,701 trainable parameters.

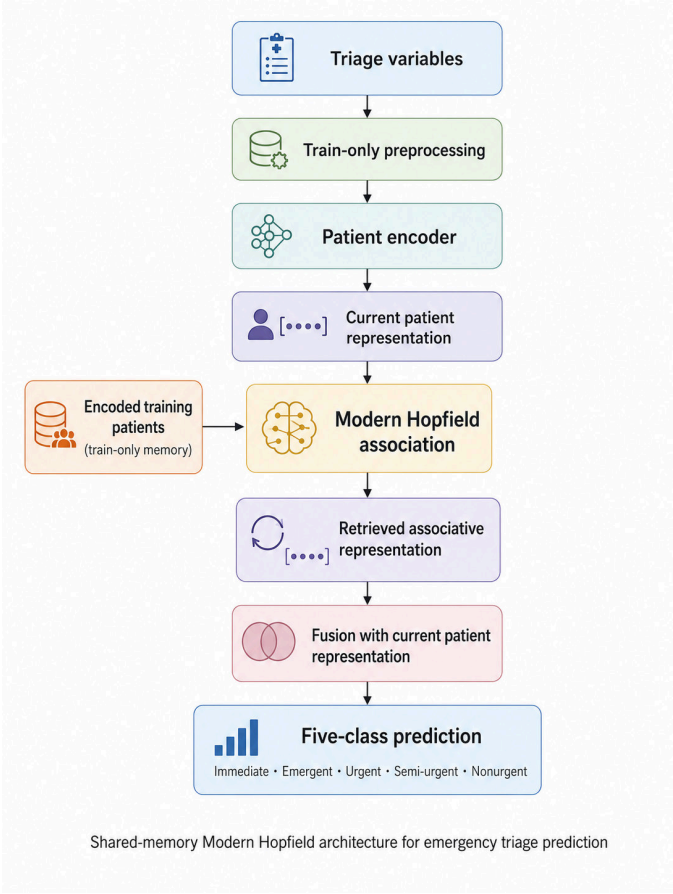

Fig. 2. Shared-memory modern Hopfield architecture. The encoded emergency department visit queries a single memory containing training visits. The retrieved representation is concatenated with the current-visit representation before five-class prediction.

In the class-aware model, the same stored patterns were separated into five banks according to their recorded urgency classes. The query independently retrieved one representation from each bank:

$$\mathbf{r}_c = \sum_{i=1}^{M_c} a_{c,i}\mathbf{v}_{c,i}, \qquad c \in \{1, \ldots, 5\}, \tag{2}$$

where M_c denotes the number of stored patterns in class c, and association weights were computed as in Eq. (1), with normalization restricted to the corresponding bank. A size-adjusted evidence score was calculated as $s_c = \log \sum_{i=1}^{M_c} \exp(\beta \mathbf{q}^\top \mathbf{k}_{c,i}) - \log M_c$, and the five scores were normalized by softmax across banks. The classifier received the current-visit representation, the five retrieved representations, and the five normalized bank scores, resulting in a $64+5\times64+5 = 389$-dimensional input followed by a $389 \to 64 \to 5$ head with GELU and dropout of 0.20. The class-aware model contained 110,405 trainable parameters. Thus, the variant differed from the shared-memory model in memory organization, the number of retrieved representations, the use of bank-level evidence, and classifier size; their comparison did not isolate memory organization alone.

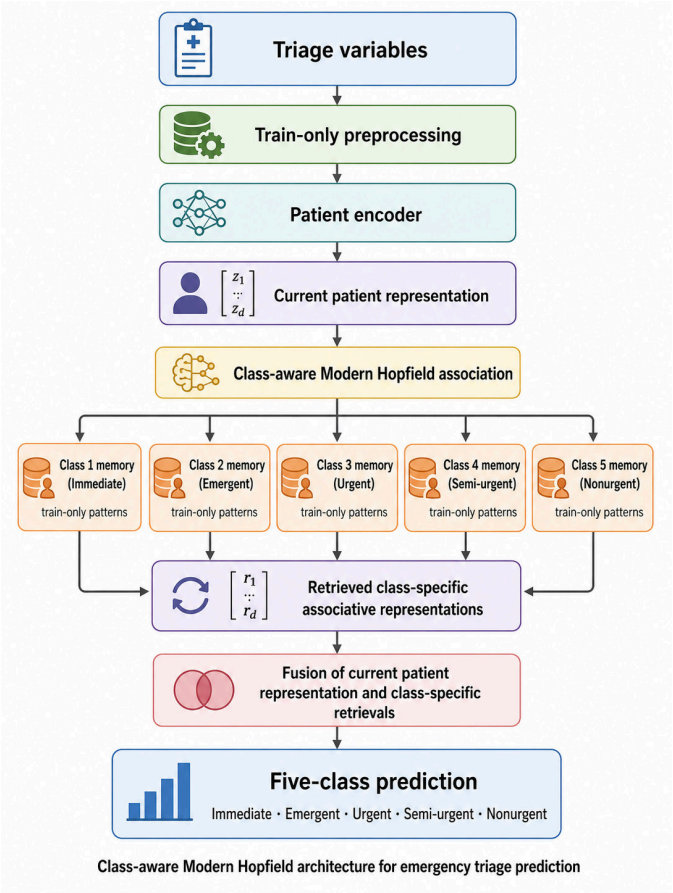

Fig. 3. Class-aware modern Hopfield architecture. Training visits are separated into five memory banks according to recorded urgency. The query retrieves one representation from each bank, and the resulting representations and bank-level evidence are combined with the current-visit representation before prediction.

D. Training and Experimental Protocol

The 10,207 visits were divided once into training, validation, and test sets using a two-stage stratified random split with seed 2022. The partitions contained 7,144, 1,531, and 1,532 visits, respectively, and the same assignments were used for every model. Splitting was performed at the visit level rather than by hospital or individual. Preprocessing and model fitting used only the training set; validation data were used for hyperparameter or checkpoint selection, and models were not refitted on training plus validation before final testing.

The Hopfield models were trained with class-weighted cross-entropy, where $w_c = N_{\text{train}}/(5n_c)$, with n_c denoting the number of training visits in class c. This yielded weights approximately equal to $[14.730, 1.280, 0.382, 0.722, 6.646]$. These weights addressed class imbalance but did not explicitly encode the ordinal distance or direction of prediction errors. Optimization used AdamW with learning rate 10^{-3}, weight decay 10^{-4}, batch size 128, and a maximum of 50 epochs. Validation log loss was monitored after each epoch; early stopping used a minimum improvement of 10^{-4} and patience of seven epochs. Both variants used seed 2026 and one formal training run.

Final predictions were obtained by selecting the class with the highest predicted probability, with probability columns consistently ordered as classes 1 through 5. Performance was assessed on the same 1,532 test visits using accuracy, macro-F1, balanced accuracy [17], ordinal mean absolute error [18], and quadratic weighted kappa [19]. Macro-F1 included all five classes, with undefined class-specific F1 values assigned zero. Quadratic weighted kappa used quadratic disagreement weights.

Undertriage relative to the recorded assignment was defined as $\hat{y} > y$, and severe undertriage as $\hat{y} - y \geq 2$, where y and $\hat{y}$ denote the recorded and predicted urgency levels, respectively. Both rates used all test visits as the denominator. These measures quantify disagreement with the recorded NHAMCS urgency and not independently adjudicated clinical error.

Comparisons were based on descriptive point estimates; no confidence intervals, paired hypothesis tests, or multiseed inferential analysis were performed. The baseline comparison evaluated the complete model configurations described above. Class weighting, memory sampling, and architectural capacity were not independently controlled, and no memory-free neural model was trained for a matched comparison. Consequently, differences between Hopfield models and conventional baselines cannot be attributed exclusively to associative retrieval.

E. Inference-Time Memory Analysis

A complementary analysis examined the dependence of the trained shared-memory model on its retrieved representation. Three conditions were evaluated: Full Memory, using the learned association weights in Eq. (1); Memory Disabled, replacing the retrieved representation with $\mathbf{r} = \mathbf{0}$; and Uniform Memory, replacing the association weights with $a_i = 1/N$, so that $\mathbf{r}$ became the mean of the stored value representations.

All conditions used the same validation-selected checkpoint, the same preprocessed test visits in the same order, and identical trained parameters. The current-visit representation and classification head were preserved. In Uniform Memory, the stored value representations and learned value projection were unchanged. Evaluation was performed with dropout disabled and without gradient computation or parameter updates. No retraining was performed.

For each condition, accuracy, macro-F1, ordinal mean absolute error, quadratic weighted kappa, undertriage, and severe undertriage were calculated. Relative to Full Memory, we additionally measured the percentage of visits whose predicted class changed and the mean Jensen–Shannon distance between the five-class probability distributions. Jensen–Shannon distance was computed per visit as the square root of the Jensen–Shannon divergence using natural logarithms, and then averaged across the test set.

III. Results

A. Overall Predictive Performance

Table I presents the performance of all models on the same 1,532 test visits. The results reveal a trade-off between overall predictive performance and recognition of less frequent urgency classes. XGBoost achieved the highest accuracy, at 0.5836, and the lowest ordinal mean absolute error, at 0.4543. It also outperformed the remaining conventional baselines across accuracy, macro-F1, balanced accuracy, ordinal MAE, and quadratic weighted kappa. All comparisons refer to descriptive point estimates from the evaluated runs.

The Hopfield architectures obtained the highest macro-F1 and balanced accuracy values. The shared-memory model achieved a macro-F1 of 0.3681 and a balanced accuracy of 0.3920, while the class-aware variant obtained 0.3861 and 0.4014, respectively. Compared with XGBoost, the class-aware model's macro-F1 was higher by 0.0732 and its balanced accuracy by 0.0964. These differences were accompanied by lower overall accuracy and higher ordinal MAE, indicating that broader recognition across classes did not translate into better performance on every metric.

Both Hopfield models also achieved higher quadratic weighted kappa than the conventional baselines. The shared-memory model obtained the highest QWK, at 0.4514, followed by the class-aware model at 0.4457. Thus, the Hopfield models exhibited greater chance-corrected ordinal agreement as measured by QWK, despite their higher MAE. The ordering of the models consequently depended on the ordinal metric considered.

The class-aware model obtained more favorable values than the shared-memory model on most reported metrics. Accuracy increased from 0.5222 to 0.5385, macro-F1 from 0.3681 to 0.3861, and balanced accuracy from 0.3920 to 0.4014. Ordinal MAE decreased from 0.5614 to 0.5366, while undertriage and severe undertriage decreased from 0.2402 to 0.2219 and from 0.0411 to 0.0307, respectively. However, QWK decreased from 0.4514 to 0.4457. These differences characterize the two

TABLE I

PREDICTIVE PERFORMANCE ON THE TEST SET. THE BEST VALUE AMONG THE LISTED MODELS FOR EACH METRIC IS SHOWN IN BOLD. UPWARD AND DOWNWARD ARROWS INDICATE WHETHER HIGHER OR LOWER VALUES ARE PREFERABLE, RESPECTIVELY. UNDERTRIAGE IS DEFINED RELATIVE TO THE RECORDED NHAMCS URGENCY.

Model	Accuracy ↑	Macro-F1 ↑	Balanced Acc. ↑	Ordinal MAE ↓	QWK ↑	Undertriage ↓	Severe Undertriage ↓
ZeroR	0.5228	0.1373	0.2000	0.5209	0.0000	**0.1704**	**0.0137**
Ordinal Logistic	0.5503	0.2524	0.2568	0.4961	0.2324	0.1991	0.0209
k-NN	0.5352	0.2130	0.2358	0.5157	0.1709	0.2422	0.0333
XGBoost	**0.5836**	0.3129	0.3050	**0.4543**	0.3844	0.2115	0.0183
Hopfield Memory	0.5222	0.3681	0.3920	0.5614	**0.4514**	0.2402	0.0411
Hopfield Class-Aware	0.5385	**0.3861**	**0.4014**	0.5366	0.4457	0.2219	0.0307

complete architectures and do not isolate the effect of memory organization from the additional retrieved representations, bank-level evidence, and larger classification head.

The lowest undertriage and severe-undertriage rates were obtained by ZeroR. This result should be interpreted in conjunction with its prediction behavior: because ZeroR always assigned the majority class, its low undertriage rates did not reflect effective discrimination among urgency levels. Among the feature-based models in Table I, XGBoost achieved the lowest severe-undertriage rate, at 0.0183. The corresponding rate for the class-aware model was 0.0307, an absolute difference of 1.24 percentage points. Neither Hopfield architecture reduced severe undertriage relative to XGBoost, and their higher class-balanced metrics should not be interpreted as evidence of greater clinical safety.

B. Class-Specific Error Patterns

Figure 4 compares the row-normalized confusion matrices of XGBoost, the shared-memory Hopfield model, and the class-aware Hopfield model. XGBoost produced predictions concentrated around class 3, the majority category. It correctly classified approximately 80% of recorded class-3 visits, but did not correctly identify any class-1 visits and correctly identified only 2% of class-5 visits. Among recorded class-1 visits, approximately 57% were assigned to class 3, while 70% of class-2 visits were also assigned to class 3.

The shared-memory Hopfield model distributed its predictions more broadly across the five classes. Its recalls for classes 1, 2, 4, and 5 were 0.14, 0.47, 0.56, and 0.24, respectively, compared with 0.00, 0.25, 0.46, and 0.02 for XGBoost. These recall patterns are consistent with the higher balanced accuracy and broader class coverage observed for the shared-memory model. Conversely, recall for the majority class decreased from 0.80 with XGBoost to 0.54 with the shared-memory model, contributing to its lower overall accuracy.

The class-aware model achieved recalls of 0.19, 0.50, 0.55, and 0.59 for recorded classes 1, 2, 3, and 4, respectively. Based on the rounded values, the largest recall increase relative to the shared-memory model occurred for class 1, followed by equal increases for classes 2 and 4. Recall for class 5, however, decreased from 0.24 to 0.17. The class-aware model also assigned approximately 50% of recorded class-5 visits to class 4, indicating that many errors for the lowest recorded urgency category involved the adjacent urgency level.

For the highest recorded urgency category, the class-aware model correctly classified approximately 19% of visits, compared with 14% for the shared-memory model and 0% for XGBoost. Nevertheless, most class-1 visits remained undertriaged relative to the recorded assignment: approximately 81% were assigned to classes 2–5 by the class-aware model and 86% by the shared-memory model. These percentages use class-1 visits as the denominator, unlike the global undertriage rates in Table I. Therefore, although the Hopfield architectures recognized more visits in the most urgent class, their absolute recall for this category remained limited.

Overall, the confusion matrices indicate that XGBoost favored the majority and central urgency categories, whereas the Hopfield architectures exchanged part of this majority-class performance for improved recognition of several less frequent classes. The class-aware model exhibited higher recall than the shared-memory model for classes 1–4, but lower recall for class 5, and substantial errors toward lower recorded urgency remained.

C. Inference-Time Memory Analysis

Table II presents the results of the inference-time interventions described in Section II-E. All three conditions used the same trained shared-memory checkpoint and the same test visits. Full Memory reproduces the Hopfield Memory results in Table I; Memory Disabled and Uniform Memory modify the retrieved representation without retraining.

Disabling the retrieved representation changed 6.66% of predicted labels and produced a mean Jensen–Shannon distance of 0.0854 relative to Full Memory. Accuracy increased from 0.5222 to 0.5300 and macro-F1 from 0.3681 to 0.3747, while ordinal MAE, undertriage, and severe undertriage decreased. QWK decreased from 0.4514 to 0.4462. Thus, disabling memory yielded more favorable point estimates for five of the six predictive metrics reported in this analysis.

Uniform Memory changed 9.33% of predicted labels and produced a mean Jensen–Shannon distance of 0.0588. This condition obtained the lowest ordinal MAE, undertriage, and severe-undertriage rates among the three interventions, at 0.5450, 0.2134, and 0.0307, respectively. However, its macro-F1 and QWK were lower than those of Full Memory. The proportion of changed labels and the mean probability-distribution distance capture different aspects of prediction sensitivity, so their ordering need not coincide.

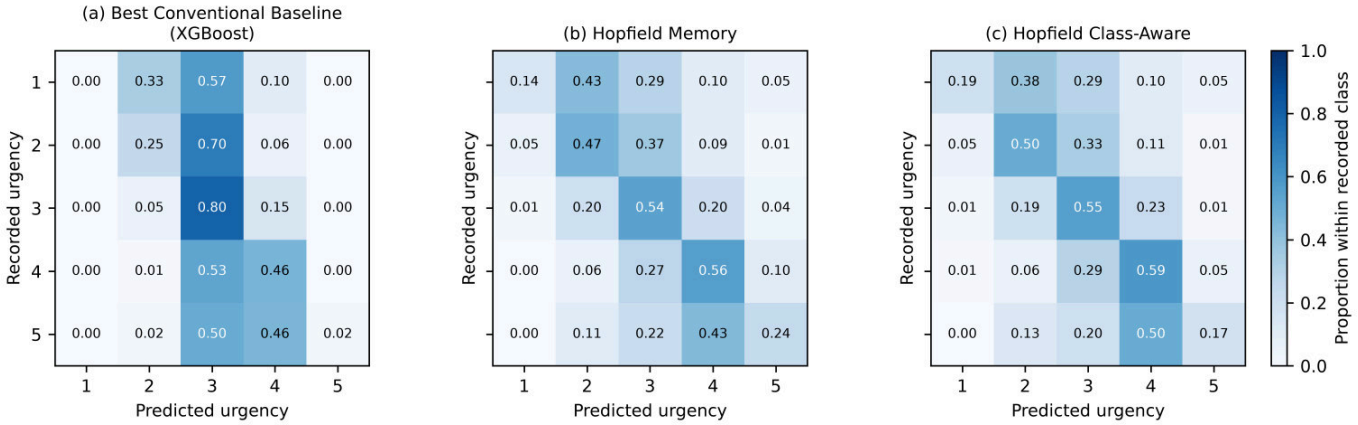

Fig. 4. Row-normalized confusion matrices for XGBoost, the shared-memory Hopfield model, and the class-aware Hopfield model. Rows indicate recorded urgency and columns indicate predicted urgency. Each cell represents the proportion of visits within the corresponding recorded class. Values are rounded to two decimal places.

TABLE II
INFERENCE-TIME INTERVENTIONS IN THE TRAINED SHARED-MEMORY HOPFIELD MODEL. BOLD VALUES INDICATE THE BEST PREDICTIVE METRIC AMONG THESE THREE CONDITIONS. PREDICTIONS CHANGED AND MEAN JENSEN–SHANNON (JS) DISTANCE ARE MEASURED RELATIVE TO FULL MEMORY; NEITHER IS A PERFORMANCE METRIC WITH A PREFERRED DIRECTION. JS DISTANCE USES NATURAL LOGARITHMS.

Condition	Accuracy ↑	Macro-F1 ↑	Ordinal MAE ↓	QWK ↑	Undertriage ↓	Severe Undertriage ↓	Predictions Changed (%)	Mean JS Distance
Full Memory	0.5222	0.3681	0.5614	**0.4514**	0.2402	0.0411	0.00	0.0000
Memory Disabled	**0.5300**	**0.3747**	0.5503	0.4462	0.2343	0.0392	6.66	0.0854
Uniform Memory	0.5281	0.3644	**0.5450**	0.4385	**0.2134**	**0.0307**	9.33	0.0588

IV. CONCLUSION

This study evaluated modern Hopfield networks with patient-level associative memory for five-level prediction of recorded emergency-triage urgency. The results revealed a trade-off between overall performance and class-balanced recognition. XGBoost achieved the highest accuracy and lowest ordinal mean absolute error, whereas the class-aware Hopfield model obtained the highest macro-F1 and balanced accuracy, and the shared-memory model achieved the highest quadratic weighted kappa. Compared with XGBoost, both Hopfield architectures showed higher recall for several underrepresented urgency classes. For the most urgent category, the shared-memory and class-aware models achieved recalls of 0.14 and 0.19, respectively, compared with zero recall for XGBoost. These findings characterize the evaluated Hopfield configurations as alternatives with broader class recognition, accompanied by losses in other performance dimensions.

The class-aware model obtained more favorable point estimates than the shared-memory model for accuracy, macro-F1, balanced accuracy, ordinal MAE, undertriage, and severe undertriage, although its QWK and class-5 recall were lower. Organizing training visits into separate banks provides a mechanism for retrieving class-specific representations, but the observed differences cannot be attributed to this organization alone. The class-aware architecture also used additional retrieved representations, bank-level evidence scores, and a larger classification head.

The inference-time analysis showed that the memory-derived representation affected the outputs of the trained shared-memory model, but learned retrieval did not provide a consistent advantage across the evaluated metrics. Full Memory retained the highest QWK. Relative to Full Memory, disabling the retrieved representation yielded more favorable values for the other five metrics, whereas uniform retrieval produced the lowest ordinal MAE, undertriage, and severe-undertriage rates among the three conditions, together with the lowest macro-F1 and QWK. Learned retrieval was therefore the best condition for only one of the six reported metrics, and sensitivity to memory should not be equated with a consistent predictive benefit. Because these interventions preserved a checkpoint trained with memory, they do not establish the performance of an independently trained memory-free model or isolate the contribution of memory during training. These findings also cannot be extended to the class-aware model without examining its corresponding intervention results.

The improved class-balanced metrics do not establish greater clinical safety. Approximately 81% of recorded class-1 visits were still assigned to less urgent categories by the class-aware model, and its global severe-undertriage rate was 0.0307, compared with 0.0183 for XGBoost. Moreover, these measures describe disagreement with recorded NHAMCS urgency rather than independently adjudicated clinical error. The observed gains in minority-class recognition must therefore be considered alongside the remaining errors toward lower recorded urgency.

The findings are limited to one unweighted NHAMCS sample, one visit-level split, one training seed per Hopfield architecture, and descriptive point estimates without inferential comparisons. Differences in class weighting, memory sampling, and architectural capacity further limit attribution of the observed performance to associative retrieval alone. Future work should prioritize a memory-free encoder–MLP baseline trained under comparable conditions, multiple training seeds with confidence intervals, and hospital-aware or temporally separated evaluation where feasible. Ordinal or asymmetric cost-sensitive objectives that explicitly penalize severe under-triage are also warranted. The present study contributes a comparative characterization of Hopfield-based triage models and their performance trade-offs, while identifying the controls needed to determine the incremental value of associative memory.

Additional research could investigate how memory size and pattern-selection strategies affect the balance between minority-class recognition and ordinal error. Comparisons between class-capped sampling, representative prototypes, and diversity-based selection could help determine whether particular memory configurations provide more useful retrieved information. Examining association weights and retrieved cases alongside prediction changes could also clarify when retrieval supports or impairs classification. Finally, probability calibration and selective prediction with abstention could be explored to identify uncertain cases requiring additional assessment, with their usefulness evaluated through both predictive performance and the proportion and urgency profile of deferred visits.

***Abstract*—Breast cancer screening via mammography is challenged by the subtlety of early lesions, such as calcifications and architectural distortions, and the inherent subjectivity of visual analysis. This study proposes a computationally efficient and interpretable hybrid protocol for the multiclass classification of mammograms into four categories: normal, calcification, asymmetry/distortion, and masses. The methodology utilizes the public MIAS dataset (322 images) and integrates a five-layer Deep Wavelet Neural Network (DWNN) for high-dimensional feature extraction (5,120 features), followed by a dimensionality reduction step using a PartitionMembership filter based on a Random Tree, yielding a compact set of 161 features. To address class imbalance, the ClassBalancer technique (instance reweighting) was applied exclusively to the training set. Classification was performed using tree-based algorithms (J48, Random Tree, and Random Forest with up to 300 trees), evaluated via 30 repetitions of 10-fold stratified cross-validation and an independent hold-out test set. Notably, the single Random Tree classifier outperformed the ensemble methods, achieving an accuracy of 87.88% and a Cohen's Kappa of 0.7676 on the test set. These results demonstrate that robust wavelet-based feature transformation enables simple, highly interpretable models to rival complex ensembles, offering a promising, low-cost decision support tool for optimizing clinical workflows in resource-constrained healthcare systems.**

***Index Terms*—Mammography, MIAS dataset, deep wavelet neural networks, multiclass classification, random tree, computer-aided diagnosis.**

I. Introduction

Mammography is the most widely used imaging modality for breast cancer screening; however, its sensitivity and specificity vary according to breast tissue density and observer experience [1]. Breast cancer remains one of the most frequently diagnosed neoplasms among women worldwide, posing a significant burden on healthcare systems [2], [3]. The inherent complexity of mammographic images, coupled with the subtlety of certain lesions, renders visual analysis a challenging task prone to inconsistencies. Although mammography is the gold standard for screening—enabling the detection of anomalies before they become palpable [4]—visual interpretation is constrained by human perceptual limitations, such as fatigue and interobserver variability, which can lead to false-negative or false-positive results [5].

In this context, machine learning and computer vision techniques have been increasingly applied to assist in the automated analysis of medical images, aiming to standardize the detection and classification of suspicious patterns [6], [7]. The performance of these models relies heavily on the algorithms' capacity to represent images through numerical descriptors that effectively capture the textural and morphological properties of the lesions.

Although deep Convolutional Neural Networks (CNNs) have achieved remarkable results in computer vision tasks, their application in scenarios with limited datasets—a common constraint in medical imaging—may be hindered by the substantial data requirements for supervised training [8], [9]. As a compelling alternative, approaches based on multiresolution transforms, specifically the Deep-Wavelet Neural Network

(DWNN), enable the hierarchical extraction of features without the need for iterative weight optimization, relying instead on deterministic wavelet-based filters [6], [10].

Nevertheless, the use of deep wavelet networks yields high-dimensional feature vectors. The presence of an excessive number of attributes relative to the sample size can compromise the generalization capability of machine learning models, a phenomenon known as the *curse of dimensionality* [11]. Consequently, applying feature selection or dimensionality reduction techniques is a critical prerequisite to eliminate redundancies and noise prior to classification [12].

The objective of this study is to investigate a processing pipeline for the multiclass classification of mammograms, encompassing four distinct categories: normal, calcification, asymmetry/distortion, and mass. Specifically, we aim to evaluate the efficacy of the DWNN in extracting mammographic textures and its integration with space-partition-based dimensionality reduction methods, utilizing the leaf structure of a Random Tree. The resulting feature set was subjected to a comparative analysis using decision tree-based classifiers, including J48, Random Tree, and Random Forest, evaluated on the Mammographic Image Analysis Society (MIAS) dataset [13].

It is imperative to contextualize the choice of the MIAS dataset for this study. Although it is a classical database comprising digitized radiographic film images, the MIAS remains a widely utilized and consolidated reference for methodological benchmarking in the literature of computer vision applied to mammography. As this is the first study proposing the integration of the DWNN architecture with a recursive partition filter (*PartitionMembership*) for a multiclass problem, utilizing a consolidated dataset is a fundamental methodological step. It allows for the validation of the proposed pipeline's robustness and reproducibility in a reference scenario, while also enabling direct comparison with decades of prior research. Once the viability of this architecture is established on this classical benchmark, future work will advance to its application on modern datasets derived from full-field digital mammography (FFDM) systems, which present greater clinical complexity.

II. Related Works

In the context of supporting breast cancer diagnosis through mammographic images, Santana and Santos [6] proposed a hybrid architecture for lesion detection and classification, combining a Deep Wavelet Neural Network for feature extraction and a Support Vector Machine for the final classification. Unlike traditional Convolutional Neural Networks, the employed DWNN does not require a training process, operating with predefined wavelet filter banks based on the Mallat algorithm and synthesis blocks, which mitigates high computational costs and the dependence on large data volumes. When evaluating the model on the IRMA database, comprising regions of interest with various types of breast tissue density, the authors demonstrated that a 5-layer DWNN configuration associated with an SVM with a second-degree polynomial kernel achieved an average accuracy of 94% and a Kappa index of 0.91 in differentiating between healthy tissues, benign, and malignant lesions. The study concludes that the use of deep networks with fixed weights is a robust and computationally viable alternative for texture analysis and clinical decision support in mammography.

Stefano et al. [14], in turn, conducted a comparative analysis between radiomic methodologies based on machine learning and deep learning techniques for the classification of breast lesions. Using the public CBIS-DDSM repository, the authors evaluated the distinction between benign and malignant lesions through two distinct methodological workflows. In the first, manual extraction of radiomic features, referring to texture, shape, and intensity, was performed using the matRadiomics platform, followed by the application of Linear Discriminant Analysis (LDA) and Support Vector Machine (SVM) classifiers. In the second, the EfficientNetB6 neural network architecture was utilized, employing transfer learning and parameter fine-tuning. The results indicated that, although the LDA model presented limited performance in the conventional radiomic approach, with an area under the ROC curve (AUC) of approximately 68% for microcalcifications and 61% for masses, the EfficientNetB6-based strategy substantially outperformed traditional methods, achieving AUCs of 81.52% and 76.24% for microcalcifications and masses, respectively. External validation on an independent dataset corroborated the robustness of the findings. The authors conclude that, although traditional radiomics provides greater mathematical interpretability of the extracted parameters, deep neural networks offer superior diagnostic accuracy and greater tolerance to imprecisions in the segmentation process, establishing themselves as a more suitable alternative for clinical decision support.

Aiming to simplify the implementation of predictive algorithms in the clinical environment, Charim et al. [15] investigated the use of automated artificial intelligence platforms for the classification of breast lesions in mammography images. Using the INBreast dataset, the authors developed binary and multiclass distinction models, evaluating the impact of different geometric transformations on the training images. The results indicated that multiclass models outperformed binary ones, with the configuration employing horizontal flipping of the images standing out, achieving the highest accuracy rate of 87.50%. The authors conclude that, despite the limitations imposed by the available data volume, the use of automated machine learning tools eliminates the need for advanced programming knowledge, constituting an accessible alternative to assist healthcare professionals in image screening and the optimization of diagnostic workflows.

On the other hand, Rehman et al. [16] proposed the BRMI-Net framework, a hybrid architecture aimed at the extraction, fusion, and selection of features in mammographic images. The workflow begins with a contrast enhancement technique based on filter fusion, followed by deep feature extraction using the ResNet-50 architecture, which was refined through transfer learning on both the original and enhanced images. To mitigate information redundancy and computational cost, the

authors developed a serial fusion method based on the mean value, integrated with a hybrid feature selection algorithm grounded in flower pollination optimization and the False Position method. When classifying the selected features using machine learning models, with emphasis on the cubic Support Vector Machine, the approach achieved accuracies of 93.8%, 99.5%, and 99.8% on the public CBIS-DDSM, INbreast, and MIAS databases, respectively. The study concludes that intelligent selection and fusion of deep features are important steps to increase diagnostic accuracy and ensure computational efficiency in clinical decision support systems.

Khourdifi et al. [17] proposed an ensemble learning model that combines three convolutional neural networks: VGG16, DenseNet121, and InceptionV3. The approach aims to extract features at multiple scales to improve the identification of benign and malignant masses in mammograms. Evaluated on the INbreast and CBIS-DDSM datasets, the hybrid model demonstrated superiority over individual architectures, achieving accuracies of 90.1% and 89.5%, respectively. The authors conclude that the fusion of the complementary capabilities of these deep networks is effective in mitigating misdiagnoses, reducing false-positive and false-negative rates, and establishing itself as a promising tool for clinical decision support in the early detection of breast cancer.

III. Methods

A. Proposed Method

The experimental workflow is illustrated in Fig. 1. Initially, the mammographic image dataset was preprocessed. This step consisted of resizing all images, loading them in grayscale, normalizing the pixel intensity, and labeling them according to the database classes: normal, calcification, asymmetry/distortion, and masses.

The resulting images served as input for the Deep-Wavelet Neural Network (DWNN), which extracted 5,120 features from the 322 images. These features underwent a dimensionality reduction process using a Random Tree for data representation, resulting in a compact set of 161 features. The instances were divided into 80% for training (n = 256) and 20% for testing (n = 66). The training set was balanced using the Weka ClassBalancer, which adjusts the weight of the instances belonging to each class rather than creating synthetic samples.

Finally, the experiments were conducted. For each analyzed classifier, 30 repetitions of 10-fold cross-validation were executed. Performance was evaluated using accuracy, Cohen's Kappa index, sensitivity, specificity, and AUC-ROC. The best-performing classifier was then evaluated on the independent test set.

B. Database

This study utilizes the Mammographic Image Analysis Society (MIAS) dataset [13]. The dataset comprises PNG images, structured across three categorization axes: BI-RADS classification, breast tissue density, and abnormality type.

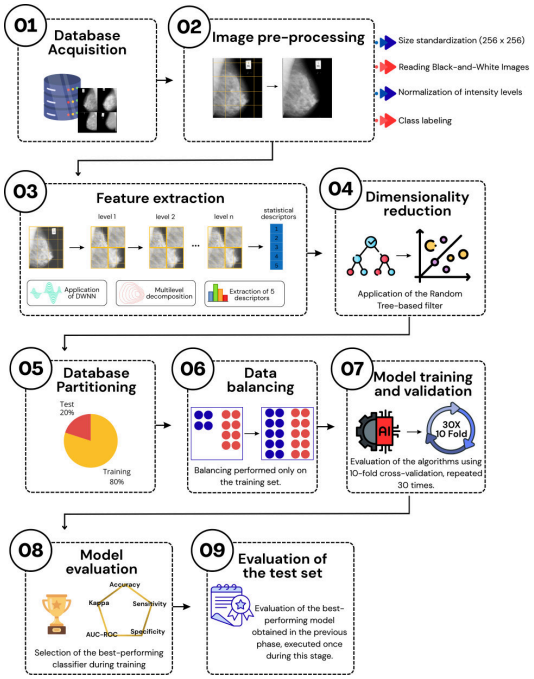

Fig. 1. Methodological workflow proposed for the development of this study.

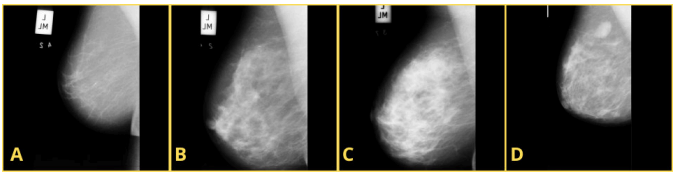

Fig. 2. Representative examples of the four mammography classes used in this study: (A) Normal, (B) Calcification, (C) Distortion/Asymmetry, and (D) Masses.

Regarding the BI-RADS classification, the database is distributed into 207 images in category 1 (normal), 31 in category 2, 32 in category 3, 34 in category 4, and 18 in category 5. Regarding tissue density, the images are categorized into three groups: 106 images of fatty tissue (A), 104 of fatty-glandular tissue (B), and 112 of densely glandular tissue (C/D).

Regarding abnormalities, the dataset encompasses 207 normal images, 25 with calcifications, 34 with architectural distortions or asymmetries, and 56 with masses. This structure allows for the evaluation of computational models in both binary and multiclass classification scenarios. In this work, the multiclass categorization regarding abnormalities was utilized (Fig. 2).

C. Data Preprocessing and Feature Extraction

Dataset processing began with the systematic loading of the 322 digital PNG images, organized in subdirectories according to the abnormality type. Each image was loaded directly in grayscale and converted to an 8-bit unsigned integer representation. For compatibility with the extraction pipeline, the original two-dimensional matrices were expanded into a three-dimensional configuration (height $\times$ width $\times$ 1). The

class labels (normal, calcification, asymmetry/distortion, and masses) were assigned based on the source folder structure, ensuring correct mapping between the input data and the validation categories.

After loading, all samples were subjected to standardized resizing to a resolution of 256×256 pixels. Subsequently, min-max normalization was applied, adjusting the pixel intensity range to the interval [0, 255] and homogenizing the acquisition conditions for the decomposition step [18].

The numerical representation of the mammograms was obtained using a *Deep-Wavelet Neural Network* (DWNN), an architecture that performs hierarchical feature extraction without the need for supervised optimization [6]. As described by Santana and Santos [6], the model replaces the iterative learning of weights with a deterministic filtering scheme based on the Haar discrete wavelet transform, inspired by the Mallat algorithm for multilevel decomposition.

The core of the processing employs a filter bank composed of four 2×2 convolution *kernels*: high-frequency vertical filter, high-frequency horizontal filter, diagonal filter, and *low-pass* filter [10]. The depth of the network is automatically determined by the relation $L = \log_2(\min(H, W)) - 3$, where H and W represent the dimensions of the input image. For images with a resolution of 256×256 pixels, this formula results in $L = \log_2(256) - 3 = 8 - 3 = 5$ layers. This configuration ensures that the final feature map maintains a minimum spatial resolution of 8×8 pixels, preserving sufficient information for statistical synthesis while progressively reducing dimensionality through the *downsampling* process [10], [18].

Upon completing the fifth layer, the network produces a tensor with 1,024 reduced feature maps (4^5) [10]. Each map is processed by a synthesis routine that extracts five statistical metrics: mean, standard deviation, minimum value, maximum value, and mode [6]. The resulting vector contains 5,120 features per image (1,024 maps multiplied by 5 descriptors), representing the textural and structural signature of the dataset images [10]. Fig. 3 illustrates the presented architecture.

D. Dimensionality Reduction

To reduce the dimensionality of the feature set generated by the DWNN, originally comprising 5,120 features, the supervised PartitionMembership filter available in Weka was applied [19]. The filter is based on a trained decision tree, from whose leaves a new dataset is generated. A Random Tree was used, resulting in 161 features, each representing the probability of the input feature vector belonging to a specific leaf.

It is important to note that the PartitionMembership filter extracts the topological structure of the decision tree, generating a generalized partition of the high-dimensional feature space rather than memorizing instance-specific patterns. Once established, this topology is applied deterministically to all instances, producing features based on leaf-node membership. Thus, the resulting 161-feature representation captures the underlying data structure without transferring instance-level information. The training and testing subsets were separated systematically prior to classification, preserving their independence and ensuring reproducibility.

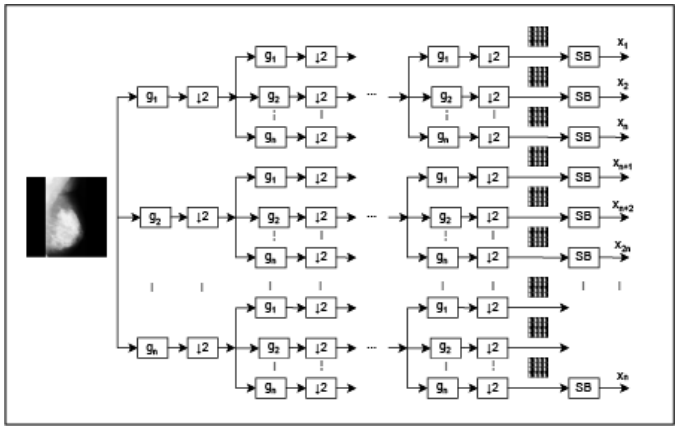

Fig. 3. The DWNN takes a 256 × 256-pixel image as input. At each layer, the image is processed through a filter bank followed by a downsampling operation. At the end of this process, the data passes through a synthesis block, where representative statistics are extracted.

E. Classification

The features were classified using the decision tree-based algorithms J48, Random Tree, and Random Forest (RF). J48 is the Weka implementation of the C4.5 algorithm [19]. For the Random Forest algorithm, different configurations regarding the number of generated trees (10, 50, 100, 150, 200, 250, and 300) were tested, aiming to evaluate the influence of this parameter on classification performance.

F. Metrics

For the evaluation of experimental performance, the following metrics were employed: accuracy, Cohen's Kappa index, sensitivity, specificity, and area under the Receiver Operating Characteristic curve (AUC-ROC) [20].

In a binary classification problem, the confusion matrix is composed of:

- True positives (TP): positive instances correctly classified as positive;
- True negatives (TN): negative instances correctly classified as negative;
- False positives (FP): negative instances incorrectly classified as positive;
- False negatives (FN): positive instances incorrectly classified as negative.

Accuracy corresponds to the ratio between the number of correctly classified instances and the total number of instances (Equation 1) [21]. The Kappa index quantifies the classification agreement, discounting the influence of chance agreement. Consequently, this metric is considered more robust than accuracy, being defined by Equation 2 [22], [23].

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

$$\kappa = \frac{\text{Accuracy} - \rho_e}{1 - \rho_e} \tag{2}$$

Where ρ_e is the chance agreement, calculated by:

$$\rho_e = \frac{(TP + FP)(TP + FN) + (FN + TN)(FP + TN)}{(TP + FP + FN + TN)^2} \tag{3}$$

The true positive rate, also denoted as recall or sensitivity, quantifies the proportion of correctly classified positive instances relative to the total number of actual positive instances (Equation 4). Specificity represents the proportion of correctly classified negative instances among all negative instances in the dataset (Equation 5) [21].

$$\text{Sensitivity} = \frac{TP}{TP + FN} \tag{4}$$

$$\text{Specificity} = \frac{TN}{FP + TN} \tag{5}$$

The ROC curve relates the false positive rate to the true positive rate. The FPR is defined as the ratio between the number of false positives and the total number of actually negative instances (Equation 6), being equivalent to 1 - specificity. The area under the ROC curve corresponds to the integral of this function, whose optimal value is 1, indicating the correct classification of all positive instances [21].

$$\text{False positive rate} = \frac{FP}{FP + TN} \tag{6}$$

For problems with more than two classes (multiclass scenarios), the metrics defined for the binary case are extended by calculating the indicators for each class individually, treating it as positive and the others as negative (one-vs-rest). Subsequently, the average of these values is obtained. Due to the pronounced imbalance inherent to the MIAS dataset (with the 'normal' class representing the vast majority of samples), the weighted average was adopted for the calculation of multiclass metrics. This approach ensures that the contribution of each class is proportional to its support (number of instances) in the dataset, preventing the overall performance from being artificially inflated by the majority class.

IV. Results and Discussion

The comparative evaluation of the algorithms revealed distinct performance patterns among the tested architectures for the classification of mammograms from the MIAS database [13]. Notably, the Random Tree classifier presented the best individual performance among all analyzed configurations, achieving 87.55% accuracy and a 0.83 Kappa index, demonstrating that simple partition models, when adequately configured, can outperform more complex approaches in certain medical imaging contexts. In contrast, the J48 algorithm presented more modest performance, with 79.37% accuracy and a 0.72 Kappa index, although it still maintains relevant discriminative capacity for the classification task. This performance difference between the two single-tree algorithms can be attributed to the sensitivity of these models to pruning parameters and the adopted splitting criteria. The difficulty in classifying among the four clinical categories—namely, normal, calcification, distortion asymmetry, and masses—resides in the subtlety of textural transitions and the overlap of visual features, requiring models capable of capturing complex nonlinear interactions among the extracted features.

Regarding ensemble methods, the Random Forest algorithm demonstrated remarkably consistent performance across all tested configurations. Table I compiles the results obtained during the training phase, revealing that all configurations, from 10 to 300 trees, converged to identical performance levels, with accuracy varying between 86.01% and 86.16% and Kappa between 0.81 and 0.82. The standard deviations remained consistent across all configurations, indicating that increasing the number of trees did not yield significant discriminative gains and that the model reaches predictive stability even with a reduced number of constituent trees.

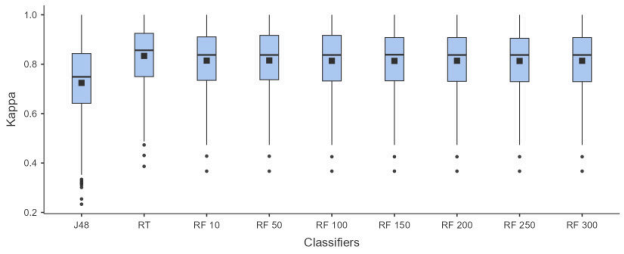

TABLE I
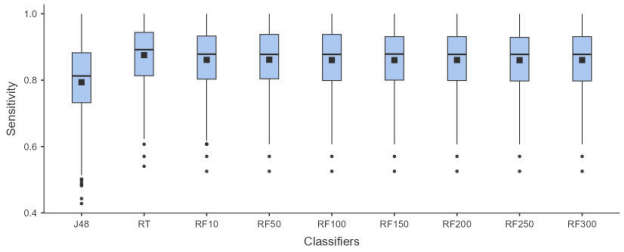
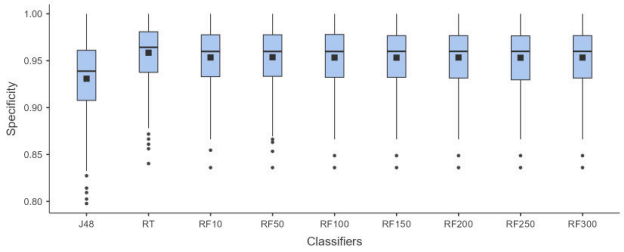
Performance of the classifiers evaluated during the training phase (cross-validation)

Classifiers	Accuracy	Kappa	Sensitivity	Specificity	AUC-ROC
J48	$79.37\% \pm 11.44$	0.72 ± 0.15	0.79 ± 0.11	0.93 ± 0.04	0.89 ± 0.07
RT	$87.55\% \pm 9.82$	0.83 ± 0.13	0.88 ± 0.10	0.96 ± 0.03	0.92 ± 0.07
RF10	$86.12\% \pm 9.66$	0.81 ± 0.13	0.86 ± 0.10	0.95 ± 0.03	0.94 ± 0.06
RF50	$86.16\% \pm 9.75$	0.82 ± 0.13	0.86 ± 0.10	0.95 ± 0.03	0.95 ± 0.05
RF100	$86.06\% \pm 9.71$	0.81 ± 0.13	0.86 ± 0.10	0.95 ± 0.03	0.95 ± 0.05
RF150	$86.03\% \pm 9.77$	0.81 ± 0.13	0.86 ± 0.10	0.95 ± 0.03	0.95 ± 0.05
RF200	$86.07\% \pm 9.78$	0.81 ± 0.13	0.86 ± 0.10	0.95 ± 0.03	0.95 ± 0.05
RF250	$86.01\% \pm 9.79$	0.81 ± 0.13	0.86 ± 0.10	0.95 ± 0.03	0.96 ± 0.05
RF300	$86.06\% \pm 9.78$	0.81 ± 0.13	0.86 ± 0.10	0.95 ± 0.03	0.96 ± 0.05

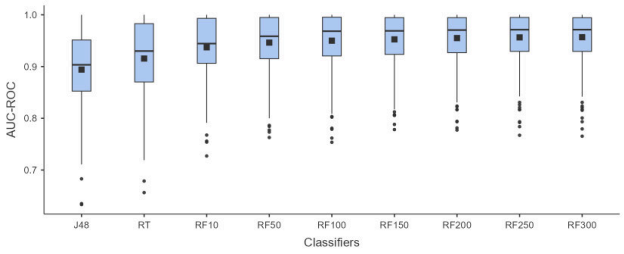


The analysis of the Kappa index distribution across the partitions of the training phase, as illustrated in Fig. 4a, visually corroborates the performance patterns observed in the summarized metrics and provides a richer perspective on model variability. The boxplot reveals that the Random Tree presents the highest median among all evaluated classifiers, positioned at approximately 0.85, with a box extending from about 0.75 to 0.92, denoting superior central performance even when compared to ensemble methods. The J48, in turn, exhibits the lowest median, approximately 0.75, a box shifted to lower levels, between 0.64 and 0.84, and an accentuated dispersion, evidenced by the presence of multiple outliers concentrated in the lower region of the graph, between 0.20 and 0.35. These outliers reflect training/cross-validation partitions in which the single-tree model suffered severe performance degradation, confirming the high variance inherent to this classifier when subjected to different data subsets.

The Random Forest configurations, ranging from 10 to 300 trees, exhibit a remarkably homogeneous visual behavior in the boxplot, in which all boxes present medians clustered around 0.83 to 0.84, practically overlapping interquartile ranges, and similar outlier patterns, concentrated in the range of 0.36 to 0.43. This graphical overlap conclusively demonstrates that increasing the number of trees did not significantly alter the performance distribution across the different cross-validation partitions. The visual consistency of the boxplot boxes for all RFs reinforces the conclusion that the model reaches



predictive maturity with just 10 trees, rendering the computational increment associated with more complex configurations unnecessary. It is relevant to note that, although the RT presents a slightly higher median than the RFs in the boxplot, the interquartile range of the RFs is comparable, suggesting that ensemble methods offer robust central performance with controlled variability.



(a) Kappa Index.

(b) Sensitivity.

(c) Specificity.

(d) AUC-ROC.

Fig. 4. Distribution of the metrics (Kappa, Sensitivity, Specificity, and AUC-ROC) of the classifiers evaluated across the 30 repetitions of the 10-fold cross-validation.

The analysis of the boxplots for sensitivity, specificity, and Area Under the ROC Curve illustrated in Fig. 4 reinforces the variability patterns observed in the Kappa index. The J48 algorithm consistently presents the lowest medians and the largest interquartile ranges across the three metrics, evidencing its greater dispersion and lower discriminative capacity compared to the other models. The Random Tree achieves the highest medians in sensitivity and specificity while maintaining moderate dispersion. In contrast, the Random Forest configurations exhibit a highly consistent distribution for all metrics, regardless of the number of trees. While the medians for sensitivity and specificity of the RFs remain stable across the configurations of 10 to 300 trees, a slight progressive increase in the AUC-ROC median is observed as the number of trees grows. However, the overlap of the interquartile ranges among the different Random Forest configurations indicates that increasing the number of trees does not substantially alter the model's variability, corroborating the conclusion that the additional complexity does not practically modify the distribution of predictions.

Regarding the statistical comparison between the Random Tree and Random Forest configurations, the 30 cross-validation repetitions provide robust empirical evidence. As shown in Fig. 4 and Table I, the interquartile ranges and confidence intervals (mean $\pm$ standard deviation) for Kappa and Accuracy substantially overlap across all configurations. This indicates comparable performance, with minor differences likely attributable to sampling variability rather than a true ensemble advantage. Therefore, following the principle of parsimony, the Random Tree is justified as the optimal choice, offering comparable stability with lower computational cost and greater interpretability.

From the perspective of clinical application, the stability visualized in the boxplot is a desirable requirement, as it suggests that the decision support system can maintain reliable performance in the face of morphological variability. In medical practice, such consistency is a prerequisite for building radiologist trust in the system as a secondary opinion. However, it is crucial to emphasize that internal cross-validation stability does not automatically guarantee diagnostic safety or consistent performance across diverse patient populations or acquisition systems. Prospective evaluations in real-world clinical workflows are strictly required before the system can be considered for automated screening.

Considering the principle of parsimony and computational efficiency, the Random Tree configuration was selected as the final model for evaluation on the test set. This decision is based on the fact that the RT achieved the best average performance in model training, with a sensitivity of 0.88, 87.55% accuracy, and a 0.83 Kappa index, outperforming both J48 and all Random Forest configurations, and it did so with a single tree, which implies significantly lower training and inference times. In clinical practice, this optimization translates to faster responses and lower demand for processing resources, facilitating the integration of the system into hospital workflows without compromising diagnostic quality.

After the consolidation of the Random Tree model, an evaluation was performed on an independent test set, comprising 20% of the database, which resulted in 66 images. The results are presented in Table II.

TABLE II
PERFORMANCE OF THE RANDOM TREE MODEL ON THE INDEPENDENT TEST SET

Classifier	Accuracy (%)	Kappa	Sensitivity	Specificity	AUC
RT	87.88%	0.7676	0.879	0.886	0.862

The confusion matrix, presented in Fig. 5, details the model's performance for each class individually. In the test set, the classifier correctly classified 58 out of 66 images, achieving 87.88% accuracy and a Kappa of 0.7676. The model stood out in identifying normal cases, correctly classifying 41 out of 42 exams. Among the pathological classes, the hit rate was 10 out of 12 for masses, 5 out of 7 for distortion/asymmetry, and 2 out of 5 for calcifications. The main confusions occurred when the model classified calcifications and distortions as normal tissue, or when interpreting masses as calcifications.

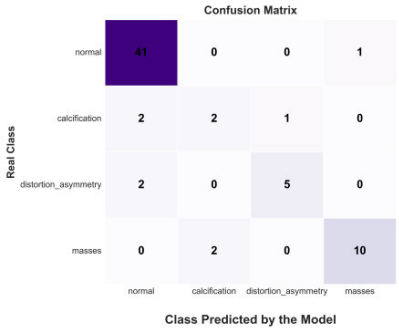


Fig. 5. Confusion matrix of the Random Tree model evaluated on the independent test set. The rows represent the actual classes (Normal, Calcification, Distortion/Asymmetry, and Masses) and the columns the predicted classes, highlighting the model's performance and main points of confusion across the four clinical categories.

The confusion matrix reveals a notable limitation in the classification of calcifications, a class of paramount clinical relevance for early detection. This reduced sensitivity can be attributed to the subtle, high-frequency nature of microcalcifications, which may be attenuated during the downsampling operations inherent to the DWNN architecture, compounded by the severe class imbalance in the MIAS dataset. Furthermore, regarding interpretability, while the final Random Tree model offers a transparent decision structure, it operates on 161 transformed attributes derived from 5,120 wavelet descriptors. Consequently, direct clinical explanation of individual predictions requires caution. Future iterations of this pipeline must incorporate Explainable AI (XAI) techniques, such as SHAP, to map the most influential wavelet-based features back to the original image space for true clinical interpretability.

In summary, the analysis of the results validates the hypothesis that low-complexity models, when supported by a robust feature representation, can rival or outperform computationally expensive ensembles. The Random Tree demonstrated not only the highest accuracy and stability in training but also a generalizable capacity confirmed on the independent test set. Although the classification of subtle lesions, such as calcifications and distortions, represents a challenge inherent to the overlap of textural patterns, the excellent performance in detecting masses and identifying normal tissues positions the model as a promising tool for automated screening. In this scenario, the system could act by filtering low-complexity exams, allowing the radiologist to concentrate their expertise on the most critical cases. Therefore, this study proves the feasibility of developing decision support systems that balance high predictive performance and computational efficiency, essential requirements for the practical integration of artificial intelligence solutions into the clinical routine of image diagnosis.

V. CONCLUSION

This study aimed to develop and evaluate a computational system for the automatic classification of mammograms using the MIAS database, comparing the performance of decision tree-based algorithms and Random Forest ensembles with varying numbers of trees in the discrimination of four clinical categories. The proposed methodology enabled the identification of the architecture that offers the optimal balance between predictive accuracy and computational cost for the multiclass classification task in medical imaging.

The results indicate that the Random Tree model achieved the best overall performance, reaching 87.88% accuracy on the independent test set. From a computational engineering perspective, the analysis demonstrated that increasing model complexity through the use of Random Forest with hundreds of trees did not yield significant improvements in the evaluation metrics, thereby validating the application of the principle of parsimony. This finding reinforces a broader insight: when feature extraction and transformation are sufficiently discriminative, the intrinsic representational capacity of a single, well-structured decision tree can rival or surpass that of computationally expensive ensembles. From a clinical standpoint, the model demonstrated high accuracy in identifying normal cases and masses, contributing to the reduction of false positives and the prioritization of exams with evident lesions. Nevertheless, it is imperative to acknowledge that the lower sensitivity observed for calcifications and architectural distortions represents the primary limitation of the current model. In radiological practice, these subtle features are frequently the earliest indicators of malignancy, such as ductal carcinoma in situ. Therefore, while the excellent performance in detecting masses and normal tissues positions the system as a promising initial screening tool for filtering low-complexity exams, its current inability to consistently capture these early signs precludes its use as a substitute for the detailed analysis performed by a radiologist.

A primary lesson learned during this preliminary study is that the intrinsic representational capacity of a single, well-structured decision tree can rival complex ensembles, provided that the preceding feature extraction and transformation pipeline is sufficiently discriminative. However, a critical research gap remains regarding the robust detection of subtle, high-frequency lesions, such as microcalcifications,

using deterministic wavelet filters on small, historical datasets. Therefore, this work should be interpreted primarily as a methodological proof of concept. Clinical validity and generalization still depend on rigorous external validation on modern FFDM datasets, stronger representation of minority classes, and prospective evaluation in real-world diagnostic workflows.

In conclusion, this study demonstrates the feasibility of employing simple and computationally efficient classifiers for breast cancer diagnostic support, provided they are underpinned by a robust and well-designed feature extraction pipeline. To advance toward the practical deployment of this tool, future work should focus on validating the model on larger and more contemporary datasets derived from full-field digital mammography (FFDM) systems, thereby extending the application of the protocol beyond this initial classical benchmark and assessing its performance in modern clinical scenarios. Furthermore, the incorporation of clinical variables and the use of deep learning techniques for automated feature extraction may enhance the detection of subtle lesions. Finally, prospective studies evaluating the real-world impact of integrating this system into hospital workflows are essential to determine its true contribution to the radiological diagnostic process and its potential to optimize clinical decision-making within resource-constrained healthcare systems.

VI. Declaration on the Use of Artificial Intelligence

The Qwen3.6-Plus language model was employed exclusively for orthographic and grammatical editing of the manuscript. No artificial intelligence was involved in the conception of the research, methodological design, data collection or analysis, interpretation of results, or generation of intellectual content. All AI-assisted processes and outputs were rigorously validated and audited by the human authors, who assume full responsibility for the accuracy, originality, and scientific integrity of this work

***Abstract*—Localising the neonate and its body parts underpins camera-based NICU monitoring, yet the Segment Anything (SAM) family has not been applied to this whole-body and body-part segmentation. We present a promptable-segmentation approach to delineate neonates in routine NICU bedside video (RGB frames from a smartphone camera above the cot), producing both a *whole-body* mask and *body-part* masks for the head, trunk, arms, and legs, plus an auxiliary diaper mask that refines the trunk. Masks are generated with SAM 3 from text prompts alone, without fine-tuning, and assessed by human validation: three evaluators judged the segmentations on 205 frames from 41 infants. Detections were rated correct in 92.8% of cases for the whole body and 94.9% averaged over the body parts, with high inter-evaluator agreement (Gwet's AC1 from 0.74 to 0.97). We release our segmentation and evaluation code, with example outputs, to support reuse for contactless neonatal monitoring. The recordings and frames themselves are not released, and in the distributed examples the infant appears only as an opaque silhouette, in keeping with our privacy-preserving data-handling protocol.**

***Index Terms*—neonatal monitoring, promptable segmentation, Segment Anything Model (SAM), body-part segmentation, NICU, computer vision**

I. Introduction

Neonates in the intensive care unit (NICU), especially preterm infants, require near-continuous physiological monitoring. The clinical standard relies on adhesive electrodes and wired transducers in direct skin contact; yet newborn skin is fragile: before roughly 29 weeks of gestational age the adhesive-to-skin bond can exceed the cohesion of the epidermis, so contact sensors risk skin injury and infection, complicate care, and impede parental skin-to-skin (kangaroo) contact [1]–[3]. These constraints motivate *contactless*, camera-based monitoring, in which one video stream can in principle recover multiple clinical signals without ever touching the infant [3], [4].

Camera-based analysis of the neonate unlocks several high-value clinical applications. Heart rate can be recovered from subtle skin-colour variations (remote photoplethysmography) and respiratory rate from the cyclic motion of the chest, abdomen, and head, with prior NICU studies drawing signals from many body regions (face, head, torso, arms, legs, feet) [2], [3]. Facial-expression analysis enables continuous, less subjective pain assessment [5]. Above all, quantifying spontaneous movement underpins the General Movements Assessment (GMA), among the most accurate early predictors of cerebral palsy: it attains roughly 98% sensitivity before five months of corrected age and supports diagnosis before six months, versus a historical 12 to 24 months, enabling intervention during peak neuroplasticity [6].

A single prerequisite underlies all these applications: the neonate and its body parts must first be reliably localised in the image. Camera vital-sign pipelines hinge on the correct region of interest, and robust localisation of the infant body and face is repeatedly called the *first step* of video-based neonatal assessment [2], [7]. More strongly, augmenting movement video with body-part parsing and pose estimation improves automated GMA for cerebral-palsy prediction [8]. Yet much prior NICU work selected regions of interest manually or with simple colour heuristics inconsistent across clinical conditions, leading one real-NICU study to conclude that "more robust image segmentation is required" for long-term monitoring [2]. Whole-body and body-part (head, trunk, arms, legs) segmentation is therefore the foundational building block for downstream neonatal video analytics.

Establishing that foundation is difficult. Off-the-shelf person, face, and skeleton detectors (e.g., YOLO, Mask R-CNN) and pose models trained on adult-centric data degrade sharply on neonates in cluttered NICU scenes, owing to occlusion by devices and clothing, variable illumination, the distinctive proportions and postures of newborns, and the near-absence of neonatal imagery in their training sets [2], [9], [10]. Infant-specific resources exist but remain small or indirect (e.g., the SyRIP pose dataset [10] and the SMIL 3D infant body model [11]), and progress is further limited by the scarcity of public neonatal data, rooted in the privacy and ethical sensitivity of infant medical imagery [9], [10]. Dedicated neonatal body-part segmentation has been shown with task-specific convolutional networks [12], but a general, low-annotation approach has been lacking.

Promptable foundation segmenters offer a promising route. The Segment Anything Model (SAM) introduced zero-shot, promptable segmentation from points or boxes [13]; SAM 2 extended it to video through a streaming memory that tracks objects across frames [14]; and SAM 3 adds *promptable concept segmentation*, detecting, segmenting, and tracking

every instance matching an open-vocabulary text or exemplar prompt [15]. Such models transfer well to medical imaging when adapted, though vanilla SAM struggles with weak object boundaries [16]. To our knowledge, no prior work applies the SAM family to whole-body and body-part segmentation of neonates in the NICU; the closest dedicated precedent predates SAM and uses a bespoke network [12].

In this work we leverage SAM 3 to segment neonates from real NICU video at two granularities (a whole-body mask and body-part masks for the head, trunk, arms, and legs, together with an auxiliary diaper mask that is segmented and removed from the trunk) as a foundation for downstream pose and movement analysis. Because the recordings depict identifiable infants, all video is processed under Brazil's General Data Protection Law (LGPD) with institutional ethics approval and without any public release of the babies' data; we treat this privacy-preserving handling as both a constraint and a contribution. Our contributions are:

- a SAM 3-based pipeline that produces whole-body and body-part (head, trunk, arms, legs) masks (together with an auxiliary diaper mask used to refine the trunk) for neonates in real NICU video;
- a human validation of this pipeline, in which three evaluators rate the whole-body and body-part segmentations on 205 frames from 41 infants, with detections rated correct in 86.3 to 98.5% of cases per target (Table I); and
- a privacy-preserving acquisition and data-handling protocol, compliant with Brazil's LGPD, that supports clinical reuse without public release of infant imagery.

II. Related Work

Promptable and foundation segmentation. Building on the SAM family introduced above (SAM [13]; SAM 2, which adds video tracking [14]; and SAM 3, which adds promptable concept segmentation [15]), these models transfer to medical imaging when adapted, yet vanilla SAM degrades on targets with weak boundaries and low contrast; MedSAM addressed this by fine-tuning SAM on more than one million medical image-mask pairs spanning many modalities [16]. In contrast, we use the full SAM 3 model with text prompts and no fine-tuning, relying on its concept-level grounding to localise the neonate and its parts.

Infant body-part segmentation and pose. Body parsing and pose estimation are mature for adults but data-scarce for infants, whose proportions, postures, and clinical surroundings differ markedly. Infant-specific resources include the SMIL statistical 3D infant body model [11], the synthetic-and-real SyRIP pose dataset [10], and the larger AggPose dataset with a transformer pose estimator [17]. Dedicated neonatal body-part segmentation has been shown with a task-specific convolutional network on NICU video [12], and augmenting movement video with body parsing and pose improves automated General Movements Assessment for cerebral-palsy prediction [8]. These efforts motivate our coarse head, trunk, arms, and legs targets, but each depends on dedicated training data rather than a promptable foundation model.

Camera-based neonatal monitoring. Contactless neonatal analysis spans vital-sign monitoring from RGB and RGB-D video [2], [3], respiration from motion [4], facial-expression pain assessment [5], [18], face and landmark detection [7], [9], and movement quantification for the General Movements Assessment [6].

SAM in neonatal and paediatric imaging. The SAM family has only recently reached neonatal and paediatric intensive-care imagery, and for narrower tasks than ours: neonatal face segmentation [19] and, with a convolutional network, device-occlusion segmentation in PICU monitoring [20]. To the best of our knowledge, ours is the first to segment both the whole body and its parts in routine NICU video with such a model, the gap addressed here.

III. Materials and Methods

We segment the neonate in routine NICU bedside video at two granularities, a single whole-body mask and four body-part masks (head, trunk, arms, and legs), plus an auxiliary diaper mask used to refine the trunk, using the promptable concept segmentation of SAM 3 [15] rather than a task-specific network. Fig. 1 overviews the pipeline, from a raw frame to whole-body and body-part masks; the temporal propagation (tracking) that SAM 3 enables is left to future work.

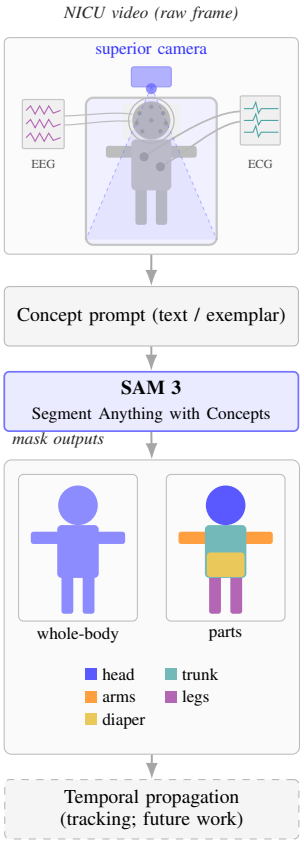

Fig. 1. Schematic of the SAM 3 pipeline: a concept prompt drives the model from a raw NICU frame to a whole-body mask and colour-coded body-part masks (head, trunk, arms, legs); the diaper is segmented as a separate auxiliary concept and subtracted from the trunk.

The following subsections detail, in turn, the dataset and acquisition setup, the segmentation targets, the SAM 3 prompting and post-processing, and the evaluation by human validation.

A. Dataset

This study was approved by the Research Ethics Committee of the Maternidade Escola Januário Cicco (CEP/MEJC), the university maternity hospital of the Federal University of Rio Grande do Norte (UFRN) administered by EBSERH, Natal, Brazil (CAAE 75772223.3.1001.0253), in accordance with Resolution CNS 466/2012. Written informed consent was obtained from the guardian of every infant included; a consent waiver is not admissible for this population. All records were de-identified before processing, and the original recordings are held on institutional storage with access restricted to the team named in the approved protocol. Under Brazil's LGPD (Federal Law 13,709/2018) an image of an identifiable patient is sensitive personal data, so we describe these frames as de-identified rather than anonymised, and no infant imagery is released publicly: the example outputs distributed with the code render the mask as an opaque silhouette. We analyse RGB frames captured with ordinary smartphone cameras positioned above the cot of neonates in the NICU; the present analysis uses a sparse sample of 205 frames, five per infant, from all 41 neonates, so the frame rate is not relevant. Owing to the sensitivity of these data, all analyses are performed on frames in which the infant's face has been obscured by blurring an elliptical region over it. Because this ellipse can extend beyond the face onto the upper trunk or an arm raised near the head, the appearance of those regions is locally altered, so part of the imprecision seen in the head, trunk, and arm masks reflects this privacy blur rather than a failure of SAM 3.

B. Segmentation targets

We segment the neonate at two complementary granularities. The first is a single *whole-body* mask covering the entire infant, which delimits the region of interest for any downstream camera-based analysis. The second parses the infant into four *body-part* masks, head, trunk, arms, and legs (the whole upper and lower limbs), the coarse anatomical regions used by movement and vital-sign pipelines. The trunk denotes the torso (thorax and abdomen); since neonates wear a diaper that occludes the lower trunk, we segment the diaper as a separate region and exclude it from the trunk, so the trunk mask corresponds to the exposed torso. Left and right limbs are not distinguished: the arms (resp. legs) target is the union of all detected arm (resp. leg) instances, leaving per-limb laterality to future work. Apart from the diaper rule above, the parts are segmented as independent concepts with no boundary enforced at their junctions, so neighbouring part masks may overlap slightly; this is acceptable here because the masks serve region localisation and movement analysis, not mutually exclusive pixel labelling. Parts occluded by devices, bedding, or posture are returned as missing or partial detections rather than reconstructed.

C. SAM 3 segmentation pipeline

We use SAM 3 as a promptable *concept* segmenter: a short text prompt naming a target returns the masks of every matching instance in the frame, each with a confidence score (Fig. 1). We run the full SAM 3 image model (the ViT-based checkpoint)[1] rather than the distilled EfficientSAM3, which produced low-confidence, fragmented detections on these NICU frames. Each frame is encoded once and then queried with one text prompt per target: `baby` for the whole body, and `head`, `torso`, `arm`, `leg` for the parts, plus `diaper`. Detections below a confidence threshold of 0.5 are discarded; the surviving instance masks of a target are unioned into its mask, and the diaper is subtracted from the trunk. Formally, for a target's text prompt the model returns instances $\{(m_i, s_i)\}_{i=1}^{k}$ on a frame, where $m_i \in \{0,1\}^{H\times W}$ is a binary mask and $s_i \in [0,1]$ its confidence; the target mask is the union of the instances above the threshold τ,

$$M = \bigcup_{i:\, s_i \geq \tau} m_i, \qquad \tau = 0.5, \tag{1}$$

that is, $M(p) = \max_{i:\, s_i \geq \tau} m_i(p)$ at each pixel p. The trunk is the torso with the diaper removed,

$$M_{\text{trunk}} = M_{\text{torso}} \wedge \neg M_{\text{diaper}} = M_{\text{torso}} \setminus M_{\text{diaper}}, \tag{2}$$

so trunk and diaper are disjoint, $M_{\text{trunk}} \cap M_{\text{diaper}} = \varnothing$. No fine-tuning, per-image tuning, or geometric (point/box) prompts are used; the masks come purely from the text concept.

D. Evaluation by human validation

We assess the pipeline by human validation rather than against a manually annotated reference: the aim is to establish whether promptable concept segmentation reliably localises the neonate and its parts, not to match a pixel-level ground truth, which no annotation of these frames provides. Three evaluators at different training levels (an undergraduate research student, a master's student in neuroscience, and a post-doctoral researcher) independently reviewed all 205 frames; for every frame and target (whole body, head, trunk, diaper, arms, and legs) each rated the segmentation overlay as correct or as one of three error types, *miss*, *false positive*, or *partial*, which are defined and counted in Table I. Two properties of this design bound what it can show. The evaluators rated the pipeline's own overlays, so the review measures whether the produced mask is acceptable, not how it compares blindly with an alternative; and they received only a written sheet defining the four verdicts, with no training on the method and no access to each other's ratings. We report, per target, the share of detections judged correct and the error breakdown, together with the inter-evaluator agreement, which we quantify with Gwet's AC1 [21], [22] because the ratings are heavily skewed toward one category. Concretely, for a given target the $r = 3$ evaluators rate N items (the frames) into $q = 2$

[1]Source code and reproduction scripts available on Zenodo: https://doi.org/10.5281/zenodo.21014348.

categories (correct or incorrect); let n_{ij} be the number of evaluators assigning item i to category j, and $\pi_j = \frac{1}{Nr}\sum_i n_{ij}$ the prevalence of category j. The observed agreement P_a and the Gwet chance term P_e are

$$P_a = \frac{1}{N}\sum_{i=1}^{N}\frac{\sum_j n_{ij}(n_{ij}-1)}{r(r-1)}, \tag{3}$$

$$P_e = \frac{1}{q-1}\sum_j \pi_j(1-\pi_j), \tag{4}$$

and the agreement coefficient is

$$\mathrm{AC1} = \frac{P_a - P_e}{1 - P_e}. \tag{5}$$

Unlike Fleiss' κ, whose chance term $\sum_j \pi_j^2$ grows toward 1 when one category dominates (deflating κ), the Gwet P_e stays small, so AC1 reflects the high observed agreement rather than the label imbalance.

IV. Results

SAM 3 first localises the whole infant: from the single text prompt `baby` it produces a whole-body mask of the neonate. Fig. 2 shows this mask on nine different infants, delineating the region of interest for downstream analysis despite device occlusion, bedding, and pose variation.

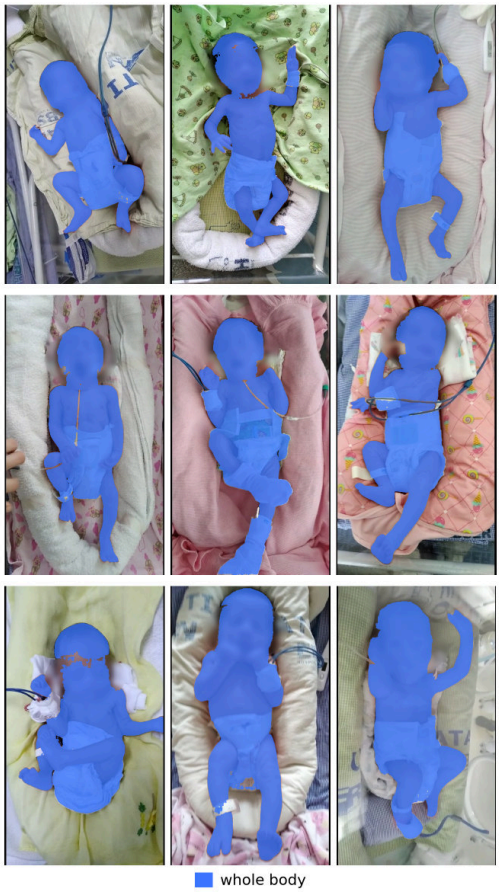

Fig. 2. SAM 3 whole-body masks on nine different neonates, from the single text prompt `baby`; the mask is rendered opaque to obscure the infant.

Beyond the whole body, the same promptable model parses the infant into individual parts. Fig. 3 shows head, trunk, arms, and leg masks across nine neonates, with the diaper segmented separately and removed from the trunk; all masks are obtained from text prompts alone, without per-image tuning.

Fig. 3. Qualitative SAM 3 body-part segmentation on face-blurred NICU frames from nine different neonates: head, trunk, arms, and legs (the diaper is segmented separately and removed from the trunk). Masks are produced from text prompts, without per-image tuning.

Per-frame inference time (Fig. 4) ranges from about 220 s on the CPU to 1.57 s on the desktop RTX 5060 Ti, and 0.43 s and 0.24 s on the NPAD A100 and H200, respectively; the H200 is thus roughly 930× faster than the CPU and 6.7× faster than the desktop GPU. At 2–4 frames per second, the data-centre GPUs make interactive, on-the-fly NICU video analysis feasible, whereas CPU-only inference (minutes per frame) is impractical for continuous monitoring. Each timing covers a full frame: SAM 3 encodes the image once and is then queried with the six concept prompts in turn, so the per-frame cost reflects one image encoding plus the six concept queries rather than a single forward pass. This also sets the model's most immediate role: at A100/H200 rates it is well suited as the offline annotation engine developed below, labelling NICU video at scale, rather than as a bedside real-time tracker.

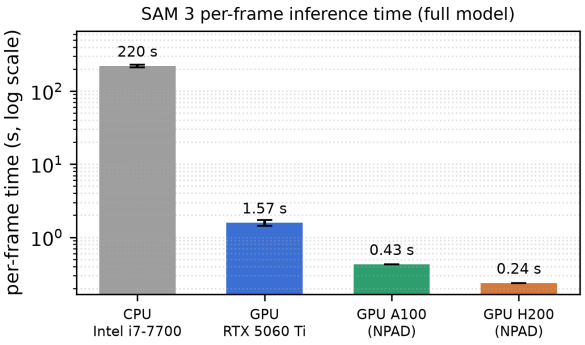

Fig. 4. Per-frame SAM 3 inference time (full model), mean over frames, log scale: CPU (Intel i7-7700), desktop GPU (RTX 5060 Ti, 16 GB), and NPAD A100 (80 GB) and H200 (141 GB). The software stack is not identical across platforms: torch 2.12/CUDA 13.0 locally, torch 2.12/CUDA 12.6 with cuDNN disabled on the A100 (whose driver rejects the bundled cuDNN), and torch 2.7/CUDA 12.6 with cuDNN on the H200, so the bars compare platform classes rather than one controlled software configuration.

Table I reports the human detection-quality review. For each target it gives the percentage of judgments rated correct (*Correct*); the number of judgments in each error class (*Miss*, *FP*, *Partial*); and the inter-evaluator agreement (AC1). Because no verdict was left blank, each target was judged on all 205 frames by the three evaluators, a constant 615 judgments per target; a target that is absent or fully occluded, and correctly left unsegmented, counts as correct rather than as a miss. The masks are usable in practice: detections were rated correct in 86.3% (arms) to 98.5% (legs) of judgments, with the whole body at 92.8%. Errors are dominated by partial masks, most evident for the arms (84 of 615 judgments); misses are concentrated on the diaper (18) and trunk (6), and false positives are rare (6 in total). Agreement is high: the three evaluators agree on 80 to 98% of judgments per target, and AC1 ranges from 0.74 (arms) to 0.97 (head and legs) across the reported targets, reaching 0.98 for the diaper, the quality-assurance layer used to clean the trunk.

TABLE I
HUMAN DETECTION-QUALITY REVIEW OF THE SAM 3 DETECTIONS (THREE EVALUATORS, 205 FRAMES; 615 JUDGMENTS PER TARGET): PER-TARGET SHARE RATED CORRECT, ITS 95% CONFIDENCE INTERVAL BOOTSTRAPPED OVER THE 41 INFANTS, ERROR COUNTS, AND INTER-EVALUATOR AGREEMENT (GWET'S AC1). ERROR TYPES AND AC1 ARE EXPLAINED IN THE TEXT.

Target	Correct (%)	95% CI	Miss	FP	Partial	AC1
Whole body	92.8	89.9–95.4	0	0	44	0.84
Head	97.6	95.6–99.2	2	0	13	0.97
Trunk	97.1	94.6–99.0	6	0	12	0.96
Diaper	95.9	91.1–99.3	18	5	2	0.98
Arms	86.3	81.8–90.6	0	0	84	0.74
Legs	98.5	96.9–99.7	0	1	8	0.97

a) Infant-level uncertainty: The 615 judgments per target are 205 frames rated by three evaluators, and those frames come from 41 infants at five frames each, so they are not 615 independent observations. Taking the infant as the sampling unit leaves the point estimates unchanged, the design being balanced, but widens the uncertainty: the standard error of the correct rate grows by a factor of 1.4 (whole body) to 2.8 (diaper) over a naive binomial on judgments. The confidence intervals in Table I are therefore bootstrapped over the 41 infants. The per-infant spread is where the residual difficulty sits: the weakest infant scores 46.7% on the arms and 66.7% on the whole body, against cohort means of 86.3% and 92.8%.

Sensitivity to the threshold and the prompt

Two free parameters could make these results fragile, the confidence threshold τ and the wording of the text prompt. We measured both on the same 205 frames.

Varying τ from 0.3 to 0.6 changes little: every target keeps a detection on at least 94.6% of frames across that range, so the value used here ($\tau = 0.5$) sits in the middle of a flat region rather than at a tuned optimum. Degradation starts above 0.7 and is target-specific: at $\tau = 0.8$ the trunk still fires on only 29.3% of frames and the arms on 50.7%, while the whole body holds at 99.0%.

Prompt wording acts differently (Table II). Substituting a near-synonym leaves the mask essentially unchanged, with a median IoU against the prompt used here of at least 0.98 for nine of the eleven alternatives tested, reaching 0.998 for `nappy` against `diaper`. What the wording does change is how often the concept fires at all: `newborn` returns a whole-body detection on 79.0% of frames against 100% for `baby`, although the masks it does return remain nearly identical (median IoU 0.988). The one substitution that breaks the pipeline is a change of concept rather than of wording: `chest` in place of `torso` fires on 26.3% of frames with a median IoU of 0.401, since it names a narrower anterior region. The pipeline is thus robust to synonym substitution but not to redefining the target, and the prompts reported here were chosen for concept coverage.

TABLE II
PROMPT SENSITIVITY ON THE SAME 205 FRAMES. FOR EACH TARGET, THE PROMPT USED IN THIS WORK IS COMPARED WITH ALTERNATIVES: SHARE OF FRAMES RETAINING A DETECTION AT $\tau = 0.5$, AND THE IOU OF THE ALTERNATIVE'S MASK AGAINST IT (MEDIAN AND 10TH PERCENTILE OVER FRAMES). AT $\tau = 0.5$ THE PROMPTS USED HERE DETECT ON 97.1 TO 100% OF FRAMES.

Target (prompt)	Alt. prompt	Det. (%)	IoU med.	IoU p10
Whole body (`baby`)	`infant`	97.6	0.994	0.961
	`newborn`	79.0	0.988	0.942
Head (`head`)	`baby head`	99.5	0.980	0.933
	`infant head`	98.5	0.980	0.947
Trunk (`torso`)	`chest`	26.3	0.401	0.283
	`baby torso`	98.0	0.985	0.918
Diaper (`diaper`)	`nappy`	97.1	0.998	0.994
Arms (`arm`)	`baby arm`	100.0	0.981	0.775
	`infant arm`	81.0	0.694	0.371
Legs (`leg`)	`baby leg`	100.0	0.995	0.968
	`infant leg`	94.1	0.994	0.911

V. DISCUSSION

The results support the central claim: a promptable foundation model, driven by text concepts and without any fine-

tuning, segments the neonate and its parts well enough on routine, face-blurred NICU frames to act as the front end of a pipeline for movement and vital-sign analysis. Across the reported targets, 86.3 to 98.5% of detections were rated correct with high inter-evaluator agreement (Gwet's AC1 from 0.74 to 0.97), and false positives were rare across the full review (six in total over the 3,690 judgments, Table I). The larger parts (head, trunk, legs) are the most reliable; the whole-body mask is noisier (it accumulates the most partial masks after the arms) but still delimits the region of interest. These are the regions most directly tied to clinical signals: the trunk for respiration and the whole body for the global movement repertoire. A reliable trunk mask is especially useful here: it could turn the chest-wall movement and thoraco-abdominal asynchrony that clinicians currently grade by eye, as in the Silverman-Andersen respiratory-distress score [23], into an objective, contactless measurement. These downstream uses are stated as hypotheses, not as results: this work evaluates localisation only, and whether these masks improve respiratory-rate estimation, pain assessment, or automated movement scoring remains to be measured on those tasks.

Errors are dominated by *partial* masks rather than misses or false positives, and they concentrate on the arms, the weakest target (86.3% correct, AC1 0.74, 84 partial masks). This is expected: the arms are thin, are often raised or flexed against the body, and are the part most frequently occluded by bedding, leads, and posture. The privacy-preserving blur compounds the problem, because the elliptical blur centred on the face can reach a raised arm or the upper trunk and locally erase the boundary the model relies on; the 44 partial whole-body masks reflect the same clipping at the extremities. The diaper carries the most misses (18), but it is segmented only as an auxiliary quality-assurance layer used to clean the trunk and is not one of the four primary body-part (movement) targets, so it does not affect those results.

Four limitations follow from the study design. First, we evaluate by structured human validation rather than against pixel-level ground truth, since no neonatal whole-body or part annotations exist for these frames; the review therefore measures whether each target is correctly localised, not the exact pixel overlap, and its verdicts are coarser and partly subjective, which we mitigate with three independent evaluators and the prevalence-robust AC1. Building a blinded pixel-level reference on a stratified subset, scored with Dice and boundary metrics, is the natural way to put a number on the overlap and is the next step we intend to take. Second, the sample is modest and sparse (205 frames from 41 infants) and comes from a single unit, so the per-target rates should be read as indicative, and nothing here establishes generalisation to other NICUs, cameras, or acquisition setups. Third, five still frames per infant cannot test temporal behaviour: continuity across a sequence, motion blur, and within-patient variation over a recording are all outside what this design measures, and the temporal stability of the masks is therefore unknown. Fourth, we do not break the results down by occlusion, support equipment, or image conditions, because those attributes are not annotated for these frames; the per-infant spread reported above is the closest available proxy for that heterogeneity.

A further limitation bears directly on the clinical motivation. Movement-based diagnostics span both granularities: whole-body movement underpins the General Movements Assessment, whereas the movement of individual limbs is informative in specific cases, such as a left-right asymmetry or abnormal movements confined to one limb. The pipeline already isolates the limbs, but it unions the two arms (and the two legs) into a single target and does not separate left from right, so resolving the two sides is a prerequisite for these asymmetry analyses and a natural next step.

VI. Conclusion and Future Work

We presented a promptable approach that delineates the neonate in routine NICU video at two complementary granularities, a whole-body mask and separate head, trunk, arms, and leg masks (with an auxiliary diaper mask segmented and removed from the trunk), using the full SAM 3 model with text prompts alone and without any fine-tuning or per-image tuning. The masks are produced under a privacy-preserving, LGPD-compliant protocol on face-blurred frames, and the model reaches interactive per-frame inference times on data-centre GPUs. Promptable concept segmentation thus offers a practical, low-annotation foundation for contactless neonatal video analysis.

A natural next step is to turn this per-frame segmentation into a real-time tracking system for both the whole body and the individual parts. Because SAM 3 inherits the streaming memory introduced in SAM 2 [14], and the full model yields high-confidence per-frame detections, these masks can be propagated across frames rather than recomputed independently, giving temporally consistent whole-body and part masks over time. Given the per-frame rates measured on the A100 and H200, we expect on-the-fly tracking to be feasible on such data-centre hardware, although the tracking path itself is not yet benchmarked. The resulting per-part tracks are the kind of input that pose estimation and automated General Movements Assessment consume [6], [8], though establishing that they improve either task is a separate evaluation that this work does not attempt.

Because the full model is not real-time on commodity hardware (video-rate use currently needs a data-centre GPU), a complementary and more deployable route is to use SAM 3 as an offline *annotation* engine. Its trunk and part masks can label large amounts of NICU video at low manual cost, providing the supervision to train a compact CNN or transformer that then runs in real time, at the frame rate a given signal demands, on ordinary bedside hardware. The trunk (thorax and abdomen) is a natural target: it is the region whose cyclic motion encodes the respiratory rate, so a distilled model could track the trunk and estimate respiration on-device, with SAM 3 providing the labels rather than the runtime.

ACKNOWLEDGMENT

This research was supported by the High Performance Computing Center at UFRN (NPAD/UFRN). We also acknowledge the Brazilian Unified Health System (Sistema Único de Saúde, SUS), under which the neonatal data were collected.

***Resumo*—Este artigo compara lógica fuzzy, multivalorada, paracompleta e paraconsistente em sistemas de apoio à decisão médica para diabetes. A análise avalia como cada formalismo trata gradação, incompletude e conflito informacional. A metodologia combina revisão crítica e experimentos determinísticos em Python, sem treinamento ou avaliação preditiva. Os mesmos registros recebem perturbações pareadas, e o comportamento lógico é medido por cobertura, rejeição e perda de cobertura. Análises de sensibilidade e uma auditoria descritiva com o rótulo original avaliam a estabilidade das conclusões e a relação entre cobertura e concordância. Utiliza-se uma base pública de marcadores clínico-sintomáticos para risco de diabetes em estágio inicial. Discutem-se vantagens, limitações e diretrizes de seleção, com código público para reprodução e extensão.**

***Palavras-chave*—Lógicas não classicas, Diabetes, Apoio à Decisão Médica.**

***Abstract*—This article compares fuzzy, many-valued, paracomplete, and paraconsistent logics in medical decision support systems for diabetes. It evaluates how each formalism handles gradation, incompleteness, and informational conflict. The methodology combines a critical review with deterministic Python experiments, without model training or predictive evaluation. Paired perturbations are applied to the same records, and logical behavior is measured through coverage, rejection, and coverage loss. Sensitivity analyses and a descriptive audit using the original label assess the stability of the conclusions and the relationship between coverage and agreement. A public dataset of clinical-symptomatic markers for early-stage diabetes risk is used. Advantages, limitations, and selection guidelines are discussed, with public code for reproduction and extension.**

***Index Terms*—Non classical Logic, Diabetes, Medical Decision Support.**

I. Introdução

Em sistemas de apoio à decisão médica, a qualidade da inferência depende não apenas da quantidade de dados, mas também da natureza de sua imperfeição. A incerteza gradual ocorre quando um sintoma, risco ou estado clínico admite intensidades intermediárias; a ausência ocorre quando uma informação não foi observada, registrada ou coletada; e a contradição surge quando fontes distintas sustentam simultaneamente uma proposição e sua negação. Esses fenômenos não são equivalentes: um campo ausente não constitui evidência negativa, e duas observações conflitantes não devem ser reduzidas automaticamente a uma média. Registros eletrônicos de saúde apresentam lacunas por diferenças de coleta, custo, disponibilidade de exames e entrada manual [1], enquanto recomendações, diagnósticos e fontes clínicas podem divergir ou contradizer-se [2], [3].

Abordagens existentes geralmente tratam essas imperfeições separadamente: sistemas fuzzy modelam gradações [4]–[6], métodos para dados ausentes priorizam imputação [1] e estudos de inconsistência detectam ou toleram conflitos [2], [3]. Lógicas multivaloradas, paracompletas e paraconsistentes oferecem semânticas específicas para estados intermediários, lacunas e contradições [7]–[9].

Entretanto, faltam comparações pareadas dos quatro formalismos sob os mesmos dados e perturbações. Este trabalho aborda essa lacuna ao avaliar como cada lógica preserva, transforma ou suspende decisões diante de gradação, ausência e contradição controladas.

A proposta diferencia-se dos estudos anteriores por não apresentar uma nova lógica, um método de imputação ou um classificador clínico supervisionado. O objetivo é construir uma comparação operacional, interpretável e reproduzível entre quatro famílias lógicas, mantendo constantes a base, os atributos perturbados e as realizações aleatórias. As diferenças observadas refletem a interação entre a representação semântica de cada formalismo e suas regras operacionais de decisão e rejeição: a fuzzy gradua evidências, a multivalorada introduz estados discretos adicionais, a paracompleta preserva lacunas e a paraconsistente mantém evidências favoráveis e contrárias sem colapso inferencial.

A comparação é conduzida no contexto do auxílio ao diagnóstico de diabetes mellitus tipo 2, utilizando como referência observacional o *Early Stage Diabetes Risk Prediction Dataset*, disponibilizado no Kaggle e documentado no UCI Machine Learning Repository. A base contém 520 registros, 16 variáveis de entrada e um rótulo binário original. Esse rótulo não participa da construção das regras nem da mensuração principal; é consultado apenas em uma auditoria descritiva

posterior. Como não há biomarcadores laboratoriais, os atributos são tratados como marcadores clínico-sintomáticos, não como substitutos de critérios diagnósticos [10], [11].

O objetivo principal deste estudo é discutir como lógicas não clássicas podem auxiliar a representação de evidências no diagnóstico e no acompanhamento da diabetes mellitus tipo 2.

As principais contribuições deste artigo são: (i) uma caracterização conjunta de incerteza gradual, estados intermediários, ausência e conflito; (ii) um protocolo pareado com níveis de ausência e contradição de 10%, 20% e 30%, em 30 repetições; (iii) a explicitação e a análise de sensibilidade dos critérios de decisão; e (iv) uma auditoria complementar da relação entre cobertura, concordância e abstinência. O código é disponibilizado publicamente.

O restante do artigo organiza-se da seguinte forma: a Seção II apresenta a fundamentação teórica; a Seção III descreve metodologia, base de dados e fluxos operacionais; a Seção IV discute os resultados; e a Seção V reúne conclusões e diretrizes de seleção dos formalismos.

II. Fundamentação Teórica

A. Diabetes mellitus tipo 2 e apoio ao diagnóstico

A diabetes é uma doença metabólica crônica caracterizada por hiperglicemia persistente, associada a alterações na secreção ou na ação da insulina. No caso da diabetes mellitus tipo 2, a evolução costuma ser gradual, podendo envolver longos períodos assintomáticos ou sintomas pouco específicos, o que reforça a importância de estratégias de triagem, acompanhamento longitudinal e apoio à decisão clínica [12]–[14].

O diagnóstico e o monitoramento da diabetes baseiam-se principalmente em HbA1c, glicemia de jejum, teste oral de tolerância e glicemia casual. A American Diabetes Association considera compatíveis com diabetes HbA1c $\geq 6{,}5\%$, glicemia de jejum ≥ 126 mg/dL, glicemia de duas horas ≥ 200 mg/dL ou glicemia casual ≥ 200 mg/dL com sintomas, mediante interpretação clínica e confirmação quando necessária [12], [15].

Sinais e fatores de risco, como idade, histórico familiar, sedentarismo, poliúria, polidipsia, fadiga e visão turva, auxiliam a triagem, mas não substituem exames diagnósticos. Sistemas interpretáveis podem apoiar a priorização de casos e integrar evidências discretas, incompletas, graduais ou conflitantes [13]–[16]. Por este motivo, a diabetes é adequada à comparação de lógicas não clássicas. As próximas subseções apresentam esses formalismos como camadas de apoio à decisão, sem substituir critérios médicos ou modelos estatísticos.

B. Lógica Multivalorada

A lógica multivalorada amplia a bivalência ao admitir estados além de verdadeiro e falso. Em aplicações médicas, um valor "indeterminado" representa informação insuficiente, distinguindo desconhecimento de negação e reduzindo ambiguidades em bases incompletas [7], [9].

Para tornar essa ideia operacional, pode-se definir um conjunto finito de estados de decisão:

$$V = \{0, \frac{1}{2}, 1\}. \tag{1}$$

Uma proposição clínica p recebe $v(p) \in V$: 0 indica evidência negativa, 1 evidência positiva e $\frac{1}{2}$ dúvida ou informação parcial.

Neste trabalho adota-se uma semântica trivalorada do tipo Kleene. Para duas proposições p e q, os operadores são:

$$v(\neg p) = 1 - v(p), \tag{2}$$

$$v(p \wedge q) = \min\{v(p), v(q)\}, \tag{3}$$

$$v(p \vee q) = \max\{v(p), v(q)\}, \tag{4}$$

$$v(p \rightarrow q) = \max\{1 - v(p), v(q)\}. \tag{5}$$

O grau de verdade é $T(p) = v(p)$, o de falsidade é $F(p) = 1 - v(p)$ e a certeza é $C(p) = |2v(p) - 1|$. Os extremos 0 e 1 possuem certeza máxima; o valor 0,5 representa máxima indeterminação. Entradas ausentes ou conflitos suspensos recebem 0,5. O escore ponderado é:

$$S_M = \frac{\sum_i w_i v_i}{\sum_i w_i}. \tag{6}$$

O risco é baixo se $S_M < 0{,}35$, moderado se $0{,}35 \leq S_M < 0{,}60$ e alto se $S_M \geq 0{,}60$. Três ou mais lacunas centrais geram saída indeterminada. Contradições são convertidas em 0,5 e, portanto, não permanecem explícitas.

Exemplo numérico: considere poliúria presente ($v_1 = 1, w_1 = 3$), polidipsia desconhecida ($v_2 = 0{,}5, w_2 = 3$), perda de peso ausente ($v_3 = 0, w_3 = 2$) e idade de 45 anos, com contribuição 0,5 e peso 0,75:

$$S_M = \frac{3(1) + 3(0{,}5) + 2(0) + 0{,}75(0{,}5)}{3 + 3 + 2 + 0{,}75} = \frac{4{,}875}{8{,}75} = 0{,}557.$$

Como existe apenas uma lacuna central e $0{,}35 \leq 0{,}557 < 0{,}60$, a saída é risco moderado. Para a polidipsia isoladamente, $T = F = 0{,}5$ e $C = 0$, explicitando a indeterminação.

C. Lógica Fuzzy

A lógica fuzzy representa conceitos graduais por valores em $[0, 1]$. Assim, categorias como "risco moderado" são descritas por funções de pertinência, e não apenas por limites rígidos [4], [5]. Sistemas fuzzy também têm sido empregados em apoio ao diagnóstico e à classificação de diabetes, preservando regras interpretáveis e graus intermediários de evidência [6], [17].

Matematicamente, essa transição gradual é descrita por uma função de pertinência:

$$\mu_A(x) : X \rightarrow [0, 1]. \tag{7}$$

Nessa expressão, x é a entrada observada, X seu domínio e A a categoria clínica. Valores de $\mu_A(x)$ próximos de 0 indicam baixa compatibilidade; próximos de 1, alta compatibilidade; e intermediários, transição gradual.

Formalmente, cada entrada clínica x_i é convertida em um grau $\mu_i \in [0, 1]$. A negação, a conjunção e a disjunção adotadas são, respectivamente:

$$N(\mu) = 1 - \mu, \tag{8}$$

$$T(\mu_1, \mu_2) = \min(\mu_1, \mu_2), \tag{9}$$

$$S(\mu_1, \mu_2) = \max(\mu_1, \mu_2). \tag{10}$$

O grau de verdade é $T_f = \mu$, a falsidade complementar é $F_f = 1 - \mu$ e a certeza é $C_f = |2\mu - 1|$. Esses valores expressam compatibilidade semântica, não probabilidade. A agregação utiliza a média ponderada:

$$S_F = \frac{\sum_i w_i \mu_i}{\sum_i w_i}, \tag{11}$$

O resultado é baixo para $S_F < 0{,}35$, moderado para $0{,}35 \leq S_F < 0{,}65$ e alto para $S_F \geq 0{,}65$. Ausências e conflitos suspensos recebem $\mu = 0{,}5$; o sistema mantém uma saída, mas o conflito deixa de ser identificável após a agregação.

Exemplo numérico: considere pertinências 0,8 para poliúria, 0,6 para polidipsia e 0,4 para perda de peso, com pesos 3, 3 e 2. A conjunção vale 0,6, a disjunção 0,8 e a negação da poliúria 0,2. Para idade de 45 anos ($\mu = 0{,}5, w = 0{,}75$), o escore é:

$$\begin{aligned} S_F &= \frac{3(0{,}8) + 3(0{,}6) + 2(0{,}4)}{8{,}75} \\ &\quad + \frac{0{,}75(0{,}5)}{8{,}75} \\ &= \frac{5{,}375}{8{,}75} = 0{,}614. \end{aligned}$$

Como $0{,}35 \leq 0{,}614 < 0{,}65$, a saída é suspeita moderada. Seu grau complementar de falsidade é $1 - 0{,}614 = 0{,}386$ e a certeza relativa é $|2(0{,}614) - 1| = 0{,}228$.

D. Lógica Paracompleta

A lógica paracompleta trata a falta de informação como um estado legítimo. Assim, quando os dados são insuficientes, uma afirmação clínica pode não ser confirmada nem descartada [7], [9]:

$$\nvdash p \quad \text{e} \quad \nvdash \neg p. \tag{12}$$

Os símbolos indicam que não há base para concluir p nem $\neg p$. Portanto, um sintoma não registrado permanece desconhecido, em vez de ser tratado como ausente.

Cada proposição recebe $E(p) = (t_p, f_p)$, em que as componentes indicam evidência favorável e contrária. Os estados são verdadeiro $(1, 0)$, falso $(0, 1)$ e lacunar $(0, 0)$. O estado contraditório $(1, 1)$ é convertido em lacuna. Os operadores são:

$$E(\neg p) = (f_p, t_p), \tag{13}$$

$$E(p \wedge q) = (\min(t_p, t_q), \max(f_p, f_q)), \tag{14}$$

$$E(p \vee q) = (\max(t_p, t_q), \min(f_p, f_q)). \tag{15}$$

Definem-se verdade $T_p = t_p$, falsidade $F_p = f_p$, certeza $C_p = t_p - f_p$ e incompletude $I_p = 1 - t_p - f_p$. No estado lacunar, $I_p = 1$. Atributos ausentes são excluídos da média:

$$S_P = \frac{\sum_{i \in O} w_i z_i}{\sum_{i \in O} w_i}, \tag{16}$$

onde O é o conjunto de atributos observados. Duas ou mais lacunas centrais geram saída inconclusiva; com uma lacuna central e escore intermediário, a saída é "suspeita com evidência incompleta". Sem essa condição, aplicam-se os limiares 0,35 e 0,65.

Exemplo numérico: considere poliúria presente, $(1, 0)$ e peso 3; polidipsia desconhecida, $(0, 0)$ e peso 3; perda súbita de peso ausente, $(0, 1)$ e peso 2; e idade de 45 anos, contribuição 0,5 e peso 0,75. A polidipsia é excluída da média, resultando em

$$S_P = \frac{3(1) + 2(0) + 0{,}75(0{,}5)}{3 + 2 + 0{,}75} = \frac{3{,}375}{5{,}75} = 0{,}587.$$

O escore é moderado, mas a lacuna central produz "suspeita com evidência incompleta". Para a polidipsia, $I_p = 1$; outra lacuna central tornaria a saída inconclusiva.

E. Lógica Paraconsistente

A lógica paraconsistente trata informações conflitantes sem permitir que uma contradição gere conclusões arbitrárias. Para isso, rejeita o princípio de explosão da lógica clássica [7], [8], [18]:

$$p, \neg p \nvdash q. \tag{17}$$

Assim, a presença simultânea de p e $\neg p$ não permite inferir uma conclusão qualquer q. O conflito é sinalizado, mas as demais evidências continuam utilizáveis.

Cada proposição recebe $E(p) = (\mu_p, \lambda_p)$, com evidências independentes, sendo elas favorável e contrária. O estado $\mu_p = \lambda_p = 1$ representa contradição máxima. Os operadores são:

$$E(\neg p) = (\lambda_p, \mu_p), \tag{18}$$

$$E(p \wedge q) = (\min(\mu_p, \mu_q), \max(\lambda_p, \lambda_q)), \tag{19}$$

$$E(p \vee q) = (\max(\mu_p, \mu_q), \min(\lambda_p, \lambda_q)). \tag{20}$$

O grau de verdade é $T_c = \mu_p$, o grau de falsidade é $F_c = \lambda_p$, o grau de certeza é:

$$G_{\text{cert}} = \mu_p - \lambda_p, \tag{21}$$

e a contradição é $G_{\text{contr}} = \mu_p + \lambda_p - 1$. A saída é inconsistente diante de um conflito central ou três conflitos no conjunto completo. Sem essa condição, $G_{\text{cert}} \geq 0{,}30$ indica alto, $G_{\text{cert}} \leq -0{,}30$ indica baixo e a faixa intermediária indica indeterminação. Ausências geram $(0, 0)$, com preservação do peso no denominador agregado, e contradições permanecem explícitas.

Exemplo numérico: considere três marcadores centrais com pesos $(3, 3, 2)$. Para poliúria, a fonte A registra 1 e a fonte B registra 0; para polidipsia, ambas registram 1; e, para perda súbita de peso, ambas registram 0. A evidência favorável ponderada, considerando as duas fontes, é:

$$\begin{aligned} \mu &= \frac{3(1) + 3(1) + 2(0)}{2(3 + 3 + 2)} \\ &\quad + \frac{3(0) + 3(1) + 2(0)}{2(3 + 3 + 2)} \\ &= \frac{9}{16} = 0{,}5625. \end{aligned}$$

A evidência contrária é $\lambda = 7/16 = 0{,}4375$, resultando em $G_{\text{cert}} = 0{,}125$ e $G_{\text{contr}} = 0$. O grau agregado indicaria indeterminação, mas o conflito central na poliúria prevalece; a saída final é "inconsistente".

III. Metodologia de Comparação

A comparação combinou revisão qualitativa e aplicação computacional de regras lógicas em Python. Os formalismos foram analisados quanto à representação da incerteza, interpretabilidade e reação a dados faltantes ou conflitantes. Não foi construído ou ajustado um modelo estatístico. Os algoritmos e experimentos foram disponibilizados em https://github.com/czkirilo/nonclassical-logics-diabetes para reprodução e extensão.

A. Base de dados

Foram utilizados os 520 registros do *Early Stage Diabetes Risk Prediction Dataset*, coletados por questionário no Sylhet Diabetes Hospital e validados por um médico [10], [11], [19]. O conjunto possui 16 variáveis de entrada e um rótulo binário original, reservado para a auditoria descritiva posterior.

As entradas são idade, gênero e 14 marcadores clínico-sintomáticos. A idade varia de 16 a 90 anos; os demais atributos são categóricos. O rótulo original contém 320 registros positivos (61,5%) e 200 negativos (38,5%) e é informado apenas para descrever a base. A estrutura completa é apresentada na Tabela I.

Tabela I
Estrutura das variáveis do conjunto de dados utilizado.

Grupo	Variáveis	Representação
Demográfica	Idade; gênero	Idade: inteiro (16–90); gênero: binário
Clínico-sintomática	14 marcadores de sinais e sintomas	Binários: presença $= 1$; ausência $= 0$
Rótulo original	Classe de risco	Binário; auditoria posterior

O arquivo analisado não contém valores ausentes ou categorias inválidas. Como não há biomarcadores laboratoriais, o rótulo constitui somente uma referência observacional: não participa da definição dos pesos, limiares ou regras, nem das medidas principais de cobertura e rejeição.

B. Pré-processamento e cenários experimentais

Os nomes e categorias foram padronizados; idade permaneceu inteira, e os campos categóricos foram codificados para a aplicação das regras. Não houve imputação, normalização, balanceamento ou divisão treino–teste: os 520 registros foram usados nas quatro lógicas para comparar regras, não para treinar modelos.

As perturbações foram aplicadas a poliúria, polidipsia, perda de peso, fraqueza, polifagia e paresia parcial. No cenário completo, os dados permaneceram inalterados. No incompleto, cada célula desses atributos foi removida, sem imputação posterior, com probabilidade $p_a \in \{0{,}10; 0{,}20; 0{,}30\}$. Os níveis representam perturbações baixa, intermediária e alta.

No cenário contraditório, a fonte A preservou o valor original $x \in \{0, 1\}$ e a fonte B o inverteu, $x' = 1 - x$, com $p_c \in \{0{,}10; 0{,}20; 0{,}30\}$. Cada nível teve 30 repetições, usando a mesma máscara aleatória nas quatro lógicas. Desacordos foram tratados como evidência suspensa nas lógicas fuzzy, multivalorada e paracompleta; na paraconsistente, as duas fontes foram mantidas separadamente.

Cada repetição seguiu a mesma sequência: (i) copiar os registros originais; (ii) gerar uma única máscara de perturbação; (iii) fornecer os mesmos registros perturbados às quatro lógicas; (iv) registrar o escore, a categoria e o eventual estado de rejeição; e (v) contar decisões e rejeições. O rótulo da base não foi consultado nesse fluxo principal.

C. Implementação computacional e fluxo dos algoritmos

A implementação foi organizada em cinco notebooks para Google Colab: quatro notebooks individuais, um para cada formalismo, e um notebook comparativo que reúne as mesmas funções. O código utiliza `pandas` para manipulação tabular, `NumPy` para cálculos e geração pseudoaleatória e `Matplotlib` para visualização. A Fig. 1 apresenta o fluxo comum do código e a tomada de decisão das quatro lógicas.

Após a leitura do CSV, as respostas `Yes` e `No` são convertidas em 1 e 0, enquanto valores não reconhecidos permanecem como `NaN`. A idade é transformada pela função de pertinência definida anteriormente. Cada função `decisao_` recebe uma linha do *DataFrame*, percorre os 14 sintomas, aplica pesos e tratamento semântico próprio e retorna uma `Series` com escore, contadores de lacuna ou conflito e categoria final. As saídas são concatenadas ao registro original e podem ser resumidas graficamente ou exportadas em CSV.

Embora os notebooks convertam a classe original em uma coluna binária para exibição e exportação, essa coluna não é consultada pelas funções de decisão. O protocolo agregado utiliza sementes inteiras de 0 a 29 para as taxas de 10%, 20% e 30%, com máscaras pareadas entre os formalismos. No painel (b) da Fig. 1, as condições em verde correspondem à ordem efetiva dos testes condicionais no código.

D. Parâmetros, limiares e critérios de decisão

As quatro implementações compartilham um escore heurístico normalizado. Para cada sintoma, $z_i = 1$ indica presença, $z_i = 0$ indica ausência e o peso w_i expressa sua contribuição relativa. Os pesos foram definidos *a priori* como escala ordinal experimental, e não como estimativas de importância diagnóstica. Valores de 2,0 a 3,0 foram atribuídos a poliúria, polidipsia, perda súbita de peso e paresia parcial; valores de 0,75 a 1,5, a polifagia, fraqueza, visão turva, irritabilidade, cicatrização tardia e idade; e valores de 0,25 a 0,5, aos marcadores auxiliares. Essa hierarquia torna explícita a contribuição relativa das evidências, sem pretensão de reproduzir critérios clínicos validados.

A idade contribui com peso 0,75 por meio de uma pertinência gradual:

$$\mu_{\text{idade}}(a) = \begin{cases} 0, & a < 30, \\ (a - 30)/30, & 30 \le a \le 60, \\ 1, & a > 60. \end{cases} \tag{22}$$

O escore básico é a média ponderada dos sintomas e da idade. Os pontos 30 e 60 anos delimitam apenas uma transição didática de baixa para alta contribuição etária; não constituem

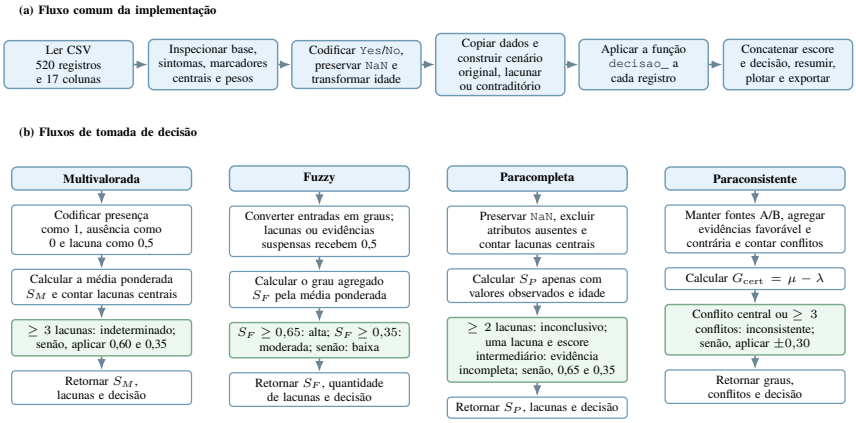

Figura 1. Implementação dos algoritmos: (a) etapas comuns dos notebooks; (b) transformação, agregação e tomada de decisão em cada lógica.

limites diagnósticos. A Tabela II resume o tratamento das imperfeições e os critérios operacionais de cada lógica, que não constituem protocolo médico.

Tabela II
CRITÉRIOS HEURÍSTICOS DE DECISÃO EMPREGADOS NAS QUATRO LÓGICAS.

Formalismo	**Tratamento e decisão**
Multivalorada	Ausências recebem 0,5. Risco baixo se $S < 0{,}35$, moderado se $0{,}35 \leq S < 0{,}60$ e alto se $S \geq 0{,}60$; três lacunas centrais geram indeterminação.
Fuzzy	Ausências ou evidências suspensas recebem 0,5. Suspeita baixa se $S < 0{,}35$, moderada se $0{,}35 \leq S < 0{,}65$ e alta se $S \geq 0{,}65$.
Paracompleta	Ausências são excluídas da média. O risco usa os limiares 0,35 e 0,65; uma lacuna central pode indicar evidência incompleta e duas geram inconclusão.
Paraconsistente	Mantém graus favorável e contrário. É inconsistente com um conflito central ou três conflitos; é alto se $G_{\mathrm{cert}} \geq 0{,}30$, baixo se $G_{\mathrm{cert}} \leq -0{,}30$ e indeterminado entre esses limites.

Os limiares 0,35 e 0,60–0,65 são divisões operacionais da escala normalizada, não pontos de corte médicos. A faixa simétrica $[-0{,}30, 0{,}30]$ cria uma zona de indeterminação paraconsistente. Os critérios de três lacunas na multivalorada e duas na paracompleta expressam diferentes tolerâncias à incompletude. Como essas escolhas influenciam diretamente a cobertura, sua estabilidade é examinada em análise de sensibilidade.

E. Repetições, divisão dos dados e validação

Cada nível aleatório de ausência e contradição foi executado 30 vezes, com sementes inteiras de 0 a 29. Em uma mesma repetição, a máscara sorteada foi reutilizada nos quatro formalismos. Essa estratégia de pareamento controla a entrada experimental: diferenças entre as saídas não podem ser atribuídas ao sorteio de registros ou atributos distintos. A condição completa foi executada uma vez, pois é determinística.

Não houve treinamento, ajuste de parâmetros, divisão treino–teste ou validação cruzada. Todos os 520 registros foram apenas submetidos às regras previamente definidas. A classe original da base não foi usada como resposta a ser prevista, nem para julgar saídas como acertos ou erros; ela permaneceu somente como informação descritiva do conjunto. Portanto, o experimento avalia comportamento inferencial, e não capacidade preditiva ou generalização.

A validação adotada é interna e procedimental. Foram verificados: (i) preservação integral da base no cenário completo; (ii) proporção realizada de células ausentes ou invertidas em relação à taxa nominal; (iii) reutilização da mesma máscara entre as quatro lógicas; (iv) manutenção das classes e dos atributos não selecionados; e (v) coerência das categorias de saída com os limiares definidos. Para cada condição aleatória, as proporções de decisão operacional, indeterminação/inconclusão e conflito, bem como o escore médio, foram calculadas em cada repetição e resumidas por média $\pm$ desvio-padrão. As 30 repetições reduzem a dependência de um único sorteio e permitem avaliar estabilidade, mas não equivalem a validação clínica ou externa.

F. Mensuração do comportamento lógico e opção de rejeição

O teste computacional verificou como cada formalismo responde à mesma entrada antes e depois da inserção de ausência ou contradição. Para cada registro, o algoritmo retornou um escore lógico, uma categoria de decisão e, quando previsto por sua semântica, um estado não operacional: indeterminado, inconclusivo ou inconsistente. Nenhuma saída foi comparada à classe da base para calcular acertos ou erros.

A *cobertura* mede a proporção de registros para os quais a lógica produziu uma decisão operacional:

$$C = \frac{N_{\mathrm{dec}}}{N}. \tag{23}$$

A *rejeição* reúne os registros nos quais o formalismo suspendeu ou bloqueou a decisão e é calculada por $R = 1 - C$. A *perda de cobertura* mede a mudança causada pela perturbação em relação aos dados completos:

$$\Delta C(p) = C(p) - C(0), \tag{24}$$

em que valores negativos indicam redução da proporção de decisões operacionais. Também foi registrado o tipo de estado responsável pela rejeição: indeterminação, inconclusão por ausência ou inconsistência por conflito.

O cenário completo foi executado uma vez por ser determinístico. Nos cenários perturbados, cobertura, rejeição e perda de cobertura foram calculadas nas 30 repetições e resumidas por média $\pm$ desvio-padrão. O desvio-padrão mede a variação entre máscaras aleatórias, não a incerteza de um modelo treinado. O teste de Friedman foi aplicado somente à cobertura das repetições pareadas; quando significativo, utilizou-se Wilcoxon com correção de Holm. Esses testes comparam políticas de decisão, não desempenho de classificação.

Além das rejeições próprias de cada lógica, avaliou-se uma regra uniforme de alta certeza. Para fuzzy, multivalorada e paracompleta, definiu-se $c = |2S - 1|$; para a paraconsistente, $c = |G_{\mathrm{cert}}|$. Com $\tau = 0{,}30$, uma saída permanece operacional apenas quando $c \geq \tau$. Essa análise mede quanto da cobertura é perdido ao exigir maior distância da zona de indeterminação.

G. Sensibilidade, cenário estruturado e auditoria do rótulo

Na análise de sensibilidade, cada peso foi variado independentemente entre 80% e 120% de seu valor original, em 200 configurações geradas com semente 20260825 e as mesmas máscaras das 30 repetições. O limiar uniforme de certeza foi avaliado em $\tau \in \{0{,}20; 0{,}25; 0{,}30; 0{,}35; 0{,}40\}$. Também foram testados critérios de rejeição de duas a quatro lacunas na multivalorada, uma a três lacunas na paracompleta e um a três conflitos centrais na paraconsistente.

Como teste complementar mais próximo de falhas concentradas de documentação, 20% dos registros perderam um bloco de três marcadores; para conflito estruturado, 20% receberam uma única discordância central na fonte B. Esses mecanismos continuam sintéticos, mas evitam que um registro acumule conflitos independentes em várias células.

O rótulo original foi usado apenas após os experimentos, sem ajuste de parâmetros. Saídas baixas foram mapeadas para a classe negativa, saídas moderadas ou altas para a positiva, e estados não operacionais foram tratados como abstinência. Reportaram-se cobertura, concordância seletiva entre os casos decididos e exposição ao erro, isto é, a proporção de decisões discordantes no conjunto completo. Trata-se de auditoria descritiva, não de acurácia diagnóstica.

IV. Resultados

Os resultados descrevem quantos registros receberam uma decisão e quantos foram encaminhados a estados de indeterminação, inconclusão ou inconsistência. Não se avalia se a saída coincide com o rótulo original da base. O foco é a mudança de comportamento de cada lógica quando a mesma entrada sofre perturbações controladas.

A. Cenário completo

A Tabela III resume a resposta das quatro lógicas na ausência de perturbações.

Fuzzy, multivalorada e paracompleta emitiram uma decisão para todos os 520 registros. A paraconsistente manteve 138 registros na zona de indeterminação definida por $|G_{\mathrm{cert}}| < 0{,}30$, resultando em cobertura de 73,5%. Essa diferença decorre da combinação entre representação semântica e política operacional de rejeição, não de erro preditivo.

Tabela III
Resposta lógica no cenário completo (%).

Formalismo	Cobertura	Rejeição
Multivalorada	100,0	0,0
Fuzzy	100,0	0,0
Paracompleta	100,0	0,0
Paraconsistente	73,5	26,5

B. Cenário incompleto

A Tabela IV apresenta a cobertura média e sua mudança em relação ao cenário completo.

Tabela IV
Cobertura sob ausência (%; média $\pm$ desvio-padrão; 30 repetições).

Formalismo	Ausência	Cobertura	ΔC
Multivalorada	10%	$98{,}4 \pm 0{,}5$	$-1{,}6$
	20%	$90{,}1 \pm 1{,}3$	$-9{,}9$
	30%	$74{,}3 \pm 2{,}1$	$-25{,}7$
Fuzzy	10%	$100{,}0 \pm 0{,}0$	0,0
	20%	$100{,}0 \pm 0{,}0$	0,0
	30%	$100{,}0 \pm 0{,}0$	0,0
Paracompleta	10%	$88{,}4 \pm 1{,}6$	$-11{,}6$
	20%	$65{,}5 \pm 2{,}4$	$-34{,}5$
	30%	$41{,}9 \pm 2{,}3$	$-58{,}1$
Paraconsistente	10%	$70{,}1 \pm 1{,}2$	$-3{,}4$
	20%	$65{,}8 \pm 0{,}9$	$-7{,}7$
	30%	$60{,}5 \pm 1{,}2$	$-13{,}0$

A fuzzy manteve 100% de cobertura porque cada lacuna recebeu grau neutro 0,5 e não há rejeição nativa. A multivalorada aplicou a mesma substituição, mas rejeitou três ou mais lacunas centrais, reduzindo a cobertura para 74,3% com 30% de ausência. A paracompleta excluiu os valores ausentes e rejeitou a partir de duas lacunas, atingindo 41,9%. Na paraconsistente, a ausência $(0, 0)$ reduziu $|G_{\mathrm{cert}}|$ em direção à zona de indeterminação, resultando em 60,5%. Assim, cobertura integral significa continuidade de decisão, não preservação da informação original.

C. Cenário contraditório

A Tabela V resume a resposta aos conflitos. A fuzzy absorveu o desacordo como grau intermediário; a multivalorada e a paracompleta suspenderam a evidência, mas aplicaram diferentes limiares de rejeição; e a paraconsistente manteve o conflito explícito.

Com 30% de inversão independente em seis marcadores, a probabilidade de não ocorrer conflito central é $(1 - 0{,}30)^6 = 11{,}8\%$. Após a zona de indeterminação, a cobertura paraconsistente foi 8,8%. Essa redução decorre diretamente da regra conservadora que bloqueia qualquer conflito central e não deve ser interpretada como desempenho preditivo inferior. A fuzzy preservou 100% de cobertura, mas o desacordo deixou de ser identificável após a agregação.

D. Comparações estatísticas

O teste de Friedman identificou diferenças de cobertura entre os quatro paradigmas em todos os níveis perturbados ($p \leq 1{,}45 \times 10^{-17}$). Isso confirma políticas distintas de

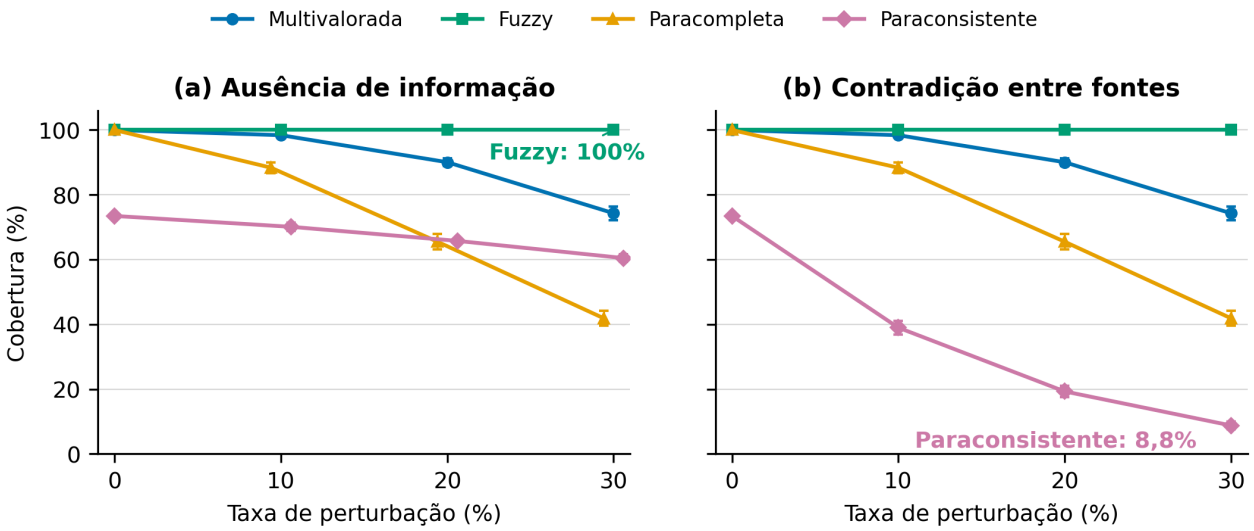

Figura 2. Cobertura das quatro lógicas nos cenários de ausência e contradição. O cenário completo é determinístico; os demais pontos representam média ± desvio-padrão em 30 repetições pareadas.

Tabela V
COBERTURA SOB CONTRADIÇÃO (%; MÉDIA ± DESVIO-PADRÃO; 30 REPETIÇÕES).

Formalismo	Contradição	Cobertura	ΔC
Multivalorada	10%	$98{,}4 \pm 0{,}5$	$-1{,}6$
	20%	$90{,}1 \pm 1{,}3$	$-9{,}9$
	30%	$74{,}3 \pm 2{,}1$	$-25{,}7$
Fuzzy	10%	$100{,}0 \pm 0{,}0$	0,0
	20%	$100{,}0 \pm 0{,}0$	0,0
	30%	$100{,}0 \pm 0{,}0$	0,0
Paracompleta	10%	$88{,}4 \pm 1{,}6$	$-11{,}6$
	20%	$65{,}5 \pm 2{,}4$	$-34{,}5$
	30%	$41{,}9 \pm 2{,}3$	$-58{,}1$
Paraconsistente	10%	$39{,}0 \pm 2{,}1$	$-34{,}5$
	20%	$19{,}3 \pm 1{,}7$	$-54{,}2$
	30%	$8{,}8 \pm 1{,}2$	$-64{,}7$

continuidade e rejeição diante das mesmas máscaras, mas não estabelece qual lógica é mais correta.

E. Sensibilidade dos parâmetros

Com variação independente de $\pm 20\%$ nos pesos, a cobertura sob 30% de ausência permaneceu em 74,3% na multivalorada, 100% na fuzzy e 41,9% na paracompleta; na paraconsistente, variou entre 58,6% e 62,9%. Sob 30% de contradição, a paraconsistente permaneceu entre 8,6% e 9,1%. Portanto, a conclusão qualitativa foi estável aos pesos.

Ao variar τ de 0,20 a 0,40, a cobertura com 30% de ausência caiu de 58,3% para 39,5% na multivalorada, de 74,8% para 47,2% na fuzzy, de 34,5% para 26,5% na paracompleta e de 60,5% para 47,2% na paraconsistente. Maior sensibilidade ocorreu nos critérios estruturais: com 30% de ausência, alterar a rejeição multivalorada de duas para quatro lacunas levou a cobertura de 41,9% a 93,1%; na paracompleta, uma a três lacunas produziram 11,7% a 74,3%. Sob contradição, rejeitar um a três conflitos centrais elevou a cobertura paraconsistente de 8,8% a 48,8%. Logo, os valores absolutos refletem a interação entre semântica e política operacional.

F. Auditoria descritiva e cenário estruturado

A Tabela VI apresenta cobertura e concordância seletiva com o rótulo original. A análise é posterior e não altera pesos ou limiares.

Tabela VI
COBERTURA/CONCORDÂNCIA SELETIVA COM O RÓTULO (%).

Formalismo	Completo	Aus. 30%	Contr. 30%
Multivalorada	100,0/83,5	74,3/81,4	74,3/81,4
Fuzzy	100,0/83,5	100,0/80,1	100,0/80,1
Paracompleta	100,0/83,5	41,9/81,6	41,9/81,6
Paraconsistente	73,5/86,7	60,5/84,1	8,8/87,8

Com 30% de ausência, a fuzzy manteve cobertura integral, mas a concordância caiu de 83,5% para 80,1%, com decisões discordantes em 19,9% do conjunto. A paracompleta apresentou 41,9% de cobertura e 7,7% de decisões discordantes; a paraconsistente, 60,5% e 9,6%. Portanto, 100% de cobertura significa que o método sempre emite uma categoria, não que decide adequadamente.

No cenário estruturado, em que 20% dos registros perderam um bloco de três marcadores, as coberturas foram 80,6% para multivalorada e paracompleta, 100% para fuzzy e 69,0% para paraconsistente. Quando 20% dos registros receberam uma única discordância, as três primeiras mantiveram 100% e a paraconsistente atingiu 59,5%, contra 19,3% no mecanismo independente por célula. A magnitude depende, portanto, de como a imperfeição é gerada, embora a distinção entre continuidade e explicitação do conflito permaneça.

V. CONCLUSÕES

Este artigo caracterizou, sob entradas e perturbações pareadas, o comportamento de lógicas fuzzy, multivalorada,

paracompleta e paraconsistente no apoio à decisão sobre risco de diabetes em estágio inicial. No cenário completo, as três primeiras apresentaram cobertura integral, enquanto a paraconsistente decidiu em 73,5% dos registros. Com 30% de ausência, a cobertura variou de $41{,}9 \pm 2{,}3\%$ na paracompleta a 100% na fuzzy. Com 20% de contradição, os valores foram 100% na fuzzy, $90{,}1 \pm 1{,}3\%$ na multivalorada, $65{,}5 \pm 2{,}4\%$ na paracompleta e $19{,}3 \pm 1{,}7\%$ na paraconsistente.

A análise de sensibilidade mostrou baixa influência de variações de $\pm 20\%$ nos pesos, mas influência importante dos critérios estruturais de rejeição e do mecanismo de perturbação. Portanto, os resultados refletem a interação entre semântica e política operacional, e não uma propriedade isolada de cada lógica. A fuzzy favoreceu continuidade; a paracompleta suspendeu decisões mais cedo sob ausência; e a paraconsistente tornou conflitos visíveis ao custo de maior abstinência.

A auditoria com o rótulo confirmou que cobertura não equivale a adequação. Sob 30% de ausência, a fuzzy decidiu em todos os registros, mas apresentou 19,9% de decisões discordantes no conjunto. Métodos mais conservadores reduziram essa exposição ao custo de menor cobertura. Essa análise permanece descritiva: o rótulo não foi usado para treinamento ou calibração e não constitui diagnóstico confirmado.

As conclusões são limitadas por uma única base de 520 registros, sintomas predominantemente autorreferidos, ausência de biomarcadores e perturbações sintéticas. O cenário estruturado mostrou que a magnitude da cobertura muda quando as falhas se concentram por registro. Além disso, pesos e limiares não foram calibrados por especialistas, e não houve validação externa ou prospectiva. As saídas representam comportamento lógico comparativo, não desempenho diagnóstico ou segurança clínica.

Como trabalhos futuros, pretende-se aplicar o protocolo a bases multicêntricas com exames laboratoriais e conflitos reais entre fontes, calibrar regras com especialistas, avaliar mecanismos empiricamente observados de ausência e desacordo e testar arquiteturas híbridas que combinem triagem gradual, verificação de suficiência e auditoria de inconsistências.

***Abstract*—The development of Artificial Intelligence (AI) models for oral lesion detection depends on the availability of high-quality and well-structured annotated datasets. However, the construction of such datasets remains a challenge, particularly due to the need for standardized annotation procedures and specialized review. This study presents IA-Bucal Files, a platform developed to organize, annotate, review, and structure clinical images of oral lesions for future applications in Artificial Intelligence and Deep Learning. The platform integrates clinical images and associated metadata, allowing the annotation of lesions, anatomical structures, and exclusion zones through vector-based tools, including polygons, rectangles, circles, and ellipses. The dataset was constructed from images obtained from scientific articles, scientific literature databases, and open-access databases. Annotation was performed by undergraduate students from Dentistry and Biomedical Engineering programs following a preliminary study of the lesions based on scientific literature. The diagnostic classification associated with each image was based on the information provided by its original scientific source, followed by review by Dentistry doctoral students and university professors with a background in Dentistry. Inconsistencies identified during the review process were returned to the annotators for correction and subsequent re-evaluation. To date, the dataset comprises 2,556 clinical images containing oral lesions and 4,067 lesion annotations, distributed among benign, potentially malignant, and malignant lesions. The results demonstrate that the platform provides a structured and standardized workflow for image annotation and review, contributing to the organization and consistency of information related to oral lesions. As the dataset remains under construction, its size and class distribution may change with the incorporation of new images and diagnostic categories. The developed structure has the potential to support future research involving Artificial Intelligence applied to oral lesion detection and analysis.**

***Keywords*—Deep Learning, Medical Image Annotation, Convolutional Neural Networks, Artificial Intelligence.**

I. INTRODUCTION

Oral cancer represents a major public health concern in Brazil due to its high incidence, elevated mortality rates, and the frequent occurrence of late-stage diagnosis. Approximately 70% of cases are identified at advanced stages, negatively affecting patient prognosis, increasing healthcare costs within the Brazilian Unified Health System (SUS), and highlighting the limited access to specialists in Oral Medicine, particularly in Primary Health Care (PHC) services [1]. In this context, Artificial Intelligence (AI) has emerged as a promising approach to support the early detection of oral lesions and assist clinical decision-making.

Among AI techniques, Deep Learning has become one of the most successful approaches for medical image analysis. As a subset of machine learning, Deep Learning employs artificial neural networks with multiple hidden layers capable of automatically extracting complex features from data. In medical imaging, Convolutional Neural Networks (CNNs) have become the state-of-the-art method for image classification, object detection, and image segmentation because of their remarkable ability to recognize complex visual patterns. These networks process digital images through successive computational layers that progressively learn features ranging from simple edges and textures to highly discriminative patterns associated with pathological alterations [2], [3].

In Oral Pathology, Deep Learning models have been increasingly applied to the detection of potentially malignant disorders, oral cancer, dental caries, periodontal diseases, and radiographic abnormalities. However, the performance of these models depends directly on the quality of the datasets used during training. In supervised learning, neural networks learn from previously labeled examples, making the image annotation process one of the most critical stages in the development of reliable and clinically applicable AI systems. Image annotations provide the reference labels required for algorithms to associate visual patterns with specific diagnostic categories, directly influencing performance metrics such as accuracy, sensitivity, and model generalization capability [4].

Given the strong relationship between annotation quality and AI model performance, specialized annotation tools play a

fundamental role in the construction of datasets for supervised learning. In this context, the IA-Bucal Files platform was developed to organize and standardize the annotation process for clinical images of oral lesions. The platform provides a vector-based annotation environment featuring polygons, rectangles, circles, and ellipses, enabling precise delineation of regions of interest. Furthermore, it incorporates contextual intelligence to automatically associate annotations with diagnostic categories previously registered in the image metadata, allowing annotations to be organized into three primary categories: lesions, anatomical structures, and exclusion zones. This approach contributes to the creation of structured and standardized datasets that support the supervised training of neural networks for oral lesion detection.

II. MATERIALS AND METHODS

A. IA-Bucal Files Platform

IA-Bucal Files is a platform developed to support the construction of annotated datasets for training neural networks applied to the detection and classification of oral lesions. Its primary objective is to provide a structured environment for organizing, annotating, validating, and exporting clinical images, thereby enabling the generation of standardized datasets for Artificial Intelligence (AI) and Deep Learning applications.

In addition to image annotation, the platform supports the storage and management of clinical metadata. The integration of imaging and clinical information enriches the dataset, facilitating the development of more robust learning models while supporting clinical and epidemiological analyses and the improvement of intelligent clinical decision-support systems.

B. Dataset Construction

Deep Learning algorithms, particularly Convolutional Neural Networks (CNNs), rely on supervised learning to recognize visual patterns in medical images. Consequently, their performance depends on the availability of large datasets containing thousands of accurately annotated images.

The database used for the IA-Bucal Files platform was built using images of oral lesions obtained from scientific articles published in journals and found in scientific literature indexing and retrieval databases and platforms including PubMed, SciELO, LILACS, Scopus, the Virtual Health Library (VHL), and the Atlas of Dentistry as well as open-access databases.

The images were identified based on the lesions and descriptions found in the respective scientific sources. Following selection, the images were incorporated into the IA-Bucal Files platform, where they were organized and defined before undergoing annotation and review processes.

Using multiple sources enabled the inclusion of a variety of oral lesion types, morphological characteristics, anatomical locations, and image acquisition conditions. Image selection was based on the presence of oral lesions and the availability of diagnostic information associated with the image in the original source.

C. Oral Lesion Annotation

The initial stage of constructing the training set involved annotating oral lesions found in images collected from public databases and scientific articles. This procedure aimed to provide structured information for the supervised training of convolutional neural networks, enabling the algorithms to learn visual patterns associated with various alterations of the oral mucosa.

In this context, Figure 1 illustrates the annotation workflow performed by the staff member on the IA-Bucal Files platform. Initially, the clinical image is uploaded without any markings. Subsequently, both the lesion and the key anatomical structures of the oral cavity are delineated. This strategy provides additional spatial information to the dataset, enabling neural networks to learn not only the morphological characteristics of the lesion but also its relationship with the oral anatomy.

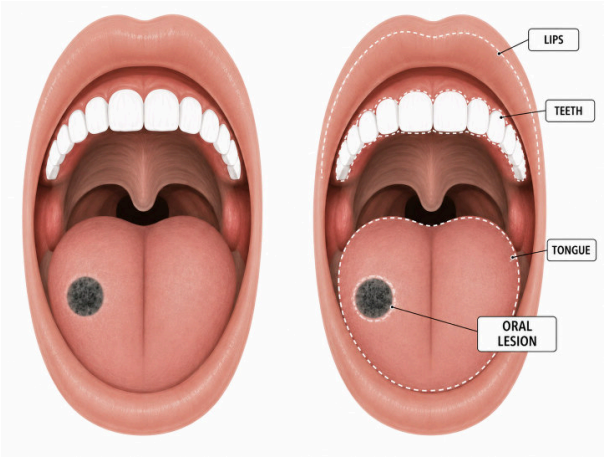

Fig. 1. Example of the annotation process carried out on the IA-Bucal Files platform.

The annotation phase was carried out by students from Dentistry and Biomedical Engineering programs. Prior to the actual marking, the students conducted a preliminary study of the lesions in the dataset, referencing scientific articles related to each specific condition. This stage involved analyzing the clinical, morphological, anatomical, and diagnostic characteristics of the lesions to equip the annotators with the necessary background knowledge for identifying and delineating the regions of interest.

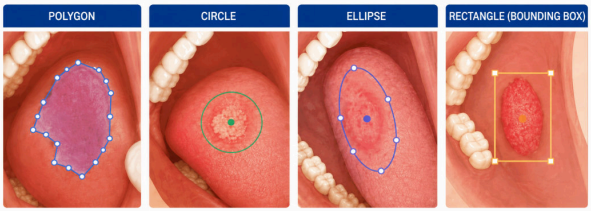

Fig. 2. Representation of the different types of vector markings used on the platform.

Following this preparation phase, annotations were created using vector drawing tools capable of representing the regions of interest. Depending on the observed morphological characteristics, bounding boxes, polygons, circles, and ellipses were employed to represent the anatomical boundaries of the lesions, as shown in Figure 2. Lesions with regular contours were generally delineated using rectangles or ellipses, whereas irregularly shaped lesions were annotated using polygons to better reflect the anatomy observed in the images.

The lesions were classified according to their corresponding diagnostic category, establishing a link between the marked region and the respective diagnostic label. In addition to the lesions, anatomical structures and exclusion zones areas that should not influence model training, such as light reflections, dental instruments, and other artifacts present in clinical photographs were also recorded.

Alongside the annotation process, the diagnostic classification assigned to the images was based on information from the original scientific sources. Thus, the lesion depicted in an image was linked to the diagnosis described in the scientific article or source from which the image was obtained. Consequently, the diagnosis associated with an image was not determined solely by the student performing the annotation but was based on the diagnostic classification provided in the original scientific source.

This procedure made it possible to link each image to its respective lesion and diagnostic category, contributing to the structured organization of the dataset intended for future Artificial Intelligence applications.

Once the annotation phase was complete, the markings underwent a specialized review process. This review was conducted by doctoral students in Dentistry and university professors with dental backgrounds, who evaluated the accuracy of the contours, the appropriateness of the assigned diagnostic category, and the recorded anatomical location.

Whenever inconsistencies were identified regarding lesion delineation, diagnostic classification, or anatomical location, the annotations were returned to the annotator with comments for correction. After corrections were made, the records were submitted for expert evaluation again. Annotations deemed satisfactory following the review process were incorporated into the dataset.

Thus, the annotation development process was structured into successive stages preliminary study of the lesions, student annotation, expert review, correction of inconsistencies, and re-evaluation aiming to enhance the consistency and quality of the information included in the dataset. The present study did not quantitatively evaluate annotation time or annotator workload. These aspects should be investigated in future studies to assess the platform's operational efficiency.

D. Data preparation for neural network training

Following the image annotation and validation phase, the dataset will be prepared for use in supervised learning models. The data will be exported in COCO JSON format—a standard widely used in computer vision applications—as it stores information regarding images, diagnostic categories, coordinates of annotated regions, and associated metadata. This format enables the integration of the dataset with various convolutional neural network (CNN) architectures used for medical image detection, classification, and segmentation tasks.

During supervised training, images are presented to the model along with their respective annotations, enabling the neural network to learn to associate visual patterns with regions previously delineated by experts [2]. This learning process enables neural networks to develop hierarchical representations of the data, making them capable of recognizing complex features present in medical images.

The quality of the training depends directly on the consistency of the annotations used. In medical applications, imprecise or inconsistent annotations can compromise model performance and reduce its generalization capability. In this regard, the review process adopted by the IA-Bucal Files platform contributes to building a more reliable dataset, fostering the development of robust models for the automatic detection of oral lesions. The dataset generated in this study can be used to train various deep learning architectures, enabling future applications in the detection, localization, and segmentation of oral lesions, as well as in clinical diagnostic support systems.

III. Results and Discussion

Following the organization and annotation process using the IA-Bucal Files platform, a total of 2,556 clinical images containing oral lesions and 4,067 lesion annotations have been recorded to date. The number of annotations exceeds the number of images because a single clinical image may display one or more lesions, with each region individually delineated and annotated for the purpose of training and validating artificial intelligence models.

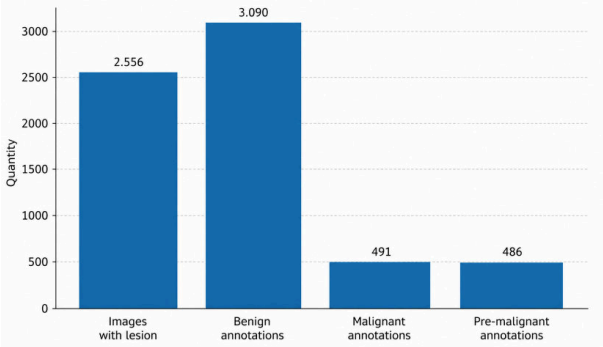

Fig. 3. Distribution of Oral Lesion Annotations in the Training Set

As shown in Figure 3, there is a predominance of benign lesions, accounting for 3,090 entries (75.98°/°), followed by 491 entries for malignant lesions (12.0°/°) and 486 entries for potentially malignant lesions (11.95°/°). This distribution aligns with the epidemiological profile observed in Stomatology and Dentistry services, where benign lesions are diagnosed more frequently than potentially malignant or malignant conditions. Consequently, the database reflects a real-world clinical

scenario in which malignant diseases occur less frequently but hold significant diagnostic importance due to the impact of early diagnosis on patient prognosis.

However, it is important to note that the dataset is still under construction and expansion; thus, the figures presented reflect the database's current state rather than its final composition. As new images and cases are incorporated particularly from various scientific sources—the quantity and proportion of the classes may change, potentially including an increase in the number of potentially malignant and malignant lesions.

Furthermore, the observed distribution reflects the characteristics of the sources used to build the dataset, which include scientific articles, open-access databases, and various scientific literature retrieval platforms. Therefore, the current class composition should not be interpreted as an estimate of lesion prevalence in the general population, but rather as a representation of the distribution of cases currently included in the dataset. In future stages, strategies such as class weighting, data augmentation techniques, and sampling methods may be evaluated to mitigate the potential effects of imbalance during model training. In addition to the volume of images, the large number of annotations demonstrates the platform's ability to produce detailed and structured annotations. Each annotation contains information regarding the location and diagnostic category of the lesion, providing essential data for training detection, classification, and segmentation models. The quality and granularity of the annotations directly influence the performance and generalization capability of algorithms applied to medical image analysis [5].

Another relevant aspect concerns the diversity of the dataset. The images encompass lesions with varying sizes, shapes, colorations, anatomical locations, and clinical presentations, exposing the models to a wide range of visual patterns. This heterogeneity facilitates the learning of discriminative features and reduces the risk of overfitting. Large, diverse datasets are a key factor in the success of Deep Learning applications in medical imaging [4].Similarly, Goodfellow, Bengio, and Courville [6] highlight that the diversity of training examples contributes to the development of more robust representations.

Furthermore, variations in image acquisition conditions—such as lighting, resolution, capture angle, and the presence of adjacent anatomical structures make the dataset more representative of conditions encountered in clinical practice. According to Shorten and Khoshgoftaar [7], this variability can be expanded through data augmentation techniques, further enhancing model robustness.

Database reliability also depends on the quality of the annotations. On the IA-Bucal Files platform, all annotations underwent a structured expert review process before being included in the final dataset. Disagreements among experts represent one of the main challenges in constructing medical databases [8], [9]. Thus, standardized annotation protocols, combined with well-defined diagnostic criteria, increase the reproducibility and consistency of the datasets used in artificial intelligence [9].

Another factor directly influencing model performance is the presence of label noise, characterized by the incorrect assignment of labels or imprecise delineation of regions of interest during the annotation process. In oral lesion detection and segmentation tasks, errors in diagnostic classification or lesion demarcation can lead the model to learn inconsistent patterns, compromising its generalization capability. Incorrect labels significantly reduce the accuracy and generalization ability of neural networks, particularly in medical applications [10], [11].

In this context, a rigorous review of annotations is important for building reliable datasets. Validating the delimited regions and the classification assigned to each lesion allows for the identification of inconsistencies, the correction of labeling errors, and the standardization of the annotation process, thereby reducing the occurrence of label noise. Furthermore, expert review enhances the reliability of the training set, ensuring that relevant morphological characteristics are accurately represented and learned by the model.

The results demonstrate that the platform enabled not only the creation of an extensive and structured dataset, but also the establishment of a standardized workflow for image annotation and review, contributing to the organization and consistency of information related to oral lesions. The developed structure has the potential to support future deep learning applications for the detection, classification, and segmentation of oral lesions.

Unlike studies focused on the development of predictive models, this work concentrates on the construction phase of the annotated dataset, which is considered a cornerstone of supervised learning. Making a standardized dataset available represents a significant contribution to future research in Artificial Intelligence applied to dentistry, providing a reliable foundation for the development and evaluation of computational models.

Finally, Topol [3] highlights that Artificial Intelligence shoul dact as a tool complementing clinical judgment, contributing to increased diagnostic accuracy and reduced inter-examiner variability. Similarly, the World Health Organization emphasizes that the early diagnosis of oral cancer is a key strategy for reducing the morbidity and mortality associated with the disease, especially in regions with limited access to specialists [12]. In this context, standardized databases, such as the one developed in this study, could support the development of systems for tele-dentistry, clinical screening, and diagnostic support based on Artificial Intelligence [13].

IV. Final Remarks

This study presented the IA-Bucal Files platform as a tool for building an annotated database intended for training artificial intelligence models to detect oral lesions. The structured process of annotation, expert review, and validation of markings enabled the creation of a standardized dataset comprising 2,556 clinical images and 4,067 diagnostic annotations to date thereby establishing a consistent for supervised learning applications.

The results demonstrate that adopting standardized annotation protocols contributes to increasing the reliability and

quality of the data used to train Convolutional Neural Networks—an aspect considered essential for developing models with greater generalization capabilities and potential for clinical application. Furthermore, the use of the COCO JSON format enhances the database's interoperability with various Deep Learning architectures designed for the classification, detection, and segmentation of medical images.

Future plans involve continuously expanding the database with new images and diagnostic categories, as well as using this training set to develop and evaluate Artificial Intelligence models for the automatic detection of oral lesions. This initiative is expected to contribute to the advancement of diagnostic support tools, fostering strategies for tele-dentistry, clinical screening, and early detection of oral cancer, particularly in settings with limited access to specialists.

ACKNOWLEDGMENTS

***Abstract*—Public observatories make indicators easier to access, but publishing a chart does not ensure that it will be read correctly, traced to its source, or disclosed safely. This limitation is particularly important when the source material contains health and disability information. Ambiguities concerning the unit of analysis, counting rules, and territorial granularity may lead to misleading interpretations and, in small subsets, increase the risk of reidentification. This paper presents ORBITA-Health, a specialization of the ORBITA-SDG methodology for the auditable curation of indicators intended for public observatories. The method organizes the work into six stages, from framing the public problem to publishing and reviewing the indicator, under cross-cutting layers of governance, metadata, quality, privacy, and transparency. The proposal was developed as a design-science artifact and examined through two sets of institutional documents: a health-indicator curation matrix and an independent validation matrix from inclusive education. Without disclosing records, source-dataset volumes, or population findings, the evaluation assessed documentation completeness and the ability of review gates to locate semantic and technical discrepancies. All 20 candidate information products in the health case contained all 22 required fields, corresponding to 440/440 documented field instances; disclosure class and protection guidance were present for every product. In the second case, 103 analytical items were checked against independent calculations: 86 were validated, whereas 17 (16.5%) were withheld from that state, including 7 requiring attention and 10 remaining partial. The findings position ORBITA-Health as a shared audit trail with explicit stop conditions applied before analytical results become public indicators. Domain validation remains a separate requirement.**

***Index Terms*—public observatories, health indicators, persons with disabilities, data curation, auditability, privacy, metadata.**

I. Introduction

Public observatories sit between data production and public decision-making. They assemble time series, maps, tables, and indicators for audiences that do not necessarily share the same technical background, including public managers, health professionals, researchers, councils, civil-society organizations, and citizens. Recent reviews show that the literature on health dashboards remains fragmented and that usefulness is often inferred from access metrics or isolated reports, with limited evidence of how published information supports concrete decisions [1], [2]. The central problem therefore begins before interface design, with the choice of what should be counted and the documentation of the path from source data to public indicator.

This distinction matters whenever a number supports more than one interpretation. A count may refer to people, records, encounters, procedures, or administrative links. Likewise, a category may express a legal concept, a local rule, or merely the vocabulary inherited from a source system. Research on health-data quality emphasizes that completeness, conformance, plausibility, correctness, and currency depend on the intended

use rather than on the absence of missing fields alone [3], [4]. A numerically reproducible result may still be conceptually inadequate when its unit of analysis, period, formula, inclusion criteria, or limitations remain unclear.

Indicators concerning persons with disabilities introduce a second requirement: they must support equity without turning the visibility of disparities into the exposure of individuals. The World Health Organization identifies monitoring as part of the actions needed to address avoidable barriers in access to care and health outcomes [5]. At the same time, the Convention on the Rights of Persons with Disabilities and the Brazilian Inclusion Act connect public information, participation, and equal opportunity with duties concerning accessibility and the protection of rights [6], [7]. Sources that combine territory, health condition, diagnosis, medical reports, or other sensitive attributes therefore require minimization and disclosure rules to be defined before a dashboard is built.

The Brazilian General Data Protection Law grants enhanced protection to health data and establishes principles such as purpose limitation, adequacy, necessity, and security [8]. Removing names alone does not eliminate every risk. Combinations of attributes and infrequent categories may still make individuals recognizable, particularly when several filters are applied at once [9], [10]. For a public observatory, curation must therefore determine not only what is relevant, but also which level of aggregation is defensible, which details should remain internal, and when publication should be blocked.

This paper introduces **ORBITA-Health**, a specialization of the general ORBITA-SDG methodology. The name ORBITA retains the original Portuguese formulation, *Organização, Rastreabilidade, Base, Interpretação, Transparência e Ação*, which corresponds to organization, traceability, data foundations, interpretation, transparency, and action. ORBITA-SDG supplies the generic six-stage cycle for SDG-oriented public information. ORBITA-Health retains that cycle but adds operational requirements for health and disability data: mandatory declaration of the observational unit before counting, disclosure classification, content minimization, review of territorial/filter granularity and small-cell risk, and human domain validation with return gates when semantic, technical, or disclosure issues remain unresolved. These controls are co-located in a 22-field curation matrix so that the calculation rule and the publication decision remain part of the same audit trail. The main contribution is a health-specific publication boundary between analytical output and public communication, supported by an operational specification that makes the process inspectable and reusable. New statistical estimators and dashboard components are outside the scope of this work.

II. Related Work

The literature survey was organized around four areas that converge in the problem addressed here: public observatories and health dashboards; data quality and provenance; metadata for official statistics; and the protection of sensitive information. The survey was not intended as a standalone systematic review. Its purpose was to identify established frameworks and recent studies that could support design, validation, and disclosure requirements, later translated into operational fields and decision gates.

A. Public Dashboards and Evidence-Informed Action

Dashboards are useful when they reduce the effort needed to identify change and compare subsets, but their effectiveness does not follow from visualization alone. Reviews in clinical and public-health settings associate successful implementations with user involvement, appropriate indicator selection, clear narrative support, and post-deployment evaluation [1]. Schulze *et al.* found substantial heterogeneity among public dashboards in both data sources and visualization strategies [11]. In a multisite study, Fareed *et al.* further showed that perceived usefulness and ease of use depend on how a dashboard fits the practices of local stakeholders [12].

The concept of *actionability* extends this discussion. Beyond asking whether a dashboard can be understood, it asks whether the sources, methods, scope, and narrative allow users to connect a result with a decision or action. Stahlman *et al.* observed that many studies describe dashboard functions, whereas few rigorously evaluate their usefulness for decision-making [2]. ORBITA-Health responds to this limitation by requiring, before any chart is selected, a guiding question, an intended audience, a supported decision, and an explicit caution against misinterpretation.

B. Data Quality, Provenance, and Reproducibility

Data quality is multidimensional. The seminal definition by Wang and Strong shifts the discussion from an abstract notion of "correct data" toward fitness for the consumer and task [13]. In health applications, later frameworks converge on dimensions such as completeness, conformance, plausibility, and correctness, while also showing that terminology and tests vary across institutions [3]. ORBITA-Health records the applied rule, the evidence used, the observed outcome, and any unresolved issue for each quality check. No single check is treated as a quality seal.

Provenance complements quality by describing the origin, transformation, and movement of data. Recent biomedical reviews associate provenance with reproducibility and trust, but also report uneven adoption of models and tools [14]. The technical sheet proposed here preserves a compact version of that lineage: source, period, observational unit, calculation rule, filters, review date, and responsible unit. For studies based on routinely collected records, this transparency is also consistent with the RECORD recommendations for reporting data selection, linkage, and processing [15].

C. Official Statistics, Metadata, and Interoperability

The Generic Statistical Business Process Model organizes statistical production from the identification of information needs through product evaluation [16]. The UN NQAF, in turn, distributes quality responsibilities across the institutional environment, processes, and outputs rather than assigning them solely to the final dataset [17]. These frameworks provide the

process logic adopted by ORBITA-SDG, although they do not specify how a local team should translate that logic into the language of a public observatory.

SDMX addresses structured statistical exchange across domains [18]. The Data Quality Vocabulary supports the description of quality dimensions and measurements [19], while the FAIR principles emphasize that assets should be findable, accessible, interoperable, and reusable [20]. ORBITA-Health adapts these foundations to a smaller unit: each indicator is handled as a documented information product rather than as a visual element detached from its source.

D. Privacy, Disability, and Public Purpose

Aggregate publication requires a separate methodological review before public release. Anonymization models and the literature on privacy-preserving data publishing show that protection depends on attribute combinations, granularity, and the auxiliary information available to a potential observer [9], [10]. ORBITA-Health classifies outputs as aggregate, sensitive, restricted, or pending assessment. This classification does not replace legal or institutional review. It functions as an editorial gate that prevents an internal table from moving directly into a public environment.

The Sustainable Development Goals provide a layer of public purpose when the association with the indicator is explicitly justified. The official metadata repository describes the concepts, methods, and limitations of global SDG indicators [21]. ORBITA-Health uses this reference to record a primary SDG, a possible secondary SDG, and, most importantly, the specific relationship between the local indicator and the corresponding public agenda.

III. Materials and Methods

A. Study Design

This is an applied methodological study. ORBITA-Health was treated as an information-system artifact under the design-science perspective, in which knowledge is produced through the construction and evaluation of solutions to relevant problems [22], [23]. The artifact comprises a conceptual model, a curation matrix, and a set of validation gates. Its purpose is not to estimate prevalence or compare population groups, but to organize the conditions under which an analytical result may become a public indicator.

B. Application Artifacts

Two sets of documents were used to examine the method. The first was a curation matrix for information products derived from an institutional health source concerning persons with disabilities. The second contained validation items produced by comparing an analytical report with an independent recalculation in the field of inclusive education. The archived validation artifact describes the recalculation as an independent technical pass within the project workflow. It was not an external assessment. It does not preserve the recalculating analyst's identifier or a blinding field; consequently, this study does not claim assessor blinding. The cases place different demands on the method. The health case requires disclosure classification and safeguards for sensitive information, whereas the education case shows whether the gates can locate discrepancies in units, terminology, temporal cutoffs, and territorial aggregation.

TABLE I
Information blocks in the ORBITA-Health matrix

Block	Content and function
Identification	ID, domain, position, data status, and development status.
Semantic	Guiding question, title, supporting text, and interpretation note.
Technical	Source, update, minimum rule, unit, filters, and interaction.
Public purpose	Primary SDG, reference indicator, and secondary relationship when relevant.
Governance	Disclosure class, protection guidance, pending issue, and next action.

Only process metadata were used in this paper. No individual record, internal filename, indicator value, number of people in a source dataset, rare clinical category, or territorial result was transcribed. The quantities reported in the following sections refer to curation items and their validation states, not to the populations represented in the institutional sources.

C. Curation Matrix Schema

The matrix contains 22 fields arranged in five blocks. The fields are: (1) product ID, (2) domain, (3) position in the observatory, (4) data status, (5) development status, (6) guiding question, (7) public title, (8) supporting text, (9) interpretation note, (10) source, (11) update/periodicity, (12) minimum technical rule, (13) unit of analysis, (14) filters, (15) interaction, (16) primary SDG, (17) reference indicator, (18) secondary SDG relationship when relevant, (19) disclosure class, (20) protection guidance, (21) pending issue, and (22) next action. Grouping these fields prevents editorial description from being mistaken for a computational rule and allows curators, domain specialists, and developers to work on the same artifact. A data-free blank CSV, de-identified example, and structural checker accompany the source; the checker verifies the 22-field schema and required cells but does not automate semantic, disclosure, or publication decisions.

D. Evaluation Criteria

The evaluation considered four criteria. *Documentation completeness* refers to the presence of the required fields and does not imply approval of their content. *Traceability* examines whether the source, rule, and period allow the origin of an indicator to be reconstructed. *Discriminative capacity of the gates* concerns whether the process separates validated items from those requiring attention or remaining partial. *Publication safety* checks whether the artifact records a disclosure classification and corresponding guidance before a product is sent to the dashboard. Frequencies were calculated over curation items, and discrepancies were grouped by type without revealing institutional values.

TABLE II
DE-IDENTIFIED STRUCTURAL EXAMPLE OF ONE ORBITA-HEALTH INFORMATION PRODUCT. SOURCE-SPECIFIC CONTENT IS GENERALIZED OR SUPPRESSED; THE EXAMPLE DEMONSTRATES FIELD USE AND IS NOT A POPULATION RESULT.

Field	De-identified value	Field	De-identified value
1. Product ID	H-XX	**12. Minimum rule**	Aggregate calculation; rule retained internally
2. Domain	Health and disability	**13. Unit of analysis**	Declared before counting (e.g., unique persons)
3. Observatory position	Health indicator area	**14. Filters**	Period and approved territorial categories
4. Data status	Restricted institutional source available	**15. Interaction**	KPI/breakdown only after disclosure review
5. Development status	Under curation	**16. Primary SDG**	SDG 3
6. Guiding question	What public information should this product support?	**17. Reference indicator**	Contextual reference documented in matrix
7. Public title	Generalized health-service indicator	**18. Secondary SDG link**	SDG 10 when equity interpretation is justified
8. Supporting text	Aggregate description; no individual content	**19. Disclosure class**	Aggregate / pending final review
9. Interpretation note	Does not estimate prevalence or unmet need	**20. Protection guidance**	No identifiers, addresses, free text, or unsafe rare cells
10. Source	Municipal administrative source [suppressed]	**21. Pending issue**	Validate denominator/granularity with responsible unit
11. Update/periodicity	Periodic [detail suppressed]	**22. Next action**	Return to domain/disclosure validation before publication

The archived education-validation matrix used categorical review states rather than a single percentage tolerance because the 103 items mixed counts, percentages, textual categories, denominators, and aggregation rules. An item was recorded as *validated* when the analytical report and recalculation agreed and no unresolved discrepancy remained in the unit, denominator, cutoff, territorial rule, or terminology. *Requires attention* denoted a localized discrepancy for which the item remained inspectable but an explicit curator decision was still necessary. *Partial* denoted insufficient or ambiguous evidence to complete reconstruction or adjudication. The historical artifact did not store a universal numerical divergence threshold; therefore, no post-hoc percentage cutoff is attributed to the 103-item assessment. For future numerical checks, the operational rule is to require agreement after the declared rounding convention and to block the validated state while any unexplained numerical divergence remains.

IV. ORBITA-HEALTH METHODOLOGY

Fig. 1 separates the ORBITA-SDG base cycle from the controls introduced by ORBITA-Health. The specialization retains the six stages of the general cycle while making five health/disability requirements explicit: declaration of the observational unit, disclosure classification, content minimization, granularity/filter-risk review, and human domain validation with return gates. The stages describe the operational order of the method; the highlighted controls define the additional publication constraints introduced by the specialization.

In **Stage 1**, the process begins with the public problem and the people who will use the information. The team records the question the indicator should answer, the intended audience, the decision it may support, and the misleading interpretation that should be avoided. This framing prevents an available field from becoming a KPI merely because it is easy to count.

In **Stage 2**, the source, institutional responsibility, period, coverage, granularity, and observational unit are mapped. The distinction between people and records receives particular attention. When several occurrences are associated with the same person, the team must state whether the product measures unique individuals, events, or intensity of follow-up. The source is also examined for update feasibility and compatibility with the declared purpose.

In **Stage 3**, semantic curation compares the vocabulary inherited from the source with the concept that will be presented publicly. Acronyms, local classifications, and historical categories may remain in internal documentation, but the public title must state precisely what was counted. The relationship with the SDGs is documented under the same requirement: the link must be explained in the context of the indicator.

In **Stage 4**, technical validation examines completeness, consistency, duplication, plausibility, currency, and traceability. The result is then submitted to decision gates. When a discrepancy is identified, the item is returned to the responsible unit together with the formula, evidence, and unresolved issue. For sensitive sources, this stage also checks whether the planned filters may create small cells or attribute combinations that increase reidentification risk.

In **Stage 5**, the information product is designed. The team defines the title, short description, technical sheet, unit, calculation, analytical dimension, filters, and visualization. The question and the users' ability to interpret the result guide the choice among a KPI, chart, map, or table. The public version contains only what is needed for interpretation; operational details remain in the governance matrix.

In **Stage 6**, the indicator is prepared for publication, use, and review. Its status may progress from proposed to under curation, validated, published, or due for review. Any change in source, formula, or disclosure classification requires another passage through the gates. Publication therefore does not close the cycle. It creates a traceable version linked to the artifact that documents how the product was produced.

Fig. 2 details the ORBITA-Health return logic. Gate A asks whether the source and declared observational unit support the result; Gate B asks whether the interpretation and calculation are sufficiently documented to be reproduced; and Gate C asks whether the planned granularity and disclosure conditions are

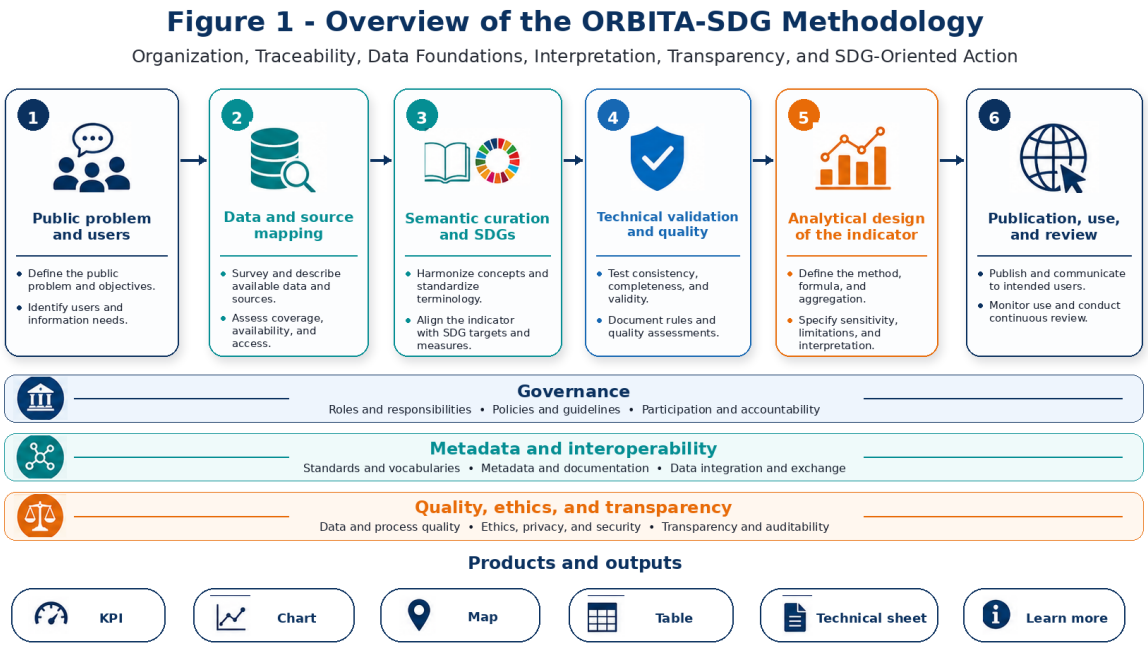

Fig. 1. ORBITA-SDG base cycle and the health/disability-specific controls introduced by ORBITA-Health.

fit for public release. A negative answer does not remove the item. It returns the product to the point at which the issue can be resolved while recording the evidence, status, pending issue, and next action in the matrix.

V. Results

A. Completeness of the Health Curation Matrix

The health-case matrix comprised 20 candidate information products. Across 22 required fields per product, all 440 expected field instances were populated. This included 80/80 governance-field instances (disclosure class, protection guidance, pending issue, and next action) and 20/20 declarations of the unit of analysis. These counts refer only to structural documentation completeness. Content correctness and approval remained subject to validation by the responsible unit.

Protection guidance was therefore present for every product before dashboard implementation and restricted public use to appropriately aggregated outputs, excluding individual records, identifiers, addresses, and free-text clinical content. The matrix does not prove that disclosure risk has been eliminated; it records that publication remains conditional on a documented review.

B. Performance of the Validation Gates

In the inclusive-education case, 103 analytical items were compared with the source document and the archived independent recalculation. The status rule followed the categorical evidence described in Section III-D: agreement without unresolved methodological discrepancy supported *validated*; a localized but inspectable discrepancy led to *requires attention*; and insufficient evidence to complete reconstruction led to *partial*. Because the source artifact did not define a common percentage tolerance across heterogeneous item types, no universal divergence threshold was applied retrospectively. Of the 103 items, 86 were validated (83.5%), whereas 17 (16.5%) were withheld from that state: 7 required attention (6.8%) and 10 remained partial (9.7%). Thus, the gate logic did not collapse all recalculable outputs into an approval state. These categories are not measures of model accuracy; they record documentary and computational sufficiency before an analytical result becomes a public indicator.

The 17 items outside the validated state were associated

TABLE III
Evaluation criteria, observed process evidence, and claim boundary

Criterion	Observed evidence	Boundary
Documentation	Health: 440/440 required field instances present.	Presence does not establish content correctness.
Traceability	Health: 20/20 products documented source, period/update, rule, and unit.	Source validity was not independently audited here.
Publication safety	Health: 20/20 products recorded disclosure class and protection guidance.	No reidentification attack or quantitative risk estimate.
Gate discrimination	Education: 86 validated; 7 attention; 10 partial; 17/103 (16.5%) withheld from validated.	Internal categorical cross-check, not blinded external validation.

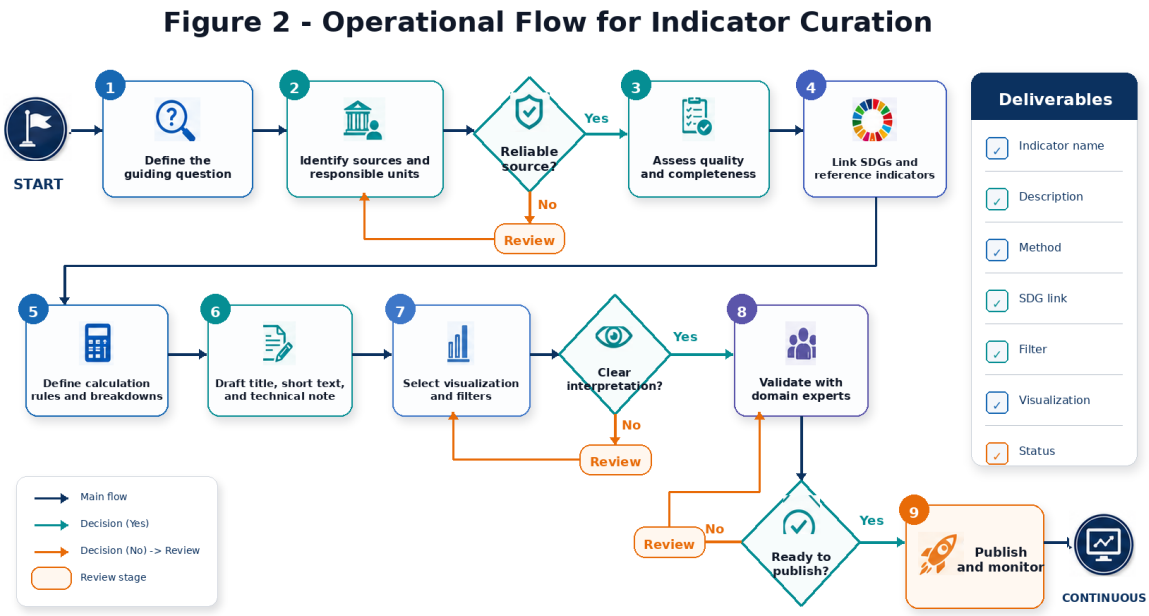

Fig. 2. ORBITA-Health operational flow. The review gates explicitly test source/unit adequacy, interpretability/reproducibility, and fitness for public disclosure.

with discrepancies that a purely syntactic spreadsheet check would be unlikely to resolve: confusion between records and unique persons, terminology covering different groups, an unspecified age cutoff, an undocumented territorial counting rule, and textual categories requiring standardization. The seven *attention* items retained enough evidence for inspection but required a localized decision before approval; the ten *partial* items lacked sufficient evidence to complete reconstruction or adjudication. The archived artifact does not provide a reliable frequency for each discrepancy subtype, so subtype counts are not reconstructed retrospectively. What separates the two non-validated states is therefore the completeness of the evidence needed to resolve the discrepancy, not a severity score or percentage-distance threshold.

C. Cross-Case Synthesis

The two cases evaluated different properties of the artifact. The health matrix examined whether semantic, technical, and disclosure information could be documented together. The education case examined whether the review logic could distinguish sufficient evidence from unresolved cases. The 440/440 documented field instances and the 17/103 items withheld from validation therefore provide complementary process evidence. The results show that the workflow can document information products and interrupt publication when evidence remains unresolved. They do not demonstrate improved decisions, usability, public comprehension, analytical accuracy, or health outcomes.

VI. Discussion

ORBITA-Health organizes decisions that are often scattered across spreadsheets, reports, and team discussions. It retains the six-stage ORBITA-SDG sequence and adds a health/disability publication boundary based on observational-unit declaration, disclosure classification, minimization, granularity/filter-risk review, and domain validation with explicit return states. Statistical frameworks and metadata vocabularies are comprehensive, but their direct adoption may be burdensome for local observatories. The matrix narrows that distance by linking each product to a question, a rule, a public purpose, a disclosure class, and an outstanding issue. It preserves the process logic of the GSBPM and UN NQAF [16], [17], while translating it to the editorial level of an indicator.

The cases also indicate that concise public information can coexist with detailed internal traceability. A public technical note may remain concise as long as the complete rule is preserved and linked to it. Provenance research similarly argues that origin and transformations should be retained to support reproducibility [14]. In the cases examined here, recording the unit of analysis and aggregation criteria was central to distinguishing a reproducible number from an indicator ready for use.

For health and disability information, the disclosure gate adds protection, but not an automatic guarantee. An “aggregate” classification should not be interpreted as permanent authorization: combined filters, small areas, and rare categories may change the risk. Final decisions still require institutional governance, a lawful basis, and specialist review. This caution is consistent with the Brazilian data-protection framework [8] and with research that treats anonymization as a contextual assessment rather than as the removal of identifiers alone [9], [10].

The study has limitations. It examined artifacts from two

institutional applications rather than a broad set of observatories. Completeness was measured through field presence, not field-content quality. The education validation was an internal technical cross-check; the archived artifact does not preserve assessor identity or blinding, and its status labels were categorical rather than based on a universal numerical tolerance. Usability, public comprehension, longitudinal maintenance, review time, inter-curator agreement, effects on decisions, and health outcomes were not assessed. The reported evidence therefore supports only process properties—documentation, traceability, review-state discrimination, and recorded disclosure guidance—and must not be interpreted as validation of the substantive indicators or of downstream organizational impact. These outcomes remain important, particularly because recent literature reports few rigorous evaluations of dashboard actionability [1], [2].

Future work should apply the methodology prospectively throughout a publication cycle. A broader assessment could compare rework before and after adoption of the matrix, measure inter-curator agreement, test users' understanding of the technical notes, and record how many products return at each gate. The supplied data-free schema and structural checker support reuse while leaving semantic, disclosure, and approval decisions to human governance.

VII. Conclusion

This paper presented ORBITA-Health, an ORBITA-SDG specialization for the auditable curation of health- and disability-related indicators in public observatories. The six-stage ORBITA-SDG cycle is retained, while ORBITA-Health adds explicit controls for observational unit, disclosure class, content minimization, granularity/filter risk, and human domain validation. Its 22-field operational matrix makes these decisions visible before an analytical result reaches a public dashboard.

Application to two sets of documents produced 440/440 required field instances in the health matrix and withheld 17/103 inclusive-education items from the validated state when evidence remained incomplete or discrepant. These results support process-level claims about documentation and gate behavior. They do not establish better decisions, usability, analytical accuracy, privacy guarantees, or health outcomes. Technical, legal, and domain validation remain necessary. ORBITA-Health provides a traceable route for documenting these validations, uncertainties, disclosure decisions, and return actions before public communication.

***Abstract*—Municipal early-childhood plans combine indicators produced by several agencies, so provenance and reporting context matter as much as visualization. This paper examines the *Plano Municipal pela Primeira Infância de Fortaleza* (PMPIF) Dynamic Report, a web platform for registering policy actions, monitoring aggregate indicators, comparing reporting cycles, and producing management reports, with emphasis on maternal and child health. The evaluation combined source-code, architecture, data-model, access-control, audit, and workflow inspection. Five design objectives guided the analysis: context preservation, scoped editing, life-cycle control, provenance, and reuse of a common data core. The deployed revision snapshot contained 80 actions, 12 responsible agencies, three reporting semesters, 28 user accounts, and 90 action-linked table structures. A frozen repository database backup provided bounded retrospective verification: 47 actions present in both 2025 cycles preserved 786 aligned cell identifiers, 501 stored values differed between cycles, and 468 audit entries covered six entity classes. All audit entries retained operation, target entity, actor, and timestamp attribution; 399 of 401 update events also retained a non-null pre-change state. These findings support cycle isolation and populated provenance without claiming effects on usability, efficiency, or health outcomes.**

***Index Terms*—biomedical informatics, digital health, early childhood, maternal and child health, dashboards, health information systems, public management.**

I. Introduction

Early childhood is marked by biological, cognitive, emotional, and social changes whose effects may extend across the life course [1]. In Brazil, Law No. 13,257/2016 calls for coordinated action in health, education, social assistance, culture, leisure, mobility, protection, and urban planning for children up to six years of age [2]. That breadth is important for policy, but it creates a practical monitoring problem: actions, responsible institutions, targets, evidence, reporting periods, and indicators are produced through different administrative routines. International frameworks reach the same point from a developmental perspective, relating child well-being to health, nutrition, responsive caregiving, safety, early learning, and cross-sector coordination [3], [4].

Maternal and child health is one part of this broader arrangement. The Brazilian National Policy for Comprehensive Child Health Care (PNAISC) covers care from pregnancy onward, health promotion, breastfeeding, reduction of morbidity and mortality, attention to vulnerability, and child development [5]. Prenatal care, well-child follow-up, immunization, mental health, and oral health indicators can support management only when their institutional origin and reporting context remain visible.

Municipal monitoring is often assembled from spreadsheets, text documents, successive file versions, and manually prepared reports. Under those conditions, even a simple question may require additional work: which cycle is current, who is responsible for an item, whether a value was revised, and which record fed the last report. The dashboard therefore represents the presentation layer of a longer information process in which institutional ownership, revision history, and reporting context are defined upstream [6], [7].

The *PMPIF Dynamic Report* was developed to organize that process for the *Plano Municipal pela Primeira Infância de Fortaleza*. It does not store medical records or provide clinical care. Instead, it links municipal policy actions to responsible agencies, reporting cycles, indicators, structured tables, supporting evidence, editing rules, analytical views, and reports.

Against this background, we use PMPIF as a case through which to examine how an intersectoral plan can be turned into a governed monitoring workflow. This paper describes a data and workflow model that keeps policy actions, indicators, institutional responsibility, reporting time, and provenance connected. It also evaluates the implemented artifact against explicit technical objectives and discusses the design trade-offs and boundary conditions relevant to adoption in other municipalities, particularly where sectoral data remain heterogeneous and direct integration with every source system is not feasible.

II. Related Work

A. Dashboards and Public-Sector Action

Research on public-health dashboards converges on a point that is directly relevant to municipal monitoring: actionability depends on context, workflow, and data integration, not only on chart design. Reviews of public-health dashboards describe substantial variation in purpose, audience, granularity, interaction, infrastructure, and evaluation practice [6]–[8]. Maternal-health dashboards show the same heterogeneity in sources and presentation [9]. Work such as QualDash demonstrates how adaptable visualization can support healthcare quality-improvement tasks [10]. For the present case, the unresolved problem sits one step earlier: the system must know which institution owns an item, when it was reported, and whether the displayed record is still being edited or has already been consolidated.

B. Information Architecture and Data Quality

Digital-health platform guidance treats information systems as shared infrastructure that combines technology, governance, people, and reusable services [11]–[13]. Software-architecture studies likewise identify modularity, APIs, services, and separation of concerns as responses to fragmentation in health information systems [14]. CARA provides a recent example in which data modeling, APIs, and visualization are separated to support retrieval and benchmarking of general-practice data [15].

Architecture alone does not guarantee useful information. Health-information studies repeatedly identify completeness, consistency, timeliness, security, accessibility, relevance, and fitness for use as data-quality concerns [16]–[18]. In an intersectoral plan, consistency cannot mean forcing every sector into an identical indicator format. A more practical requirement is to preserve enough structure to recover the action, period, responsible institution, data type, and revision history associated with a value.

C. Human Factors, Governance, and Data Protection

Decision-support systems also need to reflect the tasks and authority of their users. Human-factors research recommends examining professional roles, interaction flows, task performance, and perceived usefulness rather than treating all users as interchangeable [19], [20]. In Brazil, the LGPD adds legal requirements for processing personal and sensitive data [21]. PMPIF works with institutional and aggregate monitoring records rather than individual patient data, but access control and traceability remain necessary because the application contains internal management information and editing privileges. API security guidance is relevant for the same reason: the server is the point at which authentication, authorization, and resource handling must be enforced [22].

Prior work has focused mainly on dashboards after data are available and on architectures centered on clinical or surveillance information. Less attention is given to the governance layer between heterogeneous institutional sources and the final analytical view: who owns a policy record, which reporting cycle it belongs to, whether it is still being revised, and which version was used for consolidation. Table I positions PMPIF around that gap. The comparison concerns design emphasis rather than performance, since the referenced systems were built for different purposes.

III. Materials and Methods

A. Study Object and Evaluation Scope

The object of study was the *PMPIF Dynamic Report* web application used by Fortaleza's early-childhood coordination to monitor the municipal plan. The artifact was examined as an intersectoral system, with particular attention to the actions assigned to the Municipal Health Department.

We used a technical case-study design guided by design science [23]. Construction of the artifact preceded this study, and the evaluation examined whether the implementation contains mechanisms that address the organizational problem for which it was built. Five objectives formed the evaluation frame: O1, preserve the link among action, institution, indicator, and reporting period; O2, restrict editing according to

Table I
POSITIONING OF PMPIF RELATIVE TO SYSTEMS AND EVIDENCE STREAMS CITED IN THIS STUDY.

System / evidence stream	Primary object	Reported design emphasis	Relation to the PMPIF case
Public-health dashboard literature [6]–[8]	Surveillance and population indicators	Actionability, audience, interface, analytics, infrastructure, and connection to work practices	Establishes dashboard requirements, while PMPIF additionally models the upstream ownership, editing cycle, and consolidation of policy records.
QualDash [10]	Healthcare quality measures	Adaptable generation of visualizations for quality-improvement tasks	Shares the concern with task-oriented visualization; intersectoral policy ownership and semester-based reporting are outside its main scope.
CARA [15]	General-practice patient datasets	Data architecture, APIs, retrieval, visualization, and benchmarking	Provides an architectural point of comparison for data/API/visualization separation; PMPIF operates on aggregate policy records rather than patient datasets.
PMPIF	Action–indicator–cycle records	Role-scoped entry, traceability, consolidation, comparison, and reporting from one data core	Adds an explicit municipal governance workflow in which heterogeneous sectoral information remains linked to responsibility and reporting period.

institutional responsibility; O3, distinguish active work from completed or consolidated content; O4, retain provenance of relevant changes; and O5, reuse the same persistent records for dashboards, comparisons, and reports. The study therefore evaluates the artifact at a technical and operational level, not its effect on clinical outcomes or population-health indicators.

No individual records concerning children, pregnant women, families, or professionals were analyzed, and no human-participant data were collected for this evaluation. Credentials, internal addresses, database dumps, and sensitive operational content were excluded from the manuscript.

B. Data Acquisition and Reporting Cycles

PMPIF receives institutional, aggregate monitoring information rather than person-level health data. The 2025.1 and 2025.2 cycles were organized as semester-specific records linked to the corresponding action, responsible agency, indicator or table, and reporting period. In routine use, authorized sector focal points enter or update values and supporting text through the action editor for the period in which they have permission to work. Each stored table value is identified by action, semester, table, row, and column, while detail fields and artifacts remain linked to the same action context. Completion status and relevant changes can then be followed without separating the value from the cycle in which it was reported.

The application is not presented as an automated integration layer for all upstream municipal systems. Sectoral evidence may originate in different administrative databases, spreadsheets, reports, or internal routines before it reaches PMPIF. The platform standardizes the monitoring context in which these heterogeneous inputs are registered. The present study inspected that acquisition workflow and its data structures; it did not independently audit the source system or calculation rule behind every institutional indicator.

C. Materials and Technologies

The material examined included source code, repository documentation, the relational model, API routes, access rules, user interfaces, editing workflows, report generators, and audit structures. The deployed architecture separates a React/Vite client, NestJS application services, a REST interface, and PostgreSQL persistence mediated by Prisma ORM. Nginx provides the web entry point and reverse proxy, and Docker Compose packages the application services for deployment.

D. Technical Analysis Procedure

The assessment began by mapping components, dependencies, and responsibilities across presentation, application, persistence, and deployment. We then traced the operational path from creation of a reporting period through action editing, value entry, completion tracking, dashboard visualization, temporal comparison, and report generation. Permission rules, cycle isolation, completion/consolidation handling, and the audit trail were inspected before objectives O1–O5 were mapped to observable implementation evidence. Interface presence alone was not treated as sufficient when the corresponding behavior could be checked in application services or persistent structures. Configuration counts were read from the administrative views in the same revision snapshot, while the action-level parsing example was taken from the SMS-01 dashboard for 2026.1.

An archived database backup dated June 10, 2026 was used only for bounded retrospective verification, not as the current deployment census. For actions represented in both closed 2025 cycles, we compared persisted cell identifiers and stored contents across semesters. Audit entries were summarized by entity type and timestamp, and field-level completeness was checked for operation, target entity, actor attribution, and before/after state in update events. Raw credentials, personal identifiers, and database contents are not reproduced.

ISO/IEC 25010:2023 informed the discussion of maintainability, reliability, security, and portability [24]. Human-factors and data-quality literature informed the interpretation of workflow and information concerns [16], [19]. Formal usability

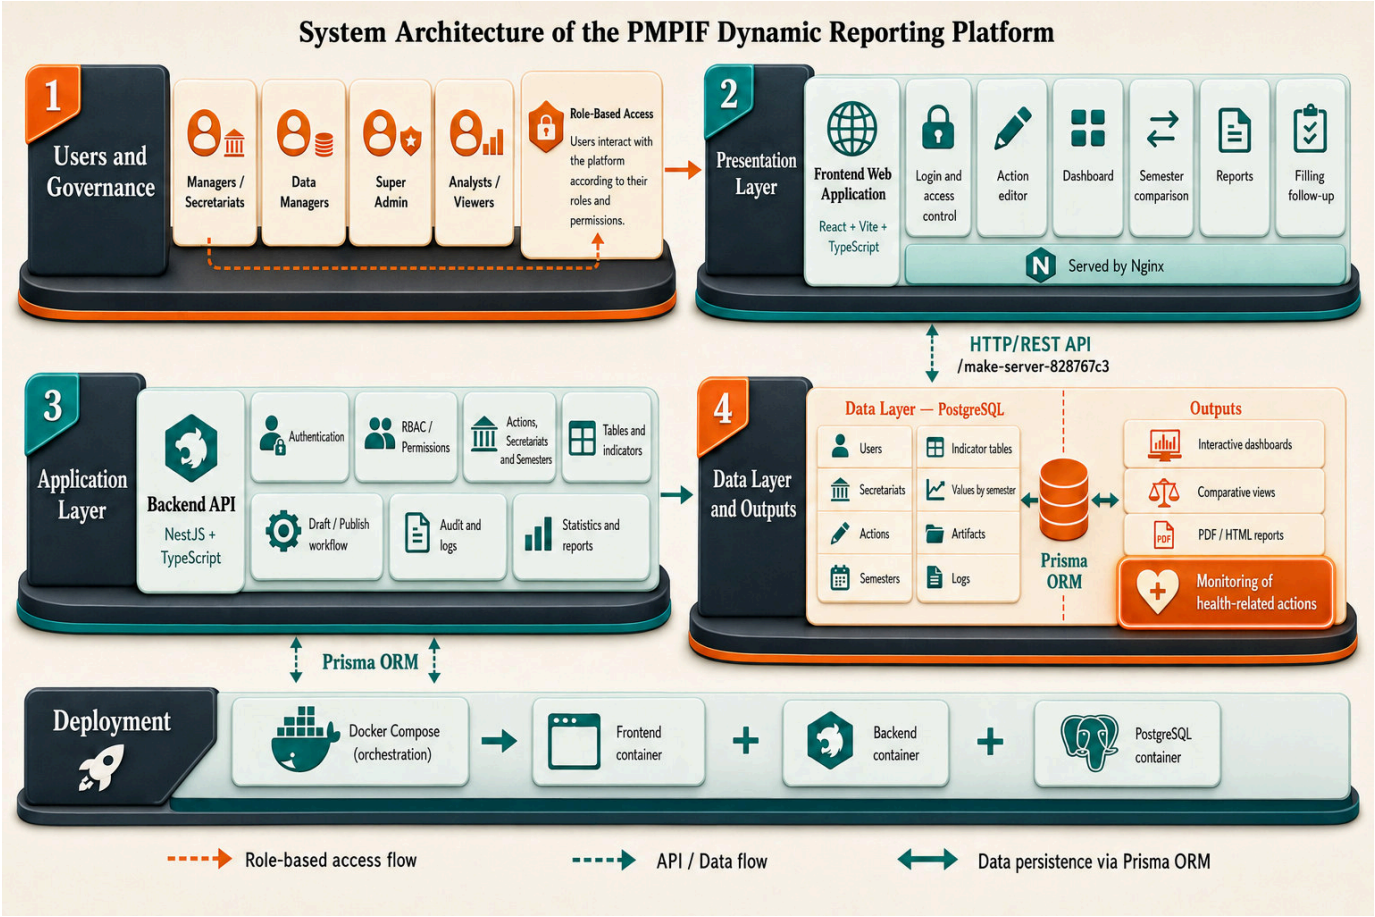

Figure 1. Functional architecture of *PMPIF Dynamic Report*. The layers separate governance and users, presentation, application services, persistence, and analytical outputs; the lower band represents the containerized deployment.

studies, penetration tests, controlled accessibility studies, and longitudinal outcome evaluations were not part of this stage.

IV. System Architecture and Operational Workflow

Figure 1 summarizes four responsibilities that the implementation keeps separate: governance, interaction, application rules, and persistence/analytical output. The separation is useful because a change in interface presentation should not silently change who is allowed to edit an institutional record, and a new report should not require a second copy of the monitored data.

A. Users, Governance, and Interaction

Managers, administrators, sector representatives, and data-entry users do not have the same authority over the plan. The access model therefore scopes users by role and, where applicable, by responsible agency or action. Focal points work on the records assigned to them, while broader management profiles supervise periods, consolidation, and cross-sector views. The frontend exposes the tasks available to each profile, but the decisive authorization checks are performed by application services rather than being left to interface state alone.

The presentation layer provides action editing, dashboards, semester comparison, report generation, and completion tracking. Communication with the application layer uses HTTP/REST interfaces. Keeping institutional rules behind those interfaces allows screens to evolve without duplicating authorization and validation logic in every visual component.

B. Application Rules and Persistence

NestJS services process authentication, permissions, user and agency administration, reporting periods, actions, tables, values, completion states, and audit events. Validation occurs before persistence and takes the current user, action scope, and reporting period into account. The data layer stores the corresponding entities in PostgreSQL, while Prisma maps the relational structures used by the services.

A value is not stored as an isolated number. Its identifiers preserve the action, semester, table, row, and column to which it belongs. The same persistent core is read by dashboards, semester comparisons, completion views, and report generators. This avoids a separate reporting database for the current scale of the platform and reduces the chance that a

manually copied report diverges from the record shown in the application.

C. Deployment and Security Maintenance

Frontend and backend are deployed as separate containers behind Nginx, with persistence handled independently. This arrangement supports reproducible deployment and makes failures easier to localize. The current code also includes password hashing with scrypt, server-side role checks, bounded sessions, HttpOnly browser cookies, session revocation/rotation, and audit records for relevant operations. These mechanisms were verified by code inspection; they were not subjected to a formal penetration test.

Security cannot be treated as fixed once the system is deployed. The JavaScript dependencies, container images, reverse proxy, ORM, and database schema all require maintenance as vulnerabilities and compatibility changes appear. Production updates should therefore include dependency review, controlled schema migration, tested backup/restore procedures, secret rotation, TLS and cross-origin configuration, API rate controls where appropriate, and regression tests for authorization rules. Centralizing those controls in the backend simplifies maintenance, but it also means that an unsafe service-layer change can affect several modules at once; staging, rollback, and audit review are consequently part of the maintenance risk model [22], [24].

D. Design Challenges and Decisions

The most consequential decision concerned heterogeneous upstream data. A direct connector for every sectoral system would automate more ingestion, but it would also bind PMPIF to external schemas, release schedules, and access arrangements that differ across agencies. The default design therefore uses a common policy-centered model and accepts controlled human-mediated entry when no stable integration path exists. This keeps the action, responsible agency, cycle, and data type consistent even when the source evidence arrives as a database extract, spreadsheet, report, or institutional note. Where stable APIs become available, automated ingestion can be added without changing those core entities.

Other decisions followed from distributed ownership. Authorization is enforced in application services rather than only in the client, which makes the same scope rules apply across screens but requires continued administrative maintenance of roles and assignments. Values remain cycle-specific and relevant changes are auditable, avoiding simple overwrite semantics at the cost of a more explicit life cycle. Dashboards, comparisons, completion views, and reports read the same persistent records, reducing duplicate consolidation while making output quality dependent on the structure registered for each action. Finally, separating client, server, and persistence helps isolate updates, but it does not remove the need for dependency patching, schema migration, tested backups, and security regression checks.

Table II
ARTIFACT EVIDENCE MAPPED TO THE FIVE DESIGN OBJECTIVES.

Obj.	Observed implementation evidence
O1	Values retain action, semester, table, row, and column context; actions remain linked to responsible agencies and indicator metadata.
O2	Backend services apply role and action/agency scope before protected edits are persisted.
O3	Across 47 actions paired in 2025.1/2025.2, 786 cell identifiers aligned and every action retained at least one changed value.
O4	468 audit entries spanned six entity classes; every entry retained operation, target, actor, and timestamp attribution, and 399/401 updates retained non-null prior state.
O5	Dashboards, comparisons, completion views, and reports reuse the same persistent action-cycle records.

E. Platform Workflow and Life Cycle

Figure 2 shows the dependencies among the main stages. E1–E5 prepare the environment: an administrator account is established, the reporting semester is configured, responsible agencies and actions are registered, and focal-point users receive their scope. Each action can carry objectives, strategy, targets, indicators, structured tables, and supporting content.

Routine monitoring begins at E6. Authorized users enter semester-specific values and update action details. E7 exposes completion and pending states while collection is underway. The same records feed E8, where the selected cycle can be visualized or compared with another, and E9, where reports are assembled for technical monitoring and accountability.

The workflow is iterative rather than strictly linear. A change in an action structure may alter its dashboard, and a value entered during E6 can affect completion tracking and report content immediately. The figure therefore represents dependency, not a one-way approval pipeline.

V. RESULTS

Artifact-level inspection found traceable implementation evidence for each of the five design objectives. Table II summarizes that mapping. The finding concerns the presence and connection of mechanisms in the inspected artifact; it does not establish usability, security effectiveness, data accuracy at the upstream source, or policy impact.

At the same revision snapshot, the platform registered 80 actions across 12 responsible departments or agencies, three reporting semesters, 28 user accounts, and 90 action-linked table structures; 11 actions were assigned to the Municipal Health Department. These figures describe the deployed artifact and are not estimates of policy effectiveness.

Figure 3 complements these counts by illustrating the intersectoral positioning of the health axis within the broader municipal plan. The visual summarizes ten original health-action themes represented in the platform; the current deployment also includes the neurodivergence care-pathway action reported below. It is therefore used as a conceptual overview rather than as the current deployment census.

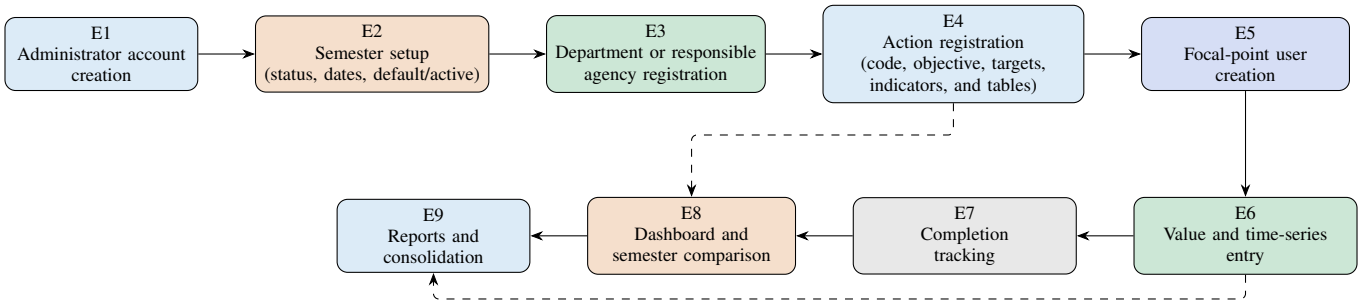

Figure 2. Operational workflow of *PMPIF Dynamic Report*, from initial setup through periodic data entry, monitoring, comparison, and consolidation.

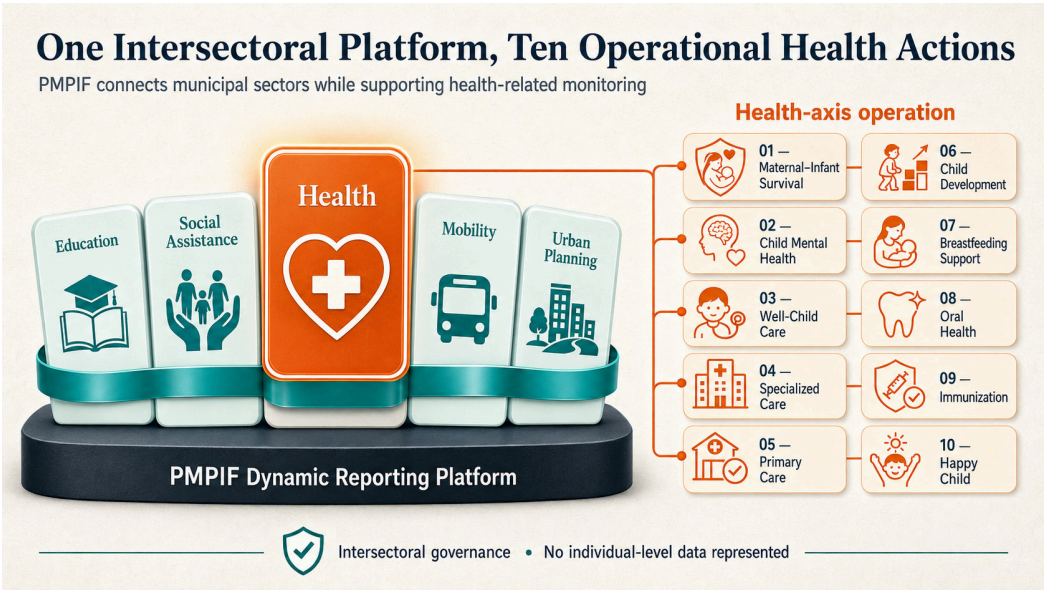

Figure 3. Intersectoral positioning of the health axis in *PMPIF Dynamic Report*. The illustration summarizes ten original health-action themes supported by the platform; the current deployment contains an additional Municipal Health Department action for the early-childhood neurodivergence care pathway. No individual-level data are represented.

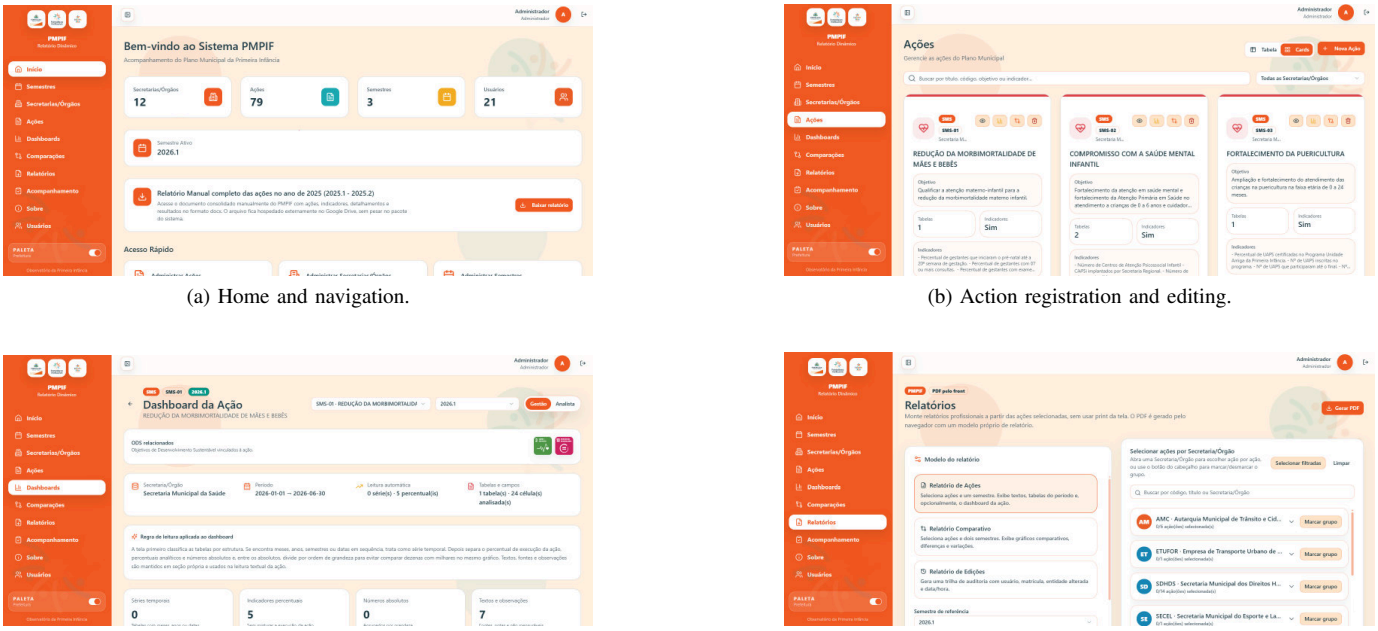

The two 2025 cycles (2025.1 and 2025.2) had already been consolidated, while 2026.1 was active for collection. In the archived snapshot, 47 actions had value records in both closed 2025 cycles. Their 786 cell identifiers were identical across semesters; 501 stored values differed, and every paired action changed in at least one position. This verifies structural reuse with cycle-specific content, not indicator improvement.

The analytical layer also produces action-specific structural counts. In the 2026.1 dashboard for action SMS-01, for example, one registered table yielded 12 analyzed cells, which the current parser classified as five percentage entries and seven textual or observational entries. This example shows that the dashboard is generated from the registered table structure rather than from a separately prepared visualization file. It is not used as a data-quality score or health-outcome measure.

Figure 4 provides complementary implementation context through representative screens for navigation, action editing, dashboard visualization, and report generation. These screens show how the action–cycle data model is exposed to users in routine operation; they are illustrative interfaces, not additional evaluation endpoints.

The same frozen snapshot contained 468 audit entries spanning May 20 to June 7, 2026: 181 concerned actions, 180 values, 59 authentication events, 37 user-administration changes, six semester events, and five agency events. Every entry contained an operation, target entity, actor identifier/name/e-mail, and timestamp. Of 401 update events, all stored a post-change state and 399 also retained a non-null pre-change state; the other two explicitly stored a null pre-change state. The bounded check verifies that provenance fields were populated and attributable across several operation classes. It does not provide an estimate of workload or audit quality. Values remain cycle-specific, while permissions restrict the actions or agencies available to scoped users.

The health component remains embedded in the intersectoral plan rather than being isolated as a separate application. At the current snapshot, 11 of the 80 actions were assigned to the Municipal Health Department, covering maternal-infant care, mental health, well-child care, specialized and primary care, child development, breastfeeding support, oral health,

The panels complement the architectural and workflow views by showing how the monitored records are presented in the operational interface.

immunization, child well-being, and the care pathway for neurodivergence in early childhood. Other sectors retain their own responsibilities but share the same cycle and monitoring model.

The retrospective checks establish structural continuity across two closed cycles and show that the audit trail was populated during a bounded interval. They do not provide cycle completeness, a long-term audit-event rate, or a measured before/after reduction in consolidation time; those outcomes require prospective observation.

VI. Discussion

PMPIF illustrates how a municipal plan can be represented as a governed information workflow. Each policy action remains linked to its responsible institution, reporting period, indicators, structured values, supporting material, workflow state, and revision history. Dashboards consume these records as analytical outputs while the underlying information remains organized around the policy action.

That choice also defines what interoperability means in this study. PMPIF does not claim automatic exchange with every database maintained by participating agencies. It handles semantic and organizational heterogeneity through a common monitoring model. Stable APIs can reduce manual entry for selected sources, but requiring them everywhere would couple the plan to external schemas and institutional release cycles. The current design therefore keeps responsibility, period, and provenance stable while allowing ingestion to remain partly human-mediated where necessary.

The resulting design pattern keeps policy identity, ownership, reporting time, authorization scope, revision history, and analytical reuse connected through a common persistent core. Table I places these concerns alongside prior work on dashboard actionability and layered information architectures.

Transferability also has limits. The approach is best suited to periodic, aggregate monitoring in which several agencies remain responsible for their own source evidence while a coordinating body needs a common reporting cycle. It should not be read as a replacement for real-time clinical surveillance, patient-level interoperability, or transaction systems. Where stable machine-readable interfaces and event-level data already exist, more automated ingestion may be preferable, with the policy-centered model serving as a governance and consolidation layer rather than as the upstream source system.

The architecture also creates maintenance responsibilities. Separation of client, server, and persistence makes individual components easier to replace or update, but security depends on keeping those boundaries correctly configured over time. Dependency patching, database migrations, backup validation, session and secret handling, and authorization regression tests are therefore part of system sustainability, not peripheral operational tasks. The current implementation contains several safeguards, yet the absence of a formal security audit prevents claims about resistance to attack.

The evaluation covers technical implementation and retrospective artifact evidence. It includes code inspection, workflow tracing, deployed configuration counts, a bounded cross-cycle persistence check, audit-log characterization, and an action-level parser example. Usability testing, penetration testing, accessibility assessment, and before/after efficiency measurement were outside its scope. Manager interactions during development were not collected under a predefined quali-

tative protocol and are therefore not reported as user-study data. Completeness, consolidation time, sustained audit-event rates, and effects on decision-making still require prospective measurement. The retrospective checks are limited to what the frozen snapshot can answer directly: structural alignment across cycles and populated provenance.

Future evaluation should define a fixed institutional observation period and measure completion by cycle, turnaround time for consolidation, rework, user task performance, and perceived usefulness. A security assessment and a documented maintenance/update procedure are also priorities. These steps would complement the artifact-level evidence reported here with human, organizational, and longitudinal outcomes [19].

VII. Conclusion

This study examined the *PMPIF Dynamic Report* as an implemented municipal information artifact and mapped observable implementation evidence to the five technical objectives used in the evaluation. The case shows how actions, responsible institutions, reporting cycles, structured values, permissions, provenance, and analytical outputs can remain connected in a single monitoring workflow.

The resulting policy-centered model preserves ownership and reporting context while keeping authorization, revision history, and analytical reuse tied to the same persistent records. The present evidence is still artifact-level. Prospective work should measure cycle completeness and consolidation time, evaluate usability with institutional users, and test security and maintainability under routine operation before organizational or public-health effects are claimed.

***Abstract*—The limited availability of continuous healthcare personnel for patient guidance underscores the need for robust Digital Health solutions. Large Language Models (LLMs) combined with Retrieval-Augmented Generation (RAG) offer a promising approach to mitigate hallucinations common in generative models, providing a structured framework for clinical decision support systems. This study developed a RAG-based Conversational Agent (CA) prototype to provide perioperative (pre- and post-operative) guidance for patients undergoing cardiac surgery. The system was implemented using a quantized Llama-3-8B-Instruct model and the LangChain library, and evaluated through a knowledge base ablation study across three configurations: pre-selected scientific articles (KB1), clinical FAQs curated by a specialist nurse (KB2), and a hybrid combination of both layers (KB3). Safety parameters, including a low temperature setting (0.2) and strict prompt constraints, were enforced to minimize the risk of speculative generation. Evaluation relied on semantic cosine similarity metrics computed via high-dimensional text embeddings, alongside qualitative analysis of safety guardrail activation against predefined protocols. The hybrid configuration (KB3) achieved the highest mean similarity score (0.64 ± 0.12), suggesting potential synergistic benefits compared to isolated baselines, although formal statistical significance testing was not performed in this preliminary study. Conversely, queries drifting out of scope or demanding individualized medical assessment triggered predefined refusal messages, resulting in lower semantic similarity scores (mean 0.38). This divergence reflects the system's adherence to safety protocols, prioritizing human redirection over speculative generation. The prototype demonstrates technical viability as a supportive tool for health education in controlled settings, though further clinical validation is required before deployment.**

I. Introduction

The evolution of Artificial Intelligence (AI) and Natural Language Processing (NLP) technologies has revolutionized digital interactions [1], [2]. These tools have evolved significantly, being applied in several areas, including healthcare, where they can offer emotional support and convey information instantly and in a personalized manner [2].

In highly complex healthcare scenarios, such as heart surgery, patients and their family members often experience high levels of stress and concern, making individualized and continuous monitoring essential [3]. In this context, pre- and post-operative guidance plays a fundamental role, with nursing professionals currently serving as the main agents for essential care instruction [4]. A failure in communication or the absence of effective support can compromise adherence to self-care, potentially affecting the effectiveness of the operation and recovery [5].

In this context, considering the limited time and continuous availability of healthcare professionals dedicated exclusively to guidance, Conversational Agents (CAs) emerge as a potential technological solution in digital health. They offer the opportunity to provide standardized information and clarify doubts about pre- and post-cardiac operative processes [6], potentially optimizing the use of clinical team time [7].

The constant evolution of Large Language Models (LLMs) represents a significant advance in AI, improving the ability of CAs to simulate human-like conversation [8]. While LLMs show potential to enhance accessibility and assist in decision support [9], their unrestricted application in healthcare remains challenging due to the risk of generating erroneous, out-of-context, or non-evidence-based content. These factors are critical barriers to the safe provision of health information [10].

To overcome these limitations, Retrieval-Augmented Generation (RAG) can be employed to restrict the LLM's knowledge base (KB) to a specific set of pre-selected documents [11], [12]. This approach aims to increase the accuracy and contextual relevance of the conversational agent's output by grounding responses in verified sources [12].

Considering the need to provide accurate and evidence-based information to cardiac patients, the objective of this work is to present a CA prototype using the RAG approach. This study serves as an exploratory evaluation of a hybrid RAG architecture combining evidence from specialized literature and local operational knowledge. The expectation is that current solution may help reduce patient and family concerns and ease the educational burden on nursing professionals. It should be seen as a supplementary support tool rather than a replacement for clinical care.

II. METHODS

The present study is characterized as a technological development work aimed at creating and simulating a CA, based on pre-selected scientific evidence [2], to provide perioperative guidance to cardiac surgery patients. The development was guided by the following steps:

1) Identify standard clinical guidelines and patient frequently asked questions (FAQs);
2) Study and apply the RAG approach for CAs;
3) Prototype implementation based on the bibliography; and
4) Semantic and qualitative validation tests using FAQ + scientific literature curated by a specialist cardiology nurse.

Supplementary material is provided at the end of this paper.

A. Knowledge Base Definition

The main KB used to anchor the RAG pipeline was composed of two distinct operational layers:

a) A selection of 10 scientific articles pre-selected (Portuguese, English and Spanish) were retrieved during the development of a systematic literature review, as detailed in Table I; and

b) Two FAQ datasets (Portuguese), capturing local workflows and the health service's operational routines. Examples of the mapped questions and their respective gold-standard clinical were translated (from Portuguese into English) and are provided in Table II.

The KB layers described above were developed with the assistance of a nurse specialist who has over four years of experience in cardiologic peri-operative care. The nurse specialist also worked at a reference cardiologic surgery center, where protocols for patient guidance developed by a multiprofessional team were reused.

B. RAG Architecture and Implementation

The implementation of the CA was based on the RAG approach [4], aiming to ensure cohesive, precise, and strictly grounded answers within the text reviewed by professionals experienced in cardiac perioperative guidance [3]. The prototype was developed in Google Colab, utilizing an NVIDIA T4 GPU instance. No specific language translation mechanism was employed in current work, i.e. translation was handled by the LLM as is. To optimize memory usage and inference speed, the LLM was loaded with 4-bit quantization. The technologies used (Table III) and the solution design (Fig. 1) are summarized below.

C. RAG Chain Configuration and Prompt Engineering

The LLM Llama-3-8B-Instruct (4-bit NF4 Quantization) was configured with a temperature parameter of 0.2. This parameter was configured empirically after qualitative validation cycles with the clinical specialist (testing values ranging from 0.0 to 0.4). This task was performed to ensure that the response generation remained limited to the retrieved facts, avoiding

TABLE II
OVERVIEW OF FAQ QUERY/ANSWER PAIRS.

Question	Expected Answer	Question	Expected Answer
Should I be hospitalized before my cardiac surgery?	Yes. Prior admission is required for physical preparation, pre-operative exams, and safety evaluation.	What devices will I use in the immediate post-operative period?	Intubation (for about 6h), chest drains, central venous catheter in the neck, peripheral venous access, and indwelling urinary catheter.
Do I need to fast before admission?	No. The fasting protocol (usually 8 hours) is controlled by the nursing staff after admission.	How long will I stay in the ICU?	Usually from one day before until 5 days after the procedure, varying according to the case.
What should I bring on the day of admission?	Recent exams, ID documents, continuous-use prescriptions, hygiene items, and comfortable clothes.	How long will I use the devices?	Generally up to two days after surgery, depending on clinical stability, urine output (diuresis), and drainage.
What will the pre-surgery preparation be like?	Admission to the ICU or inpatient unit; bedside reception; team guidance on procedures and collection of pre-operative exams.	What is important for my recovery?	Stay calm and strictly follow the health team's instructions.
Can my family member stay with me during hospitalization?	Companions are not allowed in the ICU; they are permitted in the Inpatient Unit.	Will I have pain in the post-operative period?	Yes, chest discomfort is normal due to surgical trauma. It is strictly managed with scheduled and rescue analgesics.
Is it important to report flu-like symptoms?	Yes, they must be evaluated by the physician to determine whether to proceed with or postpone the surgery.	Will I receive pain medication?	Yes, whenever necessary to ensure relief and comfort.
What are the risks of cardiac surgery?	Complications such as heart attack (infarction), arrhythmias, thrombosis, embolism, and cardiac arrest.	Will I be able to sleep with the devices?	There may be initial discomfort, but the team will perform the necessary care to promote the best possible rest.
Can I die?	There is a risk of death, but it is low in reference hospitals. As it is a major surgery, the risk is present.	Can my family member accompany me in the post-operative period?	In the ICU (1 to 5 days) visits are restricted. In the room (inpatient unit), companions are allowed.
Will I have complications in the post-operative period?	The most common are arrhythmias and sodium or potassium imbalances.	What are the care instructions when going home?	Medication management; avoid using arm strength when getting up; wound hygiene with warm water and neutral soap; gradual return to activities (4-6 weeks); do not smoke and drive only after 30 days.

discrepancies from expected answers. The maximum context of 8192 tokens was empirically defined to accommodate both the user's question chunks and the chunks retrieved from the KB.

The retrieval mechanism (retriever) was configured to fetch the most relevant chunks. The parameter $k = 5$ was empir-

TABLE III
RAG PIPELINE ARCHITECTURAL SPECIFICATIONS AND HYPERPARAMETERS.

Component/Parameter	Specification / Value
Large Language Model (LLM)	Llama-3-8B-Instruct (4-bit NF4 Quantization)
Hardware Infrastructure	Google Colab (NVIDIA T4 GPU, 16GB VRAM)
Key Libraries	LangChain v0.1.0, ChromaDB v0.4.22, PyTorch v2.1.0
LLM Temperature	0.2
Context Window	8,192 tokens
Retrieval Strategy	Vector Similarity ($k = 5$)
Text Splitter / Chunk Size	Recursive Character / 800 chars
Chunk Overlap	200 characters
Embedding Model	all-MiniLM-L6-v2 (Sentence Transformers)
Vector Database	ChromaDB
User Interface Framework	Gradio

ically defined for the indexed documents, meaning that the model retrieves the five (5) text chunks that present the highest semantic similarity with the user's query. The choice of this range ($k = 5$) is an experimental design choice intended to balance context sufficiency with noise reduction.

The system alignment and protection mechanisms (guardrails) were applied through a structured `PromptTemplate`, defining the agent's behavior as follows:

> *"You are a specialized healthcare assistant providing perioperative guidance for cardiac surgery. Provide standardized, safe, objective, and clear guidance using patient-accessible language. Your answers must be strictly grounded in the provided context. Safety Rule: If the query requires individualized medical decisions (such as precise medication dosages, personal diagnoses, or clearance for specific physical activity) or if the information is missing from the context, you must respond: 'This matter concerns your specific medical history and must be discussed directly with your cardiologist or nursing team.' OR 'This information requires an individualized clinical evaluation. Please consult your physician or the responsible healthcare team.' "*

To improve usability and enable remote asynchronous testing, an interactive web interface was deployed using the Gradio library [13]. This task was performed to allow the nurse specialist to perform a preliminary validation, in order to ensure the CA clinical safety, without local execution dependencies.

D. Preparation and indexing of the knowledge base

The processing and preparation of the documents were structured into three phases:

1) *Data Loading:* In this first stage, the use of the `UnstructuredFileLoader` was fundamental because it allowed us to maintain the context of documents structured in various ways, such as an article containing images, captions, and text columns on a page.
2) *Chunking:* In the chunking stage, the function employed was `RecursiveCharacterTextSplitter` with parameters initially set to 1000 characters and, after testing, adjusted to 800. Decreasing the chunks was necessary for a better affinity of the response with the input. To prevent discrepancies in dataset sizes between tests, the `chunk_overlap` function was used, which enables the overlap of input chunks with output chunks; the default value of 200 characters was sufficient for this application.
3) *Vectorization and Embedding:* Prior to vector storage, a filtering layer was applied to clean metadata keys that could cause any type of semantic noise. Finally, the text segments were transformed into vectors using an embedding model `all-MiniLM-L6-v2` and indexed inside a local instance of `ChromaDB`.

E. Evaluation Methodology

The evaluation of the architecture's adequacy was based on measuring the semantic alignment of the answers generated by the CA against the FAQ (n = 18 QA pairs). To overcome the limitations of purely qualitative evaluations, we employed semantic cosine similarity metrics. Unlike exact word-matching metrics (e.g., BLEU, ROUGE), which lack sensitivity to clinical nuances and synonymous variations [14], cosine similarity captures semantic proximity in high-dimensional space.

Developed as a KB ablation study, the experiment measured the individual and combined impact of each dataset on the model's performance. For the mathematical calculation, both the response produced by the model ($\hat{y}$) and the expected response from the specialist (y) were converted into vectors using the all-MiniLM-L6-v2 embedding model. Similarity was extracted through the dot product of the normalized vectors:

$$\text{Cosine Similarity}(\hat{y}, y) = \frac{\vec{\hat{y}} \cdot \vec{y}}{\|\vec{\hat{y}}\| \|\vec{y}\|} \tag{1}$$

Following the clinical validation methodology established by [15], the behavior of the conversational agent was monitored through the calculation of the overall mean and standard deviation (σ) of similarity across three knowledge base configurations, specifically:

- KB1, with query/answer (Q/A) tasks employed directly to literature data;
- KB2, with Q/A tasks employed only to the FAQ (Q/A pairs) data; and
- KB3, with Q/A tasks employed in a combination of KB1 + KB2.

Additionally, the system was subjected to out-of-scope adversarial questions to evaluate the activation rate of safety guardrails. For these cases, low similarity scores were expected, reflecting the semantic divergence between the generated refusal message and the FAQ answer. This metric serves as an indicator of protocol adherence rather than clinical correctness.

Qualitative Validation: While the primary quantitative metric was cosine similarity, a qualitative validation phase was conducted to assess clinical relevance and safety. The FAQ

responses and a subset of generated outputs were reviewed by the nurse specialist. Due to resource constraints in this preliminary prototyping phase, the evaluation was performed by a single expert. To mitigate individual bias, the evaluation criteria were strictly predefined based on institutional protocols (Table II), focusing on factual alignment and adherence to safety guardrails rather than subjective preference.

F. Ethical considerations

This study was formally reviewed and approved by the Research Commission (COMPESQ) of the Federal University of Health Sciences of Porto Alegre (UFCSPA) under registration number 1022/2024. As this research focuses on computational development using publicly available scientific literature and manually generated FAQs, no human participants were involved in the testing phase, and no private personal data were collected.

III. Results and Discussion

The quantitative performance of the CA was measured using embedding-based semantic cosine similarity. The indicators for each KB configuration are displayed in Table IV.

TABLE IV
Mean similarity and standard deviation for each KB analyzed.

Knowledge Base	Mean similarity	Standard deviation
KB1	0.61	$\pm$ 0.09
KB2	0.60	$\pm$ 0.11
KB3	0.64	$\pm$ 0.12

The experimental results indicate a viable structural topology of the RAG framework, demonstrating an ablation behavior where the synchronized data layers systematically outperformed the isolated baselines in terms of mean similarity scores. KB1 achieved a mean cosine similarity of 0.61. Although the pre-selected scientific articles provide rigorous medical evidence, they lack the specificities of clinical workflow required for adequate patient guidance. As illustrated in Table V, KB1 produced generic responses regarding hospitalization protocols and failed to specify fasting rules, leading to vague or incomplete patient instructions. On the other hand, the isolation of the clinical FAQ protocol in KB2 resulted in a score of 0.60. This performance ceiling may stem from the smaller amplitude of the context window or retrieval inefficiencies.

Notably, KB2 exhibited critical operational failures despite containing the correct information. For instance, the query regarding family accompaniment triggered a safety refusal because the relevant chunk was not ranked within the top-k results (Table V). This highlights a limitation in vector search precision for specific operational rules when relying solely on procedural FAQs. The intersection of both components in the KB3 architecture achieved the highest semantic similarity (0.64) and resolved these qualitative gaps. As shown in Table V, KB3 provided precise fasting guidelines with necessary clinical caveats and correctly nuanced the family accompaniment policy by distinguishing between ICU and Inpatient Unit restrictions. However, the overlap in standard deviations indicates that further statistical validation is required to confirm significant superiority over baseline configurations.

When exposed to queries requiring individualized diagnostic or prescriptive advice, the system suppressed its generative capability to enforce a standardized phrase of refusal and human redirection. In complex medical queries regarding prescription adjustments (for example, *"Is there any medication I should stop before surgery?"*), the semantic cosine similarity under the proposed KB3 architecture dropped to 0.38. This reduction reflects the system's adherence to refusal protocols for out-of-scope queries. The low score indicated that the model did not attempt to generate speculative medical advice, adhering to the safety protocol by prioritizing caution over generation. However, this metric reflects semantic divergence due to refusal rather than clinical accuracy of the refusal itself.

Other analysis must be taken into account. A preliminary examination of the query "*Do I need to fast before admission?*" may suggest an apparent contradiction between the FAQ in Table II (which states: "*No. The fasting protocol (usually 8 hours) is controlled by the nursing staff after admission*") and the model outputs generated under configurations KB2 and KB3 (Table V). Table V specifies an 8-hour fasting duration determined by the anesthesiologist.

In clinical practice, this discrepancy reflects complementary granularity levels within the KB, i.e. while the concise FAQ item addresses hospital admission routines, the institutional protocol explicitly indicates that patients may maintain regular nutrition until admission, after which strict fasting (8 to 10 hours) is prescribed when under the anesthesiologist's prescription and nursing oversight. Furthermore, integrating scientific literature within KB3 grounded the FAQ with established perioperative nursing protocols [**?**], [5]. Although this synthesis demonstrates the capacity of the hybrid RAG architecture to reconcile operational workflows with clinical literature not fully detailed in the initial isolated FAQ, this observation remains preliminary and warrants multi-expert clinical validation before being established as a definitive performance gain.

Finally, the performance of the architecture with a combined base stood out in queries regarding rehabilitation and exercise limits (for example, *"When can I resume physical activities?"*), where KB3 reached a similarity of 0.72. This result stems from the model's capacity to cross-reference clinical information from the scientific literature (KB1) with the practical schedules provided by the FAQ (KB2), suggesting the enrichment of the response from the RAG-based framework.

A. Limitations

The evaluations were conducted in a controlled environment under a single nurse specialist's supervision, relying on a single institutional protocol without direct end-user testing. Additionally, we acknowledge that using the same embedding model (all-MiniLM-L6-v2) for both retrieval and evaluation

TABLE V
QUALITATIVE ANALYSIS OF RESPONSES

Question	KB1 (Articles)	KB2 (FAQ)	KB3 (Combined)
Should I be hospitalized before my cardiac surgery?	Generic: Allows monitoring and reduces stress, but does not state the direct clinical necessity.	Direct: Yes, hospitalization is recommended beforehand, but without the context of safety and protocols.	Complete: Yes, hospitalization is recommended for evaluation, proper preparation, and medication adjustment.
Do I need to fast before admission?	Vague: No specific mention of fasting before admission.	Specific: Yes, 8-hour fasting is required (protocol data, but without caveats).	Precise and Safe: Yes, 8-hour fasting, with the caveat that the exact time will be prescribed by the anesthesiologist.
Can my family member stay with me during hospitalization?	Misdirected: The model shifts focus to the importance of the patient being well-informed.	Retrieval Failure: Triggered safety refusal despite information being present in KB2.	Clinical Nuance: Yes, it is possible in the Inpatient Unit, but not in the ICU (Rule with protocol exception).

may introduce self-alignment bias, potentially inflating similarity scores. Therefore, these metrics should be interpreted as indicators of contextual alignment rather than definitive measures of clinical factuality.

Future work will incorporate independent evaluation metrics, such as LLM-based judges calibrated for clinical accuracy, and multiple expert evaluation of content generated. Qualitative evaluation might be expanded to a multi-expert evaluation with inter-rater reliability calculations (e.g., Cohen's Kappa). A specific analysis of the written language in documents included in the KB was not addressed. This may generate diverse interpretations regarding its correspondence in multiple idioms (e.g., Portuguese-English). This task must be properly addressed in future work, even though it did not pose any apparent issues according to the nurse specialist.

IV. CONCLUSION

This study presented a RAG-based Conversational Agent prototype designed to support perioperative guidance for cardiac surgery. The findings suggest that combining large language models with a hybrid knowledge base, integrating scientific literature and operational protocols, offers a technically viable architecture to support patient health education in controlled settings.

The results indicate that the performance of the RAG system is highly sensitive to the composition and quality of the vectorized data, highlighting knowledge base curation as a critical factor for contextual alignment. Additionally, the implementation of safety *guardrails* in the *PromptTemplate* gives an indication on how to enforce standardized refusal protocols when facing out-of-scope or prescriptive queries, thereby prioritizing safety redirection over speculative generation.

The primary contribution of this work is demonstrating the feasibility of combining dual-layer domain data with operational refusal guardrails to reduce generative discrepancies in patient-facing health applications. Future work must encompass multi-center protocol integration, formal statistical significance testing, multi-expert blind evaluations with inter-rater reliability, and prospective clinical validation with patients and multiprofessional healthcare teams before real-world deployment.

***Resumo*—Este estudo desenvolveu um método computacional para apoiar a quantificação automatizada de neutrófilos em imagens de imuno-histoquímica do tecido periodontal apical. O sistema foi implementado em Python com interface gráfica, utiliza segmentação por superpixels e extrai características de cor nos espaços RGB, CIELAB e HSV, além de descritores de textura. Após avaliação preliminar, a configuração CIELAB + textura foi adotada nos modelos finais. Foram implementados quatro classificadores supervisionados: Random Forest (RF), Support Vector Machine (SVM), Extreme Gradient Boosting (XGBoost) e Multilayer Perceptron (MLP). Eles foram aplicados em duas etapas: primeiro, identificação e exclusão de regiões da lâmina que não contêm tecido; segundo, identificação dos neutrófilos entre outros componentes teciduais. Na Etapa 1, o XGBoost alcançou acurácia de 0.928. Na Etapa 2, o Random Forest alcançou acurácia de 0.919. A solução proposta fornece mapas visuais e estimativas percentuais da área inflamada, indicando viabilidade inicial para apoiar análises histopatológicas experimentais.**

***Palavras-chave*—Aprendizado de Máquina, Processamento de Imagens, Diagnóstico Auxiliado por Computador, Periodontite Apical.**

I. Introdução

As doenças periodontais representam um significativo problema de saúde pública, com estudos indicando que podem afetar até 90% da população mundial [1]. Nesses cenários, os neutrófilos, leucócitos que constituem a primeira linha de defesa inata, migram em grande volume para o tecido periodontal. Esse acúmulo celular é considerado um marcador clássico e direto da inflamação aguda, tornando sua quantificação em cortes histológicos submetidos à imuno-histoquímica uma etapa essencial para avaliar a progressão da doença e a eficácia de tratamentos. Para investigar a patogênese dessas afecções e testar novas abordagens terapêuticas, modelos experimentais murinos são amplamente utilizados [2]–[4].

Contudo, a abordagem tradicional para a quantificação dessas células apresenta limitações operacionais severas. Realizada manualmente por especialistas por meio de microscopia óptica, a análise visual consome tempo excessivo e é amplamente criticada por sua fragilidade analítica. Trata-se de um processo subjetivo, suscetível à fadiga visual e que resulta em baixa reprodutibilidade, caracterizada por variabilidade intra e interobservador [5]. Essas restrições justificam a investigação de métodos automatizados capazes de fornecer apoio quantitativo mais consistente em pesquisas odontológicas.

No estado da arte, a patologia digital aliada a algoritmos de visão computacional e inteligência artificial desponta como solução promissora para diversas limitações presentes nos processos tradicionais. Estratégias contemporâneas têm demonstrado sucesso ao aplicar algoritmos de agrupamento, como o Simple Linear Iterative Clustering (SLIC), para realizar a pré-segmentação das imagens em superpixels, regiões homogêneas que agrupam pixels com base na similaridade de cor e proximidade espacial [6], [7]. Esses recursos podem acelerar a anotação por especialistas, preservar a morfologia celular e otimizar a etapa de extração de características. Consequentemente, o uso de superpixels cria uma representação de dados favorável ao treinamento de classificadores supervisionados clássicos de aprendizado de máquina, como RF, SVM e XGBoost [8]–[10].

Trabalhos correlatos em patologia digital têm demonstrado que métodos computacionais baseados em visão computacional e inteligência artificial podem reduzir a subjetividade, o tempo de análise e a variabilidade intra e interobservador presentes na avaliação manual de lâminas histológicas. Pantanowitz et al. [11], por exemplo, investigaram o uso de inteligência artificial na contagem de figuras mitóticas, enquanto Karasayar, Kulaç e Kapucuoğlu [5] discutem a aplicação de ferramentas automatizadas na quantificação de marcadores histopatológicos, como Ki-67, destacando ganhos de objetividade e consistência. No contexto da segmentação de imagens biomédicas, Achanta et al. [7] propuseram o algoritmo SLIC, baseado em superpixels, que permite agrupar

pixels em regiões homogêneas de forma eficiente. Albayrak e Bilgin [12] também demonstraram que abordagens baseadas em superpixels podem favorecer a segmentação celular em imagens histopatológicas ao preservar informações espaciais e estruturais. Apesar desses avanços, ainda há carência de soluções específicas para a quantificação automatizada de infiltrado neutrofílico em imagens de imuno-histoquímica do tecido periodontal apical. Este trabalho busca abordar essa lacuna por meio da combinação de segmentação por superpixels, extração de atributos de cor e textura e classificadores supervisionados.

Diante da necessidade de métodos mais eficientes para pesquisas imuno-histoquímicas, o principal objetivo deste trabalho é desenvolver um método computacional de código aberto, implementado em Python e equipado com interface gráfica, para a análise automatizada de imagens do ligamento periodontal apical. A contribuição do estudo está na aplicação específica à quantificação do infiltrado neutrofílico em tecido periodontal apical, na estratégia de classificação em duas etapas e na integração dos modelos treinados a uma ferramenta para visualizar e estimar o percentual de área positiva inflamada.

II. Métodos

O método proposto foi organizado em três blocos operacionais. Inicialmente, realizou-se uma etapa preliminar voltada à preparação das imagens, extração das características e definição do espaço de cor mais adequado para a classificação. Em seguida, o pipeline foi dividido em duas etapas principais de classificação: a Etapa 1, destinada à identificação das regiões de fundo da lâmina, e a Etapa 2, destinada à identificação dos superpixels correspondentes a neutrófilos entre os demais componentes teciduais. Essa organização permitiu separar a remoção de regiões sem tecido da quantificação efetiva do infiltrado inflamatório.

A. Etapa Preliminar

Na etapa preliminar (Fig. 1), o conjunto de dados foi obtido a partir de 10 ratos, com extração de dois primeiros molares inferiores de cada animal: um dente controle e um dente submetido à indução da doença. Uma lâmina foi preparada para cada dente, totalizando 20 lâminas; uma lâmina do grupo controle foi descartada, resultando em 19 imagens analisadas, adquiridas em microscópio Leica DMR acoplado a câmera Leica DFC 300FX. As imagens foram segmentadas por meio do algoritmo SLIC configurado com aproximadamente 5.000 segmentos, fator de compacidade igual a 10 e pré-suavização gaussiana com $\sigma = 3$, gerando superpixels utilizados como unidades básicas de análise. Para cada superpixel, foram extraídas características cromáticas nos espaços RGB, HSV e CIELAB, além de descritores de textura baseados na matriz de coocorrência de níveis de cinza, incluindo homogeneidade, correlação, dissimilaridade e contraste.

B. Ferramenta de Rotulagem Manual

Uma ferramenta própria apoiou a construção do padrão-ouro (Fig. 2). Ela segmentava cada imagem com os mesmos parâmetros do SLIC usados no treinamento e armazenava o identificador de cada superpixel rotulado. Como esses identificadores são determinísticos quando os parâmetros do SLIC são mantidos, os rótulos puderam ser mapeados de forma consistente para a tabela de atributos. Durante a anotação, os especialistas rotulavam a imagem segmentada enquanto inspecionavam a imagem original lado a lado.

C. Etapa 1 - Classificação de Fundo

Na Etapa 1, foi treinado um classificador auxiliar para distinguir superpixels correspondentes ao fundo da lâmina daqueles pertencentes ao tecido histológico. Para isso, os superpixels foram rotulados manualmente por três especialistas como “fundo” ou “não fundo”, formando o padrão-ouro por consenso dessa etapa. Devido ao desbalanceamento entre as classes, foi aplicada subamostragem da classe majoritária antes do treinamento para equilibrar as classes e reduzir viés em direção ao rótulo predominante. O classificador foi então avaliado por meio das métricas de acurácia, sensibilidade, especificidade e área sob a curva ROC (AUC). A Fig. 3 ilustra esse processo.

D. Etapa 2 - Classificação de Neutrófilos

Na Etapa 2 (Fig. 4), foi treinado o classificador principal para identificar superpixels positivos para neutrófilos em relação aos demais componentes teciduais. Para a formação dessa base, foram excluídos os superpixels rotulados manualmente como fundo no padrão-ouro, garantindo que o treinamento fosse realizado apenas sobre regiões correspondentes a tecido. Os superpixels remanescentes foram então rotulados pelos mesmos três especialistas, por consenso, como “neutrófilo” ou “não neutrófilo”. Após o balanceamento das classes, os classificadores supervisionados foram treinados e avaliados utilizando os conjuntos de atributos definidos na etapa preliminar. Posteriormente, o modelo de melhor desempenho foi integrado à interface gráfica para geração do mapa visual dos superpixels positivos e cálculo do percentual de área tecidual inflamada.

E. Procedimentos de Treinamento e Avaliação

Após a segmentação das imagens, foram estruturados dois conjuntos de dados distintos, correspondentes às duas etapas do pipeline. Para o classificador de fundo, o conjunto totalizou 92.340 superpixels, sendo 2.700 rotulados como fundo e 89.640 como não fundo. Após subamostragem da classe majoritária para reduzir o viés causado pelo desbalanceamento entre as classes, obteve-se um conjunto balanceado de 5.400 instâncias, com 2.700 amostras por classe.

Para o classificador de neutrófilos, os superpixels rotulados manualmente como fundo foram excluídos, resultando em 94.999 superpixels. Antes do balanceamento, havia 82.137 amostras não neutrofílicas e 12.862 neutrofílicas. Após subamostragem, o conjunto final utilizado no treinamento continha 25.724 instâncias balanceadas, sendo 12.862 por classe. Todos os modelos foram avaliados por validação cruzada estratificada em 5 folds, com embaralhamento e semente

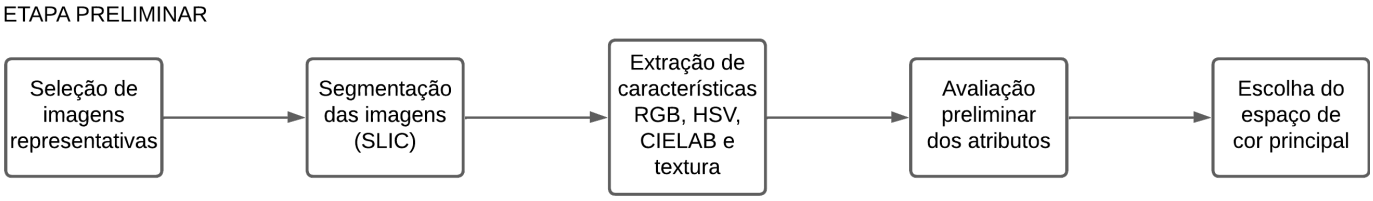

Fig. 1. Fluxograma da etapa preliminar.

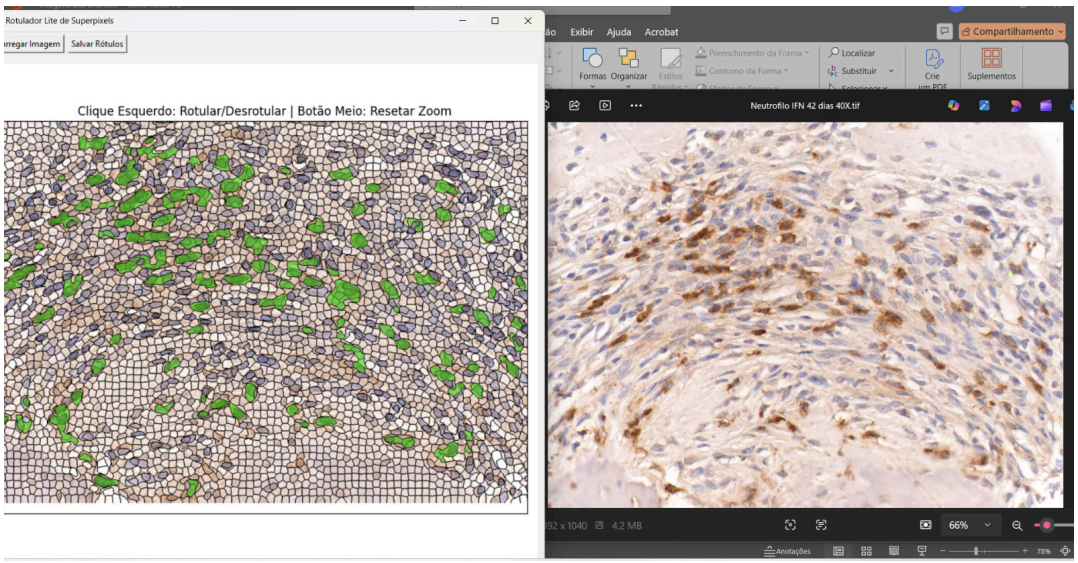

Fig. 2. Ferramenta de rotulagem manual com imagem segmentada e imagem original lado a lado.

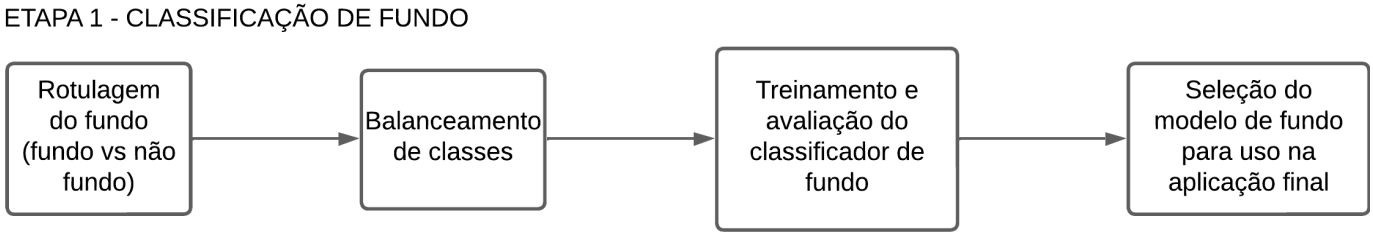

Fig. 3. Fluxograma do classificador de fundo na Etapa 1.

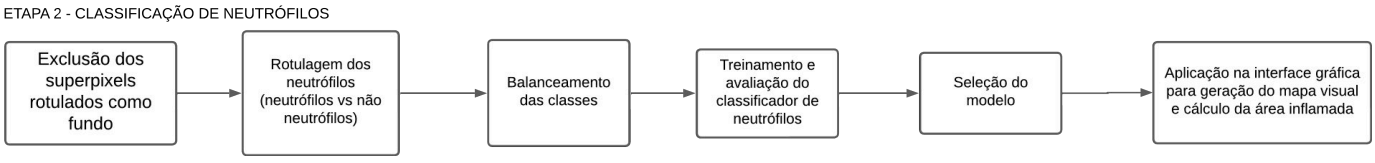

Fig. 4. Fluxograma do classificador de neutrófilos na Etapa 2.

aleatória 42, utilizando acurácia, sensibilidade, especificidade e AUC sob a representação CIELAB + textura. A divisão foi realizada no nível dos superpixels individuais no conjunto consolidado para preservar o balanceamento entre classes nesta avaliação preliminar; a validação agrupada por imagem, lâmina ou animal é, portanto, definida como etapa necessária em estudos futuros.

F. Aspectos Éticos

As imagens utilizadas neste estudo são derivadas de amostras teciduais secundárias e anonimizadas, provenientes de experimentos laboratoriais prévios conduzidos por pesquisadoras colaboradoras. Nenhum novo procedimento animal ou humano foi realizado para esta análise computacional, e os procedimentos animais primários foram aprovados pelo Comitê de Ética em Experimentação Animal da Faculdade de

Medicina de Ribeirão Preto da Universidade de São Paulo (FMRP-USP, Protocolo nº 003/2006), seguindo as diretrizes ISO 10993-2.

III. Resultados

A. Avaliação Preliminar dos Atributos

Antes da definição do modelo final de classificação, foi realizada uma avaliação preliminar dos conjuntos de atributos extraídos dos superpixels usando o modelo Random Forest. Essa análise teve como objetivo comparar o desempenho dos diferentes espaços de cor, RGB, HSV e CIELAB, bem como dos descritores de textura e de suas combinações, a fim de selecionar uma representação adequada para a etapa de classificação dos neutrófilos. Os resultados são apresentados na Tabela I.

Tabela I
Comparação dos Espaços de Cor no Random Forest

Descritor	Acurácia	Sensibilidade	Especificidade	AUC
RGB	0.880	0.886	0.874	0.952
HSV	0.880	0.889	0.871	0.950
CIELAB	0.888	0.895	0.880	0.956
Apenas textura	0.733	0.794	0.672	0.795
CIELAB + textura	0.919	0.929	0.909	0.972

Embora os modelos de cor avaliados tenham gerado resultados marginalmente semelhantes, o modelo CIELAB obteve o melhor desempenho em comparação com RGB e HSV. Verificou-se também que a combinação de descritores de cor e de textura levou a resultados melhores do que o uso desses descritores separadamente. Por isso, o espaço de cor CIELAB foi adotado como representação cromática principal, considerando o equilíbrio entre desempenho, menor dimensionalidade e interpretabilidade.

Para complementar a análise de desempenho, foi avaliada a importância dos atributos no modelo XGBoost por meio do método Gain. Essa análise permitiu identificar quais características contribuíram mais para as decisões do classificador. Os resultados da Tabela II indicaram que a média do canal 1 do CIELAB apresentou o maior ganho preditivo, reforçando a relevância desse espaço de cor para a discriminação dos superpixels positivos para neutrófilos.

Tabela II
Ganho por Atributo Usando o Método Gain do XGBoost

Posição	Atributo	Ganho
1º	Média do canal 1 CIELAB	36.710
2º	Média do canal 3 CIELAB	11.646
3º	GLCM homogeneity	8.457
4º	Média do canal 2 CIELAB	5.737
5º	GLCM dissimilarity	5.105
6º	GLCM correlation	4.277
7º	GLCM contrast	3.649

A análise por Gain no XGBoost foi utilizada apenas como avaliação complementar da relevância dos atributos, indicando contribuição importante dos canais CIELAB. No entanto, o modelo final selecionado para a Etapa 2 foi o Random Forest com CIELAB + textura, devido ao melhor equilíbrio global nas métricas avaliadas.

B. Resultados da Etapa 1 - Classificação de Fundo

A Etapa 1 teve como objetivo treinar e avaliar um classificador auxiliar capaz de distinguir regiões correspondentes ao fundo da lâmina daquelas contendo tecido histológico. Essa etapa foi necessária para evitar que áreas sem tecido fossem consideradas no cálculo da área inflamada durante a aplicação final da ferramenta. Para essa tarefa, foram utilizados os atributos CIELAB + textura.

Conforme apresentado na Tabela III, os quatro classificadores supervisionados [8]–[10], [13] foram avaliados na Etapa 1, correspondente à distinção entre superpixels de fundo e não fundo, utilizando a configuração CIELAB + textura. O XGBoost apresentou o melhor desempenho geral, com acurácia média de 0,928 e AUC de 0,981, seguido pelo Random Forest, com acurácia de 0,927 e AUC de 0,981. Embora a MLP tenha apresentado a maior sensibilidade, com 0,935, e o Random Forest tenha alcançado a maior especificidade, com 0,928, o XGBoost demonstrou o melhor equilíbrio entre as métricas avaliadas, combinando maior acurácia e alta sensibilidade. Dessa forma, o XGBoost foi selecionado como classificador final da Etapa 1, responsável pela identificação das regiões de fundo da lâmina.

Tabela III
Desempenho dos Classificadores para Identificação de Fundo Usando CIELAB + Textura

Modelo	Acurácia	Sensibilidade	Especificidade	AUC
XGBoost	0.928	0.934	0.923	0.981
Random Forest	0.927	0.926	0.928	0.981
MLP	0.924	0.935	0.913	0.978
SVM	0.917	0.931	0.904	0.973

C. Resultados da Etapa 2 - Classificação de Neutrófilos

Na Etapa 2, o objetivo foi classificar os superpixels correspondentes às regiões teciduais como positivos ou negativos para a presença de neutrófilos. Para a construção dessa base, os superpixels rotulados manualmente como fundo no padrão-ouro foram excluídos, garantindo que o treinamento fosse realizado apenas sobre regiões de tecido. Após essa exclusão, o conjunto utilizado para a classificação de neutrófilos totalizou 94.999 superpixels, sendo 82.137 rotulados como não neutrófilos e 12.862 como neutrófilos. Em razão do desbalanceamento entre as classes, foi aplicada subamostragem da classe majoritária para reduzir viés em direção às regiões não neutrofílicas, resultando em um conjunto balanceado de 25.724 instâncias, com 12.862 superpixels por classe.

Utilizando os atributos CIELAB + textura, foram avaliados os classificadores Random Forest, XGBoost, MLP e SVM por validação cruzada estratificada com cinco folds. Conforme apresentado na Tabela IV, os quatro modelos produziram desempenhos próximos. O Random Forest obteve a maior acurácia média entre os modelos avaliados, com 0,919, além da maior especificidade, com 0,909. Embora o XGBoost e

a MLP tenham apresentado AUC ligeiramente superior, e o SVM tenha alcançado maior sensibilidade, o Random Forest apresentou relação favorável entre desempenho preditivo e custo computacional, sendo selecionado como classificador final para a identificação dos neutrófilos.

Tabela IV
DESEMPENHO DOS CLASSIFICADORES USANDO CIELAB + TEXTURA

Modelo	Acurácia	Sensibilidade	Especificidade	AUC
Random Forest	0.919	0.929	0.909	0.972
XGBoost	0.918	0.930	0.906	0.973
MLP	0.917	0.926	0.907	0.973
SVM	0.915	0.938	0.893	0.970

Na Etapa 2, a matriz de confusão média (Tabela V) apresentou 2.338 verdadeiros negativos, 234 falsos positivos, 184 falsos negativos e 2.389 verdadeiros positivos. Possíveis fontes de falsos positivos incluem precipitados inespecíficos de DAB e regiões densas de tecido conjuntivo com características cromáticas ou texturais semelhantes às áreas imunopositivas. Por outro lado, os falsos negativos podem estar relacionados à imunorreatividade tênue ou à presença de células nas bordas dos superpixels, onde o valor cromático médio do segmento é atenuado por pixels adjacentes de tecido não reativo. Essas hipóteses não foram avaliadas por meio de uma revisão sistemática das instâncias classificadas incorretamente e devem ser investigadas em estudos futuros.

Tabela V
MATRIZ DE CONFUSÃO DO RANDOM FOREST USANDO CIELAB E TEXTURA, COM ARREDONDAMENTO PELA MÉDIA DOS CINCO FOLDS

	Predito Negativo	Predito Positivo
Real Negativo	2338	234
Real Positivo	184	2389

D. Aplicação na Interface Gráfica

A Fig. 5 mostra a interface gráfica destacando em vermelho os superpixels classificados como "fundo" e em verde os superpixels classificados como "neutrófilos". As métricas quantitativas são exibidas em uma aba separada de estatísticas (Fig. 6), que informa o número de superpixels classificados como neutrófilos, não neutrófilos e fundo, seguido do percentual de área positiva para neutrófilos após a exclusão do fundo. A plataforma integra o modelo Random Forest para quantificação de neutrófilos e o XGBoost para exclusão de fundo. O tempo completo de processamento por imagem, incluindo segmentação SLIC, extração de atributos de cor e textura e inferência de ambos os classificadores, foi de aproximadamente 31,5 s, variando de 28,7 a 35,0 s em amostras representativas em uma estação convencional baseada em CPU com 16 GB de RAM. Esse tempo é compatível com avaliação futura em fluxos de trabalho laboratoriais.

IV. DISCUSSÃO

Os resultados obtidos indicam viabilidade inicial da combinação de segmentação por superpixels e aprendizado de máquina para apoiar a quantificação automatizada de neutrófilos em imagens de imuno-histoquímica do tecido periodontal apical. A organização do método em duas etapas permitiu separar a identificação de regiões de fundo da classificação dos neutrófilos nas áreas teciduais. Na Etapa 1, o XGBoost apresentou o melhor desempenho para classificar fundo e tecido, com acurácia de 0.928. Na Etapa 2, o Random Forest obteve a maior acurácia para a classificação dos neutrófilos, com acurácia de 0.919.

A escolha dos atributos CIELAB + textura foi apoiada pela avaliação preliminar, pois essa representação obteve a melhor acurácia na Tabela I. Os atributos cromáticos são relevantes porque a marcação por DAB produz diferenças de coloração entre regiões positivas e negativas; o CIELAB separa luminosidade e componentes cromáticos, enquanto os descritores GLCM incorporam informações de textura. Ainda é necessário, porém, realizar um estudo formal de ablação para separar a contribuição individual dos atributos de cor e textura.

A comparação entre classificadores mostrou que o melhor modelo variou conforme a subtarefa. Na classificação de fundo, o XGBoost apresentou a maior acurácia média; na classificação de neutrófilos, o Random Forest foi selecionado porque acurácia, especificidade e custo computacional foram priorizados para reduzir a superestimação da área inflamada e preservar a execução em hardware convencional. Embora XGBoost e MLP tenham apresentado AUC ligeiramente superior, e o SVM tenha alcançado maior sensibilidade, o Random Forest produziu a maior acurácia (0,919) e especificidade (0,909). Na Etapa 2, a matriz de confusão média apresentou 2.338 verdadeiros negativos, 234 falsos positivos, 184 falsos negativos e 2.389 verdadeiros positivos. Os falsos positivos estiveram associados sobretudo a precipitados de DAB e condensações estromais, enquanto os falsos negativos se concentraram em células com marcação tênue ou nas bordas dos superpixels.

O uso de classificadores clássicos combinados a superpixels foi uma escolha voltada ao baixo custo computacional e à execução sem GPU. Ainda assim, a validação foi realizada em uma única base institucional e com folds no nível dos superpixels, o que pode permitir que regiões da mesma imagem apareçam nos conjuntos de treino e validação e inflar as métricas. Embora os rótulos tenham sido estabelecidos por consenso entre três especialistas, não foi incluído coeficiente formal de concordância. Os superpixels também podem ser imprecisos em áreas com sobreposição celular, marcação heterogênea ou transições pouco definidas entre tecido e fundo.

V. CONCLUSÃO

Este estudo demonstrou a viabilidade metodológica inicial de um pipeline em duas etapas para quantificação automatizada de infiltrado neutrofílico em tecido periodontal apical murino. A abordagem alcançou acurácia de 0.928 para classificação de fundo com XGBoost e de 0.919 para classificação de neutrófilos com Random Forest usando descritores CIELAB + textura. A ferramenta fornece mapas visuais e estimativas quantitativas da área inflamada, com tempos de processamento

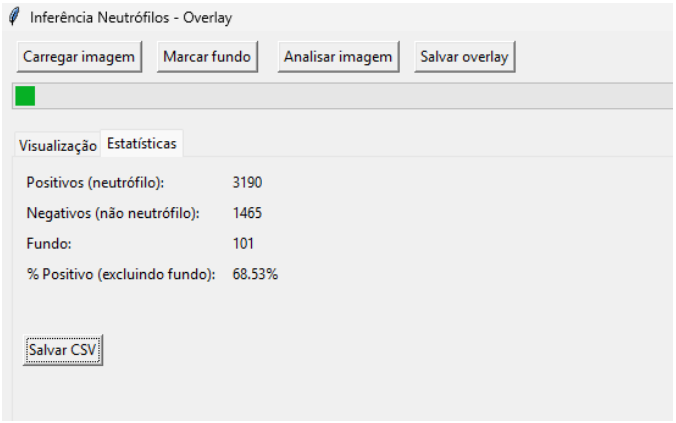

Fig. 6. Aba de estatísticas com contagem de superpixels e percentual positivo para neutrófilos excluindo o fundo. Este exemplo é ilustrativo e não corresponde necessariamente à Fig. 5.

que sugerem potenciais ganhos de execução em relação à análise manual convencional.

Como trabalho futuro, a validação deve ser ampliada com outras bases de imagens adquiridas por diferentes equipamentos, a fim de avaliar a robustez sob diferentes condições de coloração, aquisição e preparo. Estudos futuros também devem incluir divisão dos dados por imagem ou animal, análise de reprodutibilidade, comparação direta com especialistas, avaliação de modelos de aprendizado profundo e testes independentes antes de reivindicações de aplicabilidade clínica ou diagnóstica.

***Abstract*—Respiratory syncytial virus (RSV) is a leading cause of severe lower respiratory tract infections in young children, resulting in substantial morbidity and healthcare resource utilization. This study aimed to identify risk factors associated with severe RSV outcomes through a systematic review and meta-analysis. Searches were conducted in PubMed, Embase and Scopus for observational studies published between 2006 and 2026. Studies evaluating predictors of severe RSV outcomes, including intensive care unit (ICU) admission, ventilatory support, or death, in children aged 0–5 years were included. Nine studies met eligibility criteria. Across studies, younger age, prematurity, congenital heart disease, chronic lung disease, and neurological comorbidities were identified as recurrent predictors of severe disease. Random-effects meta-analyses demonstrated significantly increased odds of severe outcomes among infants younger than six months (OR = 3.42; 95% CI: 2.23–5.27), premature infants (OR = 1.80; 95% CI: 1.30–2.49), and children with congenital heart disease (OR = 2.56; 95% CI: 1.46–4.51). Although the pooled estimate for chronic lung disease suggested increased risk, the association was not statistically significant (OR = 1.30; 95% CI: 0.79–2.14). Heterogeneity was substantial for age below six months but low to moderate for the remaining analyses. These findings highlight the importance of young age, prematurity, and congenital heart disease as key determinants of severe RSV outcomes and may help identify populations at increased risk of severe disease.**

***Index Terms*—Respiratory syncytial virus (RSV), severe disease, risk factors, prematurity, congenital heart disease, meta-analysis, systematic review.**

I. Introduction

Respiratory syncytial virus (RSV) is the leading etiological agent associated with acute lower respiratory tract infections in infants and young children. The global burden of morbidity and mortality attributable to RSV is considerable among individuals aged 0 to 60 months, with the highest impact observed during the first six months of life and in low- and middle-income countries. Estimates suggest that approximately one in every 50 deaths in this age group, and one in every 28 deaths among children aged 28 days to 6 months, are due to RSV infection. Furthermore, for each hospital death related to RSV-associated acute lower respiratory infection, it is projected that about three additional deaths occur in community settings [1]. Consequently, RSV infections in young children entail substantial healthcare resource utilization. Although even severe cases typically do not require specific diagnostic tests or targeted antiviral treatments, the overall economic burden is considerable, reflecting the high costs associated with hospitalizations and outpatient care worldwide [2].

Monoclonal antibodies have emerged as important options for the prevention of RSV infection, particularly in vulnerable pediatric populations. Palivizumab, the first widely used agent, has demonstrated effectiveness but is limited in its broader application due to cost considerations and the need for repeated dosing [3]. More recently, newer long-acting monoclonal antibodies such as nirsevimab have been developed, offering the advantage of extended protection with a simplified administration schedule [4]. In parallel, advances in maternal vaccination strategies—leveraging transplacental antibody transfer—have shown promising efficacy in protecting infants during early life [5].

Together, these evolving preventive approaches represent significant progress in reducing the impact of RSV. However, given the substantial healthcare burden associated with RSV infections, particularly in young children, careful consideration of cost-effectiveness and population-level impact remains essential. Identifying those infants at highest risk of severe disease continues to be a key challenge in optimizing the use of these preventive strategies [6].

Risk factors associated with RSV-related hospitalizations have been widely investigated. However, less is known about the determinants of severe outcomes—such as mortality, admission to intensive care units, need for ventilatory support, or prolonged hospital stays—which represent the most critical events to prevent but are often difficult to study due to limited statistical power [7].

In this context, a comprehensive understanding of the factors associated with severe RSV outcomes is crucial to inform clinical decision-making and optimize preventive strategies [8]. However, existing evidence remains fragmented, with variability in study designs, populations, and outcome definitions limiting the ability to draw consistent conclusions [7].

Therefore, this study aims to systematically synthesize the available evidence on risk factors associated with severe RSV infection in young children through a systematic review and meta-analysis. By identifying and quantifying the key determinants of severe outcomes, this work seeks to support risk stratification approaches, contribute to the more efficient

allocation of emerging preventive interventions, and provide evidence that may inform the development of future predictive models for severe RSV outcomes.

II. Methods

A. Search strategy

This systematic review was guided by the research question: "Which factors are associated with severe outcomes in infants and children with respiratory syncytial virus (RSV) infection?". To address this question, a comprehensive search was conducted in PubMed, Embase and Scopus, covering the period 2006–2026. The search combined controlled descriptors (MeSH/Emtree) and free-text terms related to RSV, disease severity (ICU admission, mechanical ventilation, mortality), risk factors, and pediatric populations. Search strategies were tailored to the indexing structure of each database, and filters were applied to include observational analytical studies while excluding randomized trials, reviews, and other non-eligible designs. Full search strings for each database are provided in TABLE I, with the final search date of June 15, 2026.

The study selection process followed the PRISMA 2020 guidelines for systematic reviews and meta-analyzes [9]. All records retrieved were imported into Rayyan, a web-based application for systematic reviews [10]. Duplicate records were removed using Rayyan software, which also supported the screening. No protocol was registered for this review and screening was performed by a single reviewer in all three sequential phases: (i) title and abstract screening to exclude irrelevant studies; (ii) full-text assessment of potentially eligible articles against predefined inclusion and exclusion criteria; and (iii) final selection of studies meeting all eligibility requirements. This structured approach ensured transparency, reproducibility, and methodological rigor.

B. Eligibility Criteria

- **Inclusion:** observational analytical studies (cohort or case-control) evaluating infants and children (0–5 years) with RSV infection, reporting risk factors associated with severe outcomes (ICU admission, ventilatory support, mortality) and presenting bi-variate/multivariate analysis.
- **Exclusion:** studies with adult populations, descriptive-only designs, subjective severity scores, cross-sectional studies, randomized trials, reviews, editorials, case reports.
- **Outcomes Definition:** severe outcomes were defined as ICU admission, need for invasive or non-invasive ventilatory support, or death. Studies using composite severity scores were excluded to ensure comparability across included studies. These endpoints were chosen because they are objective events, consistently reported across studies, and therefore allow comparability. In contrast, outcomes based on symptom scores, laboratory markers, or composite severity indices are more subjective and vary widely between studies, making them difficult to standardize.

TABLE I: Search strategy by database (performed on 15 June 2026)

Database	Search strategy
PubMed	("Respiratory Syncytial Virus"[Mesh] OR RSV OR "respiratory syncytial virus") AND ("Disease Severity"[Mesh] OR severity OR ICU OR "intensive care" OR mortality OR "mechanical ventilation") AND ("Risk Factors"[Mesh] OR "risk factor*" OR predictor* OR determinant*) AND ("Infant"[Mesh] OR "Child"[Mesh] OR infant* OR child* OR pediatric* OR paediatric*) Filters: Observational Study.

C. Data Extraction and Synthesis

- **Data extraction:** study data were collected by a single reviewer using a standardized extraction form. For each eligible study, information was collected on study characteristics (author, year, country, sample size, age group, and definition of severe outcome) and risk factors reported in bi-variate or multivariate analyses. When available, odds ratios (OR) with 95% confidence intervals (CI) were extracted as the primary measure of association. Relative risks (RR) and hazard ratios (HR) were noted but not included in quantitative pooling. Extracted data were organized into structured datasets to facilitate both narrative synthesis and meta-analysis.
