Next, the cocultures were incubated for 2 h under standard conditions (37ºC and 5% CO_2) in the absence of light. Subsequently, 100 µL supernatants from each well were transferred to a 96-well microplate. Then, fluorescence intensity was detected using a microplate spectrophotometer (Excitation: 544 nm; Emission: 590 nm). The same analysis were repeated for the 24 h incubation group. Data were normalized and expressed as a percentage relative to the untreated control group. All experimental conditions were executed in independent triplicates.

D. Cell Fixation and Morphological Analysis

Following the 24 h treatment period, the culture medium was removed, and the cocultures were fixed with 4% paraformaldehyde (PFA, dissolved in phosphate-buffered saline, PBS) for 10 min at room temperature. For the assessment of cellular integrity and neurite outgrowth, digital

photomicrographs were captured using a brightfield and phase-contrast optical microscope.

Concurrently, to evaluate the formation and accumulation of protein aggregates, fixed cells were subjected to a Congo Red binding assay by incubation with a 0.5% Congo Red working solution (w/v, in PBS) for 30 min. After rinsing three times with PBS to eliminate excess dye, the protein deposition was recorded via optical microscopy.

E. Statistical analysis

The assays were performed in two independent biological experiments, with each experimental condition evaluated in triplicate. Data are expressed as mean ± standard deviation (SD). Statistical significance between groups was evaluated using one-way analysis of variance (ANOVA) followed by Dunnett's post hoc test for multiple comparisons between each group and the control, using GraphPad Prism 5.0. Graphs were generated using OriginPro 8.5.

III. Results and Discussion

A. Metabolic response of neuroglial cocultures following Spike exposure and photobiomodulation

Figure 1 shows that exposure of the SH-SY5Y/U87MG neuroglial coculture to the SARS-CoV-2 Spike protein reduced metabolic activity, as measured by the Alamar Blue assay, to approximately 77% and 75% of the control at 2 and 24 h, respectively. In contrast, PBM partially preserved metabolic activity at 2 h and promoted a marked increase after 24 h, with values reaching approximately 130% of the untreated control. PBM alone maintained metabolic activity close to the control after 2 h, whereas a lower metabolic response was observed after 24 h.

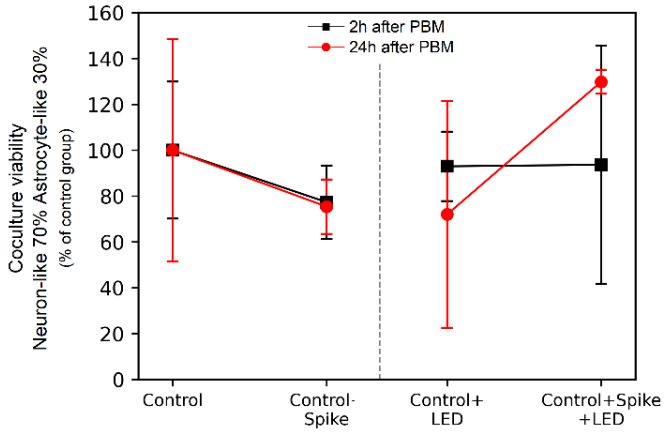

Fig. 1. Effect of photobiomodulation on the metabolic activity of SH-SY5Y/U87MG neuroglial cocultures exposed to the SARS-CoV-2 Spike protein. Metabolic activity was assessed by the Alamar Blue assay at 2 and 24 h after PBM. Data are expressed as a percentage of the untreated control and presented as mean ± SD.

The reduction in metabolic activity induced by the Spike protein is consistent with previous studies demonstrating that this viral protein impairs mitochondrial function, increases oxidative stress, and compromises neuronal metabolism [2]. Since the present model consists of a neuroglial coculture, the observed response likely reflects alterations in neuron–astrocyte interactions. Astrocytes are fundamental for neuronal metabolic support and redox homeostasis, but under pathological conditions they may acquire reactive phenotypes that contribute to neuronal dysfunction through the release of inflammatory mediators and ROS [3, 4].

PBM has been extensively described as a mitochondrial modulator capable of enhancing oxidative phosphorylation, ATP synthesis, and redox signaling, mechanisms that are largely attributed to the activation of cytochrome c oxidase [10]. These mechanisms may explain the recovery observed in the Spike + PBM group, particularly after 24 h, suggesting that PBM promotes a delayed metabolic adaptation following cellular injury.

Furthermore, in a differentiated SH-SY5Y neuronal model, PBM attenuated the deleterious effects induced by the SARS-CoV-2 Spike protein, preserving cell viability and reducing cellular damage [11]. As well, PBM demonstrated neuroprotective effects in a three-dimensional Alzheimer's disease model subjected to oxidative stress, reinforcing its ability to improve cellular responses under neurodegenerative conditions [12]. Together, these findings suggest that the beneficial effects of PBM are maintained in more physiologically relevant neuroglial coculture models.

Although the Spike + PBM group presented metabolic activity above the control after 24 h, this result should be interpreted cautiously. Alamar Blue primarily measures cellular reducing capacity rather than absolute cell number, indicating that the increased signal may reflect enhanced mitochondrial metabolism, increased proliferation, or an adaptive metabolic response rather than exclusively improved cell survival [15].

Overall, these findings suggest that PBM mitigates the metabolic impairment induced by the SARS-CoV-2 Spike protein in a neuroglial coculture model, supporting its potential as a therapeutic strategy for neuroinflammatory conditions associated with mitochondrial dysfunction.

B. Evaluation of protein aggregation by Congo Red staining

Congo Red staining performed 24 h after irradiation revealed distinct distribution patterns of Congo Red-positive material among the experimental groups (Figure 2). The untreated control exhibited predominantly intracellular and perinuclear staining, with preserved cellular morphology and elongated neurite-like processes. In contrast, qualitative inspection of the Spike-exposed co-cultures revealed discrete Congo Red-positive regions distributed along cellular processes and in pericellular areas (indicated by green arrows), accompanie by an apparent loss of neurite-like continuity.

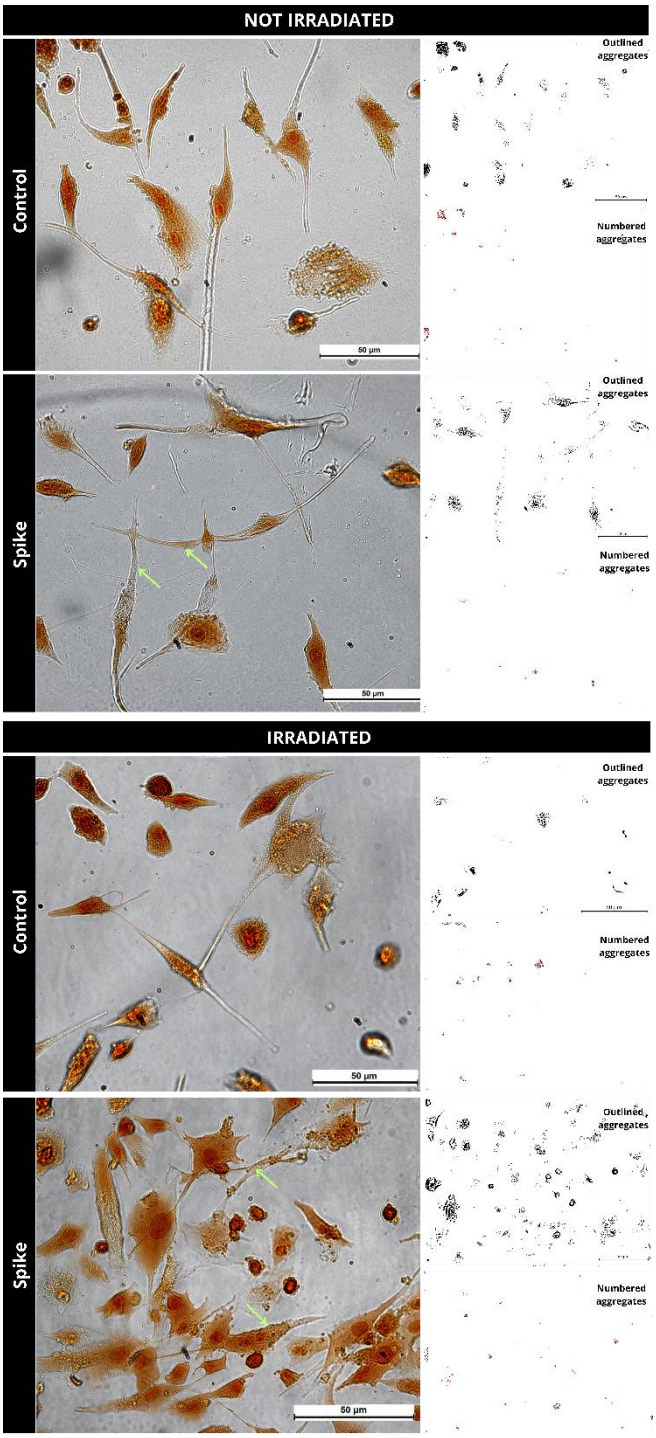

Fig. 2. Representative Congo Red staining of SH-SY5Y/U87MG neuroglial cocultures exposed to the SARS-CoV-2 Spike protein and treated with PBM. Representative brightfield images were acquired 24 h after PBM. Green arrows indicate representative Congo Red-positive regions, which are qualitatively compatible with the presence of protein aggregates. Scale bars = 50 µm

The PBM-treated control displayed Congo Red staining mainly associated with the cell bodies, without evident accumulation along cellular processes. In the Spike + PBM group, Congo Red-positive material remained detectable; however, the staining was predominantly localized around the cell bodies and in discrete pericellular regions, unlike the Spike group, which exhibited more pronounced deposits along neurite-like processes.

To quantitatively complement the citological findings, morphometric analysis of Congo Red-positive deposits was performed across the experimental groups (Figure 3). Evaluation of the total number of aggregates revealed no statistically significant differences among the groups (Figure 3A), despite a numerical trend toward increased aggregate counts in the Spike + PBM condition ($109.8 \pm \mathrm{SD}$; $p = 0.2025$ vs. Spike). Similarly, assessment of the total aggregate area per field demonstrated comparable coverage across all conditions (Figure 3B; $p = 0.6660$ for Control vs. PBM; $p = 0.9958$ for Control vs. Spike; and $p = 0.5724$ for Spike vs. Spike + PBM). Furthermore, analysis of individual aggregate dimensions indicated that average particle size remained statistically unaltered among groups (Figure 3C; $p > 0.05$).

Taken together, these morphometric analyses indicate that neither Spike exposure nor PBM treatment significantly altered the gross accumulation, total area coverage, or size profile of Congo Red-positive material at 24 h post-irradiation. Instead, the differences observed microscopically (Figure 2) reflect a spatial redistribution—shifting aggregates away from vulnerable neurite-like extensions toward somatic and pericellular compartments in the Spike + PBM group-rather than an immediate bulk clearance of protein deposits.

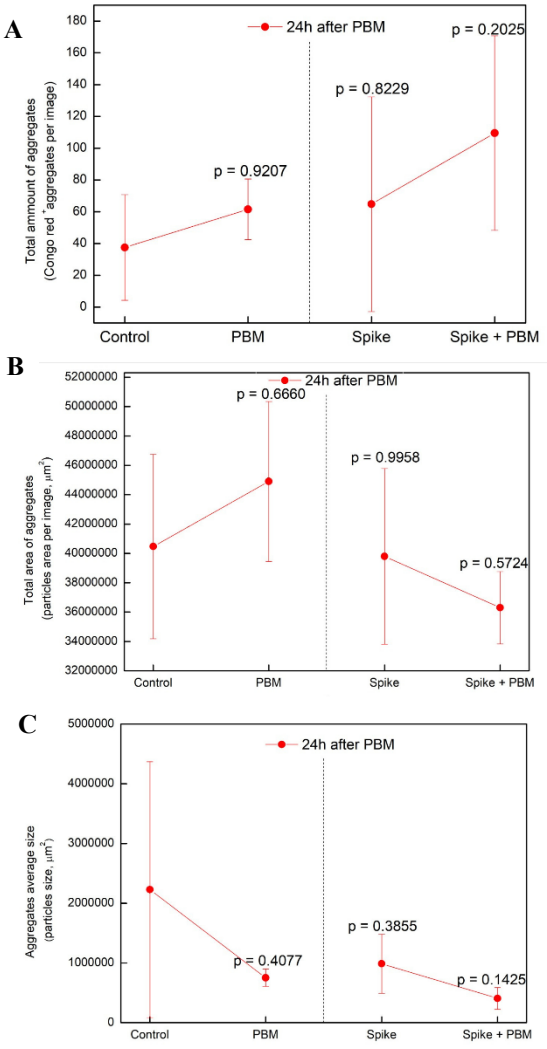

Fig. 3. Morphometric quantification of Congo Red-positive aggregates in SH-SY5Y/U87MG neuroglial cocultures. Cocultures exposed to the SARS-CoV-2 Spike protein and treated with photobiomodulation (PBM) were evaluated 24 h post-irradiation. Quantitative particle analyses include: (A) total number of Congo Red-positive aggregates per image field; (B) total aggregate area per image (µm²); and (C) average aggregate size (µm²).

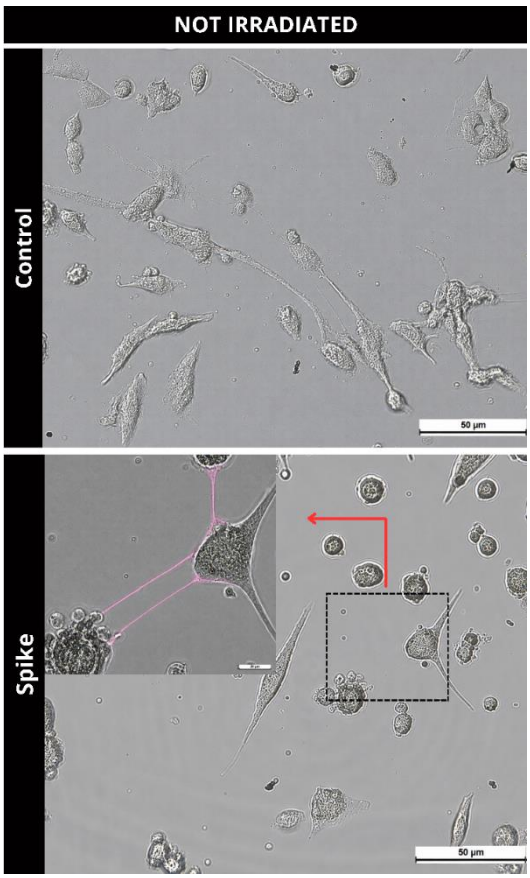

The SARS-CoV-2 Spike protein contains amyloidogenic segments capable of self-assembling into β-sheet-rich fibrillar aggregates following proteolytic cleavage [16]. Furthermore, Spike-derived fragments have been shown to interact with amyloid- β , accelerating aggregation and enhancing neurotoxicity in experimental models [17]. Consistent with these mechanisms, the presence of Congo Red-positive material in Spike-treated cultures is compatible with amyloid-like aggregation.

Consistent with the present findings, our previous work demonstrated that PBM protects neuronal cells against the deleterious effects of the SARS-CoV-2 Spike protein [11] and mitigates oxidative stress in a three-dimensional neurodegenerative model [12]. These findings are consistent with literature demonstrating that PBM improves mitochondrial function, cellular redox balance and protein homeostasis [10], mechanisms that may be associated with the cellular response to protein aggregation.

Importantly, while quantitative assessment revealed that PBM did not significantly alter the overall number of Congo Red-positive aggregates at 24 h post-irradiation (Figure 3), microscopic examination revealed a clear spatial redistribution: aggregates shifted from vulnerable neurite-like processes in the Spike group toward somatic and pericellular compartments in the Spike + PBM group. This suggests that the protective effects of PBM in this model may be related to cellular compartmentalization and preservation of neurite integrity rather than an immediate clearance of amyloid aggregates at this early time point.

C. Structural organization of the neuroglial network

Brightfield microscopy performed 2 h after PBM revealed distinct differences in the structural organization of the neuroglial network among the experimental groups (Figure 4).

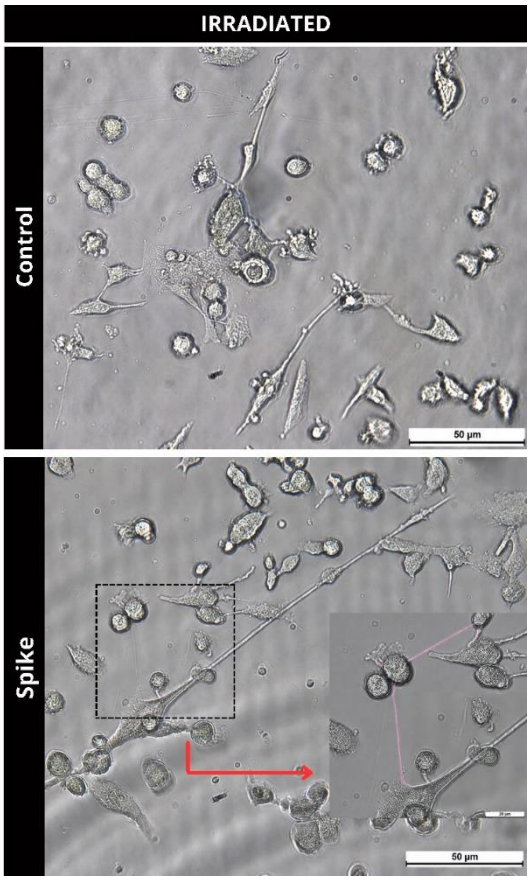

Fig. 4. Representative brightfield images showing the structural organization of SH-SY5Y/U87MG neuroglial cocultures exposed to the SARS-CoV-2 Spike protein and treated with photobiomodulation. Images were acquired 2 h after PBM. Enlarged regions highlight representative neurite-like processes establishing physical contacts between neighboring cells. Scale bars = 50 µm

In the control group, the coculture exhibited an organized cellular architecture composed of elongated neuron-like cells interconnected by thin neurite-like processes, together with cells displaying astrocyte-like morphology. Representative enlarged regions highlighted numerous fine cellular projections establishing physical contacts between neighboring cells, Suggesting the presence of neuron–glia-like cellular interactions within the SH-SY5Y/U87MG coculture.

These observations are consistent with previous studies demonstrating that neuroglial coculture models promote the formation of complex cellular networks through reciprocal interactions between neurons and astrocytes. Astrocytes provide structural and metabolic support, regulate extracellular homeostasis, and contribute to neurite stabilization, resulting in a more physiologically relevant in vitro microenvironment than neuronal monocultures [5, 6].

Exposure to the SARS-CoV-2 Spike protein Qualitative inspection of the brightfield images revealed apparent alterations in the structural organization of the neuroglial network in the Spike-treated group. The Spike-treated group qualitatively exhibited greater cell rounding, an apparent reduction in neurite-like continuity, and fewer visible intercellular contacts compared with the untreated control compared with the untreated control. These findings are consistent with previous reports demonstrating that the SARS-CoV-2 Spike protein promotes cytoskeletal remodeling, mitochondrial dysfunction, and oxidative stress, ultimately impairing neuronal morphology and cellular homeostasis [2].

Interestingly, Qualitative inspection suggested that the PBM-treated coculture retained a structural organization broadly comparable to that of the untreated control, preserving elongated neurite-like processes and extensive intercellular contacts. Likewise, although morphological alterations remained evident in the Spike + PBM group, representative enlarged regions demonstrated the persistence of thin neurite-like processes establishing physical contacts between neighboring cells. The apparent maintenance of these structural connections is consistent with a possible role of PBM in preserving aspects of neuroglial network organization during the early response to Spike exposure of the neuroglial network during the early response to Spike-induced injury.

The maintenance of neuron–glia interactions is essential for neuronal survival and tissue homeostasis. Astrocytes actively regulate synaptic function, neurotransmitter recycling, metabolic support and antioxidant defenses, while neurons provide reciprocal signals that modulate astrocytic activity [3-5]. Therefore, disruption of this structural organization may compromise the coordinated cellular responses required for maintaining neural tissue integrity. Conversely, preservation of the neuroglial network, even in the presence of cellular injury, may represent an important component of the neuroprotective effects associated with PBM.

These observations are supported by previous evidence showing that PBM preserves mitochondrial bioenergetics, reduces oxidative stress, and contributes to cytoskeletal maintenance, thereby favoring neuronal morphology and neurite integrity [10, 13]. Collectively, these mechanisms may explain the greater preservation of the neuroglial network architecture observed in the Spike + PBM group.

Overall, qualitative morphological observations suggest that exposure to the SARS-CoV-2 Spike protein is associated with alterations in the apparent structural organization of SH-SY5Y/U87MG neuroglial cocultures, whereas PBM appears to partially preserve aspects of the cellular network organization and visible intercellular contacts during the early period following Spike exposure , at least partially, the physical intercellular connections that characterize the neuroglial network during the early stages following Spike-induced.

IV. Conclusion

Overall, the present findings indicate that exposure to the SARS-CoV-2 Spike protein is associated with metabolic impairment and qualitative alterations in the structural organization and distribution of Congo Red-positive material in SH-SY5Y/U87MG neuroglial co-cultures. PBM partially attenuated the metabolic impairment induced by Spike exposure and was associated with the preservation of apparent neurite-like processes and intercellular contacts, particularly during the early response. Although the morphological and Congo Red findings were evaluated qualitatively in the present study, quantitative analysis of the Congo Red-positive area will be performed to further characterize the observed staining pattern.

Future studies should also incorporate quantitative assessment of morphological parameters, including the number and length of cellular processes, connection density, and other relevant structural features, together with appropriate statistical analyses. These complementary approaches may provide a more comprehensive understanding of the effects of Spike exposure and the potential neuroprotective mechanisms of PBM in neuroglial co-culture models.

Acknowledgment

The authors gratefully acknowledge Prof. Dr. Leandro José Raniero and his research team for providing access to the microplate reader and for their technical support. The authors also thank Prof. Dr. Juliana Ferreira Strixino and her research team for granting access to the LED irradiation chamber.

***Abstract*—Spinal cord injury can result in persistent motor, sensory, and autonomic deficits, and functional recovery remains limited, particularly in individuals with chronic complete injuries. Strategies combining different levels of the sensorimotor system have been investigated as alternatives to increase neural engagement during rehabilitation. This study presents and discusses the neuroanatomical, neurophysiological, and experimental foundations supporting the integration of motor imagery, brain-computer interfaces, transcutaneous spinal direct current stimulation, and robotic locomotor training. Available evidence indicates that individuals with complete spinal cord injury may retain cortical activity related to motor imagery, that this activity can be identified and used by brain-computer interfaces during locomotor training, and that transcutaneous spinal direct current stimulation can modify measures related to spinal excitability. Studies also indicate the feasibility of combining spinal neuromodulation with locomotor training. However, this evidence is mainly derived from investigations of the individual components or partial combinations and does not demonstrate that temporally conditioning stimulation to cortical activity produces effects superior to stimulation applied independently of cortical state. Therefore, the synchronization of motor intention, spinal modulation, and locomotor afferent input represents a neurophysiologically plausible hypothesis whose contribution to plasticity and functional recovery after spinal cord injury still requires specific experimental evaluation.**

***Index Terms*—transcutaneous spinal cord stimulation; motor imagery; brain–computer interface; spinal cord injury; paraplegia; robotic gait; neurorehabilitation.**

I. Introduction

Spinal cord injury (SCI) is associated with motor, sensory, and autonomic impairments that may persist throughout life and impose important limitations on functional independence. Global Burden of Disease data indicate that the global age-standardized incidence was estimated at 7.1 cases per 100,000 population and prevalence at 183.6 cases per 100,000 population, with heterogeneous distribution across regions, age groups, and sexes [1]. In developing countries, traumatic SCI occurs predominantly in young men, with motor vehicle accidents and falls being its main etiologies [2]. In Brazil, Faleiros et al. observed a predominance of traumatic injuries in a national sample, with traffic accidents accounting for 40.8% of cases, followed by firearm or knife injuries, at 17.5%, and falls, at 10.7% [3]. Locomotor rehabilitation after SCI remains challenging, particularly in the presence of severe neurological impairments. Robotic technologies have been employed to provide repetitive and standardized training of the lower limbs, with the possibility of controlling assistance, body-weight support, and gait speed. However, systematic reviews indicate that the benefits of robotic training vary according to the population, outcome, and protocol employed, and the available evidence does not support consistent superiority of robotic training across all functional domains assessed [4], [5]. These findings have encouraged the investigation of strategies capable of combining locomotor training with interventions acting at different levels of the nervous system. Among these strategies are brain-computer interfaces (BCIs), which use neural signals to identify states related to movement intention or representation and convert them into information capable of controlling external systems and/or devices. Electroencephalography (EEG) is widely used in this context because it enables noninvasive acquisition with high temporal resolution. During motor imagery (MI), changes in sensorimotor rhythms can be used as features for classification, although the performance of these systems depends on the protocol employed, signal quality, and interindividual variability [6]. In individuals with complete SCI, MI remains capable of recruiting cortical sensorimotor regions, providing neurophysiological support for the use of this activity as an input signal for BCIs even in the absence of observable voluntary movement [7].

Studies conducted specifically in the context of locomo-

tor training also demonstrate the possibility of integrating MI and cortical activity with the use of the Lokomat. Serafini et al. investigated visual neurofeedback associated with gait imagery during passive Lokomat training in individuals with complete SCI, observing modulation of sensorimotor rhythms and electrophysiological changes throughout training [8]. Subsequently, Blanco-Diaz et al. developed a multichannel EEG-based BCI capable of discriminating passive walking without MI from passive walking associated with gait imagery, achieving a mean classification accuracy of 74.4% in individuals with motor-complete SCI [9]. These results demonstrate the feasibility of accessing and classifying cortical states associated with gait imagery during robotic training, although they do not, in isolation, constitute evidence of the clinical efficacy of the BCI. In parallel, noninvasive spinal neuromodulation techniques have been investigated as a means of modifying the functional state of circuits located below the injury. Among them, transcutaneous spinal direct current stimulation (tsDCS) applies low-intensity direct current for neuromodulatory purposes. Studies conducted in individuals with SCI have demonstrated changes in measures of spinal excitability after tsDCS, whereas studies combining the technique with locomotor training have indicated the feasibility of repeated application, although there is still insufficient evidence to establish consistent functional benefits [10], [11].

The possibility of relating voluntary cortical activity, spinal modulation, and sensorimotor afference produced by locomotor training therefore represents a relevant question for neuroengineering applied to SCI. Although these components have been investigated individually or in different combinations, it remains uncertain whether establishing a temporal association between the cortical state related to motor intention and spinal neuromodulation produces effects different from those observed when stimulation is applied independently of the cortical state. In this context, this study presents and discusses the neuroanatomical, neurophysiological, and experimental foundations supporting the integration of motor imagery-based BCI, tsDCS, and robotic locomotor training, considering the available evidence, its limitations, and the questions that remain open for investigation.

II. Literature Review

1) Neuroanatomical and neurophysiological bases of sensorimotor integration: Motor imagery corresponds to the internal representation of an action without its physical execution and can recruit components of the cortical network involved in movement planning and control. In the kinesthetic modality, this representation emphasizes the sensations associated with task execution, including proprioceptive and kinesthetic aspects. In individuals with complete SCI, neuroimaging studies demonstrate that MI remains capable of activating sensorimotor regions. Wang et al. observed, in individuals with complete SCI, greater activation of sensorimotor areas during MI, associated with changes in effective connectivity between sensorimotor regions and areas related to cognitive processing [7]. These findings indicate that components of the cortical networks related to movement representation remain functionally recruitable after injury, although their organization may differ from that observed in neurologically intact individuals. The clinical classification of an SCI as complete should not be interpreted as evidence of absolute anatomical interruption of all connections across the injury site. Sherwood et al. identified, through neurophysiological assessments, residual brain influence below the level of injury in individuals clinically classified as having complete SCI, a condition termed "discomplete SCI" by the authors [12]. The high frequency observed in that study should not be generalized to the entire population with complete SCI, considering the specific characteristics of the sample investigated. Nevertheless, the findings demonstrate that the absence of clinically detectable voluntary movement and the absolute absence of descending influence are not equivalent concepts. The spinal cord, in turn, is not merely a passive pathway for the transmission of supraspinal commands. Spinal interneuronal circuits integrate descending and afferent information and participate in the organization of motor activity. Particularly during locomotion, sensory information from muscles, tendons, joints, and skin continuously modifies the activity of these networks. Experimental evidence highlights proprioception as a relevant component of motor circuit reorganization after SCI, influencing the plasticity of spinal networks and movement recovery [13]. However, an important part of this mechanistic knowledge derives from experimental models, and caution should therefore be exercised when extrapolating it directly to individuals with complete SCI. Sensory afferents produced by movement also participate in reorganization at supraspinal levels. Moreno-López and Hollis highlight that SCI can induce remodeling of sensory circuits at different levels of the nervous system and that the interaction between somatosensory and motor processing is relevant to the reorganization associated with movement recovery [14]. Thus, peripheral feedback produced during locomotor training should be understood as an active component of sensorimotor dynamics rather than merely as a mechanical consequence of movement.

In this context, tsDCS represents a means of modifying the excitability state of spinal circuits without necessarily directly producing action potentials. Hubli et al. demonstrated that the application of anodal tsDCS over the spinal region in individuals with motor-complete SCI increased spinal reflex amplitude and reduced its threshold, whereas equivalent effects were not observed under the other conditions evaluated [10]. The authors themselves emphasized that the mechanisms responsible for the effect remained partially unknown. Thus, these results support the ability of tsDCS to modify measures related to spinal circuit excitability but do not allow its effects to be considered uniformly excitatory. This caution is reinforced by subsequent studies. Powell et al. investigated the effects of different tsDCS polarities on corticospinal excitability in individuals with chronic incomplete SCI and did not observe consistent significant differences in motor-evoked potential amplitude between conditions [15]. More recently, Sayed Ahmad and Knikou observed muscle-

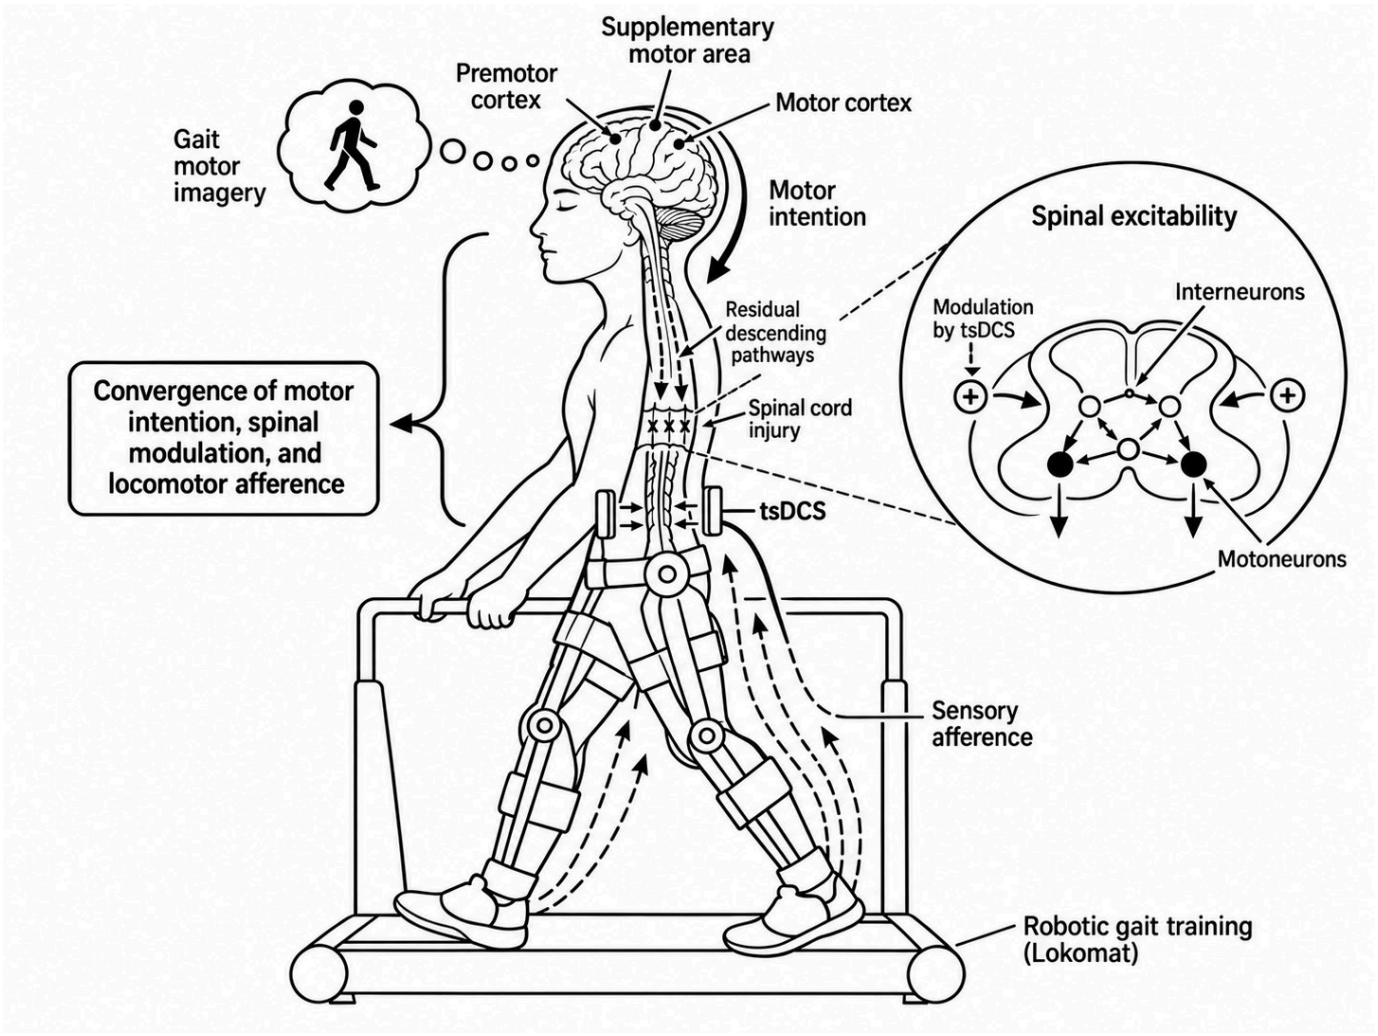

Fig. 1. Neuroanatomical and neurophysiological bases of sensorimotor integration. Gait motor imagery recruits cortical areas involved in movement planning and representation, while possible residual descending pathways maintain influence over spinal circuits below the injury. Transcutaneous spinal direct current stimulation modulates the excitability of spinal networks, and robotic gait training provides task-related sensory afferent input. The convergence of motor intention, spinal modulation, and sensorimotor feedback constitutes the physiological basis for investigating activity-dependent neuromodulation strategies.

and circuit-dependent responses after repeated applications of transspinal direct current stimulation in individuals with SCI [16]. Taken together, these findings suggest that polarity, electrode placement, neurological characteristics, and the neurophysiological variable analyzed may influence the response to stimulation, making it inappropriate to attribute a simple relationship between polarity and functional effect to tsDCS. The integration of these mechanisms provides a physiological basis for investigating interventions that bring voluntary cortical activity, spinal modulation, and sensory afference into closer temporal association. MI enables the recruitment of cortical networks related to movement representation; tsDCS can alter the excitability state of spinal networks; and locomotor training produces repetitive task-related afferent input. These components act at different but functionally interdependent levels of the sensorimotor system [7], [10], [13], [14]. The possibility of bringing them into temporal proximity constitutes a physiologically plausible hypothesis of activity-dependent modulation, but this plausibility should not be confused with demonstration of the clinical superiority of the combination.

2) neurofeedback and brain-computer interfaces in motor rehabilitation: Neurofeedback (NFB) and MI-based BCIs use cortical activity in complementary ways. In NFB, information derived from neural activity is presented to the participant in order to enable training in the self-regulation of specific electrophysiological patterns. In BCIs, neural signals are processed to identify different states and produce a control output. In EEG- and MI-based systems, changes in sensorimotor rhythms, particularly in the mu and beta bands, can contribute to discrimination between states related to the motor task [6], [9] . The performance of these interfaces varies among participants, making training and calibration relevant components. Zhou et al. investigated NFB based on relative alpha-band power in neurologically intact individuals and observed an increase in this power associated with an overall improvement

in the performance of an MI-based BCI [17]. However, the effects showed interindividual variability, and not all comparisons related to classification performance showed significant improvement. These results demonstrate that the ability to self-regulate cortical rhythms can be trained, but they also reinforce that the effects of NFB are not uniform across individuals. In people with SCI, the possibility of using cortical activity associated with MI is supported by both neuroimaging studies and BCI applications. Preservation of sensorimotor area recruitment during MI [7] provides the neurophysiological basis for this type of interface. In the specific context of gait, Blanco-Diaz et al. used multichannel EEG recordings to classify passive walking without MI and passive walking associated with gait imagery during Lokomat use. The BCI employed participant-specific calibration and achieved a mean accuracy of 74.4% [9]. The study also demonstrated changes in features related to class separability and cortical self-regulation over the sessions. These results should be interpreted primarily as evidence of the technical feasibility of classification and NFB, rather than as proof of functional recovery resulting from the BCI. Serafini et al. also investigated gait MI and NFB during robotic locomotor training in individuals with complete SCI. In a study involving two participants who underwent 12 sessions, changes in sensorimotor rhythm power, increases in measures of brain connectivity, and changes in clinical assessments were observed after the intervention [8]. However, the small sample size, the absence of a parallel control group in the published study, and the multimodal nature of the intervention prevent the clinical findings from being attributed specifically to NFB or MI. The study is particularly relevant because it demonstrates that this paradigm can be implemented in individuals with complete SCI during Lokomat training and provides preliminary data on cortical modulation in this context. Cortical activity classified by the BCI can also be used as a signal to condition an external intervention. Kumari et al. evaluated an EEG-based BCI associated with functional electrical stimulation before physical practice of the upper limbs in people with SCI. The mean BCI accuracy was approximately 85%, demonstrating the feasibility of cortical activity-dependent control [18]. Nevertheless, no significant differences were identified between groups in the main physical outcomes, and the authors emphasized limitations related to sample size. Therefore, the study supports the feasibility of temporally conditioning an external intervention to cortical activity but does not allow the conclusion that such conditioning is, by itself, sufficient to produce greater clinical recovery. When the output of a BCI is used to directly control another intervention, classifier performance assumes additional importance. A classification error no longer affects only the quality of neurofeedback and may determine whether an intervention occurs or fails to occur at an inappropriate moment. In this scenario, individual calibration, discriminative ability, false activations, and the temporal relationship between identification of the neural state and device response become relevant parameters for characterizing the control architecture. The study by Blanco-Diaz et al. provides an important technical basis by demonstrating individual calibration and classification of gait imagery [9], but the use of this signal as a controller of a neuromodulatory intervention represents a different purpose from that originally evaluated.

III. Integration of cortical activity, spinal neuromodulation, and robotic locomotor training

The combination of BCI, tsDCS, and robotic locomotor training enables the integration of cortical, spinal, and peripheral components of the sensorimotor system. In this arrangement, cortical activity related to MI can be used not only to provide feedback to the participant but also as a variable to determine the timing of an external intervention. tsDCS may act on the excitability state of spinal circuits, while locomotor training provides task-related afferent input. Thus, the association does not imply replacement of corticospinal conduction but establishes a functional relationship between the detection of a cortical state and an intervention applied at the spinal level. The concomitant application of tsDCS and locomotor training has already been investigated independently of BCI. Hawkins et al. evaluated the safety and feasibility of this combination in individuals with chronic incomplete SCI. Following an initial single-session study, the authors conducted a 16-session intervention comparing tsDCS combined with locomotor training with sham stimulation combined with the same training. The combination was considered safe and feasible, and gait outcomes varied among participants; three of the four participants in the active group showed improvements in speed above the minimal clinically important difference, compared with one of the four participants in the sham group, whereas endurance gains above this threshold occurred in one participant in each group [11]. Given the small sample size, the authors themselves considered further investigation of the efficacy of the approach necessary. Thus, the conceptual difference between continuous tsDCS application and its application conditioned by the BCI lies mainly in dependence on the cortical state. In the first situation, stimulation occurs independently of activity related to motor intention. In the second, detection of a cortical pattern associated with MI can determine when spinal modulation is applied. The hypothesis of interest is therefore whether the functional state of the nervous system at the time of stimulation influences the response produced by the combination of neuromodulation and locomotor practice. The available literature provides support for the components of this integration, but at different levels of evidence. Activity related to gait imagery can be detected during Lokomat training [9]; individuals with SCI can use cortical activity to control external interventions [18]; tsDCS can modify measures of spinal excitability [10], [15], [16] and the combination of tsDCS and locomotor training has been shown to be feasible in individuals with incomplete SCI [11] . However, none of this evidence demonstrates that temporally conditioning tsDCS to MI during robotic locomotor training produces effects superior to those obtained when stimulation

is applied independently of cortical state. Investigation of this difference therefore remains an open experimental question.

IV. Discussion

The evidence analyzed supports the possibility of accessing different components of the sensorimotor system after SCI, but it also demonstrates that these components are at different levels of scientific maturity. Cortical activity associated with MI may persist after clinically complete injuries [7], and studies by Serafini and Blanco-Diaz demonstrate that this activity can be incorporated into robotic locomotor training paradigms using EEG and NFB [8], [9]. At the same time, studies using tsDCS indicate an ability to modify spinal neurophysiological measures, although the direction of the effects varies across experiments and depends on methodological and individual characteristics [10], [15], [16]. Therefore, the integration of these technologies has an experimental basis but cannot be presented as an intervention whose efficacy has already been established. The studies by Serafini et al. and Blanco-Diaz et al. are particularly relevant because they were conducted in the same functional context considered in this line of investigation: gait imagery during passive Lokomat training in people with severe SCI [8], [9]. Serafini et al. demonstrated that participants with complete SCI were able to perform NFB training related to mu and beta rhythms during assisted movement, whereas Blanco-Diaz et al. demonstrated that passive walking states with and without MI can be discriminated by a multichannel BCI, with a mean accuracy of 74.4% [8], [9]. Together, these studies support the feasibility of using brain activity related to gait imagery during robotic training. However, their results do not demonstrate that using this classification to control tsDCS produces an additional benefit, since conditioned spinal stimulation was not part of these protocols. Another relevant source of evidence comes from the randomized pilot trial by Nicolelis et al. [19]. The study included eight men with chronic traumatic SCI classified as AIS A, allocated to either assisted locomotor training alone or locomotor training combined with BMI, virtual reality, and tactile feedback. Both groups showed sensory and motor changes throughout the protocol, whereas the group receiving the multimodal intervention showed greater mean changes in measures such as Lower Extremity Motor Score, light touch, and pinprick [19]. Three of the four participants in the multimodal group and one of the four participants receiving locomotor training alone were classified as AIS C at the end of the protocol. However, the authors emphasized the small sample size and other limitations, including the absence of blinding of participants and caregivers. This study is important to the present discussion, but its interpretation requires caution. The experimental group in Nicolelis et al. simultaneously received BMI, visuohaptic feedback, and virtual reality, in addition to locomotor training, making it impossible to attribute the results specifically to the BMI. Furthermore, the BMI and locomotor training sessions did not constitute an architecture in which cortical classification temporally controlled spinal stimulation. The study provides evidence that a multimodal intervention incorporating cortical participation may be associated with greater neurological recovery than locomotor training alone in that pilot trial, but it does not test the specific hypothesis of synchronization between motor intention and tsDCS [19]. In the field of spinal neuromodulation, the available results also warrant a moderate interpretation. Hubli et al. demonstrated modulation of spinal reflexes after anodal tsDCS in individuals with motor-complete SCI [10]. Powell et al. found less consistent results when evaluating corticospinal excitability in individuals with incomplete SCI [15], and Sayed Ahmad and Knikou subsequently demonstrated that responses to transspinal direct current stimulation can vary according to muscles, circuits, and neurological characteristics [16]. Hawkins et al., in turn, provided evidence of safety and feasibility for repeated application of tsDCS during locomotor training, but with a sample insufficient to establish clinical efficacy [11]. These studies converge in demonstrating the ability of stimulation to modify the neurophysiological state of the spinal system, but they do not support a uniform response nor do they allow, based solely on the current literature, the definition of a universally superior configuration. This heterogeneity reinforces the relevance of separating two potentially distinct effects: the effect related to the application of tsDCS itself during training and a possible additional effect associated with its temporal conditioning to cortical activity. If a conditioned intervention is studied without an active nonconditioned condition, differences relative to sham would not allow determination of whether the outcome results from synchronization with motor intention or simply from the presence of spinal stimulation. Consequently, the conceptual comparison between cortical state-dependent and cortical state-independent stimulation is important for specifically investigating the contribution of temporal coupling, without assuming in advance that such coupling is superior. The plausibility of this hypothesis derives from the interdependent organization of the sensorimotor system. MI provides a cortical state related to the voluntary representation of movement; residual descending signals may remain present in some individuals clinically classified as complete [12]; tsDCS may modify the responsiveness of spinal circuits [10] ; and assisted movement provides task-related sensory afferents [13], [14]. However, the simultaneous presence of these mechanisms does not demonstrate that their synchronization necessarily produces functionally relevant plasticity. The temporal relationship between stimuli constitutes, in this context, a mechanistic hypothesis to be tested rather than an established effect. In addition to physiological uncertainties, there are important technical limitations. The performance of EEG-based BCIs varies among individuals, and an overall accuracy above chance does not fully describe the reliability required to control another intervention. In a conditioned architecture, false positives may trigger stimulation outside the intended cortical state, whereas false negatives may prevent its application when MI is present. For this reason, classifier performance metrics, calibration stability, and temporal characterization of the system become relevant components

in evaluating the integration. Blanco-Diaz et al. demonstrated that individual calibration and online classification are feasible during robotic gait [9], but transforming this output into a neuromodulation trigger introduces requirements that were not evaluated in that study. It is also necessary to consider that neurophysiological changes do not necessarily correspond to clinical recovery. Changes in EEG rhythms, connectivity, spinal excitability, or muscle recruitment may provide information about the response of the nervous system before or even in the absence of detectable changes in clinical scales. This distinction is particularly relevant in individuals with chronic complete SCI, in whom voluntary motor gains may be limited. Thus, future studies on the integration of BCI, tsDCS, and locomotor training should jointly interpret technical, electrophysiological, and clinical measures, avoiding the use of biomarker changes as automatic surrogates for functional recovery. Taken together, the literature analyzed allows a sequence of complementary evidence to be established: motor imagery can recruit cortical networks after complete SCI [7]; its activity can be detected and trained during assisted gait [8], [9]; cortical signals can control external interventions [18]; tsDCS can modify measures related to spinal excitability [10], [15], [16]; and its association with locomotor training is technically feasible [11] . The element that has not yet been demonstrated is whether temporally linking these components produces additional effects compared with stimulation applied independently of cortical state. This gap more precisely delineates the scientific contribution of the approach and avoids interpreting results from partial or multimodal interventions as direct evidence of the efficacy of a conditioned system.

V. Conclusion

The available evidence supports the neurophysiological plausibility of integrating MI-based BCI, tsDCS, and robotic locomotor training after SCI. These resources act on complementary components of the sensorimotor system: MI enables the recruitment of cortical networks related to movement representation, the BCI allows this activity to be identified and used as a control variable, tsDCS may modify the excitability state of spinal circuits, and locomotor training provides task-related sensory afferents. Previous studies demonstrate that people with complete SCI can exhibit cortical activity related to motor imagery and use NFB and BCI systems during locomotor training, whereas tsDCS studies provide evidence of neurophysiological modulation and the feasibility of combining it with locomotor training [8]–[11]. Multimodal interventions involving BMI and locomotor training have also shown relevant neurological outcomes in pilot studies [19]. However, none of this evidence directly demonstrates that temporally conditioning tsDCS to cortical activity produces effects superior to stimulation applied independently of cortical state. Thus, the main question arising from the literature is not whether each of these components can act on the sensorimotor system, but whether the temporal relationship between cortical motor intention, spinal modulation, and locomotor afference modifies the response produced by their combination. Experimental evaluation of this hypothesis, accompanied by objective measures of BCI performance, synchronization, safety, neurophysiological responses, and clinical outcomes, may contribute to clarifying the role of activity-dependent conditioning in future neuromodulation strategies after SCI.

***Abstract*— Parkinson's disease (PD) is a neurodegenerative disease of the Central Nervous System (CNS) characterized by motor symptoms. Bradykinesia is one of the most disabling manifestations of PD, generally defined as slowed movement execution; however, it is also associated with reduced spontaneous movements, decreased range of motion, and increased reaction time (RT). RT is a quantitative physiological marker widely used as an indicator of motor function in individuals with PD. This pilot study aimed to analyze RT in patients with PD in their ON and OFF medication states and in healthy controls. RT was calculated while participants performed a gross manual dexterity task with five interruption blocks. An inertial sensor with an accelerometer was placed on the dorsum of participants' hands to detect movement onset after auditory stimulation. Non-parametric tests were used given the small sample sizes, with Benjamini-Hochberg correction for multiple comparisons. Results indicate that RT was significantly longer in both PD groups compared to controls at Block 1. The PD-OFF group showed additional significant differences in Blocks 4 and 5, suggesting that without dopaminergic support, RT impairment persists under higher cumulative motor demand. The PD-ON group converged toward control performance across subsequent blocks, consistent with a preserved short-term adaptive effect. No significant ON vs OFF differences were found after correction.**

Keywords — Parkinson's disease, Bradykinesia, Reaction Time, Manual Dexterity, Inertial Sensor.

I. Introduction

Parkinson's disease (PD), first described by the physician James Parkinson (1755–1824) in his seminal "An Essay on the Shaking Palsy" [1] in 1817, is a chronic neurodegenerative disease of the Central Nervous System (CNS) that specifically affects the basal ganglia. It involves the degeneration of dopaminergic neurons in the substantia nigra, leading to decreased dopamine levels in the striatum and abnormal motor control [2]. PD is characterized by primary motor symptoms: tremor (involuntary oscillatory movements), bradykinesia (slowness and hesitation of movement), rigidity (increased muscle tone) and postural instability [3].

Bradykinesia is one of the most disabling manifestations of PD, broadly defined as slowness of movement execution [4]. It is also associated with reduced spontaneous movements, decreased range of motion, and increased Reaction Time (RT) [5, 6]. Evidence suggests that hypoactivation of the primary motor cortex (M1) or premotor areas may underlie the difficulties in preparing and initiating voluntary movements in individuals with PD [7–9]. Studies have shown this hypoactivation leads to a delay in neural activation onset, manifesting as increased premotor RT, a longer time to reach peak velocity, and prolongation and variability in movement duration [10].

Reaction time is a quantitative physiological marker widely used as an indicator of motor function in PD [11]. This variable reflects the central neural processing preceding movement execution, being prolonged in complex tasks and reduced in the presence of preparatory signals. Difficulty initiating volitional movements is a hallmark of PD [12]. In complex multi-joint upper limb movements such as grasping or picking up objects, bradykinesia becomes even more prominent [13, 14].

To quantitatively characterize motor symptoms in PD, several studies have used wearable technologies such as gyroscopes, accelerometers, magnetometers, electromyography, force sensors, and smartphone applications [15]. A previously developed protocol using inertial sensors investigated the role of movement termination in difficulty initiating movement and bradykinesia in PD during complex manual dexterity tasks [16].

Although RT is a well-established marker of motor dysfunction in PD, most protocols assess it in single, brief trials, offering limited information on how RT behaves under sustained or repeated motor demand, and whether dopaminergic medication modulates this pattern differently over time. To address this gap, the present pilot study tested the hypothesis that the RT impairment in PD would be more pronounced and sustained in the OFF state of medication, using the inertial-sensor protocol described in [16] during a manual dexterity task in patients with PD (ON and OFF medication states) and healthy controls, employing a repeated-block protocol, thereby contributing to a more quantitative characterization of motor function in PD.

II. Materials and Methods

A. Participants

Participants were divided into three groups: PD under dopaminergic medication (PD-ON, n = 7), PD without medication (PD-OFF, n = 7), and healthy controls group (CG, n = 7). Patients diagnosed with PD without history of bronchoaspiration or musculoskeletal sequelae in the upper limbs were included. Controls comprised individuals without upper limb musculoskeletal sequelae. Individuals with cognitive impairments, inability to understand instructions, or severe hearing impairments were excluded from both groups. One Control Group (CG) participant was subsequently excluded due to a hearing impairment identified during the experimental session that directly interfered with the auditory protocol, yielding a final CG of n = 6.

This study was conducted in accordance with the Declaration of Helsinki and approved by the Human Research Ethics Committee of the Instituto de Ensino e Pesquisa Alberto Santos Dumont (CAAE 61005322.3.0000.0129). All participants provided written informed consent.

B. Inertial Sensor

Upper limb movement was monitored using an accelerometer (acquisition rate: 148 Hz) from the Trigno™ wireless system (Delsys Inc., USA). A sensor was placed on the dorsum of the participant's most-affected hand during the manual dexterity task (Fig. 1).

C. Experimental Protocol

Participants performed the Box and Blocks Test (BBT), in which they transferred 2.5 cm wooden cubes between two compartments of a box using their more-affected hand as quickly as possible. The task requires coordinated multi-joint movements and demands gross motor skills.

The protocol used two auditory stimuli, chosen to allow unrestricted movement. A high-frequency tone (2000 Hz) signaled task initiation; a low-frequency tone (1000 Hz) signaled interruption. Five blocks were performed in randomized order: Block 1 (30 s execution / 60 s pause), Block 2 (55 s / 55 s), Block 3 (60 s / 30 s), Block 4 (45 s / 15 s), and Block 5 (40 s / 10 s). Randomization prevented anticipation of the stimulus.

D. Data Analysis

Data were collected using EMGWorks software (Delsys) and processed in R. To ensure precise temporal alignment between the auditory stimulus and the accelerometer signal, the synchronization unit was connected to an electromyography (EMG) electrode channel. The onset of each auditory stimulus produced a detectable electrical artifact in this channel, providing a hardware-level timestamp of stimulus delivery independent of software latency. Accelerometer signals (x, y, z axes) were filtered using a band-pass filter (0.5–10 Hz). RT was computed as the interval between this stimulus-onset timestamp and movement onset, the latter identified from the vector magnitude of the three axes as the point exceeding the baseline mean plus two standard deviations.

E. Statistical Analysis

All estimated parameters were averaged for each participant for subsequent statistical analyses. All statistical analyses were performed using R. Given the small sample sizes (n = 6–7 per group), non-parametric tests were adopted regardless of normality screening. The Mann-Whitney U test was used for independent group comparisons (CG vs PD-ON and CG vs PD-OFF), and the Wilcoxon signed-rank test was applied for the paired comparison between medication states (PD-ON vs PD-OFF), as the same patients were assessed under both conditions.

To control for Type I error inflation across the five blocks, p-values were adjusted using the Benjamini-Hochberg (BH) false discovery rate procedure. Effect sizes were calculated as r = |Z| / N, and interpreted as small (r < 0.3), moderate (0.3 r < 0.5), or large (r 0.5). Given the small sample sizes, 95% confidence intervals (CIs) for the group medians were estimated using a non-parametric bootstrap (10,000 resamples with replacement, percentile method) and are reported alongside the median and IQR in Table 2. A significance level of 5% was used for all analyses.

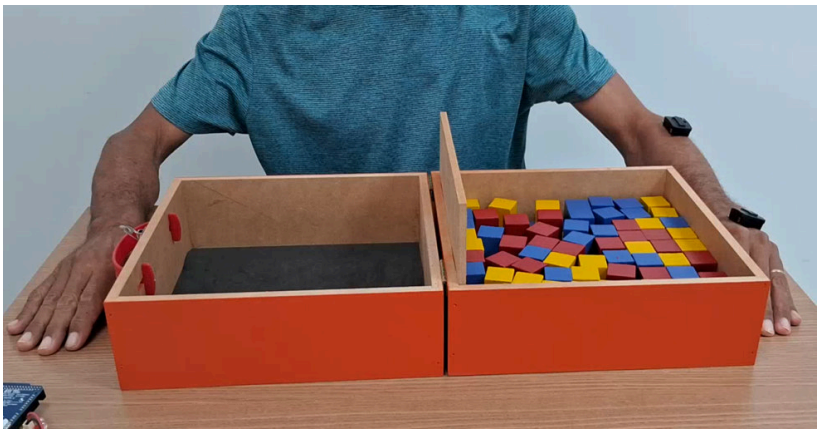

Fig. 1. Participant from the PD group with the inertial sensor placed on the dorsum of the hand to perform the Box and Blocks Test (BBT).

III. Results

A. Demographic and clinical characteristics

Table 1 presents participant characteristics. The PD group was predominantly male (F = 2, M = 5), with normal cognitive status Mini-Mental State Examination (MMSE) (27 ± 1.73) and mild motor impairment in both ON and OFF states (Hoehn & Yahr (H&Y) Stage 2). One CG participant was excluded due to hearing impairment, yielding CG n = 6.

TABLE 1. Demographic and clinical characteristics of the participants.

	PD-ON (n=7)	PD-OFF (n=7)	CG (n=6)
Age	60.29 ± 6.95	60.29 ± 6.95	60 ± 5.39
Female/Male	2/5	2/5	2/4
Time Disease (year)	8.57 ± 6.95	8.57 ± 6.95	-
H&Y Scale	2	2	-
MMSE Score	27 ± 1.73	27 ± 1.73	-

B. Reaction Time in BBT

Table 2 presents detailed data on the median reaction times of the groups across blocks. In Block 1, the first time the stimulus was presented requiring participants to initiate the task, reaction time was significantly longer in both PD-ON and PD-OFF groups compared to healthy controls (p = 0.027 for both comparisons), with large effect sizes (r = 0.792). In the subsequent blocks, the PD-ON group no longer differed significantly from controls, suggesting a progressive reduction in the RT gap over repeated stimulus presentations.

In contrast, the PD-OFF group continued to show significantly longer RT compared to controls in Blocks 4 and 5 (p = 0.031 for both, r = 0.674), and a trend toward significance in Block 2 (p = 0.067, r = 0.555). This pattern indicates that without dopaminergic medication, the impairment in movement initiation persists and is more sustained across the task. No significant differences were found between the PD-ON and PD-OFF states in any block after BH correction, although Block 5 showed a trend (p = 0.035, p_BH = 0.173, r = 0.799), suggesting a possible late-task effect of medication on RT that warrants investigation in larger samples. The graph in Figure 2 shows the reaction times of the participants in all groups across the five blocks of the protocol during the BBT task.

As expected for a small sample, the bootstrap CIs for the group medians were wide, particularly in later blocks, visually reinforcing the limited precision of the estimates and reinforcing the need for larger samples in future confirmatory studies.

IV. Discussion

This study aimed to analyze reaction time in PD patients under the influence of dopaminergic medication, without the effect of medication, and healthy patients during the performance of a gross manual dexterity task, Box and Block Test, which requires the execution of more complex multi-joint movements.

TABLE 2. Median (Scale e interquartile range - IQR) [95% bootstrap CI] of reaction time in seconds for each group across the five blocks of the experimental protocol, with pairwise comparisons and Benjamini-Hochberg correction. (* p_BH < 0.05; # p_BH < 0.10; ns = non-significant).

Block	PD-ON Median (IQR) [95% CI]	PD-OFF Median (IQR) [95% CI]	CG Median (IQR) [95% CI]	CG vs ON (p_BH)	CG vs OFF (p_BH)	ON vs OFF (p_BH)

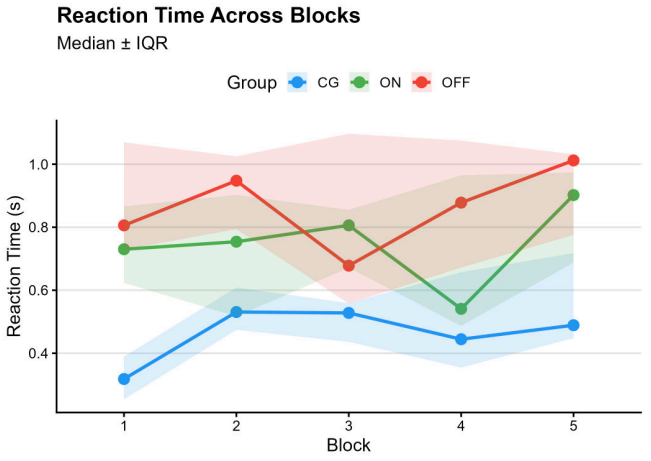

Fig. 2. Reaction times in second of the participants across the five blocks.

Our results showed that reaction times in patients with Parkinson's disease are longer than those in participants without the disease, both under the influence of dopamine medication and not.

These findings corroborate the literature, as studies indicate that bradykinesia and difficulty initiating movements are more prominent without the effect of dopaminergic activation, especially in novel motor tasks [5]. Furthermore, another important factor to note is that the BBT task requires rapid grasping, visual-motor coordination, and transportation, factors that depend on efficient activation of the motor cortex and the integrity of dopaminergic circuits [17]. According to Lorek (2024) [18], impaired manual dexterity in PD is associated with decreased dopamine in the striatum.

A notable finding of the present analysis is the divergent pattern between PD-ON and PD-OFF across blocks. While PD-ON patients showed significantly longer RT only in Block 1, converging toward control performance in subsequent blocks, PD-OFF patients exhibited sustained and significant differences in Blocks 4 and 5 as well. In the absence of dopaminergic support, this increased cumulative motor demand may have been sufficient to unmask and sustain the RT impairment, whereas medicated patients retained the capacity to maintain performance. This interpretation aligns with evidence that dopaminergic medication is particularly effective in attenuating bradykinesia under conditions of greater motor load [5].

It is important to note that this convergence of PD-ON patients toward control performance occurred within a single testing session; while it may reflect short-term adaptive processes, it should not be interpreted as motor learning in the strict sense, which requires evidence of retention beyond the testing session. The cross-sectional, single-session design of this pilot study does not allow this distinction, and future studies incorporating retention tests are needed to confirm this hypothesis.

This interpretation is further supported by the concept of motor fatigability in PD, an objectively measurable decline in motor performance during repeated or sustained tasks, distinct from the subjective perception of fatigue [19]. Its pathophysiology is multifactorial, involving disrupted dopaminergic signaling across fronto-striatal circuits, and dopamine depletion has been directly linked to fatigability in PD [20]. Without dopaminergic support, the basal ganglia may therefore be less capable of compensating for fatigue-related decrements in motor drive, resulting in the sustained RT impairment observed in PD-OFF across the later blocks. The absence of a statistically significant direct comparison between PD-ON and PD-OFF, despite large effect sizes ($r = 0.799$ at Block 5), likely reflects the limited statistical power of the paired analysis with $n = 7$, and should be interpreted with caution.

According to Trevarrow (2024) [21], antiparkinsonian medications reduce the impaired effects of PD by improving motor function; however, medication does not improve all aspects of movement equally, being more effective in improving movement speed than in improving the range of motion in tasks involving visual guidance. Together, these findings highlight the importance of multimodal approaches combining pharmacological and rehabilitative strategies.

Future studies should expand the sample size to increase statistical power, particularly for paired ON vs OFF comparisons, which showed large effect sizes but did not reach significance likely due to limited power, and control for disease duration, medication dose, and time since last administration. Test-retest sessions would help establish the stability of RT measures over time. Incorporating direct kinematic parameters such as movement duration, amplitude, and peak velocity alongside RT, would further strengthen the characterization of motor function in PD; these analyses are currently being conducted on the same dataset as part of a broader doctoral research program and will be reported in future publications.

V. Conclusion

The results of this study indicate that reaction times in patients with Parkinson's disease are longer than those in participants without the disease, both under the influence of dopamine medication and not. This difference was statistically significant at Block 1 for both medication states, and persisted across Blocks 4 and 5 exclusively in the PD-OFF group, highlighting the partial but meaningful role of dopaminergic medication in attenuating RT impairments. Over the course of the task, PD-ON patients showed a convergence toward control-level performance within the testing session, a pattern that may reflect short-term adaptive processes rather than motor learning in the strict sense, since the cross-sectional, single-session design of this pilot study does not allow assessment of long-term retention; PD-OFF patients did not exhibit the same convergent pattern.

Limitations include the small sample size, which may have limited the statistical power to detect significant differences between PD-ON and PD-OFF states, particularly in later blocks where large effect sizes were observed; the lack of control over medication dose and time since last administration; the absence of test-retest sessions; and the absence of independent validation (e.g., video or electromyography) of the accelerometer-based movement-onset detection threshold. Future studies should expand the sample, address these methodological points, and investigate range of motion, movement duration, and velocity alongside reaction time.

Conflict of interest

The authors declare that they have no conflict of interest.

Carta Resposta aos Revisores

Manuscrito: Reaction Time During a Manual Dexterity Task in Parkinson's Disease: A Pilot Study.

Os autores agradecem aos revisores pelos comentários detalhados e construtivos, que contribuíram significativamente para a clareza e o rigor do manuscrito. Abaixo, respondemos ponto a ponto a cada comentário.

Revisor 1

Comentário 1.1

"A avaliação utiliza 7 pacientes com doença de Parkinson e seis controles, o que reduz o poder estatístico e dificulta determinar se as diferenças observadas entre os estados ON e OFF representam efeito da medicação ou variabilidade individual. Sugiro ampliar a amostra e controlar fatores como duração da doença, dose e tempo desde a última administração da medicação, além de repetir as avaliações em sessões diferentes para verificar a estabilidade do tempo de reação."

Resposta:

Os autores agradecem o comentário e concordam que a ampliação da amostra, o controle detalhado da dose e do tempo desde a última administração da medicação, e a realização de sessões de teste-reteste representam melhorias metodológicas relevantes. Tratando-se de um estudo piloto (pilot study, conforme indicado no título) com amostra já coletada sob aprovação ética específica (CAAE 61005322.3.0000.0129), a implementação dessas sugestões exigiria um novo recrutamento de paciente com Doença de Parkinson no estado ON e OFF e controle, nova coleta e análise de dados, o que não é exequível no prazo de revisão deste manuscrito. Essas limitações foram explicitamente incorporadas à seção de Conclusão e os autores destacam esses pontos como prioridades metodológicas para a próxima fase do estudo, atualmente em desenvolvimento com amostra ampliada.

Comentário 1.2

"O início do movimento é definido automaticamente quando a magnitude da aceleração ultrapassa a média basal acrescida de dois desvios padrão, sem validação desse limiar contra

uma referência independente. Acrescentaria uma validação do instante de início do movimento por vídeo, EMG ou outro método de referência."

Resposta:

Os autores esclarecem que o método de detecção por limiar (média basal + 2 desvios-padrão sobre a magnitude vetorial do acelerômetro) é amplamente utilizado na literatura de sensores inerciais para detecção de onset de movimento em tarefas motoras. Cabe esclarecer também que o momento do estímulo sonoro já era validado por hardware: a unidade de sincronização estava conectada a um canal de eletromiografia (EMG), e cada estímulo auditivo produzia um artefato elétrico detectável nesse canal, fornecendo um timestamp do disparo do estímulo independente de qualquer latência de software. Esse detalhe metodológico, antes implícito, foi agora explicitado na seção de Análise de Dados do manuscrito revisado. Reconhecemos, no entanto, que o instante de início do movimento em si (detectado unicamente pelo limiar no acelerômetro) ainda careceria de uma validação cruzada com referência independente (vídeo ou EMG do próprio movimento) para confirmar sua acurácia. Essa limitação foi adicionada explicitamente ao texto (seção de Limitações/Conclusão) e será incorporada ao desenho do próximo estudo.

Comentário 1.3

"Avaliaria também duração, velocidade e amplitude do movimento."

Resposta:

Os autores concordam que a análise de duração, velocidade e amplitude do movimento complementaria de forma relevante os achados de tempo de reação. Esses parâmetros cinemáticos já vêm sendo extraídos dos dados coletados no mesmo protocolo experimental e estão sendo analisados em maior profundidade no âmbito da tese de doutorado associada a este estudo, com submissão planejada para periódicos de maior escopo. Optou-se por não incluir essa análise neste manuscrito de congresso para preservar a originalidade e o ineditismo dos dados nas publicações futuras (tese e artigo de periódico), evitando sobreposição de conteúdo entre publicações. Uma referência a essa análise em andamento foi adicionada à seção de trabalhos futuros.

Comentário 1.4

"Os resultados mostram diferenças entre pacientes e controles em alguns blocos, mas nenhuma diferença significativa entre os estados ON e OFF após correção para múltiplas comparações."

Resposta:

Concordamos com essa observação, que já era discutida no manuscrito original. Reforçamos no texto revisado que a ausência de diferença significativa entre ON e OFF após correção, apesar de tamanhos de efeito grandes em alguns blocos (ex.: r = 0,799 no Bloco 5), provavelmente reflete o poder estatístico limitado da amostra pareada (n = 7), e não a ausência de um efeito real da medicação. Essa interpretação foi explicitada tanto na Discussão quanto na Conclusão.

Revisor 2

Comentário 2.1

"Reestruturar a introdução para focar diretamente na lacuna e hipótese do estudo."

Resposta:

Atendido. O parágrafo final da Introdução foi reescrito para apresentar explicitamente a lacuna na literatura (avaliação de RT majoritariamente em ensaios únicos e breves, sem caracterizar o comportamento sob demanda motora sustentada) e a hipótese do estudo (maior e mais sustentado comprometimento do RT no estado OFF sob demanda motora cumulativa).

Comentário 2.2

"Ajustar a seção final para pontuar brevemente caminhos futuros para expandir o tamanho da amostra e alcançar poder estatístico adequado em comparações pareadas de medicação, incorporar parâmetros cinemáticos diretos, como duração do movimento, amplitude de movimento, tempo de reação entre outros."

Resposta:

Atendido. O parágrafo de direções futuras, ao final da Discussão, foi expandido para mencionar explicitamente a necessidade de ampliação amostral para comparações pareadas ON vs OFF, a incorporação de parâmetros cinemáticos diretos (duração do movimento, amplitude e velocidade de pico), e a validação independente da detecção de início do movimento.

Comentário 2.3

"Definir explicitamente todas as siglas na primeira ocorrência no texto: CG, MMSE, H&Y e IQR."

Resposta:

Atendido. Todas as siglas foram definidas por extenso na primeira ocorrência no corpo do texto: Control Group (CG), Mini-Mental State Examination (MMSE), Hoehn & Yahr (H&Y) Scale e interquartile range (IQR).

Comentário 2.4

"Incluir os intervalos de confiança nas tabelas para aumentar a precisão estatística."

Resposta:

Atendido. Intervalos de confiança de 95% para as medianas de cada grupo em cada bloco foram calculados por bootstrap não paramétrico (10.000 reamostragens com reposição, método dos percentis), consistente com o uso de testes não paramétricos ao longo do manuscrito, e foram incluídos na Tabela 2 do manuscrito revisado, ao lado da mediana e do IQR já reportados. Como esperado para amostras pequenas (n = 6–7 por grupo), os ICs obtidos são amplos, o que é discutido no texto como reforço visual da limitação de precisão associada ao tamanho amostral reduzido.

Comentário 2.5

"Moderar as conclusões sobre 'aprendizado motor', reconhecendo as limitações impostas pelo tamanho reduzido da amostra, pelo design transversal, visto que o aprendizado motor real exige retenção a longo prazo."

Resposta:

Atendido. A linguagem foi revisada tanto na Discussão quanto na Conclusão para não caracterizar a convergência do grupo PD-ON em direção ao desempenho do grupo controle como "aprendizado motor" no sentido estrito. O texto agora indica que esse padrão pode refletir processos adaptativos de curto prazo dentro de uma única sessão, e que o desenho transversal e de sessão única do estudo não permite distinguir isso de retenção a longo prazo, que caracterizaria aprendizado motor verdadeiro.

Ressonância magnética na investigação de biomarcadores associados à identificação antecipada do transtorno do espectro autista: uma revisão de escopo

***Resumo*—**O Transtorno do Espectro Autista (TEA) é uma condição do neurodesenvolvimento caracterizada por déficits persistentes na comunicação e interação social, associados a padrões restritos e repetitivos de comportamento. Como o diagnóstico permanece baseado predominantemente em avaliações clínicas, a identificação de biomarcadores objetivos constitui um desafio relevante. Nesse contexto, a ressonância magnética (RM), incluindo técnicas estruturais, funcionais e por tensor de difusão, tem sido investigada para caracterizar alterações cerebrais associadas ao TEA. Foi realizada uma revisão de escopo da literatura conforme as princípios do PRISMA ScR, com buscas nas bases PubMed, Scopus, Embase, realizadas até 30 de maio de 2026. Foram identificados 642 registros, dos quais 36 estudos foram incluídos após aplicação dos critérios de elegibilidade.Os estudos incluídos demonstraram alterações associadas ao TEA em aspectos estruturais, funcionais e de conectividade cerebral, envolvendo medidas como volume cerebral, espessura cortical, integridade da substância branca e padrões de conectividade funcional. Entretanto, os achados apresentaram heterogeneidade relacionada às características das amostras, métodos de aquisição e estratégias de análise, limitando a comparação entre estudos e a aplicação clínica dos biomarcadores identificados. Conclui-se que a RM apresenta potencial como ferramenta complementar para investigação dos mecanismos neurobiológicos do TEA e identificação de biomarcadores candidatos, mas as evidências atuais ainda não sustentam sua utilização isolada para diagnóstico clínico. Estudos futuros com maior padronização metodológica, amostras ampliadas e validação multicêntrica são necessários para determinar sua aplicabilidade clínica.

Palavras-chave: Transtorno do Espectro Autista; Ressonância Magnética; Diagnóstico Precoce; Neuroimagem; Biomarcadores; Engenharia Biomédica.

I. Introdução

O Transtorno do Espectro Autista (TEA) é uma condição do neurodesenvolvimento caracterizada por déficits persistentes na comunicação e interação social, associados a padrões restritos e repetitivos de comportamento [3]. Devido à sua elevada heterogeneidade clínica e etiológica, o diagnóstico permanece predominantemente baseado em critérios clínicos e comportamentais, o que frequentemente retarda a identificação do transtorno e o início de intervenções antecipadas, período considerado crítico em razão da elevada neuroplasticidade cerebral [35]. Neste contexto, cresce o interesse pela identificação de biomarcadores objetivos capazes de complementar a avaliação clínica e contribuir para o diagnóstico antecipado do TEA [33].

Entre as tecnologias de neuroimagem disponíveis, a ressonância magnética (RM) destaca-se por fornecer imagens de alta resolução do sistema nervoso central sem a utilização de radiação ionizante, permitindo a investigação não invasiva de alterações estruturais e funcionais do cérebro [22]. A RM estrutural possibilita avaliar modificações no volume cerebral, na espessura cortical e em regiões como cerebelo, corpo caloso, amígdala e hipocampo [4]. Por sua vez, a ressonância magnética funcional (fMRI) utiliza o sinal *Blood Oxygen Level Dependent* (BOLD) para inferir a atividade neuronal por meio das respostas hemodinâmicas, permitindo a análise da conectividade funcional em repouso ou durante a execução de tarefas específicas [31]. Complementarmente, a imagem por tensor de difusão (Diffusion Tensor Imaging – DTI) possibilita avaliar a integridade da substância branca por meio da difusão das moléculas de água ao longo dos feixes nervosos, fornecendo informações relevantes sobre a conectividade estrutural cerebral [37].

Nas últimas décadas, os avanços no processamento digital de imagens e na inteligência artificial ampliaram significativamente a capacidade de análise dos dados obtidos por ressonância magnética [17]. Técnicas de aprendizado de máquina e aprendizado profundo têm sido empregadas para integrar informações provenientes das modalidades estrutural, funcional e de difusão, possibilitando a identificação de

padrões complexos e de potenciais biomarcadores associados ao TEA [30]. Entretanto, a elevada heterogeneidade dos estudos, as diferenças nos protocolos de aquisição e processamento das imagens, os reduzidos tamanhos amostrais e a ausência de validação multicêntrica ainda representam obstáculos importantes para a incorporação dessas abordagens na prática clínica [7].

Sob a perspectiva da engenharia biomédica, a integração entre neuroimagem, processamento de sinais, inteligência artificial e análise computacional representa uma estratégia promissora para o desenvolvimento de ferramentas capazes de apoiar o diagnóstico antecipado e ampliar a compreensão dos mecanismos neurobiológicos envolvidos no TEA [21]. Apesar dos avanços observados, as evidências disponíveis ainda são insuficientes para estabelecer biomarcadores de imagem com aplicabilidade clínica consolidada, tornando necessária a realização de estudos metodologicamente mais robustos e padronizados [10].

Diante desse cenário, o presente estudo tem como objetivo sintetizar criticamente as evidências científicas acerca da utilização da ressonância magnética estrutural, funcional e por tensor de difusão na investigação de biomarcadores associados ao Transtorno do Espectro Autista [1]. Por meio de uma revisão de escopo conduzida conforme as recomendações do PRISMA ScR, busca-se analisar o potencial dessas modalidades de neuroimagem para a identificação antecipada do TEA, discutir suas limitações metodológicas e apontar perspectivas futuras para sua aplicação na prática clínica e no desenvolvimento de tecnologias em Engenharia Biomédica [19].

II. Materiais e Métodos

Esta revisão de escopo foi conduzida e relatada de acordo com as recomendações do Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews (PRISMA-ScR), conforme as diretrizes propostas por Tricco et al. [32].

A. Estratégia de Busca

A busca bibliográfica foi realizada nas bases PubMed/MEDLINE, Scopus e Embase, utilizando descritores MeSH e DeCS relacionados ao TEA, ressonância magnética, neuroimagem, biomarcadores e diagnóstico antecipado, combinados por operadores booleanos e adaptados à sintaxe de cada base.

B. Critérios de Elegibilidade

O recorte temporal de 2015 a 2026 foi definido com o objetivo de contemplar a produção científica mais recente e representativa sobre o tema investigado, refletindo os avanços conceituais, metodológicos e tecnológicos ocorridos na última década. O ano de 2015 foi adotado como marco inicial por representar um período em que houve maior consolidação das abordagens contemporâneas relacionadas ao objeto de estudo, permitindo a inclusão de evidências atuais sem comprometer a abrangência da revisão.

Embora 2026 ainda esteja em andamento, as publicações desse ano foram incluídas por estarem disponíveis nas bases de dados até o momento da realização da estratégia de busca. Para garantir transparência e reprodutibilidade, a busca bibliográfica foi realizada até 30 de maio de 2026, de modo que somente os estudos indexados e disponíveis nas bases consultadas até essa data foram considerados elegíveis.

C. Processo de Seleção

A busca eletrônica nas bases PubMed/MEDLINE, Embase e Scopus identificou inicialmente 642 registros. Após a remoção de 156 registros duplicados, permaneceram 486 estudos para triagem por títulos e resumos. Nessa etapa, 381 publicações foram excluídas por não atenderem aos critérios de elegibilidade previamente estabelecidos. Os 105 artigos potencialmente relevantes foram avaliados em texto completo, dos quais 69 foram excluídos por diferentes motivos metodológicos. Ao final, 36 estudos preencheram todos os critérios de inclusão e compuseram a síntese qualitativa desta revisão de escopo [32].

D. Extração dos Dados

A seleção dos estudos foi realizada por um único revisor, que conduziu independentemente a triagem dos títulos e resumos, a avaliação dos textos completos e a extração dos dados. Os estudos potencialmente elegíveis foram avaliados segundo os critérios de inclusão e exclusão previamente estabelecidos. Para garantir a padronização da coleta das informações, foi elaborado um instrumento de extração de dados contendo as principais variáveis analisadas em cada estudo incluído na revisão. Esse instrumento foi utilizado durante a leitura completa dos artigos para registrar informações relacionadas às características metodológicas, população estudada, modalidade de ressonância magnética empregada, biomarcadores investigados, principais resultados e limitações dos estudos. A Tabela 1 apresenta as variáveis que compuseram esse processo de extração de dados, não correspondendo aos resultados individuais dos estudos incluídos.

TABLE I
Variáveis planejadas para extração de dados dos estudos incluídos na revisão de escopo.

Variável	Descrição
Autor	Primeiro autor.
Ano	Ano de publicação.
País	Local do estudo.
Tipo de estudo	Coorte, transversal, caso-controle, ensaio clínico etc.
Amostra	Número de participantes.
Faixa etária	Idade dos participantes.
Modalidade de RM	Estrutural, fMRI ou DTI.
Biomarcadores avaliados	Região cerebral, conectividade ou outro parâmetro avaliado.
Principais resultados	Achados relevantes do estudo.
Limitações	Limitações metodológicas.

E. Síntese dos Dados

A síntese dos estudos foi conduzida por meio de síntese narrativa, em razão da expressiva heterogeneidade entre os trabalhos incluídos. Os estudos foram inicialmente agrupados de acordo com a modalidade de neuroimagem empregada, compreendendo: ressonância magnética (RM) estrutural, ressonância magnética funcional (fMRI) em estado de repouso, fMRI baseada em tarefas, imagem por difusão (Diffusion Tensor Imaging – DTI e técnicas correlatas) e abordagens multimodais, que combinaram diferentes técnicas de aquisição e análise de neuroimagem [5].

Dentro de cada grupo, os estudos foram comparados considerando aspectos metodológicos, incluindo características da amostra (tamanho, faixa etária, critérios diagnósticos e características clínicas), protocolos de aquisição das imagens, métodos de processamento e análise, regiões cerebrais investigadas e principais desfechos [11]. Essa organização permitiu identificar padrões de convergência e divergência entre os achados, bem como avaliar a consistência das evidências produzidas por cada modalidade de imagem [20].

A heterogeneidade metodológica foi considerada durante a interpretação dos resultados [15]. Diferenças relacionadas às características das populações estudadas, aos delineamentos, aos parâmetros de aquisição de imagem, aos métodos analíticos e às medidas de desfecho foram utilizadas para contextualizar variações entre os estudos. Quando resultados conflitantes foram identificados, estes foram apresentados de forma explícita e discutidos à luz de possíveis explicações metodológicas e clínicas, sem atribuição de maior peso a um estudo isolado, mas considerando a qualidade metodológica, a consistência dos achados entre estudos semelhantes e a plausibilidade biológica das interpretações propostas.

A condução da síntese narrativa seguiu os princípios recomendados pelas diretrizes para síntese narrativa em revisões de escopos científicos, envolvendo a organização dos estudos em grupos conceitualmente homogêneos, a descrição analítica das características e dos resultados, a exploração das fontes de heterogeneidade e a elaboração de uma interpretação crítica das evidências disponíveis [27].

Não foi realizada metanálise porque os estudos apresentaram heterogeneidade substancial quanto aos delineamentos, às populações avaliadas, às modalidades de neuroimagem, aos protocolos de aquisição, às estratégias de processamento dos dados e aos desfechos analisados. Além disso, os resultados foram frequentemente apresentados por meio de diferentes métricas, regiões de interesse e métodos estatísticos, impossibilitando a obtenção de estimativas quantitativas comparáveis e a combinação estatística dos achados de forma metodologicamente robusta. Dessa forma, a síntese narrativa foi considerada a abordagem mais apropriada para integrar criticamente as evidências disponíveis [31].

F. Limitações

Esta revisão apresenta algumas limitações que devem ser consideradas na interpretação dos resultados. A triagem dos estudos, a avaliação dos textos completos e a extração dos dados foram realizadas por um único revisor, o que pode aumentar o risco de viés de seleção e de possíveis erros na extração ou interpretação das informações [32]. Embora tenham sido empregados critérios de elegibilidade previamente definidos e procedimentos padronizados ao longo dessas etapas, a ausência de um segundo revisor independente constitui uma limitação metodológica relevante. Estudos futuros poderão minimizar esse risco mediante a participação de revisores independentes em todas as etapas de seleção e extração dos dados, com resolução de eventuais discordâncias por consenso.

Também devem ser consideradas as limitações relacionadas ao recorte temporal adotado (2015-2026), aos idiomas de publicação e às bases de dados consultadas, fatores que podem ter restringido a identificação e a inclusão de estudos potencialmente relevantes. Adicionalmente, não se pode descartar a possibilidade de viés de publicação, uma vez que estudos com resultados negativos, inconclusivos ou menos expressivos podem estar sub-representados na literatura disponível.

Por fim, os estudos incluídos apresentaram considerável heterogeneidade quanto às características das amostras, modalidades e protocolos de ressonância magnética, estratégias de processamento das imagens e métodos de análise empregados. Essa variabilidade metodológica inviabilizou a realização de uma metanálise e justificou a adoção de uma síntese narrativa dos achados. Somada às diferenças na qualidade metodológica dos estudos primários, essa heterogeneidade limita a comparabilidade entre os resultados e deve ser considerada ao interpretar a generalização das conclusões.

III. Resultados

A estratégia de busca realizada nas bases PubMed/MEDLINE, Embase e Scopus resultou na identificação de 642 registros. Após a remoção de 156

TABLE II
Comparação das modalidades de Ressonância Magnética aplicadas ao diagnóstico do Transtorno do Espectro Autista.

Modalidade	**Principal aplicação**	**Biomarcadores investigados**	**Vantagens**	**Limitações**
RM Estrutural	Avaliação anatômica cerebral	Volume cerebral, espessura cortical, cerebelo e amígdala	Alta resolução espacial	Baixa especificidade para o TEA
fMRI	Avaliação da conectividade funcional	Redes neurais, Default Mode Network (DMN) e conectividade social	Avalia a atividade cerebral em tempo real	Sensível a movimentos e à variação dos protocolos
DTI	Avaliação da integridade da substância branca	Anisotropia fracionada e difusividade	Detecta alterações microestruturais	Requer processamento avançado das imagens

TABLE III
VISÃO GERAL DO PROCESSO DE SELEÇÃO DOS ESTUDOS CONFORME O PRISMA 2020.

Etapa do PRISMA 2020	Quantidade (n)
Registros identificados na PubMed	182
Registros identificados na Embase	247
Registros identificados na Scopus	213
Total de registros identificados	**642**
Registros duplicados removidos	156
Registros após remoção de duplicatas	486
Estudos selecionados para leitura de título e resumo	486
Estudos excluídos na triagem	381
Artigos avaliados em texto completo	105
Artigos excluídos após leitura completa	69
Estudos incluídos na revisão de escopo	**36**

duplicatas, permaneceram 486 estudos para a etapa de triagem por títulos e resumos. Desses, 381 foram excluídos por não atenderem aos critérios de elegibilidade previamente estabelecidos. Foram selecionados 105 artigos para leitura na íntegra, dos quais 69 foram posteriormente excluídos por não responderem à questão de pesquisa. Ao final do processo de seleção, 36 estudos foram incluídos na síntese qualitativa desta revisão de escopo, seguindo os processos de um fluxograma PRISMA-ScR [32]. A Tabela IV sintetiza as informações centrais dos 36 artigos selecionados, incluindo o tipo de desenho experimental, o tipo de ressonância utilizado e o foco de cada artigo.

Os estudos incluídos foram publicados entre 2015 e 2026 e apresentaram diferentes delineamentos metodológicos, contemplando principalmente estudos transversais, de coorte e caso-controle. As pesquisas envolveram indivíduos com diagnóstico ou suspeita de Transtorno do Espectro Autista, predominantemente crianças e adolescentes, e utilizaram diferentes modalidades de ressonância magnética, incluindo ressonância magnética estrutural, ressonância magnética funcional (fMRI), imagem por tensor de difusão (DTI) e abordagens multimodais associadas a técnicas de inteligência artificial. Os principais biomarcadores investigados compreenderam alterações no volume cerebral, espessura cortical, conectividade funcional, integridade da substância branca e organização de redes neurais [34].

Os estudos que utilizaram ressonância magnética estrutural identificaram alterações em diferentes regiões encefálicas, incluindo modificações no volume cerebral, na espessura cortical, no cerebelo, no corpo caloso, na amígdala e no hipocampo. De modo geral, esses achados indicaram diferenças morfológicas entre indivíduos com TEA e controles, embora os resultados tenham apresentado variabilidade entre as populações estudadas [37]. Nos estudos que empregaram ressonância magnética funcional, foram observadas alterações na conectividade de redes neurais relacionadas à comunicação, cognição social, linguagem e processamento emocional [23]. As diferenças identificadas envolveram tanto a conectividade em estado de repouso quanto durante a execução de tarefas cognitivas, variando conforme as características clínicas das amostras e os protocolos utilizados [30].

Os estudos baseados em imagem por tensor de difusão demonstraram alterações na integridade da substância branca, evidenciadas por diferenças em parâmetros relacionados à organização dos feixes neurais e à conectividade estrutural cerebral [9]. Além disso, alguns trabalhos combinaram diferentes modalidades de neuroimagem com algoritmos de aprendizado de máquina e aprendizado profundo, buscando identificar padrões capazes de auxiliar na classificação de indivíduos com TEA. Essas abordagens multimodais apresentaram resultados promissores na identificação de biomarcadores candidatos, embora a maioria dos estudos tenha destacado a necessidade de validação em amostras independentes antes de sua aplicação clínica [8].

De maneira geral, os estudos incluídos evidenciaram alterações estruturais, funcionais e de conectividade cerebral associadas ao transtorno do espectro autista, indicando o potencial da ressonância magnética para a investigação de biomarcadores relacionados ao transtorno [31]. Entretanto, também foi observada elevada heterogeneidade entre os estudos quanto às características das populações avaliadas, modalidades de imagem empregadas, protocolos de aquisição, métodos de processamento e estratégias analíticas, aspecto que dificultou a comparação direta entre os resultados e impossibilitou a realização de metanálise [34].

IV. DISCUSSÃO

Os achados desta revisão de escopo demonstram que a ressonância magnética tem desempenhado papel relevante na ampliação do conhecimento acerca das alterações neurobiológicas associadas ao transtorno do espectro autista [26]. A análise dos estudos incluídos evidencia que as diferentes modalidades de neuroimagem, incluindo a ressonância magnética estrutural, a ressonância magnética funcional e a imagem por tensor de difusão, são capazes de identificar alterações na morfologia cerebral, na conectividade funcional e na integridade da substância branca [16]. Esses resultados reforçam a hipótese de que o TEA está associado a alterações em redes neurais distribuídas, envolvendo diferentes regiões cerebrais e múltiplos mecanismos do neurodesenvolvimento, ao invés de uma única alteração anatômica ou funcional específica [9], [28].

Embora as alterações estruturais tenham sido observadas de forma recorrente em regiões como córtex cerebral, cerebelo, amígdala, hipocampo e corpo caloso, os estudos analisados apresentaram resultados heterogêneos quanto à localização, magnitude e direção dessas alterações [13]. Essa variabilidade pode ser explicada pela própria natureza multifatorial do TEA, bem como pelas diferenças entre as populações estudadas, incluindo faixa etária, gravidade clínica, presença de comorbidades, critérios diagnósticos utilizados e tamanhos amostrais. Além disso, diferenças nos protocolos de aquisição das imagens e nas metodologias empregadas para processamento e análise contribuem para a inconsistência dos achados descritos na literatura [10].

TABLE IV: Artigos analisados e utilizados no escopo.

Nota: ABIDE = Autism Brain Imaging Data Exchange; DTI = imagem por tensor de difusão; fMRI = ressonância magnética funcional; IA = inteligência artificial; ML = aprendizado de máquina; MRS = espectroscopia por ressonância magnética; N/A = não se aplica; NI = não informado; RM = ressonância magnética; TEA = transtorno do espectro autista.

Resultados semelhantes foram observados nos estudos que empregaram ressonância magnética funcional [29]. Embora diversas pesquisas tenham identificado alterações na conectividade de redes neurais relacionadas à comunicação social, linguagem, funções executivas e processamento emocional, não foi possível estabelecer um padrão universal de conectividade funcional aplicável a todos os indivíduos com TEA [24]. Essa diversidade de resultados evidencia que a organização funcional cerebral apresenta grande variabilidade entre os pacientes, reforçando a complexidade biológica do transtorno e a necessidade de abordagens individualizadas para sua investigação [11].

As pesquisas baseadas em imagem por tensor de difusão também demonstraram alterações na organização microestrutural da substância branca, sugerindo comprometimento da conectividade estrutural entre diferentes regiões cerebrais [18]. Entretanto, assim como observado nas demais modalidades de neuroimagem, diferenças metodológicas relacionadas aos parâmetros de aquisição, métricas utilizadas e estratégias de processamento limitaram a comparação direta entre os estudos, dificultando a consolidação desses achados como biomarcadores confiáveis para utilização clínica [6].

Outro aspecto que merece destaque é o crescente emprego de métodos de inteligência artificial aplicados aos dados de ressonância magnética [25]. A combinação entre neuroimagem e algoritmos de aprendizado de máquina ou aprendizado profundo tem possibilitado a identificação de padrões complexos dificilmente detectáveis por métodos estatísticos convencionais, aumentando o potencial para classificação automatizada de indivíduos com TEA [14]. Apesar dos resultados promissores, a maior parte dos estudos ainda apresenta limitações relacionadas ao reduzido número de participantes, ao risco de sobreajuste dos modelos computacionais, à limitada interpretabilidade dos algoritmos e à ausência de validação externa em populações independentes, fatores que restringem sua utilização rotineira na prática clínica [13].

De forma geral, os resultados desta revisão indicam que a ressonância magnética constitui uma importante ferramenta para investigação dos mecanismos neurobiológicos do Transtorno do Espectro Autista e para a identificação de potenciais biomarcadores de imagem [36]. No entanto, as evidências atualmente disponíveis ainda não sustentam sua utilização como método diagnóstico isolado, uma vez que a elevada heterogeneidade metodológica dos estudos, associada à ausência de protocolos padronizados e de validação multicêntrica, reduz a reprodutibilidade dos achados e limita sua aplicação clínica [12].

Sob a perspectiva da Engenharia Biomédica, os resultados reforçam a importância do desenvolvimento de protocolos padronizados de aquisição e processamento de imagens, bem como da integração entre neuroimagem, inteligência artificial e outras modalidades de biomarcadores biológicos [10]. A utilização de abordagens multimodais poderá contribuir para aumentar a precisão diagnóstica e favorecer a identificação precoce do TEA. Entretanto, a consolidação dessas tecnologias dependerá da realização de estudos multicêntricos, com amostras representativas, validação externa e metodologias harmonizadas, permitindo que os biomarcadores identificados possam ser incorporados de forma segura e eficaz à prática clínica [2].

Em síntese, os estudos analisados evidenciam avanços significativos na utilização da ressonância magnética como ferramenta de investigação científica do TEA. Contudo, a tradução desses achados para a prática assistencial ainda requer o fortalecimento das evidências disponíveis, especialmente por meio de pesquisas colaborativas de grande escala, capazes de reduzir a heterogeneidade metodológica atualmente observada e estabelecer biomarcadores robustos, reprodutíveis e clinicamente aplicáveis [2].

V. Conclusão

A presente revisão sintetizou os achados publicados entre 2015 e 2026 sobre a aplicação da ressonância magnética estrutural, da ressonância magnética funcional, da imagem por difusão e de abordagens multimodais na investigação do Transtorno do Espectro Autista (TEA). Em conjunto, os estudos identificaram alterações recorrentes na morfologia cerebral, na conectividade funcional e na integridade da substância branca em indivíduos com TEA. Entretanto, os padrões observados não foram uniformes entre as pesquisas, variando conforme a faixa etária, as características das amostras, os protocolos de aquisição e processamento das imagens e os métodos analíticos empregados.

A análise das evidências indica que as técnicas de neuroimagem apresentam potencial para ampliar a compreensão dos mecanismos neurobiológicos do TEA e para identificar biomarcadores candidatos. Contudo, a heterogeneidade metodológica e clínica observada entre os estudos, aliada à ausência de protocolos padronizados e à limitada reprodutibilidade de alguns achados, reduz a consistência das evidências atualmente disponíveis e impede a definição de biomarcadores de imagem com aplicabilidade clínica estabelecida. Dessa forma, os resultados desta revisão devem ser interpretados como evidências de potencial diagnóstico e investigativo, e não como demonstração de utilidade clínica consolidada.

As abordagens que integram diferentes modalidades de neuroimagem e métodos computacionais, incluindo técnicas de processamento de imagens e inteligência artificial, mostraram resultados promissores em alguns estudos para a discriminação entre indivíduos com TEA e controles. No entanto, esses achados ainda necessitam de validação em estudos multicêntricos, com amostras maiores, protocolos harmonizados e validação externa antes de sua incorporação à prática clínica.

Em síntese, os estudos revisados sustentam que a ressonância magnética constitui uma importante ferramenta de pesquisa para a caracterização das alterações cerebrais associadas ao TEA, mas as evidências atualmente disponíveis ainda apresentam certeza limitada a moderada, principalmente em decorrência da heterogeneidade dos estudos incluídos. Assim, os dados disponíveis não sustentam o uso da neuroimagem como substituta da avaliação clínica nem permitem concluir que sua utilização, isoladamente, resulte em melhora dos

desfechos clínicos ou da qualidade de vida dos indivíduos com TEA.

***Abstract*—Motor imagery brain-computer interfaces (BCIs) require rapid, stable decisions for real-time operation, yet decoding pipelines are typically selected based solely on offline accuracy. To address this, we applied a causal pseudo-online evaluation framework on a public database, incorporating a within-session protocol and a rest class to investigate how decoder architecture and temporal parameters (window length and overlap) jointly affect BCI usability. Comparing Common Spatial Pattern (CSP) and Riemannian Tangent Space (TGSP) approaches, mixed-effects modeling revealed that decoder architecture primarily dictates decision quality and confidence, whereas temporal stability is strictly governed by temporal processing. Larger windows consistently improved classification performance, confidence, and stability, but increased detection latency. Also, smaller steps between windows accelerated responsiveness and increased prediction confidence in nonlinear Riemannian decoders. These findings demonstrate that real-time BCI configuration is a multiobjective design problem: rather than relying on offline accuracy alone, temporal and algorithmic parameters must be tailored to the latency and stability requirements of specific clinical applications.**

***Index Terms*—Brain-computer interface (BCI); Motor imagery; Electroencephalography (EEG); Pseudo-online evaluation; Temporal processing.**

I. Introduction

Brain-computer interfaces (BCIs) establish a closed-loop interaction between neural activity, user intention, external devices, and sensory feedback. In motor imagery (MI)-based neurorehabilitation, this interaction is particularly important because the feedback generated by the system can reinforce task-related cortical activity, promote neuroplasticity, and facilitate motor recovery. However, once a BCI operates in real time, the user's neural activity continuously adapts to the feedback provided by the decoder, making online operation fundamentally different from the static conditions typically assumed during offline model development [1], [2].

Despite this distinction, decoding pipelines are still predominantly selected according to offline classification performance. While offline accuracy is essential for evaluating discriminability, it does not necessarily reflect how a decoder behaves during continuous operation [3]–[6]. Practical BCIs must simultaneously satisfy several additional requirements, including rapid response, reliable decision making, high prediction confidence, and temporal stability. These objectives are often competing, meaning that maximizing a single offline metric does not necessarily produce the best real-time behavior.

Pseudo-online evaluation has emerged as an intermediate step between conventional offline analysis and fully online experiments [4]. By processing continuous EEG recordings using causal sliding windows, pseudo-online frameworks approximate many characteristics of real-time operation while avoiding the logistical complexity of repeated online experiments. Nevertheless, most BCI studies remain focused on comparing decoding algorithms, providing limited insight into a more fundamental question: which design choices actually determine different dimensions of online usability?

In particular, the temporal organization of signal processing has received considerably less attention than decoder architecture. Decisions such as window length and temporal sampling density directly determine how much neural information is integrated before each prediction and how frequently new decisions become available. These parameters may therefore influence system responsiveness, confidence, and stability independently of the decoding algorithm itself. Understanding the relative contribution of temporal processing and decoder architecture is essential for designing BCIs whose behavior matches the requirements of different clinical and assistive applications.

In this work, we adapt a pseudo-online evaluation protocol to investigate how temporal processing parameters and decoder architecture jointly shape multiple dimensions of BCI performance. Continuous EEG recordings are processed causally using sliding windows and an additional rest class to reproduce realistic operating conditions. Classical CSP-based pipelines are compared with tangent-space Riemannian approaches under different temporal configurations, while performance is evaluated through complementary measures of classification performance, detection latency, prediction confidence, and temporal stability.

Rather than identifying a single optimal decoding pipeline, our objective is to characterize how different design parameters influence different aspects of pseudo-online behavior. This analysis provides a multiobjective view of decoder evaluation, allowing pipeline configurations to be selected according to application-specific requirements instead of offline accuracy alone.

Specifically, this study investigates: (i) whether offline classification performance predicts online responsiveness and stability; (ii) the relative contribution of decoder architecture versus temporal processing to each dimension of usability; and (iii) whether these dimensions can be jointly optimized or require application-specific trade-offs

The remainder of this paper is organized as follows. Section II describes the proposed pseudo-online analysis, the evaluated decoding pipelines, and the performance metrics. Section III presents the experimental results, emphasizing how temporal processing and decoder architecture affect different dimensions of system behavior. Finally, Section IV discusses the implications of these findings for the design and evaluation of real-time BCIs and concludes the paper.

II. Materials and Methods

A. Computational setting

The analysis was conducted on a CPU Google Colaboratory environment, using Python as programming language. The decoder pipelines used standard implementations available on *sklearn* [7] and *pyriemann* [8] (for riemannian manifold based methods). Preprocessing was done with *MNE* [9] library. Data analysis and visualization were made with help of *Pandas* [10], *matplotlib* [11] and *seaborn* [12] libraries.

B. Dataset

The analysis was conducted using the BNCI2014-001 motor imagery database from the BCI Competition IV [13]. The dataset comprises EEG recordings from nine healthy participants performing four different motor imagery tasks following visual cues: left hand, right hand, both feet and tongue. Each subject completed two recording sessions acquired on the same day, each containing six runs of 48 trials. EEG was recorded from 22 scalp electrodes at a sampling frequency of 250 Hz.

Unlike conventional offline analyses based on random cross-validation, the objective of this study is to approximate the conditions encountered during online operation. Therefore, all evaluations were performed using a causal within-session protocol that preserves the temporal order of the recorded signals.

C. Pseudo-online evaluation framework

The pseudo-online framework was inspired by previous continuous motor imagery decoding approaches, but introduces modifications designed to better reproduce realistic online operation while allowing the evaluation of multiple dimensions of decoder usability.

The only preprocessing step was the band-pass filtering in the sensorimotor frequency range (8–30 Hz) of the continuous EEG recording. Instead of segmenting the data into isolated motor imagery epochs, the entire recording was processed continuously using causal sliding windows. Each prediction therefore relied exclusively on information available up to the current instant, reproducing the causal constraint of an online BCI.

To emulate continuous operation, windows were extracted throughout the recording, including both motor imagery and non-imagery periods. Windows outside the motor imagery interval were assigned to an additional rest class, allowing the decoder to distinguish intentional control from background activity. When a window contained samples belonging to multiple classes, its label was assigned according to the majority of contained samples; ties were resolved in favor of the most recent label, reflecting the user's latest motor intention.

Although the overall framework follows the pseudo-online strategy proposed by Carrara and Papadopoulo, two important modifications were introduced. First, decoder training and evaluation followed a causal within-session protocol, in which training was performed using the initial 70% of each session recording while testing used exclusively subsequent data, avoiding cross-validation and eliminating future information leakage. Second, the evaluation was extended beyond conventional classification performance by incorporating metrics specifically designed to characterize online usability.

Each subject completed two same-day recording sessions, which were processed independently under the causal within-session protocol described above, yielding one train/test fold per session. For each subject, the resulting performance metrics were averaged across the two sessions to obtain a single subject-level estimate, which was then used as the unit of observation in the mixed-effects models

D. Decoding pipelines

Five decoding pipelines were evaluated to investigate the relative influence of decoder architecture and temporal processing.

The baseline pipeline consisted of Common Spatial Patterns (CSP) followed by Linear Discriminant Analysis (CSP+LDA), representing one of the most widely adopted approaches for motor imagery BCIs.

To isolate the effect of the classifier, CSP features were also combined with both linear and radial basis function (RBF) Support Vector Machines (CSP+SVM).

Finally, covariance matrices were projected onto the Riemannian tangent space prior to classification using linear and RBF SVMs (TGSP+SVM). By exploiting the geometry of covariance matrices, tangent-space representations provide richer descriptions of sensorimotor activity than conventional CSP features [14].

Classifier hyperparameters were optimized independently for each pipeline using a randomized search with internal k-fold cross-validation on the training set, without any test data, maximizing the offline normalized Matthews Correlation Coefficient (nMCC). Selected hyperparameters include number of selected CSP components, ranging from 4 to 8; SVM regularization, ranging from 0.1 to 10; and LDA shrinkage coefficient, ranging from 0.1 to 0.5 and also comparing the value obtained from Ledoit-Wolf lemma, as implemented in *sklearn* package.

E. Experimental factors

The objective of this study is not only to compare decoding pipelines, but to investigate how different design choices influence pseudo-online behavior.

Three experimental factors were considered. Decoder architecture, represented by the evaluated pipelines. Window length, ranging from 0.5s to 2.0s in 0.5s intervals, corresponding to the temporal interval integrated before each prediction. Temporal sampling density, or step size, namely 0.15s, 0.3s and 0.5s, controlled through the step between consecutive windows. The step size controls overlap between windows and increasing overlap produces more frequent predictions while maintaining the same window duration.

By varying these factors independently, the proposed analysis enables the investigation of how temporal processing and decoder architecture contribute to different dimensions of system performance.

F. Performance Metrics

Performance was evaluated using complementary metrics describing different aspects of pseudo-online usability.

1) Classification performance: Classification quality was measured using the normalized Matthews Correlation Coefficient (nMCC). Unlike conventional accuracy, nMCC is robust to moderate class imbalance and provides more information as it summarizes all four elements of the confusion matrix, which is particularly important due to the inclusion of the additional rest class [15].

2) Detection latency: Detection latency was defined as the elapsed time between cue onset and the first correctly classified window. This metric represents the responsiveness perceived by the user during online operation.

3) Prediction confidence: Prediction confidence was computed as the posterior probability assigned to the predicted class. Higher confidence indicates greater certainty in the generated decisions.

4) Temporal stability: Rather than evaluating isolated correct predictions, temporal stability was quantified from continuous blocks of consecutive correct classifications.

Predictions were first partitioned into maximal contiguous blocks according to both trial identity and classification correctness. Consecutive correctly classified windows belonging to the same trial were grouped into a single stability block. For each block, its proportion relative to the entire trial was computed.

G. Statistical Analysis

The influence of decoder architecture and temporal processing on each performance metric was investigated using linear mixed-effects models.

For every dependent variable, fixed effects included decoder architecture, window length, step between windows, and all interaction terms. Subject identity was included as a random intercept to account for repeated observations within participants.

This modeling strategy allows the independent contribution of each design parameter to be quantified while accounting for inter-subject variability, enabling the identification of which experimental factors govern different dimensions of pseudo-online behavior.

Residual diagnostics were inspected to assess model adequacy; while some deviations from normality and homoscedasticity were observed, model estimates were considered robust given the large sample sizes involved. Reported effects were also verified against Benjamini-Hochberg false discovery rate correction for multiple comparisons. All findings remained significant after this correction, with the exception of the CSP+SVM (RBF) effect on nMCC ($p = 0.015$, $p_FDR = 0.063$), which is interpreted with corresponding caution.

III. Results

A. Responsiveness

The first objective of this study was to determine how different design choices influence system responsiveness. Contrary to the common assumption that response time is governed solely by temporal windowing, mixed-effects modeling revealed that decoder architecture also plays a critical role.

Using the conventional CSP+LDA pipeline as the reference, all Support Vector Machine (SVM)-based approaches significantly reduced the time to the first correct detection (all $p < 0.001$). The largest reductions were observed for CSP+SVM with RBF kernel and TGSP with linear kernel ($\beta = -0.71$ and $\beta = -0.73$, respectively), while TGSP with RBF SVM and CSP with linear SVM showed a smaller reduction ($\beta = -0.55$ and $\beta = -0.68$, respectively) indicating that SVM classifiers consistently produce faster responses regardless of the feature extraction strategy.

Temporal processing parameters also exerted a strong influence on responsiveness. Increasing window length systematically delayed the first correct detection ($\beta = 0.40$, $p < 0.001$), while increasing the temporal step between consecutive windows, which corresponds to reducing the sampling density,

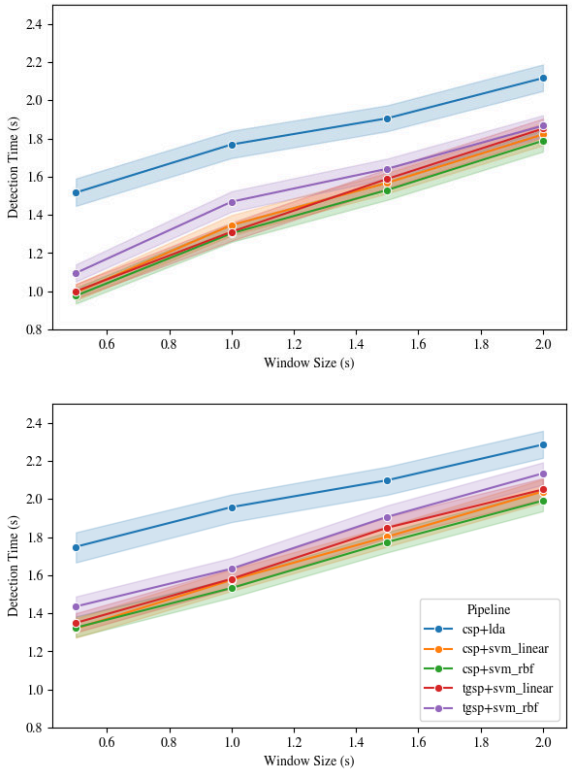

Fig. 1. Effect of window size on system detection time under two temporal sampling rates. Top: window step of 0.15 s (higher sampling density). Bottom: window step of 0.50 s (lower sampling density).

also increased detection latency ($\beta = 0.70$, $p < 0.03$). The interaction between window length and temporal step was not significant indicating that increasing window overlap (reducing step size) does not compensate for the latency penalty introduced by larger windows. Fig. 1 shows the effects of temporal parameters in latency.

B. Decision quality

Unlike temporal sampling density, which primarily affected response dynamics, decision quality was jointly determined by decoder architecture and the amount of neural information integrated before each prediction.

In terms of classification performance, measured by the normalized Matthews Correlation Coefficient (nMCC), SVM-based pipelines consistently outperformed the conventional CSP+LDA approach. Significant improvements were observed for CSP+SVM RBF ($\beta = 0.03$, $p = 0.015$), TGSP+SVM Linear ($\beta = 0.03$, $p = 0.003$), and TGSP+SVM RBF ($\beta = 0.03$, $p = 0.004$). Window length also produced a consistent increase in nMCC across all pipelines ($\beta = 0.04$, $p < 0.001$), whereas temporal sampling density and classifier linearity showed no significant effects. Fig. 2 shows how nMCC is impacted by pipeline and window size given a window step.

Prediction confidence followed a similar pattern. Relative to CSP+LDA, the Riemannian pipelines TGSP+SVM Linear

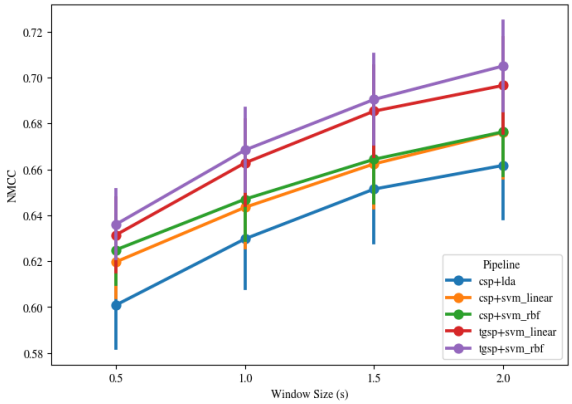

Fig. 2. Effect of window size in nMCC with 0.3s window step.

($\beta = 0.035$, $p < 0.001$) and TGSP+SVM RBF ($\beta = 0.27$, $p < 0.001$) generated substantially higher classification probabilities, indicating more confident decisions. Larger temporal windows also increased prediction confidence ($\beta = 0.04$, $p < 0.001$). Sparser temporal sampling (bigger temporal steps) had significant impact only on tangent space based classification, reducing its confidence, particularly for TGSP+SVM RBF ($\beta = -0.62$, $p < 0.001$). This effect was partially mitigated by increasing window length ($\beta = 0.35$, $p < 0.001$), demonstrating that the benefits of richer feature representations depend on an appropriate temporal parameterization. Fig. 3 shows the effect of window size and pipeline on classification probability.

C. Temporal stability

Unlike responsiveness and decision quality, temporal stability was determined almost exclusively by the temporal organization of signal processing.

Temporal stability was quantified as the proportion of each trial occupied by contiguous blocks of correct classifications, providing a measure of how consistently the decoder maintained correct decisions over time. Mixed-effects analysis revealed no significant differences among any of the evaluated decoding pipelines or classifier architectures (all $p > 0.74$), indicating that improving the classifier alone does not substantially increase the continuity of correct predictions.

Instead, stability was strongly governed by the temporal processing parameters. Increasing window length significantly increased the proportion of sustained correct classification blocks ($\beta = 0.022$, $p < 0.001$), indicating that longer temporal integration favors more persistent decoding. Likewise, increasing step between windows also produced a substantial improvement in temporal stability ($\beta = 0.092$, $p < 0.001$), suggesting that sparser temporal sampling promotes longer uninterrupted periods of correct classification.

Importantly, no significant interactions were observed between temporal parameters and decoder architecture, indicating that these improvements were consistent across all evaluated pipelines.

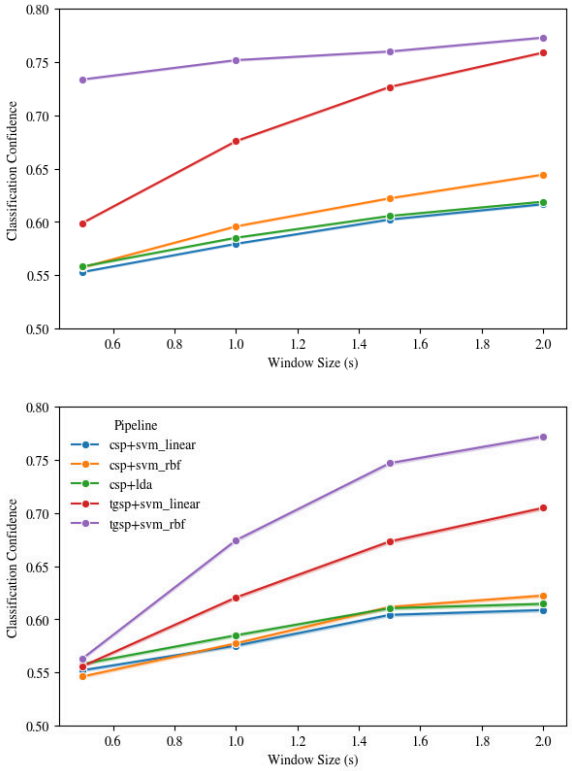

Fig. 3. Effect of window size on classification confidence under two temporal sampling rates. Top: window step of 0.15 s (higher sampling density). Bottom: window step of 0.50 s (lower sampling density).

D. Decision and responsiveness trade-off

The combined analysis of these results demonstrates that configuring a pseudo-online BCI requires balancing competing objectives rather than optimizing a single performance metric.

Maximizing decision quality—expressed by higher nMCC values and promoting earlier convergence to stable decoding both require longer temporal integration windows. However, these same windows substantially increase detection latency.

Conversely, increasing window overlap accelerates system responses by producing more frequent predictions, but delays the emergence of stable decoding and reduces the confidence of the Riemannian decoder. These competing effects define the Pareto frontier shown in Fig. 4., illustrating that improvements in one performance dimension generally require compromises in another. Each point in the analysis represents the average performance of a unique combination of classification pipeline, window size, and window step across all subjects. A configuration was considered Pareto-optimal if no other configuration simultaneously achieved a higher nMCC and a lower mean latency.

Table I summarizes the Pareto-optimal configurations considering the trade-off between responsiveness and classification performance (nMCC). Interestingly, all Pareto-optimal solutions employ the smallest evaluated window step (0.15 s), indicating that a high temporal sampling density is required to achieve the best latency–accuracy compromise. Although

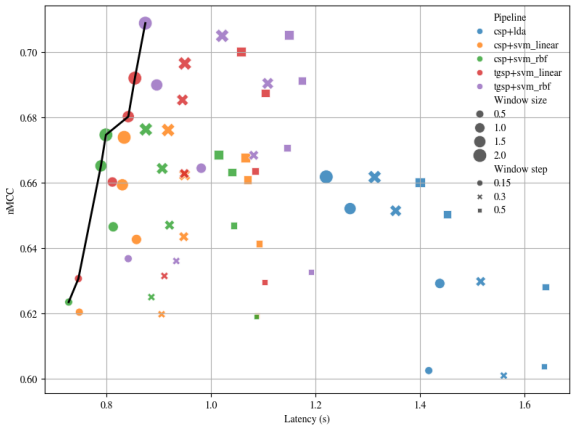

Fig. 4. Pareto frontier for conflicting objectives: nMCC and latency.

increasing the sampling density does not significantly improve nMCC by itself, it consistently reduces detection latency, allowing these configurations to dominate alternatives with larger temporal steps.

The frontier also illustrates that no single pipeline dominates the entire operating range. CSP+SVM (RBF) provides the fastest operating points, whereas TGSP-based pipelines progressively replace CSP-based solutions as larger temporal windows become available, yielding higher classification performance at the expense of increased response time. In particular, TGSP+SVM (RBF) achieves the highest nMCC on the frontier, but only with the longest evaluated window (2.0 s), highlighting that the most expressive decoder also requires the largest amount of temporal information before producing reliable predictions.

Therefore, rather than identifying a universally optimal decoder, the Pareto frontier defines a family of optimal operating points from which the appropriate configuration should be selected according to the latency constraints and accuracy requirements of the intended application.

Importantly, the Pareto frontier only considers latency and classification performance. Other metrics analyzed in this work, such as prediction confidence and temporal stability, exhibit different dependencies on temporal parameterization. Consequently, a configuration that is Pareto-optimal in the latency–accuracy space is not necessarily optimal when additional performance dimensions are considered, reinforcing that pseudo-online BCI design should be formulated as a genuinely multiobjective optimization problem.

E. Decoder error profile

The error distribution of each decoding pipeline provides critical insight into their operational failure modes under continuous evaluation. Table II summarizes the performance metrics, false positive rate (FPR, active classifications during background rest), and false negative rate (FNR, rest classifications during motor imagery intervals) for a fixed 1.0 s window.

While CSP+LDA exhibits a remarkably low FPR ($11.8\% \pm 6.3\%$), it suffers from an excessively high FNR ($77.4\% \pm$

TABLE I
PARETO-OPTIMAL CONFIGURATIONS CONSIDERING LATENCY AND NMCC AVERAGED OVER SUBJECTS.

Pipeline	Window Size (s)	Window Step (s)	Latency (s)	nMCC
CSP+SVM (RBF)	0.5	0.15	0.728	0.623
CSP+SVM (RBF)	1.5	0.15	0.789	0.665
CSP+SVM (RBF)	2.0	0.15	0.799	0.675
TGSP+SVM (Linear)	0.5	0.15	0.746	0.631
TGSP+SVM (Linear)	1.5	0.15	0.842	0.680
TGSP+SVM (Linear)	2.0	0.15	0.854	0.692
TGSP+SVM (RBF)	2.0	0.15	0.874	0.709

TABLE II
CLASSIFICATION PERFORMANCE, LATENCY, AND ERROR TRADE-OFFS ACROSS EVALUATED PIPELINES (1.0 S WINDOW SIZE)

Pipeline	Window step (s)	nMCC	Latency (s)	FPR	FNR
CSP+LDA	0.15	0.629 ± 0.066	1.438 ± 0.477	0.119 ± 0.063	0.771 ± 0.148
CSP+LDA	0.50	0.628 ± 0.065	1.640 ± 0.458	0.118 ± 0.063	0.774 ± 0.146
CSP+SVM (BOTH)	0.15	0.645 ± 0.053	0.835 ± 0.210	0.570 ± 0.100	0.543 ± 0.125
CSP+SVM (BOTH)	0.50	0.644 ± 0.053	1.068 ± 0.212	0.573 ± 0.100	0.544 ± 0.124
TGSP+SVM (BOTH)	0.15	0.662 ± 0.052	0.896 ± 0.219	0.385 ± 0.119	0.586 ± 0.125
TGSP+SVM (BOTH)	0.50	0.667 ± 0.051	1.115 ± 0.183	0.385 ± 0.102	0.575 ± 0.116

14.6%). This asymmetry reveals a severe class collapse toward the predominant rest state, as the linear discriminant struggles to establish a balanced decision boundary. Consequently, the low latency responsiveness observed in SVM pipelines is absent in CSP+LDA, as transitioning out of the rest state probably requires fully motor imagery windows.

Conversely, combining CSP with SVM alleviates this bias, reducing the FNR to $54.3\% \pm 12.5\%$, but at the expense of the highest false alarm rate across all candidates ($57.0\% \pm 10.0\%$ FPR). Projecting covariance matrices onto the Riemannian tangent space (TGSP+SVM) effectively regularizes this trade-off, retaining a low FNR ($57.5\% \pm 11.6\%$) while substantially curbing spurious activations down to $38.5\% \pm 10.2\%$, achieving the highest overall discriminability ($nMCC = 0.667 \pm 0.051$).

Notably, varying the window step from 0.15 s to 0.50 s systematically penalizes detection latency across all decoders without altering their underlying error profiles (FPR and FNR remain invariant within error margins). This indicates that the operational balance between false alarms and missed intentions is dictated primarily by the feature extraction geometry and classifier loss formulation.

IV. DISCUSSION

The present study demonstrates that pseudo-online BCI performance emerges from the interaction between decoder architecture and temporal processing rather than from the choice of a single decoding pipeline. More importantly, different design parameters influence different dimensions of system behavior, revealing that pseudo-online decoder evaluation should be treated as a multiobjective design problem instead of a conventional classifier comparison.

One of the main findings is the distinct role played by temporal window length and temporal sampling density. Although both parameters define the temporal processing strategy, they affect different aspects of decoder behavior. Larger windows consistently improved classification performance, prediction confidence, and the proportion of contiguous stable blocks, suggesting that integrating longer EEG segments provides a more informative and resilient representation of motor imagery patterns. This improvement, however, comes at the expense of increased response latency, illustrating the classical trade-off between information integration and responsiveness.

Temporal sampling density exhibited a more complex, double-edged behavior. Unlike window length, modifying the overlap by changing step size between consecutive windows had little influence on overall classification performance (nMCC). Instead, increasing the sampling density accelerated system responses but also decreased the proportion of stable blocks, as a denser temporal tracking may produce more confusing windows. Also, sparser sampling introduced computational uncertainty, significantly reducing the prediction confidence of highly expressive decoders (such as TGSP+SVM RBF). This distinction suggests that window length and temporal sampling density should not be regarded as interchangeable parameters, despite both belonging to the temporal processing stage.

The role of decoder architecture was also more nuanced than simply identifying a ”best” classifier. Tangent-space representations combined with SVMs consistently produced higher classification performance and confidence, whereas SVM-based classifiers reduced detection latency relative to the conventional CSP+LDA pipeline. However, decoder architecture had no significant effect on temporal stability (measured as the proportion of continuous correct classifications), indicating that replacing the classifier alone is insufficient to obtain more sustained online behavior. This behavior might be explained by neural dynamics. In any neural task, subject attention may not be fully in the task all the time, making the signal more confusing to classifiers. Also, the rest class introduced in this pseudo-online processing is not homogeneous. It might contain some motor imagery task and many other neural states, making it not very separable from the other classes. Further work should investigate neural representations associated with each

class to provide explanation on temporal stability. Also, many other decoder architectures could be used in order to achieve higher stability, such as ones possessing memory (e.g recurrent neural networks). However, this work suggests that stable decoding is mostly determined by temporal integration rather than by the discriminative power of a memoryless classifier.

In continuous asynchronous operation, the inclusion of a rest class exposes critical vulnerabilities that remain concealed under balanced, epoch-based evaluations. The conventional CSP+LDA pipeline exhibits an apparent selectivity (FPR $\approx 12\%$) that in reality represents a failure mode as the classifier collapses toward the majority rest class, rejecting active motor imagery commands at a high rate (FNR $\approx 77\%$). Mitigating this collapse by pairing CSP with SVM architectures accelerates responsiveness, but introduces an operational penalty of over-activation (FPR $\approx 57\%$). In functional settings such as robotic navigation or prosthetic manipulation, a spontaneous false activation every other window can lead to safety hazards and user frustration. In contrast, projecting spatial covariance matrices onto the Riemannian tangent space (TGSP+SVM) effectively regularizes the decision boundary, reducing false activations to 38.5% while sustaining high sensitivity. This confirms that capturing the intrinsic geometry of EEG signal manifolds provides richer class separability without succumbing to majority-class attraction.

Although smaller step sizes inevitably introduce strong serial correlation among contiguous evaluation epochs, the marginal error rates (FPR and FNR) remain virtually unchanged within each pipeline family. Crucially, the invariance of FPR and FNR across different temporal steps demonstrates an architectural decoupling as the operational bias between missed detections and false alarms is determined by feature extraction and classifier, whereas temporal sampling density strictly dictates the latency with which transitions are registered.

Because performance metrics were averaged across each subject's two same-day sessions prior to statistical modeling, potential within-subject, between-session variability, such as due to electrode impedance changes, fatigue, or short-term nonstationarity in sensorimotor rhythms, was not explicitly modeled and may have been partially masked by this averaging step. Future analyses could treat session as an additional random-effects level to explicitly quantify this source of variability and its relationship with signal nonstationarity.

From a practical perspective, these findings reinforce that different BCI applications require different operating points. Applications demanding rapid interaction, such as assistive device control, may benefit from shorter windows and denser temporal sampling despite a moderate reduction in decision quality and confidence. Conversely, neurorehabilitation protocols, where reliable and sustained feedback is generally more important than minimum response time, may benefit from longer temporal windows that favor confidence and stability. The Pareto analysis illustrates that these objectives cannot generally be optimized simultaneously, emphasizing that decoder configuration should be guided by application-specific priorities rather than by offline accuracy alone.

Finally, this study is limited by its pseudo-online nature. Although the proposed analysis reproduces causal processing and continuous decision making more faithfully than conventional offline evaluation, it does not capture user adaptation to decoder feedback, which is an inherent characteristic of fully closed-loop BCIs. Future work should therefore validate whether the design principles identified here remain consistent during real-time experiments and across different motor imagery paradigms and clinical populations.

Ultimately, rather than identifying a universally optimal decoder, these results provide a principled way to navigate the design space of pseudo-online BCIs by explicitly relating design parameters to different dimensions of online usability.

V. Conclusion

This study demonstrates that pseudo-online BCI performance cannot be adequately characterized by offline classification accuracy alone. Instead, practical system behavior emerges from the combined influence of decoder architecture and temporal processing, with each design parameter governing distinct dimensions of online usability.

Our results show that decoder architecture primarily determines the quality of neural decisions. In contrast, temporal processing plays a broader role. Window length influences every evaluated performance dimension, improving classification performance, confidence, and temporal stability while inevitably increasing detection latency. Temporal sampling density, on the other hand, primarily affects the dynamics of decoder operation, accelerating system responses at the expense of temporal stability and, for Riemannian decoders, prediction confidence.

These findings demonstrate that configuring a pseudo-online BCI inherently involves balancing competing objectives. Improving one performance dimension generally requires compromises in another, indicating that no single configuration simultaneously optimizes responsiveness, decision quality, confidence, and stability. Consequently, decoder selection should not be formulated as the search for the most accurate offline model, but rather as a multiobjective design problem whose optimal solution depends on the intended application.

The adapted pseudo-online evaluation protocol employed here offers a design-oriented methodology for characterizing these trade-offs under realistic causal processing conditions. Rather than identifying a universally optimal decoding pipeline, it enables researchers and engineers to understand how different design choices shape online system behavior, supporting the selection of operating points that better match the clinical and functional requirements of applications ranging from rapid assistive control to highly stable neurorehabilitation protocols.

Despite offering a latency-aware and causally constrained perspective, this study is inherently bounded by the pseudo-online nature of its evaluation. Static offline recordings cannot capture real-time user co-adaptation, voluntary strategy shifts,

or the closed-loop neuroplasticity elicited by immediate sensory feedback. Future work should validate whether the design principles and error dynamics identified here hold during fully closed-loop implementations across longitudinal sessions and diverse clinical populations. Additionally, future efforts should pursue the development of composite usability metrics that formally integrate latency, stability and decision into a unified real-time benchmark.

***Abstract*—Cervical Vestibular Evoked Myogenic Potential (cVEMP) recordings were evaluated in five patients with otoneurological symptoms (Experimental Group [EG]; 46.6 $\pm$ 14.88 years) and three healthy subjects (Control Group [CG]; 26 $\pm$ 7.21 years) using 500 Hz tone-burst stimuli at 95 dB nHL. Unfiltered signals were processed in Python to evaluate P13 and N23 peak latencies, peak-to-peak amplitudes, and pre-stimulus background EMG RMS. Continuous Wavelet Transform (CWT) was implemented for time-frequency signal decomposition, assessing multi-scale energy distribution across slow, transition, and fast muscle fiber bands. The CG demonstrated larger P13–N23 amplitudes and shorter latencies compared to the EG, with attenuated EG responses attributed to sacculocollic pathway hyporesponsiveness rather than reduced tonic muscle contraction. Wavelet scalograms revealed distinct time-frequency patterns: CG participants exhibited concentrated low-frequency energy (25–50 Hz) at 20–35 ms, whereas the EG displayed signal desynchronization, prolonged inhibitory bands, elevated fast-fiber energy distribution ($p = 0.0007, r = 0.358$), and significantly lower dominant frequencies ($p = 0.0001$). These findings suggest vestibulocollic reflex dysregulation in patients with vestibular complaints and demonstrate that Wavelet-based spectral analysis effectively complements conventional cVEMP assessment by resolving temporal and spectral dynamics obscured in standard time-domain averaged waveforms.**

I. Introduction

Vestibular function assessment relies on methods capable of objectively characterizing the integrity of the sensory pathways involved in balance control. The vestibular system, specifically its otolithic component, plays a role in detecting linear acceleration and maintaining postural stability[1]. Alterations in this system are associated with symptoms such as vertigo, postural instability, and oculomotor deficits, which are frequently observed in various neurological and vestibular conditions[2].

Cervical Vestibular Evoked Myogenic Potential (cVEMP) is used to assess the vestibulocollic pathway, specifically the function of the saccule and the inferior vestibular nerve. The signal is elicited via acoustic or vibratory stimuli and recorded using surface electromyography (sEMG) of the sternocleidomastoid (SCM) muscle. It reflects an inhibitory vestibulocollic reflex, manifesting as a transient reduction in SCM tonic activity[3]. The P13 and N23 potentials correspond to a transient suppression of SCM tonic activity resulting from a decrease in the firing rate of a subset of alpha motoneurons.

In clinical practice, cVEMP interpretation relies on time-domain parameters, such as P13 and N23 wave latencies and peak-to-peak amplitude[2]. Conversely, sEMG spectral information, such as frequency (Hz, is not utilized in conventional cVEMP clinical metrics. Frequency-domain parameters are influenced by inter-subject variability (e.g., age, sex, clinical condition and muscle length) and the level of tonic muscle contraction required during the test, all of which can induce subtle changes in signal dynamics[4].

Furthermore, individuals with vestibular complaints may exhibit responses within normal ranges, suggesting that conventional analysis may fail to detect subtle physiological alterations[5]. Such limitations demonstrate the need for methods capable of simultaneously evaluating the temporal and spectral information of the signal while preserving local variations relevant to its characterization. The Wavelet Transform enables the time-frequency decomposition of non-stationary signals, allowing for the extraction of coefficients associated with transient components that are not captured by global time-domain metrics[6, 7]—unlike the Fourier Transform or Fast Fourier Transform, which do not provide information regarding the specific time instants at which these frequencies occur[8].

In this context, applying the Wavelet Transform to raw cVEMP EMG signals can enhance the characterization of the vestibulospinal response by enabling the identification of subtle changes in the temporal dynamics of SCM activity, including modifications in the onset, duration, and evolution of the inhibitory response, that might go undetected by conventional latency (P13 and N23) and amplitude measurements. Despite this potential, this approach remains under-explored in cVEMP analysis.

Therefore, this study proposed the application of Wavelet

Transform to the raw cVEMP signal in patients with otoneurological complaints to explore the time-frequency feature extraction of the signal as a complementary tool to conventional analysis.

II. Materials and methods

This study was approved by the Research Ethics Committee of the Alberto Santos Dumont Institute of Education and Research (CEP/ISD), under number 7.890.476. The analyzed data were derived from routine diagnostic procedures performed at the clinical facility. This pilot observational study used a convenience sample of eight participants, who were assigned to two groups: an experimental group (EG) and a control group (CG).

A. Sample characterization

The EG consisted of five participants: three females and two males, aged 26 to 65 years (mean: 46.6 ± 14.88 years). The main complaints reported included dizziness, noise-induced vertigo, imbalance, and difficulties with activities involving linear acceleration and vertical body movement, such as climbing and descending stairs, using elevators, and traveling in vehicles. The CG comprised two females and one male, aged 20 to 32 years (mean: 26 ± 7.21 years), with no otological complaints.

B. Test execution and data acquisition

The tests were performed using an EP25-Eclipse system (Interacoustics®). The participants remained seated, and to activate the target SCM, all individuals were instructed to rotate their heads contralaterally to the muscle being tested. Muscle contraction levels were monitored using electromyographic biofeedback provided by the cVEMP module, targeting electromyographic activity between 50 and 150 μV[2]. Electrodes were positioned bilaterally: active electrodes on the middle third of the SCM, reference electrode at the sternoclavicular joint, and ground electrode on the forehead[2, 9]. cVEMP responses were recorded via air conduction using ER-3A insert earphones, employing a 500 Hz tone-burst stimulus (2-0-2 cycles) at a presentation rate of 5.1 stimuli per second and an intensity of 95 dB nHL[2]. Data acquisition was performed within a -20 to 80 ms time window, using a 10 Hz high-pass filter (6 dB/octave) and a 1 kHz low-pass filter, with an average of 200 stimuli[2, 9]. Two independent and consecutive runs were performed for each ear, labeled L and L1 for the left ear and R and R1 for the right ear. Within each run, four responses were recorded: two ipsilateral (IPSI A and IPSI B) and two contralateral responses (CONTRA A and CONTRA B). Point-by-point averaging was applied to combine IPSI A with IPSI B and, CONTRA A with CONTRA B, yielding one representative ipsilateral and one contralateral response per run. These repeated acquisitions were conducted to assess the trace consistency and potential reproducibility. The cVEMP amplitudes were normalized to the background electromyographic (EMG) activity using the equipment software. The normalized amplitude was calculated as the ratio between the raw peak-to-peak response amplitude and the root mean square (RMS) value of the baseline muscle EMG activity, according to the following equation:

$$\text{Normalized Amplitude} = \frac{\text{Raw Peak-to-Peak Amplitude } (\mu\text{V})}{\text{Baseline EMG RMS } (\mu\text{V})} \quad (1)$$

This calculation is used to minimize the influence of variations in muscle contraction levels on the recorded amplitudes. Conventional cVEMP parameters were analyzed from the waveforms, including the P13 and N23 peak latencies and peak-to-peak amplitude.

C. Data preprocessing

The cVEMP recordings were exported via the EP25 system's Research module in XML format and subsequently processed in a computational environment. Signals were acquired at a sampling rate of approximately 3.000 Hz with a 100-ms recording window, resulting in 467 samples per segment. The signals were organized and exported to a spreadsheet format (Microsoft Excel®) for subsequent processing and analysis.

The time axis of each response was reconstructed based on the sampling frequency and number of pre-stimulus samples specified in the XML file. Following the consolidation of responses A and B, as previously described, the ipsilateral and contralateral waveforms for each averaged trace were retained for subsequent processing steps. Baseline correction was performed by subtracting the signal median calculated over the pre-stimulus window from -20 to -5 ms. The signals were arranged in a standardized structure containing the time axis and the corresponding ipsilateral and contralateral waveforms for acquisitions L, L1, R, and R1.

For each participant, the parameter values extracted from acquisitions L, L1, R, and R1 were subsequently consolidated by computing their mean, yielding a single final value for each analyzed parameter.

D. Data processing

The cVEMP signals were processed using a Python code executed in the Google Colab environment. XML files exported by the equipment were automatically imported, and the two recording replications corresponding to the IPSI A Raw and IPSI B Raw vectors were extracted.

The time axis was reconstructed based on the sampling frequency and the number of pre-stimulus samples recorded in each file. Subsequently, the average waveform of the two replications was calculated, while the individual signals were preserved to assess response reproducibility. Baseline correction was performed by subtracting the signal median within the pre-stimulus interval of -20 to -5 ms.

Polarity orientation was defined according to the expected cVEMP morphology, with P13 designated as a positive deflection and N23 as a negative deflection. Component identification was conducted using the "find peaks" function. For the participants, the search was conducted within broad windows: 8 to 20 ms for P13 and 14 to 32 ms for N23.

These windows allowed for the identification of responses with latency variations, while normative intervals of approximately 13 to 16 ms for P13 and 21 to 25 ms for N23 were considered for the clinical interpretation of the results[9].

Within each window, the algorithm identified local extrema based on a minimum distance of 2 ms between peaks and a prominence criterion that was adjusted to signal variability. To identify N23, the component was required to occur after P13, with an interpeak interval of 3 to 20 ms. When multiple peaks were identified within the window, the peak with the highest combination of amplitude and prominence was selected. In the absence of a peak meeting these criteria, the extremum with the greatest magnitude within the window was selected. After determining the latencies, the P13 and N23 amplitudes were obtained at the respective signal points. The peak-to-peak amplitude was calculated as the difference between the P13 and N23 amplitudes.

The response was classified as absent when it was not possible to identify a P13–N23 complex with a positive amplitude and appropriate temporal ordering. The pre-stimulus RMS value provided by the equipment was analyzed separately as an indicator of SCM muscle contraction level during the examination.

For raw signal processing, the Wavelet Transform was applied to decompose the signal in the time-frequency domain and characterize its multiscale structure, as represented by the following expression:

$$W(a,b) = \frac{1}{\sqrt{|a|}} \int_{-\infty}^{+\infty} x(t)\, \psi^* \left(\frac{t-b}{a} \right) dt \qquad (2)$$

where x(t) represents the analyzed signal, ψ^* denotes the complex conjugate of the wavelet function, a corresponds to the scale parameter, and b indicates the temporal position.

This approach allowed for the observation of energy distribution over time and across the different frequency bands of the cVEMP. The acquired data were processed individually, enabling an assessment of response consistency both within and across participants, as well as the identification of variations in the morphology and pattern of the evoked response.

III. Results and discussion

Two trials were performed for each acquisition (ipsilateral and contralateral), resulting in four trials per ear. The results of the conventional cVEMP analysis are presented in Table 1, which shows the P13 and N23 latency values and peak-to-peak amplitudes obtained from the sample.

The CG exhibited shorter latencies and larger amplitudes of the P13–N23 complex, particularly in the right ear. In the same ear, three of the five participants in the EG showed an absent response; consequently, mean latency and amplitude values were calculated using only the valid responses. In the left ear, latencies were similar between the groups, whereas amplitudes remained larger in the CG.

The lower amplitudes observed in the EG do not appear to stem solely from a low level of muscle contraction, given that the mean pre-stimulus RMS values were similar across groups and fell within the baseline range for cVEMP testing. This finding may be explained by the reduced responsiveness of the sacculocollic pathway in the EG, potentially involving differences in the excitability of saccular sensory cells, conduction via the inferior vestibular nerve, or reflex activation of the SCM muscle, a hypothesis further supported by the higher number of absent responses in the right ear.

TABLE I
Results of the conventional cVEMP analysis for the evaluated participants, divided into the experimental group (EG) and CG (CG).

Right Ear				
	EG (n=5)		**CG (n=3)**	
	Mean	**SD**	**Mean**	**SD**
P13 Latency (ms)	20.33	± 1.41	15.89	± 0.51
P13 Amplitude (μV)	12.42	± 5.69	48.65	± 22.43
N23 Latency (ms)	30.50	± 0.71	25.33	± 1.76
N23 Amplitude (μV)	−7.14	± 1.16	−64.16	± 15.51

Pre-stimulus RMS (μV)	86.00	± 26.90	95.67	± 14.57

Data are presented as mean ± standard deviation (SD). **EG**: Experimental Group; **CG**: CG; **cVEMP**: Cervical Vestibular Evoked Myogenic Potential; **n**: number of participants ; **SD**: Standard Deviation; **ms**: milliseconds; **μV**: microvolts; **RMS**: Root Mean Square.

N23 latency in the left ear showed a different pattern than that observed in the right ear, being slightly longer in the CG. However, the small difference between means and the data variability suggest that this result may represent sampling variation rather than indicating vestibular dysfunction in CG participants, especially given their lack of comorbidities or vestibular complaints.

The Wavelet Transform, when applied to sEMG analysis, allows for the assessment of energy distribution across different frequency bands, providing insights into muscle recruitment patterns. Frequencies below 100 Hz are known to be associated with the combined activity of slow-twitch (Type I) and fast-twitch (Type II) muscle fibers [8]. Thus, this analysis can serve as an indirect indicator of motor unit recruitment patterns. Characterizing these patterns has been employed in the study of motor tasks such as walking and running [8]. Time-frequency analysis of the signal obtained during cVEMP testing can contribute to the assessment of motor fiber recruitment in various vestibular pathologies; in the future, alterations observed in spectral distribution and muscle recruitment dynamics could be investigated as potential functional biomarkers for different clinical conditions.

Furthermore, individual analysis of the recordings allows for the examination of intra- and inter-individual variability, considering aspects such as amplitude, morphology, energy distribution, coherence between replications, and inter-aural differences. Such information is often reduced or obscured

when the assessment is limited to the average waveform, as the averaging process attenuates variations present in individual responses[10].

Participants 2 and 3 in the CG exhibited, in recordings L, L1, R, and R1, a higher concentration of energy between 20 and 35 ms (predominantly in the 25–50 Hz range) in both the IPSI A and IPSI B replications, alongside an absence of response in the contralateral channels. This finding may be related to a greater contribution from motor units with slower conduction characteristics (10–90 Hz), as shown in Figure 1.

For CG Participant 1, acquisition L showed temporal inconsistency between the IPSI A and IPSI B replications (Figure 2A). Although both displayed regions of high energy, desynchronization was observed in the timing of their responses. In the IPSI A replication, the highest-intensity activity occurred at a later latency, with energy concentrated predominantly in the 50–65 Hz range. In contrast, the main energy concentration in the IPSI B replication was observed at the beginning of the recording. These differences indicate low temporal and morphological reproducibility between replications, which may be attributable to instability in the level of muscle contraction, differences in motor unit recruitment between acquisitions, or the presence of artifacts not synchronized with the stimulus. In acquisition L1, IPSI A replication showed a reduction in background energy throughout the recording. Conversely, IPSI B replication revealed a continuous horizontal band of high energy concentrated at approximately 50 Hz across the entire analyzed window, suggesting sustained inhibition of the SCM muscle fibers in this frequency range (Figure 2B). In the right-side acquisitions (R and R1), the pattern was similar to that of the other two controls. However, foci of energy were also detected in the contralateral channels, occurring at time intervals coinciding with the ipsilateral responses (Figure 2C).

Analysis of the Wavelet scalograms for Participant 1 of the EG revealed transient and prolonged energy patterns, with differences observed between the acquisitions and their respective replications. In acquisition L, the IPSI B replication displayed a phasic pattern characterized by a delimited region of higher energy between approximately 40 and 80 ms, predominantly in the 50–75 Hz range. Conversely, in the IPSI A and IPSI B replications of acquisition L1, the highest energy concentration occurred at the beginning of the recording (Figures 3C and 3D).

In acquisition R1, both ipsilateral replications showed two distinct energy foci (Figures 3A and 3B). Additionally, the IPSI A replication exhibited a continuous, prolonged horizontal band around 50 Hz (Figure 3A), a pattern also observed in Participant 5 of the EG (Figure 3D). This shift in response suggests two possibilities: a continuous inhibitory signal or sequential firing of inhibitory events via the vestibulocollic pathway.

A continuous energy pattern throughout the analyzed interval suggests the sustained inhibition of SCM motor units. Notably, no EG participant reported pain, muscle weakness, or limited cervical mobility, which reduces the likelihood that the observed differences were related to peripheral musculoskeletal alterations. Regarding the sequential firing of inhibitory events, this could manifest as peaks and troughs in conventional cVEMP analysis when observing variations over time.

The findings observed in the EG suggest that the output of the vestibulocollic pathway may not elicit the expected motoneuronal suppression in response to the auditory stimulus. This raises the hypothesis of a dysregulation in the processing of this reflex, which aligns with the primary complaints of patients regarding dizziness in situations requiring postural maintenance against linear acceleration stimuli, a function mediated by the otolithic organs [9].

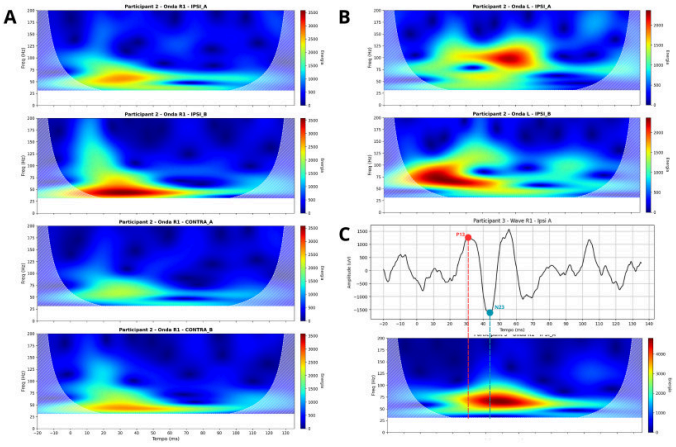

Fig. 4. Conventional signal results and wavelet scalogram for Participant 2 of the GE group. **A** – Wavelet scalogram of the R1 wave for Participant 2 of the GE group, showing contralateral responses; **B** – Wavelet scalogram of the L wave for Participant 2 of the GE group, showing responses above 75 Hz; **C** – Comparison between the raw signal in the frequency domain and the wavelet scalogram.

One argument that could be raised to challenge these assumptions is the presence of various peaks and troughs between -20 and 0 ms that are not clearly defined in the wavelet analysis. However, no sound was emitted during this period. Therefore, it was impossible to trigger a vestibular response. From t = 0 ms, coinciding with the onset of the auditory stimulus, there was an increase in wave amplitude and the appearance of energy clusters, occurring immediately after the triggering of the initial P1 response at the 10 ms mark (Figure 3).

Participant 2 stood out due to the appearance of frequencies above 75 Hz for the L-wave (IPSI A and B; Figure 4B) and contralateral activation for the R and R1 waves (Figure 4A). Participant 3 demonstrated a pattern closer to normal on the left side, with a longer latency for the appearance of the energy focus in the right ear and frequencies above 50 Hz. This result resembled the conventional analysis of the test, which indicated a delayed latency.

Finally, Participant 4 (data not shown) demonstrated a pattern similar to that of the controls on the left side; on the right side (R), a patch extended from 15 to 110 ms within the 25–50 Hz frequency range for IPSI A at R1, while IPSI B showed a patch extending from -10 to 110 ms, with more distinct energy foci at 15 and 80 ms (also in the 25–50 Hz range) and a contralateral response (CONTRA B) with similar morphology. Quantitative analysis evaluated the percentage of energy in slow (10–60 Hz), transition (60–90 Hz), and fast (90–270 Hz) muscle fibers, based on the classification by Koenig et al. (2018)[1], with an adaptation for transition fibers, in addition to the dominant frequency and peak energy latency. Following the consistency assessment between responses A and B across all conditions, no statistically significant differences were observed (p ¿ 0.05). Consequently, IPSI A and IPSI B responses were averaged, as were CONTRA A and CONTRA B. The parameter values obtained from runs L, L1, R, and R1 were subsequently averaged to yield the final value for each parameter per participant (Table 2). Both groups exhibited a predominance of energy in slow fibers, accounting for over 95% of the total energy, with approximately 4% attributed to transition fibers and less than 1% to fast fibers, demonstrating similar behavior between the sides. In the EG, the mean dominant frequency was 39 Hz in the ipsilateral condition, with a latency of approximately 71 ms, and 25 Hz in the contralateral condition, with a duration near 10 ms. In the CG, similar values were observed between the ipsilateral and contralateral conditions, with dominant frequencies of approximately 39 Hz at 55 ms and 38 Hz at 56 ms, respectively.

Statistical analysis was performed using the Mann–Whitney U test as a non-parametric method to compare groups, given the data distribution. The level of significance was set at 5% (p ¡ 0.05), and effect size r was calculated to assess the magnitude of the observed differences.

Energy allocation analysis across muscle fiber types revealed no statistically significant differences between the EG and CG for slow (U = 1874, p = 0.8228, r = 0.024) or transition fibers (U = 1776, p = 0.4800, r = 0.075). However, a statistically significant difference was observed for fast fibers (U = 2607, p = 0.0007), with a moderate effect size (r = 0.358). Median comparison demonstrated values of 0.77 for the EG and 0.40 for the CG, indicating a higher proportion of energy attributed to fast fibers in the EG. This finding suggests that a higher activation pattern of fast fibers may be associated with otoneurological alterations, analogous to observations in other neuromuscular pathologies[10]. Given that motor fiber activation patterns are precisely coordinated through distinct firing frequencies, disruption of this pattern may serve as

TABLE II
SPECTRAL ENERGY DISTRIBUTION, DOMINANT FREQUENCY, AND LATENCY DERIVED FROM CONTINUOUS WAVELET TRANSFORM.

** Statistically significant ($p < 0.05$).

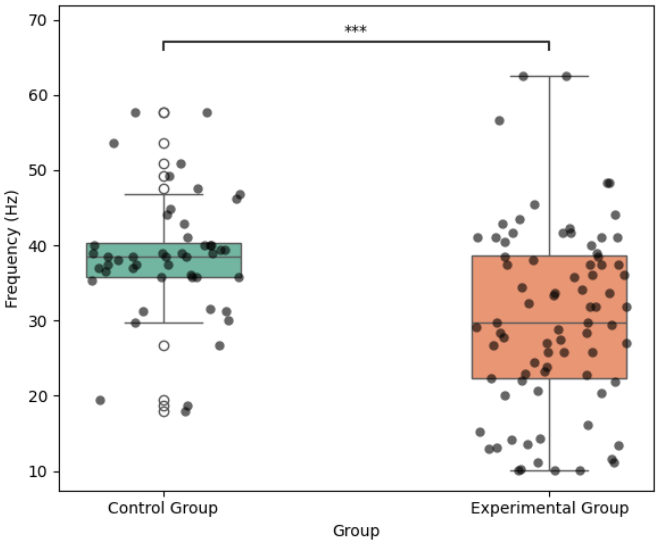

Fig. 5. Boxplot of dominant frequency distribution between the CG (CG) and Experimental Group (EG). Individual data points are overlayed as jittered scatter points. The horizontal line inside each box represents the median frequency. *** p = 0.0001 (Mann–Whitney U test).

a potential biomarker for diagnosing and evaluating clinical neurodegenerative and neuromuscular disorders[9]. Dominant frequency analysis demonstrated a statistically significant difference between the groups (U = 1134.0, p = 0.0001), with the CG exhibiting a higher median (38.46 Hz) than the EG (29.70 Hz). When evaluating the slow and transition frequency bands, the CG also displayed consistently higher medians.

Taken together, the findings regarding dominant frequency and energy percentage across fiber categories revealed a trend toward a higher concentration of frequencies below 90 Hz in the CG, whereas the EG presented a larger proportion of energy attributed to fast fibers. Furthermore, the mean latency of the dominant frequency was prolonged in both ipsilateral and contralateral conditions for the EG compared to the CG. Based on these observations, we hypothesize that individuals without otological complaints exhibit a preferential activation pattern of lower frequencies along with a shorter latency of the dominant frequencies.

The median comparison demonstrated that the EG had a higher energy proportion attributed to fast fibers than the CG, raising the hypothesis of distinct motor unit recruitment patterns between groups. In this context, age-related structural and functional modifications of muscle tissue are well recognized. Previous literature highlights a selective reduction of type II muscle fibers in elderly individuals, while type I fibers remain relatively preserved [10].

This process is closely tied to age-related motor unit remodeling, characterized primarily by the denervation of type II fibers and subsequent collateral reinnervation by motoneurons

supplying type I fibers [10]. However, because our sample was not homogeneous regarding advanced age, aging alone cannot account for the increased fast-fiber activation observed in the EG.

Although statistically significant differences and a moderate effect size for fast fibers were identified, these results should be interpreted with caution. Limitations such as the small sample size, lack of age and sex matching, heterogeneity of otoneurological complaints, and unequal group sizes may influence the findings. Additionally, the absence of a more rigorous methodological design restricts definitive conclusions regarding the observed recruitment patterns.

Consequently, the hypotheses derived from time-frequency characteristics do not allow, at this preliminary stage, for the establishment of specific recruitment profiles or precise clinical associations. Confirmation in future studies with larger, age-matched, and clinically stratified cohorts is required.

Despite these limitations, our findings highlight the potential of time-frequency analysis as a complementary tool in cVEMP signal evaluation. Ongoing research aims to deepen the understanding of time-frequency signal properties and their relationship with conventional cVEMP parameters.

Future investigations featuring larger, clinically stratified cohorts should quantitatively assess the presence and distribution of energy across distinct frequency bands and their correlation with standard cVEMP metrics. Identifying consistent spectral signatures may clarify the utility of time-frequency analysis in characterizing and differentiating otoneurological conditions (e.g., Meniere's Disease, Vestibular Hypofunction, Tinnitus) from central nervous system disorders (e.g., Parkinson's Disease, Multiple Sclerosis) as an adjunct to standard assessment. Furthermore, a relative attenuation of low-frequency components accompanied by a spectral shift toward higher frequency bands across the recording window warrants further investigation regarding transient alterations in sternocleidomastoid motor unit activity during vestibular stimulation.

IV. Conclusion

Time-frequency analysis using the Wavelet Transform revealed differences in energy distribution, temporal organization, and response reproducibility of cVEMPs between participants with vestibular complaints and control subjects. In the EG, greater variability between replications, absent responses, and distinct energy patterns were observed. These findings indicate that Wavelet-based analysis can complement conventional cVEMP assessment by providing additional insights into the signal's temporal and spectral dynamics, which may not be detected solely through averaged waveforms.

Thus, this study offers a complementary approach to cVEMP signal processing, suggesting that time-frequency analysis may aid in identifying response patterns related to alterations in vestibulo-collic pathway modulation and sternocleidomastoid neuromuscular recruitment. However, as this is a preliminary study, further validation in larger cohorts using standardized criteria and quantitative metrics is necessary to confirm its clinical applicability and diagnostic contribution to otoneurology.

***Abstract*—The Internet of Medical Things (IoMT) is driving a profound digital transformation in healthcare, interconnecting medical devices, sensors, and software applications to enable data-driven, proactive asset management in Clinical Engineering. This paper presents a low-cost, non-intrusive IoMT prototype designed to estimate the operational status of a hospital air compressor without altering its original circuitry. This paper presents a low-cost, non-intrusive Internet of Medical Things (IoMT) prototype designed to estimate the operational status of a hospital air compressor without altering its original circuitry. Utilizing an ESP32 microcontroller paired with an MPU6050 accelerometer, the system captures triaxial vibration data and computes Root Mean Square (RMS) values at the edge to classify equipment status as active or idle. Collected data is transmitted via HTTP POST requests to a cloud pipeline comprising Google Apps Script and Google BigQuery, paired with a companion interface for real-time visualization. A preliminary evaluation was conducted on a single FANEM 089/CAL compressor using manually logged start/stop events as ground truth across five observation sessions: three 10-minute sessions for the compressor alone and 10-minute sessions for each of two external interference sources. The results demonstrate that this non-intrusive approach effectively tracks device duty cycles, despite the simplicity of using a single fixed RMS threshold. Overall, this work presents an early-stage architecture and its initial validation, laying the groundwork for future multi-device studies, frequency-domain analysis, and tiny machine-learning-based (tinyML) fault detection.**

***Index Terms*—Clinical Engineering, Internet of Medical Things, medical devices, data-driven**

I. Introduction

The modern healthcare ecosystem is undergoing a profound digital transformation driven by the integration of the Internet of Medical Things (IoMT)—a specialized domain of the Internet of Things (IoT) that encompasses interconnected medical devices, sensors, and software applications designed to communicate within clinical environments [1]. In this context, ensuring the continuous availability and operational reliability of medical equipment is essential to maintaining patient safety and optimizing healthcare workflows [2]–[4].

Currently, Clinical Engineering teams face substantial operational challenges in managing decentralized support assets, such as laboratory air compressors. The lack of automated real-time monitoring hinders precise tracking of actual equipment running hours, forcing reliance on manual, error-prone logs or periodic maintenance schedules that do not reflect true usage patterns [5]. Furthermore, Clinical Engineers must comply with stringent regulatory frameworks that prohibit alterations to the electrical circuitry of certified medical equipment, preventing the adoption of standard current- or power-monitoring solutions. Consequently, key reliability metrics—such as the *Mean Time Between Failures* (MTBF)—are frequently distorted because they rely on rough estimations rather than precise operational data [6]. This lack of visibility limits proactive management, complicates the identification of overloaded or underutilized assets, and elevates the risk of unexpected downtime in critical clinical applications.

To address these limitations, this paper introduces a low-cost telemetry prototype specifically tailored for Clinical Engineering applications. Built around an ESP32 microcontroller and an MPU6050 accelerometer, the system continuously acquires and processes triaxial vibration signals from a laboratory air compressor–used as a testing model. By executing edge-processing algorithms, the device calculates the Root Mean Square (RMS) to estimate the operational state ("*On*" or "*Off*") and dynamically monitor the equipment's duty cycle.

A central design requirement of this architecture is complete non-intrusiveness. By relying exclusively on an external vibration sensor attached to the chassis, the system captures operational indicators without requiring physical or electrical modifications to the device. This approach aligns with regulatory directives, such as ANVISA's frameworks (e.g., RDC 509/2021 [7] and RDC 665/2022 [8]), which restrict changes to an approved device's manufacturing profile. However, non-intrusive mounting does not automatically imply full regulatory compliance: a dedicated risk assessment evaluating stability and potential environmental interference remains necessary prior to clinical deployment. Within these constraints, the proposed system provides automated, per-compressor running-time telemetry to support asset management in decentralized environments.

The acquired data is transmitted via HTTP POST requests to a cloud backend, where Google Apps Script manages ingestion

and streams records into Google BigQuery for persistent storage. Because BigQuery is a general-purpose, SQL-based Data Warehouse, the resulting historical log is compatible with external business-intelligence platforms (e.g., Looker Studio or Power BI), which could be connected in future deployments to provide Clinical Engineers with interactive operational dashboards; the present prototype, however, relies on a lightweight custom web interface for real-time monitoring, described in the Methodology. Ultimately, this paper presents the architectural design and preliminary single-device validation of the proposed prototype, offering an accessible, low-cost solution to track real-time operational cycles of decentralized medical compressors.

II. Methodology

The development of the non-intrusive IoMT telemetry prototype was structured into three primary layers: (*i*) edge hardware data acquisition, (*ii*) cloud-based middleware ingestion, and (*iii*) a data warehouse.

A. Hardware Setup and Non-Intrusive Data Acquisition

The data acquisition node consists of an ESP32 microcontroller integrated with an MPU6050 triaxial accelerometer. The sensor was externally attached, via mechanical coupling (with a double-sided tape) to the chassis of a single FANEM 089/CAL laboratory compressor, a model often used in hospital/clinical settings for vacuum and pressure supply. The sensor attachment did not require any electrical or physical modification of the equipment's original internal circuitry. The system was configured to sample raw acceleration data along the X, Y, and Z axes through an I^2C communication interface at a sampling frequency adjusted via firmware. The proposed prototype is illustrated in Figure 1. To evaluate potential interferences, the same tests were ran with a magnetic stirrer Fisatom (Model 752A, 650 W, 220 V) and a water distiller Gnatus Aquaclean (750 W, 220 V). Both magnetic stirrer and water distiller were placed about 12 cm next to the laboratory compressor, in distinct moments. Hence, manual log and automated responses from the device were obtained.

B. Edge Signal Processing and Feature Extraction

To isolate mechanical vibrations from the static gravitational acceleration, the ESP32 samples triaxial acceleration data at a frequency defined by a 5 ms interval. For each sampling cycle, the system collects a sequence of $N = 60$ readings. The vibration intensity is calculated by determining the magnitude of the acceleration vector (A_{mag}) and subtracting the constant gravitational component ($g = 9.81$ m/s^2). The Root Mean Square (RMS) value is then computed to represent the vibration energy, as defined by (1):

$$\text{RMS} = \sqrt{\frac{1}{N}\sum_{k=1}^{N}(A_{mag,k} - g)^2} \tag{1}$$

where $A_{mag,k} = \sqrt{a_{x,k}^2 + a_{y,k}^2 + a_{z,k}^2}$ is the magnitude of the acceleration vector at sample k. This RMS value was compared against an empirically defined operational threshold of 1.195 m/s^2 (Section III-C discusses about this choice). If the calculated RMS exceeds this value, the status is updated to "*Em operacao*"; otherwise, it is flagged as "*Desligado*".

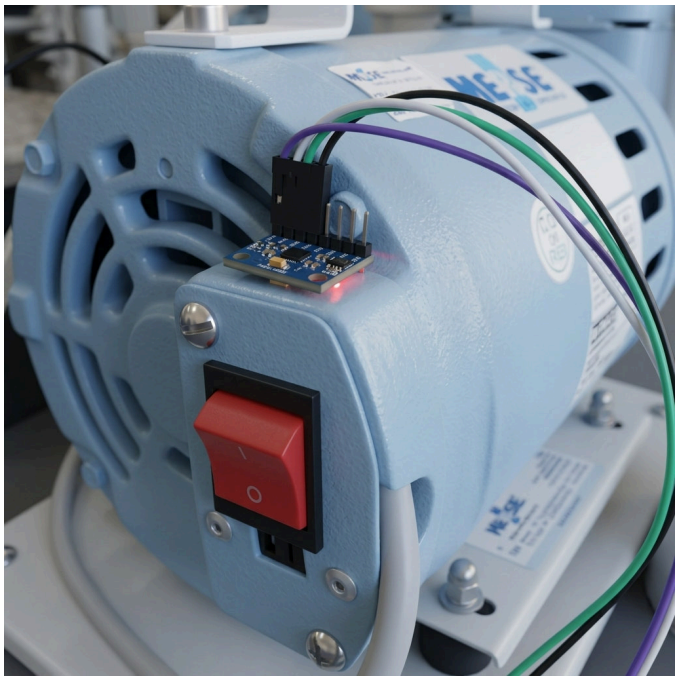

Fig. 1. Proposed IoMT-based prototype.

C. Cloud Ingestion and Data Warehousing Architecture

The ESP32 processes vibration data in batches of 60 samples and transmits the resulting status via an HTTP POST request to the cloud-based architecture, typically achieving a reporting frequency of approximately 2 samples per second. To maintain asset traceability, the system utilizes a relational mapping between the hardware's unique *id_iot*, the equipment's official asset number (*patrimonio*), and its physical location (*localizacao*), so that telemetry data is attributed to the specific compressor unit.

To ensure authenticity and integrity of the telemetry, each payload is signed on the device using HMAC-SHA256 over a canonical string composed of the device identifier, the RMS value, and the operational status, with a pre-shared secret key. The cloud script recomputes this signature upon receipt and discards any payload whose signature does not match, mitigating spoofed or tampered readings. Confidentiality in transit is provided by the HTTPS endpoint of the proposed architecture.

Upon receiving and validating a payload, the cloud script performs two tasks:

- **Real-time Caching:** it stores the raw JSON in the global *CacheService* to feed the client-side user interface, at the full sampling resolution of the device.
- **Historical Logging:** it writes to Google BigQuery (table: *tb_monitoramento_iot*) using an event-driven, throttled

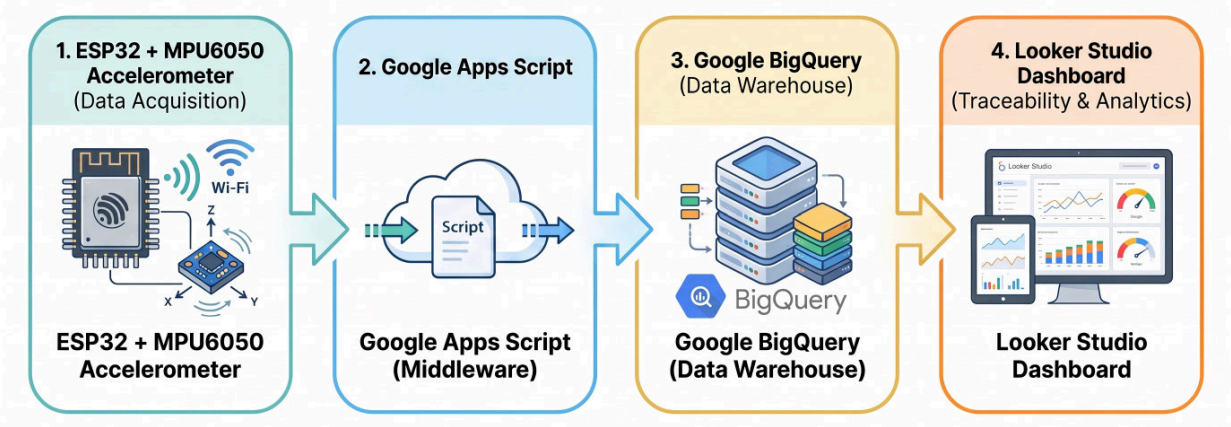

Fig. 2. Architectural framework of the proposed IoMT system.

persistence strategy: a record is written immediately whenever the operational status changes (preserving precise transition timestamps for duty-cycle analysis), and, while the status remains unchanged, at most once every 5 seconds as a heartbeat. This reduces the insertion rate by an order of magnitude compared to logging every sample, while still reconstructing a continuous "on/off" history – including idle periods, which the previous status-gated design did not persist.

The pipeline of the developed prototype is shown in Figure 2. It is important to note that the pre-shared HMAC key is currently embedded in the firmware and manually mirrored in the script's configuration, with no key-rotation mechanism, replay protection, or local buffering strategy for network outages yet implemented. These aspects are discussed further in Section III-C.

D. User Interface

The user interface was developed using HTML5, CSS3, and JavaScript, embedded within the Google Web App environment. The data architecture mapping between the clinical asset and its telemetry records is shown in the Entity-Relationship Diagram (ERD) in Figure 3.

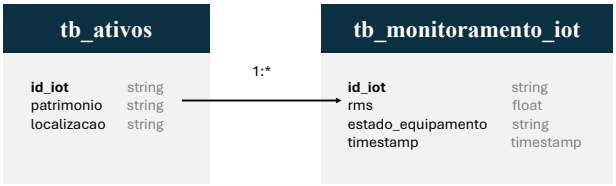

Fig. 3. Entity-Relationship Diagram illustrating the data architecture mapping between the clinical asset and its telemetry monitoring records.

E. Evaluation Protocol

To assess the system's ability to detect compressor operational status, a preliminary evaluation was conducted on the single FANEM 089/CAL unit, as described above. Ground truth was established through a manually recorded log of start and stop events, kept in parallel with the system's automated readings across five observation sessions: three 10-minute sessions for the compressor alone and 10-minute sessions for each of two external interference sources. For each condition, the events were compared between the manual log and the system log to compute sensitivity.

III. Results and Discussion

The proposed IoMT prototype is presented through a web interface (Figure 4) that visualizes the current status of the monitored compressor and its recent vibration telemetry.

Fig. 4. Custom web interface displaying the real-time operational status and RMS vibration reading of the monitored compressor.

TABLE I
RESULTS OBTAINED DURING OPERATIONAL MONITORING

Condition	State	N	Mean	Std	Min	Max	Q1	Q2	Q3
Normal	Off	158	0.456	0.031	0.398	0.582	0.427	0.468	0.477
	On	338	2.127	0.124	1.808	2.923	2.000	2.135	2.218
Magnetic stirrer interference	Off	29	0.446	0.010	0.432	0.492	0.441	0.445	0.447
	On	69	2.197	0.069	2.044	2.351	2.145	2.193	2.240
Water distiller	Off	25	0.442	0.020	0.421	0.520	0.434	0.437	0.520
	On	44	2.252	0.067	2.089	2.373	2.200	2.261	2.373

N: sample count, Std: Standard Deviation, Min: minimum, Max: maximum, Q1: first quartile, Q2: second quartile, Q3: third quartile.

TABLE II
COMPARISON BETWEEN COMMERCIAL IOT PLATFORMS AND THE PROPOSED ARCHITECTURE.

Criterion	Commercial platforms (Blynk, ThingSpeak, Arduino IoT Cloud)	Proposed architecture (ESP32 + BigQuery + custom Web App)
Cost	Low, typically with limited free tiers	Low, variable cost based on data volume (serverless pricing model)
Data ownership	Data hosted on third-party provider infrastructure	Data stored in the institution's own cloud project
Analytical granularity	Pre-configured dashboards, limited customization	Custom SQL queries over raw data (BigQuery), enabling ad-hoc analysis
Integration with hospital systems	Limited, typically via generic APIs	Potential direct integration with hospital BI tools via SQL
Scalability	Adequate for few devices; paid tiers required at scale	Serverless architecture natively scalable to hundreds of assets
Initial setup effort	Low – optimized for rapid prototyping	Moderate – requires cloud project configuration and custom scripting
Security and governance	Depends on provider; limited customization	Requires custom configuration; not yet fully implemented in the current prototype
Maturity / validation	Mature, widely tested platforms	Early-stage prototype, validated in a restricted scope (single device)

A. Operational Monitoring

The statistical summary of the RMS acceleration measurements (m/s^2) obtained by the IoMT monitoring device under various operating conditions is presented in Table I. Across all evaluated scenarios, the proposed system demonstrated a clear and consistent separation between the operational states of the FANEM laboratory air compressor (*Off* vs. *On*).

In the *Normal* condition, the inactive state (*Off*) yielded a mean RMS acceleration of $0.456 \pm 0.031\,\mathrm{m/s^2}$, whereas active compressor operation (*On*) produced a mean RMS acceleration of $2.127 \pm 0.124\,\mathrm{m/s^2}$. The introduction of external vibrational noise sources—specifically a magnetic stirrer and a water distiller—induced negligible variations in the baseline acceleration. Under magnetic stirrer interference, the mean *Off* value for RMS was $0.446 \pm 0.010\,\mathrm{m/s^2}$, while under water distiller operation, it reached $0.442 \pm 0.020\,\mathrm{m/s^2}$. Noteworthy, the recordings displayed a low variability, once coefficient of variation (CV) values ranged from 2–7%.

Crucially, the maximum RMS acceleration recorded across all inactive states remained bounded at $0.582\,\mathrm{m/s^2}$, whereas the minimum acceleration recorded during active compressor operation was $1.808\,\mathrm{m/s^2}$. This established an unpopulated decision margin between $0.582\,\mathrm{m/s^2}$ and $1.808\,\mathrm{m/s^2}$, confirming that external laboratory interference does not trigger false positives and supporting the observed 100% classification sensitivity.

B. Comparison with Commercial IoT Platforms

Table II summarizes how the proposed architecture compares to general-purpose commercial IoT platforms commonly used for rapid prototyping, such as Blynk, ThingSpeak, and Arduino IoT Cloud. The comparison highlights that the main advantage of the proposed architecture lies in data ownership and analytical flexibility, rather than in ease of initial setup, where commercial platforms remain more accessible.

C. Limitations

The present study has several limitations that should guide interpretation of the results and future work.

Scope of validation. The system was evaluated on a single compressor unit (FANEM 089/CAL) over a limited observation period (Section II-E), using manually logged events as ground truth. Also, the current sample size does not capture variability across different compressor models, ages, or mounting conditions. Evaluation across multiple compressors and longer time frames would be interesting before generalizing these results.

Thresholding approach. Operational status was determined by comparing the RMS of vibration against a single, empirically chosen threshold (1.195 m/s^2). Within the tested conditions, this simple approach proved robust: the two external interference sources evaluated (a magnetic stirrer and a water distiller, both placed 12 cm from the compressor) induced only minor shifts in baseline vibration (Table I), and the resulting decision margin remained wide enough that no false activations were observed. This robustness, however, should not be generalized beyond the specific sources, distances, and intensities tested here: a single static threshold calibrated for one installation may not transfer directly to other compressor models, mounting surfaces, or nearby equipment without recalibration. Data loss due to Wi-Fi oscillation or outages was also not evaluated in the present study and is left for future work.

Security and data governance. The cloud ingestion pipeline (Google Apps Script and BigQuery) was implemented as a functional prototype and has not undergone a formal security review. Payload authenticity and integrity were enforced via HMAC-SHA256 signing with a pre-shared key, and confidentiality in transit relied on the Web App's HTTPS endpoint; however, the shared key is embedded in the firmware without a rotation mechanism or secure on-device storage, and the current design does not include replay protection (e.g., nonces or timestamp-based expiry), leaving it potentially vulnerable to replayed payloads. Data-retention policy and local buffering behavior during network outages also remain to be developed and tested before deployment in a production hospital environment, for example.

Regulatory claims. The non-intrusive nature of the sensor attachment is consistent with the intent of ANVISA RDC 665/2022 and RDC 509/2021, in that it avoids modification of the device's original circuitry; however, this work does not constitute a formal regulatory compliance assessment or risk analysis, which would be required before clinical deployment.

IV. Conclusion

This study presented the design and a preliminary, single-device evaluation of a low-cost, non-intrusive IoMT prototype for monitoring the operational status of a laboratory air compressor. By combining edge-based vibration sensing with a cloud-based data pipeline, the proposed architecture avoids any physical or electrical modification to the monitored equipment's circuitry, addressing a practical constraint faced by Clinical Engineering teams operating under strict device-integrity regulations.

Testing on a single FANEM 089/CAL unit over five sessions indicated that the RMS-thresholding approach could distinguish active and idle states with 100% sensitivity. When working next to magnetic stirrer and water distiller, the baseline RMS suffered a little variation, however, such variations did not affect the device's ability to track on/off states of the FANEM unit. These findings suggest that the architecture is technically feasible as a low-cost alternative to manual duty-cycle estimation, while they also showed that a single, static RMS threshold worked well to guarantee operational classification of laboratory air compressor.

Is worthy pointing out that this work should be understood as an initial architectural proof of concept for duty-cycle tracking rather than a validated, fleet-scale operational-monitoring solution. Future work should prioritize: (*i*) multi-device and multi-site data collection; (*ii*) lightweight machine learning (e.g., TinyML) to move beyond simple thresholding; and (*iii*) a formal security and data-governance review of the cloud pipeline, including authentication strength, encryption policy, and retention rules.

Acknowledgment

The authors would like to thank the Franciscan University (UFN) for providing the infrastructure used in this research. This work was also developed within the scope of the telehealth service, linked to the funding project *Tech Futuro*, from the Secretaria de Inovação, Ciência e Tecnologia (process number 23/2500-0000819-7).

***Abstract*—Medical devices are designed for the benefit of the population; however, they must be accessible to meet the diverse needs of the entire population, considering different ethnicities, races, genders, disabilities, as well as diverse contexts and locations. This study generates real-world evidence on accessibility barriers in medical devices within healthcare settings from a Clinical Engineering perspective, proposing strategies to enhance inclusivity. An online questionnaire administered to 68 clinical engineering professionals revealed a gap in Healthcare Technology Management (HTM); 55.6% of respondents were unaware of accessible technologies within their equipment inventory. Among the remaining 44.4% who confirmed such availability, the inventory was concentrated in mobility-related assistive technologies, such as wheelchairs and walkers (17.5%), followed by diagnostic imaging equipment (9.5%). Qualitative analysis indicates that the conceptualization of "accessible medical devices" remains narrowly restricted to mobility aids. To ensure patient safety and functional autonomy, HTM frameworks must incorporate accessibility and Universal Design as a criteria in procurement processes. Adopting this equity-driven approach is important to transform medical devices into tools that guarantee inclusive care and equal access in healthcare systems.**

Keywords—Accessibility; Medical Devices; Clinical Engineering; Health Technology Management.

I. Introduction

Health technologies consist of medical devices, medications, vaccines, procedures, and systems developed to solve a health problem and improve quality of life. Due to the increasing incorporation of technology, Health Technology Management (HTM) becomes essential to assist in its safe and reliable use. One area that can support the development, implementation, and monitoring of the HTM program in healthcare settings is Clinical Engineering (CE), a field within Biomedical Engineering [1]. Due to the complexity and interdisciplinary nature of the involvement, interconnectivity among the various actors in the healthcare field becomes essential for the safety and comprehensiveness of the appropriate use and accessibility of these technological solutions for health

HTM can be understood as a set of activities that ensure quality in technological processes within healthcare facilities. The Institute of Biomedical Engineering (IEB-UFSC) bases its management model on three main pillars: infrastructure, technology, and human resources, as shown in Fig 1. The interaction between them aims to analyze the entire context in which the technology is embedded, and the pursuit of quality in the technological process results in improved safety, reliability, and effectiveness in the use of these technologies [2]. This work presents an additional perspective on the importance of accessibility in the quality of the technological process in healthcare and presents improvement strategies to make technologies more inclusive for the population.

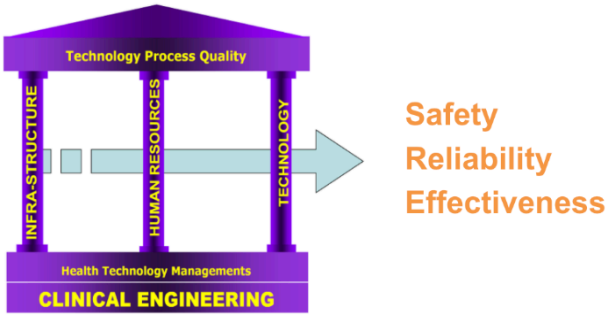

Figure 1. Health Technology Management Model based on the pillars of infrastructure, technology, and human resources of the IEB-UFSC

Medical devices are designed for the benefit of the population, however, they must be accessible to meet the diverse needs of the entire population, considering different ethnicities, races, genders, disabilities, as well as diverse contexts and locations. According to data from the World Health Organization, it is estimated that 1.3 billion people suffer from significant disabilities. This represents 16% of the world's population. Considering accessibility aspects in the development of health technologies is essential to ensure inclusion and improve usability [3].

Accessibility, as defined by ABNT NBR 17060:2022, consists of "the extent to which products, systems, services, environments, and facilities can be used by people from a population with the widest variety of characteristics and abilities, to achieve a specific goal in a specific context of use" [4]. The goal of accessibility is to expand the target

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

population, ensuring that products, systems, services, environments, and facilities are usable by a wider range of individuals in diverse contexts of use.

Accessibility is not only required by law, but is also crucial for reducing inequalities and ensuring the inclusion of all people in the use of healthcare technologies [5][6]. Accessibility should be considered throughout the entire lifecycle of healthcare technology, from product development to the design of customizable technology for people with different limitations and characteristics, to post-commercialization stages [7][8]. Inclusive and human-centered design focuses on developing solutions that consider human diversity beyond people with disabilities, the elderly, and physical accessibility. It takes into account psychosocial dimensions and values quality of life and user experience. When investigating barriers to inclusion, the goal is to involve diverse user profiles and create innovative solutions that benefit everyone [9]. Therefore, it is recommended that the design be adjustable and customizable [10].

Although usability is discussed in medical devices, accessibility, specifically from the perspective of those who manage the technology, is rarely explored. Medical devices are often not designed to meet the needs of some specific users [11]. Therefore, this work aims to generate real-world evidence on accessibility barriers in medical devices in healthcare settings from a Clinical Engineering perspective, as well as to elucidate improvement strategies to make healthcare more inclusive for all people.

II. Methodology

This research is characterized as an exploratory and descriptive study, with a mixed, quantitative and qualitative approach, based on the collection of real-world data, with the objective of generating evidence of accessibility problems in medical devices from the perspective of Clinical Engineering. One of the authors of this work is a clinical engineer and has aphasia, contributing significantly to the analysis and establishment of strategies for the inclusive design of Medical Devices.

The target population comprised professionals working directly in Clinical Engineering departments across hospital institutions (public, private, and philanthropic) in Brazil. The inclusion criterion was being a mid-level or higher-level professional (engineers, technologists, technicians, and managers) with an active role in hospital Clinical Engineering services. Responses with incomplete data were excluded. The final valid sample consisted of 68 participants.

Data collection took place between August 2025 and April 2026. Data were collected using a structured online questionnaire administered through an electronic research platform. The survey link was strategically disseminated via professional networks, social media, and technical forums dedicated to Clinical and Biomedical Engineering nationwide. The research instrument was constructed based on human factors engineering, usability guidelines, and multidimensional accessibility frameworks.

Content validation was conducted prior to deployment through expert review by Clinical Engineering researchers to assess item clarity, thematic relevance, and comprehensiveness. The final questionnaire comprised multiple-choice blocks (demographic characteristics, institutional profile, team composition, and technology incorporation practices) and open-ended items exploring accessibility barriers in medical devices and management strategies.

Quantitative data were analyzed using simple descriptive statistics (absolute frequencies and percentages). Inferential statistics were not applied due to the non-probabilistic nature of the sample. Qualitative responses from open-ended items were subjected to thematic content analysis. All open-ended responses were independently read and assigned to initial thematic categories aligned with multidimensional accessibility domains (e.g., operational, spatial, informational, economic, sociocultural, and interoperability).

The research protocol was approved by the Research Ethics Committee of the Federal University of Santa Catarina (UFSC) under approval No. 7.706.804 (CAAE: 87849125.4.0000.0121). Electronic informed consent was obtained from all participants prior to survey completion, ensuring anonymity and data confidentiality.

III. Results

The exploratory study with Clinical Engineering professionals on accessibility included the participation of 68 professionals working in Clinical Engineering in public, private, and philanthropic hospitals. Regarding education, 43 were professionals with engineering degrees, 13 with technical training, 10 technologists, 1 administrator, and 1 health professional.

The research highlighted a gap in hospital technology management, where 55.6% of participants reported being unaware of the existence of specific accessible technologies in their equipment inventory. Among the 44.4% who confirmed availability, there was a concentration on assistive technology items to aid mobility, such as wheelchairs and walkers (17.5%), followed by diagnostic imaging equipment (9.50%). Although 44.4% of institutions report having accessible technologies, the qualitative analysis reveals that the concept of 'accessible medical device' is still strongly linked to mobility items such as wheelchairs. Adapted diagnostic technologies, such as mammograms and specific scales, are emerging, demonstrating a vast field for Clinical Engineering to manage more inclusive technologies throughout the lifecycle.

Table 1 illustrates the types of accessible technologies present in the hospital as reported by those working in the Clinical Engineering sector. Because respondents were able to identify multiple types of devices within their inventories, the technology categories are not mutually exclusive. Percentages in Table I are calculated relative to the total valid study sample (n=68) to reflect overall population prevalences. Another factor analyzed in the research was related to the process of incorporating medical devices in hospitals. It was observed that 44% of professionals reported not considering accessibility as a decision-making factor. The contrast with the scarcity of accessible devices reported previously suggests that the assessment of accessibility at the time of purchase is often subjective or insufficient, lacking standardized technical criteria to guarantee Universal Design.

TABLE I - REPORT ON ACCESSIBLE MEDICAL DEVICES IN HOSPITALS AS REPORTED BY PROFESSIONALS WORKING IN CLINICAL ENGINEERING.

Technological Category	Examples of Devices and Resources Mentioned	Sample Prevalence (%)
Mobility and Support	Wheelchairs, walkers, hospital beds, patient lifts, adapted stretchers, and beds with minimum height adjustment.	**17,50%**
Diagnostic Imaging	CT scanners, MRI, Mammography (height adjustment), ceiling stands and layout adaptation (wide doors/ramps).	**9,50%**
Weight Supported	ICU beds, stretchers and surgical tables reinforced for obese patients (focus on load and ergonomics).	**8,20%**
Communication and Sensory	Medvoice (speech/hearing aid), sound amplification devices, screen readers, adapted keyboards, intercoms with video and subtitles.	**7,80%**
Scale and Triage	Scale for wheelchair users (low-profile platforms).	**6,30%**
Other / Innovation	Automated instrument carts, AI-powered equipment and adapted audiometry booths; Pediatric autorefractors (rapid measurement for agitated patients or those with difficulty concentrating).	**6,40%**
Absence / Lack of Knowledge	Professionals who do not identify or claim not to possess specific devices.	**55,60%**

The main barriers reported by the participants were categorized in the pillars of Health Technology Management of IEB-UFSC related to infrastructure, human resources and technology (Table 2). Regarding infrastructure, the presence of old hospitals that prevent modern adaptations, lack of accessible elevators and ramps with inadequate inclination, narrow doors, high counters and lack of adapted furniture stand out. Related to technology, the lack of adapted equipment, incompatibility of technologies that meet the needs of people with disabilities, absence of braille, tactile floors and audio-visual resources; lack of sign language interpreters or assistive technologies to mediate care. Regarding human resources, the following stand out: professional unpreparedness, lack of training to deal with diversity and specific situations involving people with disabilities; prejudice and lack of prioritization, perception that accessibility is not a management priority or is not seen as an essential part of clinical care; poor budget management and lack of investment directed towards adaptations.

TABLE II - ACCESSIBILITY BARRIERS IN MEDICAL DEVICES CATEGORIZED ACCORDING TO THE GTS PILLARS.

Pillar (Frequency of citations)	Barrier identified	Description of the report
Infrastructure (56%)	Obsolete Buildings Access Barriers Environmental Signage	*"Old hospitals", "Physical structure not designed for accessibility". "Steep ramps", "Lack of elevators", "Narrow doors", "Access only by stairs". "Lack of tactile paving", "Non-adapted bathrooms", "High countertops"*
Human Resources (28%)	Lack of Technical Preparation Communication Failure Organizational Culture Lack of Prioritization	*"Unqualified professionals for the service", "Lack of knowledge of the team in general". "Lack of people who know sign language", "Assistance and support team without training". "Prejudice", "Lack of management priority", "Lack of perception of the needs of others" "Lack of effective institutional policies" "Corruption"*
Technology (16%)	Inaccessible interface Obsolescence Economic barrier Interoperability of use Non-compliance with regulations	*"Outdated technology park," "Equipment not adapted (button height, interface)." "High cost of good devices," "Lack of renewal of the technology park." "Incompatibility of equipment and suitable furniture," "Lack of equity solutions." "Failure to minimally comply with current standards and legislation" "Not communicating by voice, no audiovisual equipment, the height to operate the buttons is too high"*

Another result analyzed was the composition of Clinical Engineering teams with people with disabilities. A low representation rate was found, with only 17.6% of institutions having professionals with disabilities on their technical staff (Fig 2). This data is concerning when combined with the perception of technological barriers. The absence of professionals with disabilities in the management of health technologies can result in the neglect of usability and accessibility requirements because they are not part of the direct experience of decision-makers. Promoting the inclusion of people with disabilities in Clinical Engineering teams is not just a matter of diversity, but a co-design strategy, essential for the specification and evaluation of medical devices to be genuinely inclusive and user-centered.

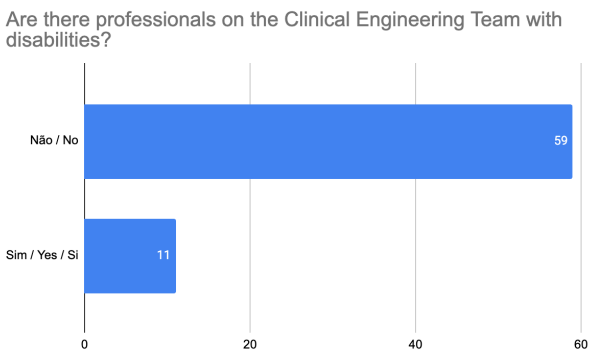

Figure 2. Representation of professionals with disabilities in the Clinical Engineering Team in Hospitals

The suggestions for accessibility improvements in medical devices reported were categorized from the perspective of the domains based on the accessibility framework for medical devices [12]. The domains are: operational, economic, informational, infrastructure and spatial accessibility, connectivity and interoperability, and sociocultural accessibility, as presented in Table 3. The strategies elucidated were multidimensional to ensure safety and equity in care.

In the operational domain, the reports highlight the urgency of inclusive interfaces including audio and braille resources. In the infrastructure domain, a concern emerges regarding physical safety in emergency situations, exemplified by the need for universal fixation supports so that portable equipment is not positioned over the patient. The evidence in the sociocultural domain reinforces the importance of participatory design, suggesting that the inclusion of people with disabilities from the design phase is the fundamental path to converting technological innovation into functional autonomy and dignified care.

IV. Discussion

The integrated analysis of the data reveals a divergence between theoretical awareness and institutional practice in Clinical Engineering. Although a majority of professionals (56%) stated that accessibility is a relevant consideration during device incorporation, 55.6% reported either an absence or a lack of identification of accessible technologies in their institutions. This finding suggests that beyond physical availability, professionals themselves may lack sufficient awareness or technical training to recognize accessibility features already embedded in medical equipment. Furthermore, this scenario suggests that accessibility is still treated as an infrastructure add-on and not as an intrinsic safety requirement, which contrasts with the view of Panagiotopoulou (2020), who argues that health services should be equally accessible to all, regardless of present or future disabilities [13].

This technological gap is underpinned by a crisis of representation, where only 17.6% of Clinical Engineering teams have professionals with disabilities. Without the user's perspective in the incorporation process, essential devices may be being neglected in favor of traditional metrics of cost and technical performance. These findings converge with the barriers identified by Bonanno (2025), who points to accessibility disparities, training needs, and limited user participation in design as obstacles to an inclusive health technology assessment (HTA) [14].

The suggestions for improvement collected indicate future perspectives in the convergence between emerging technologies and the principles of Universal Design. As proposed by Kaminska (2023) and Brandão (2026), the design should be useful and accessible to people with diverse abilities; accommodate a wide range of individual preferences and abilities; be easy to understand and use, regardless of the user's experience, knowledge, language skills, or level of concentration; provide information in multiple ways to accommodate different abilities and sensory preferences, as well as tolerance for errors. Universal design is essential because it promotes inclusion, autonomy, and social engagement for people of all abilities [15][16].

Table III - Improvement Strategies categorized into accessibility domains to make Medical Devices more Accessible

Domain	Improvements and Suggested Resources	Participant Reports (Evidence)
Operational	Inclusive interface; audio and braille requirements; contrast and size adjustments on display; support technology resources; height adjustment, customization; intuitive interfaces, ambidextrous design and remote controls; technologies that support the patient's weight	*"Ambidextrous design is a necessity." "Braille, audio command" "Inclusive user interface, configuration customization, visual instructions on the equipment itself and accessible communication" "Adaptations to cables and accessories to measure basic parameters in patients without limbs" "More visible alarms for people with hearing problems, clearer and larger images for people with visual impairments" "Height adjustments, sound effects and support features for people with reduced mobility." "Specific stretcher or surgical table for weight capacity and physical structure of the patient"*
Infrastructure and Space	Height adjustment, universal hooks and transport ergonomics	*"A hook to attach a monitor to the bed... for defibrillator and portable ventilator"; "Shorter stature, difficulty accessing monitoring." "Doors with automatic locks, disabled people need to open them and sometimes end up falling."*
Informational	Audio/Braille manuals, redundant visual alarms, and instructions on the equipment itself; staff training	*"More visible alarms for people with hearing problems"; "Written and dictated instructions"; "Braille manual... voice translation." "Accessible keys and buttons and clear and objective information." Specific training for the care team.*
Interoperability and Connectivity	Self-positioning cameras, remote interface tablets and adapted sensors; AI voice command, features accessible via tablets	*"Devices having a portable tablet for these people"; "Self-positioning cameras on the equipment". "Integrate voice command with the use of AI to enable/program the device"*
Sociocultural	Co-design and humanization of care.	*"Bringing people with disabilities into the area so that they can express their vision from the design stage"; "Listening to accounts from people with disabilities"; "There should be more respect and care for people with disabilities."*
Economical	Cost reduction and increased availability of adapted accessories from manufacturers.	*"High cost of good devices"; "Suppliers increasingly addressing the issue of accessibility."*

In this context, Clinical Engineering plays a crucial role in generating data to establish strategies that make technological use universal. The implementation of co-design strategies in Living Labs environments presents itself as the path to a collaborative innovation ecosystem, as discussed in previous works [12][17]. This approach is aligned with Meinert's research (2024), where co-production places people with disabilities and their caregivers at the center of the process as co-researchers. By integrating universities, industry, government and, fundamentally, end users, Brazilian Clinical Engineering can move from passive management to the creation of solutions that guarantee, as the literature and field data suggest, autonomy and dignity in access to health. Regarding the limitations of the work, due to the lack of discussions and evidence on accessibility in medical devices, there is a lack of understanding on the part of clinical engineering on this topic, which may have interfered with the participants' responses. There is also a limited view on accessibility. The lack of representation of people with disabilities in Clinical Engineering also reflects a bias in the data.

V. Conclusion

In conclusion, this work makes an original scientific contribution by presenting exploratory, real-world evidence regarding the incorporation and perception of accessibility within clinical engineering practice in Brazil. By highlighting how professionals in the field experience this issue, the study establishes a novel empirical foundation to guide the development of procurement guidelines, management policies, and future research on the subject.The results of this study demonstrate that accessibility in medical devices from a Clinical Engineering perspective is still underexplored. Although most professionals recognize the relevance of the topic, the persistence of technological gaps indicates that accessibility is still often perceived as an additional cost or merely an adaptation of infrastructure, rather than a requirement for patient safety.

This study has limitations that must be taken into account when interpreting the findings. First, the cross-sectional design and non-probabilistic restrict the generalizability of results across all Brazilian hospital settings. Second, the data rely exclusively on self-reported perceptions, which are susceptible to response bias, and varying levels of individual technical literacy regarding accessibility. The lack of representation of people with disabilities in Clinical Engineering also reflects a bias in the data. The conceptual definition of accessibility provided in the instrument may have framed participant responses. Finally, the lack of statistically matched subgroups by hospital size, region, and type precluded inferential tests of association, highlighting the need for future studies with robust stratification and objective device audits.

The consolidation of the data reveals a complex management scenario. While the low representation of professionals with disabilities points to limited diversity within Clinical Engineering teams, this factor alone does not directly establish that their absence causes the neglect of usability or accessibility requirements. Nevertheless, the reported demands for assistive communication, adapted sensory interfaces, and artificial intelligence integration signal a growing awareness and a potential paradigm shift in technology incorporation.

The authors consider it relevant to consider the incorporation of usability techniques throughout the life cycle of technologies involving people with disabilities, to explore accessibility flaws and propose effective strategies for inclusive design. Another recommendation is to incorporate Human Factors Engineering indicators into the HTM process to ensure better usability and safety for all people involved with medical devices. Accessibility is evolving to become an active and fundamental element in technical specification. Clinical Engineering must, therefore, assume its role as an integrating link, overcoming infrastructure and human resource barriers to ensure that the technology is, in fact, usable and operable by everyone.

In conclusion, while the findings reveal a limited understanding of accessibility within Brazilian Clinical Engineering, this study represents an innovative contribution to the field. By filling a critical evidence gap in HTM, it establishes a valuable foundation and offers a promising framework for inclusive procurement, design, and management practices. Nevertheless, broader normative recommendations will still require future studies supported by larger representative samples, formal validation and involvement of users with disabilities.To guarantee safety and functional autonomy, it is recommended that standard operating procedures in HTM incorporate accessibility and Universal Design as a criteria in the acquisition processes. Only through a vision based on equity will it be possible to transform medical devices into an instrument for democratizing care and human dignity in healthcare.

***Abstract*—Falls, in general, can cause various damages to individuals, such as abrasions, bruises, fractures, and physical and psychological trauma. When they occur in the hospital environment, in addition to the effects already mentioned, the patient's clinical condition may worsen, especially in cases where it takes time to identify these events. Consequently, a fall can result in higher financial expenses for the hospital due to the increased length of stay. Based on this scenario, the present study proposes a patient monitoring system for hospital beds using YOLOv8, a state-of-the-art real-time object detection algorithm. Unlike binary fall/no-fall approaches reported in the literature, the proposed system classifies five distinct patient behaviors, enabling preventive alerts before fall events occur.**

***Index Terms*—Artificial Intelligence, Hospital Fall, Image Monitoring, Pattern Recognition**

I. Introduction

A patient fall is an undesirable and harmful occurrence, an unpredictable event for which there is still little incentive directed toward prevention and/or immediate assistance. Studies addressed by the Secretariat of the Federal District State [1] indicate that the patient fall rate in hospitals in developed countries ranged between 3 to 5 falls per 1,000 patients/day.

According to Lima et al. [2], in Brazil, 22.5% of deaths of elderly people that occurred in the period from 1996 to 2005 resulted from falls. That study presents an analysis of AIHs (Autorizações de Internação Hospitalar), carried out with data from the SIH (Sistema de Informações Hospitalares) of the SUS (Sistema Único de Saúde), and found that 1,746,097 AIHs due to falls in elderly people were recorded in the period from 2000 to 2020, corresponding to a cost of R$ 2,315,395,702.75 for the health system.

In addition, the study by de Frutos et al. [3] emphasizes the problem related to falls, especially among the elderly. The document states that falls are the second leading cause of death from unintentional injuries worldwide, and the highest number of fatal falls occurs mainly among adults over 60 years of age. In the United States, about 700,000 to 1,000,000 fall cases are reported annually in hospitals. These cases are considered *never events* (events that should never occur), meaning that insurance companies do not cover the expenses related to these incidents. As a result, hospitals in the USA spend about 50 billion dollars per year to cover these expenses [3].

The consequences of a fall range from skin injuries, dislocations, and fractures to impairment of physical mobility, progressive reduction of functional capacity, and worsening of the previous clinical condition. Falls can also generate psychological consequences such as anxiety, insecurity, social isolation, and loss of confidence due to fear of falling again, as well as loss of autonomy to perform basic activities of daily living. Furthermore, falls can increase the length of hospital stay and compromise the clinical condition and recovery of the individual, negatively impacting healthcare costs.

As a result of the numerous complications and serious damages that a fall can cause, together with the high cost of prolonged hospitalization, it is necessary to use methods and techniques that enable the identification of fall patterns, allowing the responsible clinical staff to be informed as quickly as possible about these situations and enabling faster and more effective intervention.

The present work aims to present a simpler method that is as effective as existing approaches for detecting fall situations in hospital beds. This environment was selected as the focus because it is where individuals are found, generally with reduced physical capacity, under the effect of medication and adverse conditions that may lead to fall events.

Currently, similar works exist focused on fall detection. However, in the literature, there is a greater focus on binary systems that identify patients as either in bed or out of bed. In this type of analysis, other patterns beyond falls, such as risk situations and movement out of bed, tend to be overlooked.

The system proposed in this study addresses different patient behaviors, enabling the issuance of alerts to the hospital clinical staff in different situations — such as the patient

leaving the bed or being in a near-fall condition — and not being limited only to fall events. In this way, it is possible to provide better monitoring and medical intervention to patients whenever necessary. The analysis of patient behavior patterns brings more efficiency in fall prevention, reducing the damage caused by this event.

II. Related Work

Several camera-based approaches to fall detection have been proposed in the literature, predominantly relying on binary classification schemes. This section reviews three representative systems whose methodologies and results serve as baselines for the proposed work.

Bian et al. [4] proposed a system based on a depth camera, which enables image acquisition even in low-lighting environments. The methodology corrects the image position to a vertical orientation to enable better analysis of the torso. Articulable body points — such as the neck, head, elbows, and knees — are identified using a Randomized Decision Tree, a machine learning algorithm that generates decision nodes. Head orientation is then analyzed using a Support Vector Machine (SVM) for pattern recognition, enabling the identification of body trajectory in fall situations. A fall recovery analysis mechanism concludes the pipeline by comparing the height position of the hip and head over time to confirm whether a fall trajectory has been completed. The system was trained on a dataset with 100 thousand data points of head trajectory patterns, and its results are shown in Table I.

TABLE I
Results of Model 1 [4]

Metrics	Results
True Positives	188
True Negatives	104
False Positives	86
False Negatives	2
Sensitivity	98.8%
Specificity	54.7%
Accuracy	76.8%
Error Rate	23.2%

Nguyen et al. [5] proposed a camera-based surveillance model aimed at elderly supervision. The system acquires 30 frames per second, applies joint segmentation, and uses a moving average filter to attenuate noise, followed by background removal. Objects are then identified through comparison with predefined detection probability thresholds, and the resulting images are classified using a rule-based system that distinguishes fall from non-fall movements based on body proportion and angulation. The model was evaluated on 3,996 frames — 2,873 fall frames and 1,123 non-fall frames — and its results are shown in Table II.

De Miguel et al. [6] presented a home-based fall detection system using 2D and 3D cameras. After image acquisition and background removal, the frames pass through a Kalman filter that reduces noise and absorbs repetitive changes in detected action behaviors by comparing noisy and clean images. This filter also enables object tracking and position prediction at each frame. The OpenCV library is used alongside the Kalman filter, applying optical flow techniques for precise tracking of items of interest. Classification is performed by the K-Nearest Neighbors (KNN) algorithm, which assigns class labels based on neighboring data sets. The system was trained on frames from 53 videos recorded in two different environments, and its results are shown in Table III.

TABLE II
Results of Model 2 [5]

Metrics	Results
True Positives	2587
True Negatives	1111
False Positives	11
False Negatives	286
Sensitivity	90.0%
Specificity	99.0%
Accuracy	92.5%
Error Rate	7.4%

TABLE III
Results of Model 3 [6]

Metrics	Results
True Positives	24
True Negatives	40
False Positives	1
False Negatives	1
Sensitivity	96.0%
Specificity	97.6%
Accuracy	96.9%
Error Rate	3.0%

All three systems described above adopt a binary classification approach, distinguishing only between fall and non-fall events. The present work extends this paradigm by introducing a five-class model capable of recognizing intermediate and preventive behaviors, enabling intervention before a fall event occurs.

III. Theoretical Background

A. Evaluation Criteria

For the evaluation and comparison of results, metrics similar to those of other studies were used, following the quality criteria for the analysis of fall detection systems suggested by Noury et al. [7]. The evaluation parameters consist of data provided by the confusion matrix, a tool used for performance analysis of classification systems, and its derived metrics:

- **True Positives (TP)**: The model correctly predicts the class being predicted, when it is actually present;
- **False Positives (FP)**: The model incorrectly predicts the class being predicted, when it is not present;
- **True Negatives (TN)**: The model correctly predicts the class that is not being predicted, when it is not present;
- **False Negatives (FN)**: The model incorrectly predicts the class that is not being predicted, when it is present.

Based on these parameters, the following metrics can be derived:

- **Accuracy**: Provides the rate of correct predictions in relation to the total number of predictions.

$$\frac{TP + TN}{TP + FP + TN + FN}$$

- **Sensitivity**: Ability to correctly identify results belonging to the positive class.

$$\frac{TP}{TP + FN}$$

- **Specificity**: Ability to correctly identify results that belong to the negative class of the model.

$$\frac{TN}{TN + FP}$$

- **Error Rate**: Provides the rate of incorrect predictions in relation to the total number of predictions.

$$\frac{FP + FN}{TP + TN + FP + FN}$$

IV. Materials and Methods

A. Image Collection and Processing

Initially, a corpus of images was created from videos and photos of various individuals and situations to ensure that the dataset was diverse and representative of the target scenarios.

These images and videos were used to perform detailed annotations, marking specific and relevant characteristics in each frame. This labeling stage is essential for the AI model to learn to recognize patterns, behaviors, and distinct characteristics of individuals captured in each scenario. The diversity of both individuals and environments allows the model to learn more effectively and better generalize its predictions, expanding its applicability in different contexts. Dataset preparation is a key factor for the success of AI training and the accuracy of the final results.

The captured videos were processed and split into frames, allowing the collection of a greater variety of scenarios and capture conditions, making the dataset more robust and representative for future analyses.

Another fundamental aspect is the proper positioning of the camera. It must be strategically adjusted to ensure that the entire relevant environment is within the field of view. This includes framing the bed, the user, and the surrounding floor. This positioning is crucial to ensure that important events, such as falls or user movements, are clearly captured, providing a comprehensive view of the space and user interactions with the environment. In this work, the camera was always positioned facing the beds, also capturing the floor to enable fall event identification.

Once the image/video upload is completed, the next step is labeling and classification. This process was carried out using the *Roboflow* platform [9], which provides facilitating tools such as contour selectors and class definitions, enabling the demarcation of an area through multiple points that form a polygon around the object of interest, in this case, the individuals.

Annotation is performed image by image, selecting the object or person present and assigning it a class.

The project uses five classes:

- *person-in-bed*: shown in Figure 2, refers to the moment when the individual is in the bed;
- *person-moving-out*: shown in Figure 3, refers to the moment when the individual is moving out of the bed;
- *person-out*: shown in Figure 4, refers to the moment when the individual is outside the bed but standing;
- *person-near-fall*: shown in Figure 5, refers to a situation of imbalance or risk, a near-fall condition;
- *person-fall*: shown in Figure 6, refers to the moment when the individual experiences a fall.

Figure 1 shows an example of frame classification.

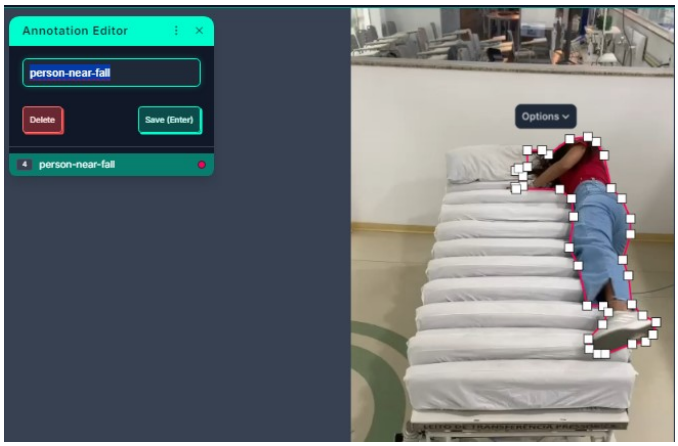

Fig. 1. Image classification process.

Fig. 2. Person-in-bed class.

Training was performed using pretrained weights from YOLOv8 *small* [8], with 300 epochs and an input resolution of 640×640 pixels.

Currently, the dataset contains 1,201 images divided into the five previously mentioned classes, obtained from videos recorded in five different environments, with 7 individuals, including 2 women and 5 men aged between 20 and 24 years. All individuals depicted in the dataset are the authors of this

Fig. 3. Person-moving-out class.

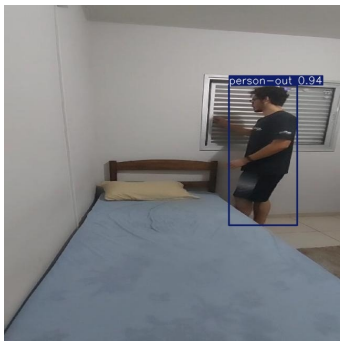

Fig. 4. Person-out class.

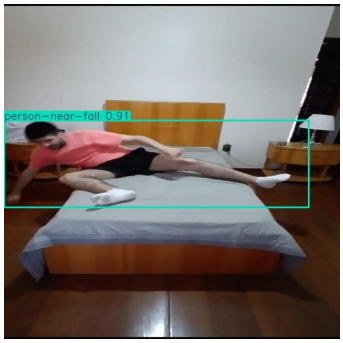

Fig. 5. Person-near-fall class.

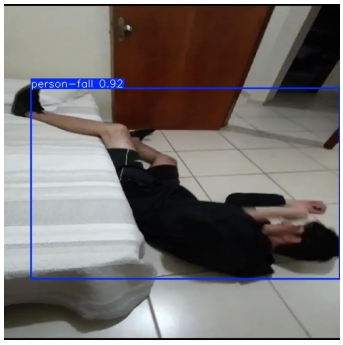

Fig. 6. Person-fall class.

work, who provided informed consent for image capture and publication. These images were used for model training. From the dataset, 841 images were used for training, 240 for testing, and 120 for validation. Figure 7 shows some sample images.

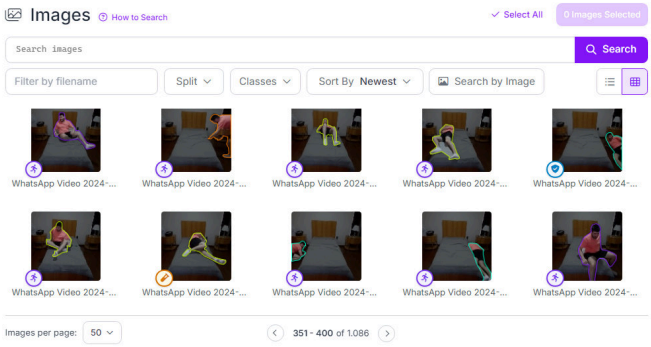

Fig. 7. Some images from the dataset with their respective classes.

B. YOLO

To develop a system capable of detecting different situations, a real-time image detection system was used. Such systems use computer vision algorithms to identify and locate objects, patterns, or features in images or videos. YOLO (*You Only Look Once*) [8] was chosen due to its fast processing, which is ideal for real-time detection applications.

Using a different approach from traditional methods, YOLO processes the entire image at once, making it faster and more efficient than two-stage methods. The image is passed through a Convolutional Neural Network (CNN), which extracts features and distributes them across a grid of cells. Each cell is responsible for predicting the presence of an object. The result is a set of bounding boxes, which are filtered to remove overlaps and provide class labels for each object in the image, resulting in an output similar to that shown in Figure 8.

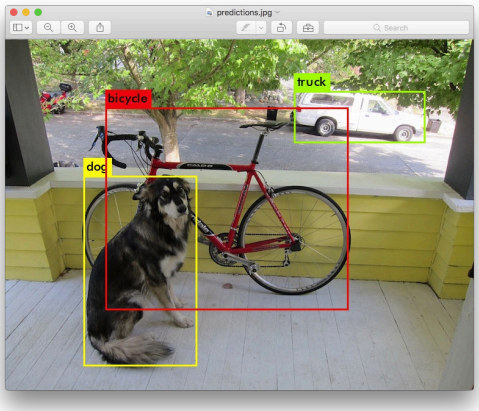

Fig. 8. Class identification using YOLO.

V. Developed Application

A. API

The system developed for this study consists of a camera with internet connectivity integrated with software responsible for image processing, which returns results obtained from inference based on the trained model weights.

The HTTP (*Hypertext Transfer Protocol*) [10] enables communication between systems through the exchange of requests and responses over the internet between clients and servers. In the developed application, the API (Application Programming Interface) acts as the server, while the hospital information systems act as clients.

Based on this protocol, integration between the camera and the application is carried out through an API, which exposes a POST HTTP endpoint allowing image submission to the system. The API was developed in Python [11], a high-level programming language with a wide range of libraries and resources focused on Artificial Intelligence and web systems.

The Flask micro-framework [12] was used, consisting of a set of functions and components for web application development, aiming to enable a system with internet connectivity. Through this tool, the API became exposed to the network, allowing it to receive requests.

Requests containing images go through the YOLO inference process, which includes computer vision capabilities. The inference function performs object detection based on the trained weights, which are preloaded into the model. The system does not store any images; it only processes them once. This process returns the detected class, if any, along with its confidence score, ranging from 0 to 100%.

The data is returned in key-value format following the JSON (JavaScript Object Notation) standard [13], which enables system integration across different platforms due to its simple and compact structure.

API responses follow the HL7 FHIR (Health Level 7 - Fast Healthcare Interoperability Resources) standard, established for healthcare data exchange, enabling system interoperability [14]. Thus, the developed application is ready for integration with other systems used in hospital environments.

Additionally, the system uses the Twilio library [15], which provides programmable communication functionalities such as email sending, phone calls, and Short Message Service (SMS) delivery. In this project, SMS messaging was used to notify the responsible clinical staff. These alerts are triggered based on the confidence level returned by YOLO when identifying a class in the processed image.

For system validation in a controlled environment, a webcam positioned facing the bed was integrated, sending one image per second to the API. In addition, a control center interface was developed to simulate a monitoring hub, displaying real-time images from the camera. When an alert was received, the system was configured to emit a visual and audible warning to the staff, in addition to the SMS notification.

Figure 9 shows the basic flow of information received and sent by the API.

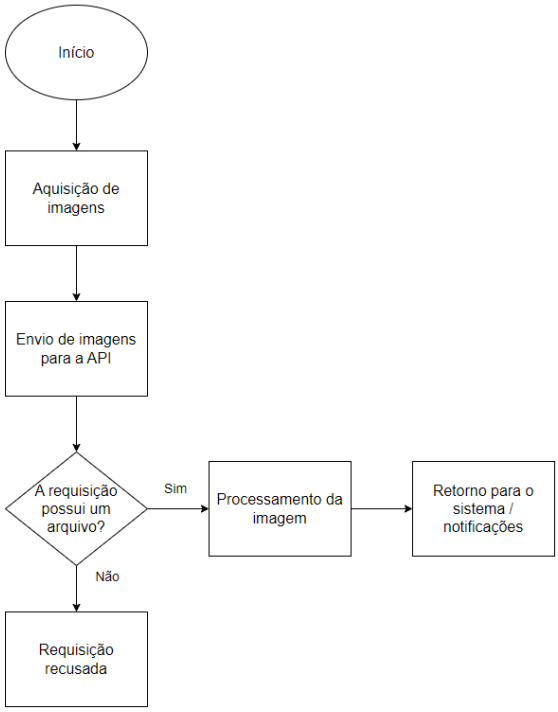

Fig. 9. Basic communication flow diagram.

B. Cloud Hosting

Cloud computing consists of making applications, programs, and data available over the internet instead of relying on local physical infrastructure, allowing users in different locations to access and use available resources and content [16]. Cloud hosting follows the same concept and involves deploying systems such as APIs through allocated resources on virtual machines [17] or similar environments.

Based on this concept, the application was structured so that hospital information systems can use its functionalities without needing to add a new service to their infrastructure, accessing system resources via HTTP requests.

Thus, cloud hosting was implemented using a virtual machine with a Linux operating system provided by Microsoft Azure [18], which offers sufficient computational resources for fast processing of information and images, ensuring efficient system response given that execution occurred in a single test environment.

Furthermore, aiming at future portability and scalability, Docker container technology [19] was used. It packages the application into a self-contained environment that can run on different machines and services, facilitating replication and distribution across servers through a set of instructions known as images.

The diagram shown in Figure 10 summarizes the system infrastructure.

C. Alarm Emission

The developed application includes a notification system that informs both the patient and the clinical staff. The alarms

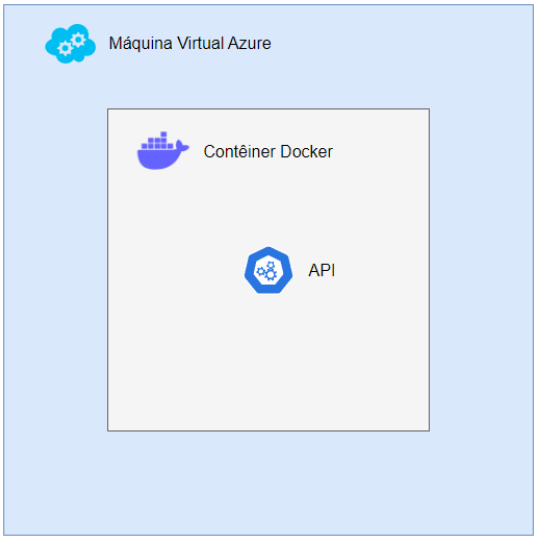

Fig. 10. Infrastructure diagram.

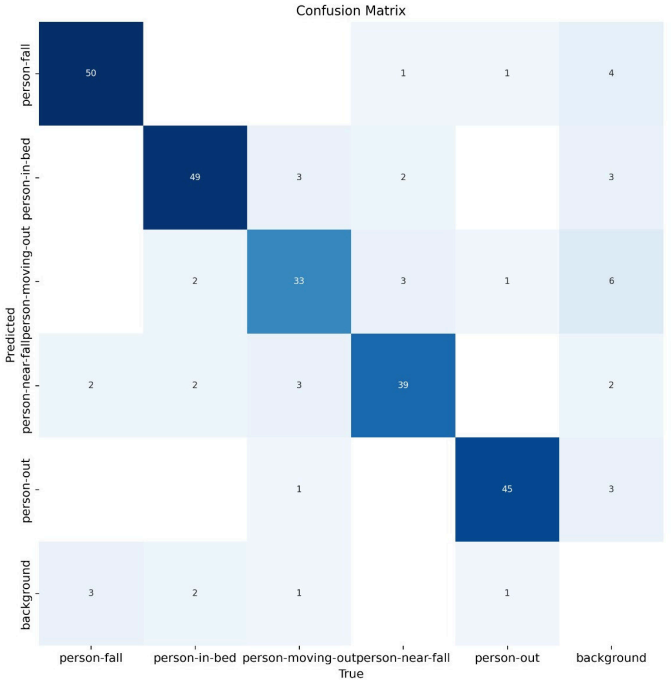

Fig. 11. Confusion matrix.

are customizable and adaptable to each patient's context through an interface that allows parameter adjustments. Their main goal is to mitigate harm caused by falls through faster intervention and to prevent falls by alerting responsible staff in potentially dangerous situations.

The basic configuration includes an audible alarm for the patient when *person-moving-out* and *person-out* situations are detected, reinforcing the importance of remaining in bed. In cases of *person-near-fall* and *person-fall* events, an alert is sent to the clinical staff through a notification to the central monitoring system.

In addition, the system uses the Twilio library [15], enabling SMS messaging to hospital staff describing whether a fall or other incident has been detected. SMS alerts also serve as a redundancy mechanism, ensuring that clinical staff are notified even when not present at the monitoring center at the time of the event.

VI. Results

To obtain the results, the test set was used, containing 240 images and representing 20% of the dataset.

The confusion matrix shown in Figure 11, obtained through YOLO, displays the actual classes on the Y-axis and the predicted classes on the X-axis. By analyzing the main diagonal, it is possible to obtain the True Positive (TP) results for each class, as well as derive the other metrics based on the information contained in the rows and columns of the matrix.

Based on the analysis of the confusion matrix, it can be observed that the *near-fall* class, together with the *person-moving-out* class, presented the highest number of False Negatives and False Positives, representing, together, 45.65% and 30.43%, respectively, of the total of these metrics.

It is observed that the confusion matrix presents information related to the *background* class, which represents frames in which no class was identified. The absence of detections in this pseudo-class indicates a need to more clearly address situations in which the patient is not in bed.

The *near-fall* class presented the lowest performance during the conducted tests, which is likely due to the fact that the near-fall position can vary significantly depending on the patient's situation. To improve the metrics of this class, which is considered one of the most important for the developed application, it is necessary to expand the dataset by capturing more scenarios. More images provide more learning possibilities for the AI model and, consequently, a greater ability to achieve more reliable detection.

The overall results of the model developed in this work are shown in Table IV.

TABLE IV
Results of the Developed Model

Metrics	Results
True Positives	216
True Negatives	1264
False Positives	46
False Negatives	46
Sensitivity	82.44%
Specificity	96.49%
Accuracy	94.15%
Error Rate	5.85%

When performing a numerical comparison with the model proposed by Bian et al. [4], which used a training dataset of 100 thousand data points, the proposed model performs better in terms of accuracy, specificity, and error rate. Sensitivity, however, shows a lower result, which may be related to the greater number of classes in this study. It is important to

note that such comparisons carry methodological limitations, since the datasets, environments, and class definitions differ substantially between works.

All studies used as comparison present a computer vision approach with binary output, where the systems distinguish whether a fall occurred or not. In this study, five output classes were addressed, allowing not only fall detection, but also the recognition of different patient behaviors, such as moving out of bed, being out of bed, and near-fall conditions.

Analyzing different patterns, without being restricted to a binary fall/no-fall decision, provides a more precise reading of patient behavior; thus, fall events can be not only detected but also potentially prevented.

VII. Conclusion

The system developed for the detection of fall events and related conditions achieved an accuracy of 94.15% in controlled environments.

The use of the YOLOv8 algorithm together with cloud-based systems enables fast processing of images captured by the camera, which are quickly interpreted and classified as "Patient in bed", "Patient moving out of bed", "Patient out of bed", "Patient in a near-fall situation", and "Patient fallen". In this way, the situation at the hospital bed can be monitored and reported in real time.

The implementation of this system in hospital beds can help identify falls in a shorter period of time, without the need for wearable devices or structural adaptations to the hospital bed. The real-time image transmission, combined with fast image processing, can identify the patient in a near-fall situation or moving out of bed and issue an alert to the care team, allowing for faster and more efficient medical intervention.

The model showed results comparable to those found in the literature, such as those reported by Nguyen et al. [5] and de Miguel et al. [6], given that five identification classes were used and the dataset is more limited when compared to those works.

Limitations and Future Work

The current work presents limitations that should be addressed in future studies. The dataset was composed exclusively of young adults aged 20 to 24 years, whereas the target population in clinical practice consists primarily of elderly patients, who may exhibit substantially different movement patterns. Furthermore, the validation was conducted exclusively in a controlled environment; experiments in real hospital settings are needed to assess the system's robustness against variable lighting, partial occlusions, and different bed configurations. Future work should also explore per-class performance optimization, particularly for the *near-fall* class, and evaluate system latency end-to-end (camera to alert) under real network conditions.

Systems for detecting patient conditions in hospital beds are gaining recognition in the research community. The developed project has proven to be efficient for detection in controlled environments and may serve as a viable alternative for the proposed problem, presenting potential for future integrations and improvements that expand its applicability to broader hospital contexts.

Resumo — A gestão eficiente da água em hospitais é essencial para a sustentabilidade ambiental, a redução de custos e o cumprimento dos Objetivos de Desenvolvimento Sustentável (ODS) 6 (Água Potável e Saneamento) e 12 (Consumo e Produção Responsáveis). Este estudo analisou o consumo hídrico, o volume de esgoto e os impactos financeiros no Hospital Universitário Oswaldo Cruz (HUOC/UPE), em Recife-PE, durante e após o período da pandemia COVID-19 de 2020 a 2024. Os dados mensais de consumo e custos, fornecidos pela Companhia Pernambucana de Saneamento (COMPESA), foram avaliados de forma quantitativa. No intervalo de cinco anos, registraram-se 129.173 m³ de água consumida e 132.377 m³ de esgoto gerado, com despesa total de R$ 2.776.107,50. As médias anuais foram de 25.834,6 m³ de consumo de água, 26.475,4 m³ de volume de esgoto e R$ 555.221,50 em custos. Os resultados demonstraram o forte impacto da pandemia de COVID-19 nas operações e nos custos hospitalares entre 2020 e 2022, seguido por um período de estabilização do consumo em 2023 e 2024, evidenciando a relevância do monitoramento sistemático e de auditorias operacionais para a sustentabilidade de hospitais públicos.

Palavras-chave — Gestão Hídrica Hospitalar; Sustentabilidade; Saúde Pública; ODS; Eficiência de Recursos.

I. INTRODUÇÃO

O gerenciamento dos recursos ambientais e financeiros em estabelecimentos assistenciais de saúde é um componente crítico da governança contemporânea em saúde pública. Entre esses insumos, a água se destaca como um recurso estratégico vital, indispensável não apenas para a subsistência humana e higiene básica, mas também para a viabilização de procedimentos de alta complexidade, tais como diálise, esterilização de materiais cirúrgicos, processamento de roupas hospitalares e climatização de ambientes críticos[1,2,3].

O Hospital Universitário Oswaldo Cruz (HUOC), vinculado à Universidade de Pernambuco (UPE), atua como um importante pólo assistencial do Sistema Único de Saúde (SUS) do Estado de Pernambuco. Caracterizado como um hospital universitário integrante do Complexo Hospitalar Enio Lustosa Cantarelli, o HUOC desempenha funções assistenciais de média e alta complexidade, além de exercer papel estratégico na formação acadêmica e no desenvolvimento científico regional[4]. Sua infraestrutura horizontal, localizada no bairro de Santo Amaro em Recife-PE, estende-se por uma área de 18.000 m² distribuída em 10 pavilhões, abrigando uma capacidade instalada de 487 leitos conforme registro no Cadastro Nacional de Estabelecimentos de Saúde - CNES[4,5].

Dada a magnitude de sua operação, que abrange desde consultas ambulatoriais especializadas até transplantes de órgãos e terapias oncológicas complexas, o consumo de água e a consequente geração de esgoto representam importância no orçamento operacional da instituição[4,5]. O consumo hídrico é amplamente afetado por flutuações na taxa de ocupação dos leitos, variações sazonais de patologias e emergências sanitárias, como a pandemia da COVID-19[6].

Embora diversos estudos tenham avaliado o consumo hídrico hospitalar durante a pandemia[6,7,8], poucos investigaram simultaneamente a dinâmica operacional da infraestrutura hídrica, os efeitos dos reajustes tarifários e a existência de mudanças na série temporal por meio de métodos estatísticos de detecção de rupturas[9,10,11].

Diante disso, este artigo analisou o perfil do consumo hídrico, do volume de esgoto e do correspondente impacto financeiro no HUOC durante e após o período da pandemia COVID-19 de 2020 a 2024. A relevância desta análise alinha-se diretamente com os Objetivos de Desenvolvimento Sustentável (ODS) da Organização das Nações Unidas (ONU), especificamente o ODS 6 (Água Potável e Saneamento) e o ODS 12 (Consumo e Produção Responsáveis), além de repercutir no ODS 3 (Saúde e

Bem-estar) ao promover a infraestrutura necessária para a segurança do paciente[2].

Com base na literatura e nas mudanças operacionais observadas durante a pandemia, este estudo testou as seguintes hipóteses:

H1: O período da pandemia esteve associado ao maior consumo de água em decorrência da intensificação dos protocolos de higienização, da ampliação da capacidade assistencial e da expansão dos leitos destinados ao tratamento de pacientes infectados.

H2: A evolução dos custos hídricos hospitalares não foi determinada exclusivamente pelo volume consumido, sendo influenciada também pelos reajustes tarifários e pelas alterações regulatórias aplicadas ao serviço público de abastecimento de água e esgoto sanitário.

H3: A redução progressiva da demanda assistencial associada à COVID-19 promoveu uma reorganização da dinâmica operacional da infraestrutura hídrica hospitalar, resultando em uma mudança do consumo de água e na transição para um regime operacional pós-pandemia estatisticamente distinto daquele observado durante os períodos de maior pressão assistencial.

As principais contribuições deste estudo são:
- Apresentar uma caracterização temporal do comportamento hídrico hospitalar, identificando diferentes estágios operacionais associados às mudanças epidemiológicas e regulatórias observadas entre 2020 e 2024.
- Demonstrar a influência conjunta dos fatores assistenciais e tarifários sobre a evolução dos custos de abastecimento de água em hospitais públicos, contribuindo para modelos de planejamento orçamentário e gestão sustentável dos recursos hídricos.
- Disponibilizar evidências que possam subsidiar auditorias operacionais, políticas públicas de sustentabilidade hospitalar e estratégias de gestão de infraestrutura, alinhadas aos Objetivos de Desenvolvimento Sustentável (ODS) 3 (Saúde e Bem-estar), ODS 6 (Água Potável e Saneamento) e ODS 12 (Consumo e Produção Responsáveis).

II. MATERIAIS E MÉTODOS

Este trabalho constitui-se como um estudo de caso quantitativo, descritivo e retrospectivo, focado na avaliação dos padrões de consumo de água potável, descarte de efluentes e evolução dos custos hídricos do HUOC durante e após a pandemia COVID-19. A unidade de análise corresponde ao imóvel institucional cadastrado sob a matrícula número 057774649 junto à Companhia Pernambucana de Saneamento (COMPESA), concessionária pública responsável pelo abastecimento hídrico e coleta de esgoto na região metropolitana do Recife.

A série temporal compreende 60 meses observados entre janeiro de 2020 e dezembro de 2024. Os dados secundários relativos aos volumes medidos/faturados em metros cúbicos (m³) e aos valores financeiros expressos em Moeda Corrente Nacional (R$) foram extraídos diretamente das faturas de serviços emitidas mensalmente pela concessionária. A análise englobou a caracterização do perfil operacional por meio do balanço hídrico, definido pela relação percentual entre o volume de esgoto registrado e o consumo de água faturado.

Adicionalmente, investigamos a evolução da estrutura tarifária aplicada ao perfil da instituição durante o quinquênio, mapeando os reajustes regulatórios autorizados e suas respectivas fórmulas de cálculo. Para o processamento estatístico e avaliação de sazonalidade, os dados foram agregados e segmentados por quadrimestres (Primeiro Quadrimestre: janeiro-abril; Segundo Quadrimestre: maio-agosto; Terceiro Quadrimestre: setembro-dezembro), permitindo isolar a volatilidade decorrente de fatores sazonais e operacionais de acordo com os respectivos períodos anuais. A agregação quadrimestral foi adotada para reduzir oscilações mensais sem comprometer a resolução temporal necessária para identificação das tendências anuais.

Foram levantados e analisados os principais indicadores assistenciais do HUOC ao longo do período de estudo, incluindo a evolução da capacidade instalada de leitos destinados ao atendimento da COVID-19, a distribuição por nível de complexidade assistencial, o número de hospitalizações relacionadas à doença e indicadores de desempenho hospitalar, tais como a Taxa de Ocupação Hospitalar (TOH), o Tempo Médio de Permanência (TMP) e a Taxa de Mortalidade Hospitalar (TMH) obtidos através de informações operacionais publicadas nos Anuários Estatísticos do Complexo Hospitalar da UPE[12,13,14]. Esses indicadores foram utilizados para contextualizar as alterações observadas no comportamento do consumo hídrico e interpretar sua relação com a dinâmica operacional da instituição durante e após a pandemia.

A validação das hipóteses foi conduzida por meio de diferentes métodos estatísticos, selecionados de acordo com a natureza de cada hipótese investigada[15].

Para a Hipótese H1, que avaliou a diferença no consumo hídrico entre os períodos crítico e pós crítico da pandemia, empregou-se o teste *t* de Welch, apropriado para comparação entre médias de grupos independentes com variâncias potencialmente distintas.

A Hipótese H2, referente à relação entre consumo de água e impacto financeiro, foi investigada inicialmente por meio do coeficiente de correlação de Pearson e, posteriormente, por um modelo de regressão linear múltipla, incorporando simultaneamente o volume consumido e os diferentes períodos tarifários. Para a Hipótese H3, que analisou a reorganização do padrão operacional de consumo após a pandemia, aplicou-se o Teste de Pettitt, para identificação de mudanças estruturais na série temporal, seguido de um modelo de Regressão Segmentada por Séries Temporais Interrompidas *(Interrupted Time Series – ITS)*, utilizado

para estimar a mudança imediata no nível de consumo, a alteração da tendência temporal e a estabilização do novo regime operacional. Em todas as análises adotou-se nível de significância de 5% ($\alpha = 0,05$), sendo os resultados apresentados com respectivos valores de p e intervalos de confiança de 95% quando aplicáveis.

A ruptura estatística considerada foi identificada pelo teste de Pettitt (maio/2022). Contudo, para avaliar a consolidação do regime pós-pandemia utilizamos janeiro de 2023 como marco correspondente ao encerramento das medidas emergenciais.

Antes da aplicação do coeficiente de correlação de Pearson, a relação entre consumo hídrico e custo mensal foi analisada por meio de gráfico de dispersão, evidenciando comportamento aproximadamente linear. A análise de Pearson forneceu evidências da associação linear positiva extremamente forte ($r = 0,9801$; $p < 0,001$), sustentando a utilização de modelos lineares para investigar essa relação. Para avaliar os pressupostos da regressão linear múltipla e do modelo de Séries Temporais Interrompidas *(Interrupted Time Series – ITS),* foram realizados diagnósticos adicionais. A independência dos resíduos foi investigada pelo teste de Durbin-Watson (DW = 1,382), cujo resultado indicou autocorrelação serial positiva de baixa a moderada. A homocedasticidade foi avaliada pelo teste de Breusch–Pagan, que indicou evidências de heterocedasticidade (LM = 10,89; p = 0,0279), demonstrando que a variância dos resíduos não pode ser considerada constante.

A normalidade dos resíduos foi examinada pelos testes de Jarque-Bera (JB = 13,205; p = 0,0014) e Shapiro-Wilk (W = 0,919; p = 0,0007), que evidenciaram desvio da normalidade. Embora esses resultados indiquem violações dos pressupostos clássicos da regressão linear, não foram aplicadas técnicas de correção da inferência, como erros-padrão robustos ou procedimentos de reamostragem (*bootstrap*). Contudo, considerando o tamanho amostral (n = 60) e a robustez assintótica dos estimadores de mínimos quadrados ordinários, os modelos foram mantidos para fins de inferência estatística.

A multicolinearidade foi avaliada pelo Fator de Inflação da Variância (VIF), cujos valores variaram entre 1,41 e 2,44, indicando baixa colinearidade entre as variáveis explicativas e estabilidade dos coeficientes estimados.

A tendência temporal anterior apresentou declínio significativo (β=-50,16; p=0,001). Após a intervenção institucional de janeiro de 2023 observou-se alteração significativa da inclinação da série (β=69,82; p=0,023), indicando mudança na dinâmica temporal do consumo. Entretanto, a redução imediata do nível médio não foi estatisticamente significativa (β=-682,70; p=0,155). Considerando especificamente o período pós-pandemia (2023–2024), a tendência estimada de 19,66 m³/mês não diferiu significativamente de zero (p=0,456), caracterizando estabilização do consumo em um novo regime operacional.

A metodologia adotada neste estudo está sintetizada no fluxograma apresentado na Fig. 1, que ilustra as etapas sequenciais de coleta, processamento, análise e interpretação dos dados.

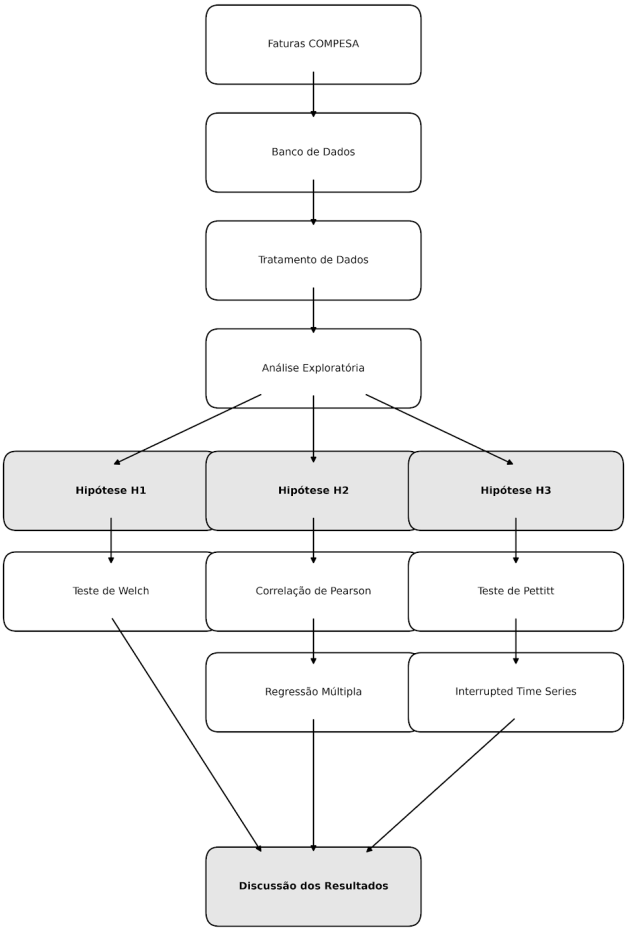

Fig. 1 - Etapas da pesquisa

III. RESULTADOS E DISCUSSÃO

A. Panorama Geral Quinquenal

No acumulado do período investigado (2020–2024), o HUOC contabilizou um consumo hídrico total de 129.173 m³ de água e uma geração de efluentes mensurada em 132.377 m³ de esgoto. Esse fluxo de consumo e descartes resultou em um dispêndio financeiro global de R$ 2.776.107,50 junto à concessionária. Em termos de médias anuais, a instituição demandou 25.834,6 m³ de água, gerou 26.475,4 m³ de esgoto e incorreu em custos anuais médios da ordem de R$ 555.221,50.

A importância do HUOC como centro de referência para o tratamento de patologias infectocontagiosas no Estado de Pernambuco gerou a mobilização e reestruturação de sua capacidade para o fornecimento de leitos dedicados à COVID-19. Em 2020, sob demanda da Secretaria de Saúde do Estado (SES/PE), a instituição disponibilizou 183 leitos para tratamento da pandemia. A distribuição dessas vagas ocorreu sendo 135 leitos de enfermaria/urgência e 48 leitos

de Unidade de Terapia Intensiva (UTI), conforme observado na Fig. 2.

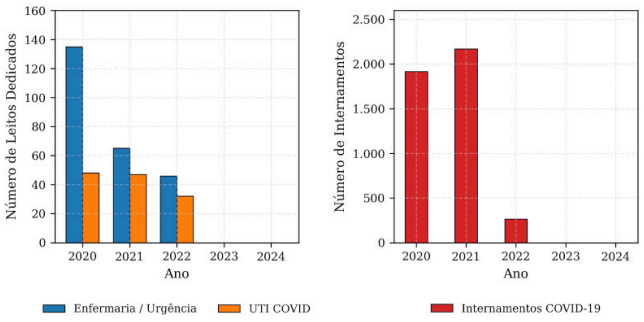

Fig. 2 - Enfrentamento à Pandemia por SARS-CoV-2 no HUOC UPE, fonte SCH/UPE

Esse arranjo de contingência sofreu um processo de desmobilização e redução progressiva ao longo dos anos subsequentes. Esse recuo foi impulsionado pela inserção de novos serviços de saúde na rede de assistência do Estado, pelas flutuações dos cenários epidemiológicos locais e pelo avanço expressivo da cobertura vacinal. Como resultado, a infraestrutura de enfermarias/urgência foi reduzida para 65 leitos em 2021 e 46 leitos em 2022. Os leitos críticos de UTI foram reduzidos para 47 em 2021 e 32 em 2022, até a completa desmobilização física nos anos posteriores.

No ano de 2020, o serviço registrou 3.650 atendimentos na triagem/emergência direcionados a pacientes com suspeita ou confirmação de infecção por COVID-19. Desses, 1.914 indivíduos necessitaram de admissão e internamento hospitalar. O índice de positividade laboratorial foi de 42,8%, consistindo em 819 internamentos com diagnóstico confirmado para COVID-19. A série de internamentos sob suspeita ou confirmação registrou seu pico em 2021, atingindo 2.170 ocorrências, antes de sofrer uma expressiva redução de 87,8% em 2022, quando computou apenas 265 internamentos, conforme demonstra a Fig. 3.

Devido à ausência de um serviço de pronto-atendimento de "porta aberta" convencional, o hospital operou por meio de seu serviço de triagem de doenças infecciosas para adultos e crianças. Consequentemente, o fluxo de admissão de pacientes foi realizado ou por encaminhamentos regulados externos, intermediados pela Central de Regulação Hospitalar da SES/PE, ou por meio de demanda interna do próprio hospital.

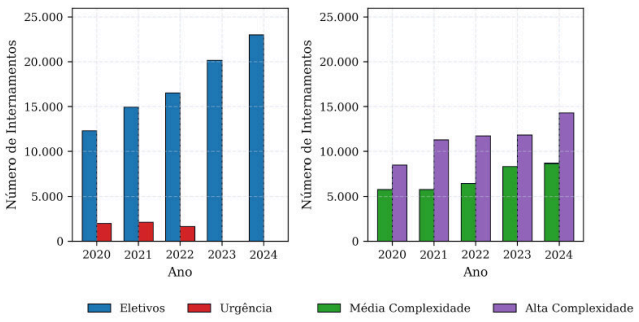

Fig. 3 - Números de internamento e nível de complexidade, fonte SCH/UPE

O ano de 2022 marcou o início da descompressão do sistema de saúde após as ondas críticas da pandemia de COVID-19. Observou-se a continuidade do crescimento das internações impulsionada por uma retomada assistencial programada. O HUOC registrou um aumento de 11% nas internações eletivas de pacientes regulados, um reflexo direto da reativação de leitos clínicos e cirúrgicos operados em regime de rotina.

Concomitantemente, identificou-se uma redução nas internações por urgência motivada pela queda sustentada do número de casos suspeitos e confirmados de COVID-19. Sob a perspectiva de severidade, a alta complexidade expandiu-se em 4%.

O comportamento de fluxo em 2023 revelou uma assimetria nas taxas de crescimento entre os níveis de complexidade. O HUOC apresentou uma variação positiva expressivamente maior no quantitativo de internamentos de média complexidade (+29%) em comparação aos de alta complexidade (+1%). Este desalinhamento temporário de crescimento foi determinado por uma resposta emergencial a um surto epidemiológico de Síndrome Respiratória Aguda Grave (SRAG) ocorrido no primeiro semestre de 2023. O hospital absorveu os casos expandindo em 50% os internamentos pediátricos de média complexidade.

Para além da resposta à crise sanitária infantil, o segmento de média complexidade foi sustentado pela reativação da demanda reprimida de procedimentos regulados, registrando incremento de 37% nos internamentos cirúrgicos e 19% nos clínicos. Em 2024, o HUOC atingiu 23.008 internamentos (alta de 14% em relação ao ano anterior). Por não possuir um serviço de urgência/emergência de "porta aberta" e amparada por uma queda substancial de internamentos regulados para as triagens de Doenças Infectocontagiosas adulto e infantil, o HUOC optou por considerar 100% dos internamentos como eletivos.

Considerando que pacientes acometidos por quadros de Síndrome Respiratória Aguda Grave (SRAG), sejam suspeitos ou confirmados para COVID-19, apresentaram disfunções ventilatórias que exigiram um tempo médio de permanência (TMP) hospitalar prolongado para reabilitação, analisamos os indicadores de tempo de ocupação, permanência e mortalidade considerando o período de 2019 (pré-pandemia) a 2024(pós-pandemia) conforme apresentado na Fig. 4.

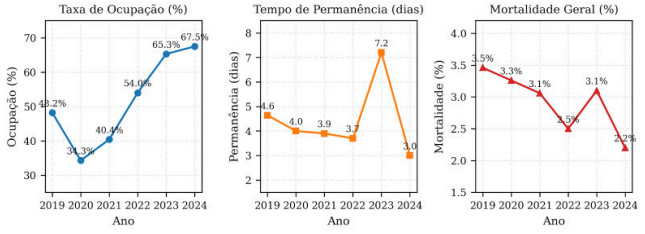

Fig. 4 - Indicadores de ocupação, permanência e mortalidade do HUOC, fonte SCH/UPE

No período pré-pandemia (em 2019), o hospital registrou uma Taxa de Ocupação Hospitalar (TOH) de 48,2%. Com o advento da emergência sanitária em 2020, o indicador

sofreu uma redução significativa, atingindo o mínimo de 34,27%. Esse recuo de 13,93% decorreu da necessidade de bloqueio de leitos de rotina, da suspensão temporária de cirurgias eletivas e da alocação de áreas físicas exclusivas para o isolamento de doenças infectocontagiosas. A partir de 2021, ocorreu uma recuperação gradual, com a TOH subindo para 40,4% em 2021 e 54,0% em 2022. Esse movimento de expansão acelerou progressivamente em 2023, alcançando 65,3%, impulsionado pelo acréscimo de 11% nos internamentos hospitalares totais e pela expansão de 22% nos procedimentos cirúrgicos eletivos. Em 2024, a taxa atingiu seu ponto máximo com 67,5% de ocupação.

O Tempo Médio de Permanência (TMP) apresentou um padrão de estabilidade durante os primeiros quatro anos da série histórica, oscilando de 4,64 dias em 2019 para 4,00 dias em 2020, 3,90 dias em 2021 e 3,70 dias em 2022. No entanto, em 2023 o indicador subiu para 7,20 dias, representando um acréscimo de 3,5 dias em relação ao ano anterior. A reversão desse indicador ocorreu em 2024, quando o TMP registrou uma queda acentuada de 4,2 dias frente a 2023, estabelecendo o menor índice de 3,00 dias. A redução no tempo de internação elevou o giro de leitos e permitiu absorver o aumento da demanda sem sobrecarregar a capacidade física da instituição, demonstrando eficiência dos processos de regulação interna.

A Taxa de Mortalidade Hospitalar (TMH) manteve uma trajetória de declínio sustentado ao longo de quase todo o período analisado, evoluindo de 3,46% em 2019 para 3,26% em 2020, 3,06% em 2021 e atingindo 2,50% em 2022. Esses resultados demonstraram a resiliência dos protocolos assistenciais do hospital mesmo durante os anos mais críticos da crise sanitária. Em 2023, observamos uma discreta elevação do indicador para 3,10%. Em 2024, a TMH registrou uma redução de 0,9%, alcançando o menor valor com 2,20%. A convergência entre a maior taxa de ocupação do período (67,5%), o menor tempo de permanência (3,00 dias) e o menor índice de mortalidade geral (2,20%) indicam que o ganho de produtividade e a aceleração do giro de leitos ocorreram acompanhados pela melhoria da qualidade e da segurança do cuidado prestado aos pacientes.

B. Estágios Operacionais do Balanço Hídrico

A análise da relação entre o consumo de água e o esgoto sanitário permitiu identificar três estágios operacionais distintos na série histórica, evidenciando modificações no comportamento do consumo e nas metodologias de faturamento da concessionária:

1) Estágio 1 (Janeiro de 2020 a Agosto de 2021): Caracterizou-se por elevados volumes absolutos de consumo de água induzidos pelo ápice da crise sanitária da COVID-19. Nesse estágio, o balanço hídrico manteve-se estritamente estável, com o volume de esgoto faturado fixado em equivalência exata a 100% do consumo de água medido. Foram registrados picos expressivos de consumo associados à intensificação das atividades de higienização, desinfecção e abertura de leitos críticos de UTI, destacando-se os meses de novembro de 2020 (4.245 m³) e julho de 2021 (4.331 m³), contrapondo-se a períodos de menor intensidade assistencial como março de 2020 (1.649 m³) e fevereiro de 2021 (1.374 m³).

2) Estágio 2 (Setembro de 2021 a Dezembro de 2022): Este estágio foi marcado por uma mudança metodológica no registro dos efluentes pela concessionária, rompendo o equilíbrio de 100% e gerando a ocorrência de volumes de esgoto superiores ao volume de água consumido. Em setembro de 2021, o consumo hídrico foi de 3.429 m³ frente a 3.617 m³ de esgoto. Em outubro do mesmo ano, registrou-se o teto máximo de consumo do ano, com 4.618 m³ de água e 4.694 m³ de esgoto. Em dezembro de 2021, o consumo de 3.422 m³ gerou 3.577 m³ de esgoto. Concomitantemente, o ano de 2022 representou o início de um declínio acentuado no consumo físico de água, registrando mínimos históricos em maio (658 m³) e julho (799 m³) e máximos em janeiro (3.866 m³) e março (2.907 m³).

3) Estágio 3 (Anos de 2023 e 2024): Consolidou a estabilização de um novo patamar operacional pós-pandêmico. Observou-se a manutenção do excedente de esgoto em relação à água em todos os meses, porém sob patamares de consumo de água drasticamente inferiores aos anos iniciais. Em 2023, o consumo hídrico oscilou entre o mínimo atípico de 303 m³ (abril) e o máximo de 1.692 m³ (agosto). No ano de 2024, verificou-se comportamento assemelhado, com o consumo variando de 846 m³ (março) a 1.828 m³ (agosto).

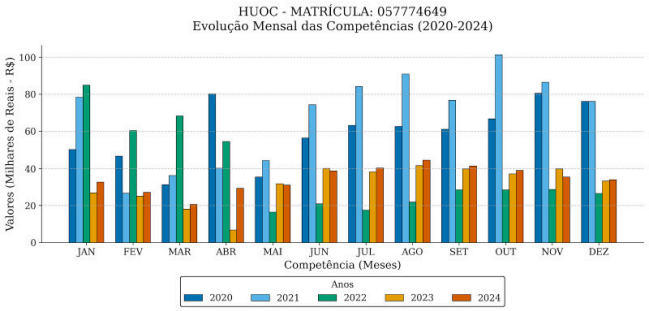

Fig. 5 - Evolução do desempenho hídrico do HUOC 2020/2024, fonte COMPESA

C. Evolução da Estrutura Tarifária

O impacto financeiro sofrido pela instituição não decorre exclusivamente do volume de água/esgoto demandado, mas também da evolução da estrutura de tarifas aplicadas pela concessionária. O modelo de faturamento comercial da COMPESA baseia-se em uma taxa fixa de disponibilidade de serviço aplicada aos primeiros 10 m³ consumidos, acrescida de um valor variável indexado por metro cúbico excedente.

Ao longo da série histórica, identificaram-se três reajustes tarifários. No ano de 2020, as tarifas vigentes estipulavam R$ 62,67 para a faixa de consumo básico (até 10 m³) e R$ 9,50 para cada metro cúbico excedente. Em janeiro de 2021, o primeiro reajuste elevou a taxa básica para R$ 64,17 e a tarifa excedente para R$ 9,73 por m³. Em agosto de 2021, um segundo reajuste elevou os parâmetros para R$ 71,81 (faixa básica) e R$ 10,89 (excedente), coincidindo com o período imediatamente anterior à mudança metodológica do cálculo de esgoto.

Esse modelo permaneceu inalterado ao longo de todo o ano de 2022. Por fim, em maio de 2023, foi implementado o terceiro reajuste, fixando a taxa básica em R$ 79,86 e a tarifa excedente em R$ 12,11 por m³, valor que permaneceu vigente até o encerramento de 2024.

VIGÊNCIA INICIAL	TARIFA BÁSICA (ATÉ 10 M³)	TARIFA EXCEDENTE (POR M³)
Janeiro de 2020	R$ 62,67	R$ 9,50
Janeiro de 2021	R$ 64,17	R$ 9,73
Agosto de 2021	R$ 71,81	R$ 10,89
Maio de 2023	R$ 79,86	R$ 12,11

Tabela 1 - Evolução cronológica da estrutura tarifária (COMPESA)

A flutuação financeira também sofre influência da composição tributária e regulatória inerente ao faturamento de serviços de saneamento básico. Em termos de tributação federal, as faturas de água e esgoto estão sujeitas à incidência do Programa de Integração Social (PIS) e da Contribuição para o Financiamento da Seguridade Social (COFINS). Estes tributos incidem sobre a receita bruta da concessionária e são repassados ao consumidor.

No âmbito estadual, o fornecimento de água tratada por concessionárias de serviço público possui natureza jurídica de serviço público essencial, não configurando circulação de mercadoria. Dessa forma, amparado por jurisprudência consolidada do Supremo Tribunal Federal (STF RE 607.056/RJ), não há incidência do Imposto sobre Operações relativas à Circulação de Mercadorias e sobre Prestações de Serviços de Transporte Interestadual e Intermunicipal e de Comunicação (ICMS) sobre o valor da fatura, o que difere a matriz de custos hídricos da matriz de custos com energia elétrica.

D. Sazonalidade Quadrimestral e Volatilidade Financeira

A análise dos custos mensais refletiu a interação entre a demanda assistencial hospitalar e os reajustes tarifários descritos, revelando uma flutuação sazonal quando segregada por quadrimestres, conforme apresentado na Fig. 6.

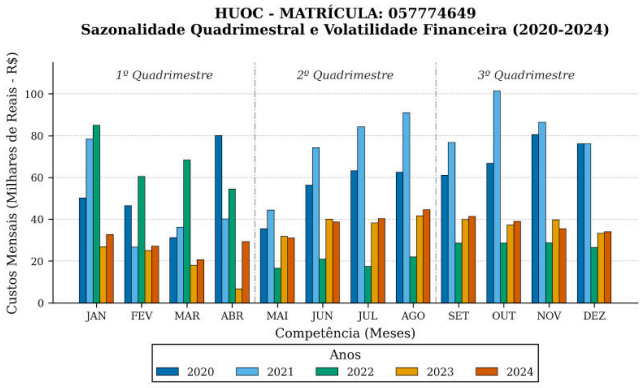

Fig. 6 - Sazonalidade quadrimestral e volatilidade financeira, fonte COMPESA

A análise quadrimestral dos custos evidenciou elevada variabilidade durante o período da pandemia, seguida de estabilização no biênio pós-pandemia. O primeiro quadrimestre apresentou as maiores oscilações, com picos entre 2021 e 2022, associados ao aumento da demanda assistencial decorrente da COVID-19 e de surtos sazonais de arboviroses, seguidos por redução expressiva dos custos em 2023 e estabilização em 2024. O segundo quadrimestre exibiu comportamento semelhante, com custos elevados em 2020–2021, redução acentuada em 2022 e posterior estabilização, refletindo a diminuição da pressão assistencial e a retomada gradual das atividades eletivas. O terceiro quadrimestre apresentou menor variabilidade relativa, embora tenha concentrado o maior custo mensal de toda a série histórica, registrado em outubro de 2021 (R$ 101.333,50), resultado da combinação entre o elevado consumo durante a pandemia e os reajustes tarifários implementados pela concessionária. Nos anos de 2023 e 2024, os custos permaneceram relativamente estáveis em todos os quadrimestres, caracterizando um novo padrão operacional pós-pandemia.

E. Desempenho hídrico anual

Nos dois primeiros anos analisados, a instituição manteve um patamar de consumo acima de 37.000 m³ anuais, atingindo o pico de 39.328 m³ em 2021. Este volume acentuado correlaciona-se diretamente com o período de enfrentamento crítico da pandemia de COVID-19, onde os protocolos de higienização, desinfecção e operação contínua de blocos de internação demandaram uma carga hidráulica máxima da infraestrutura predial conforme demonstrado na Fig. 7.

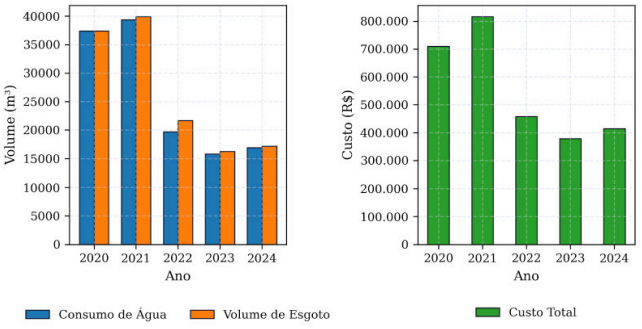

Fig. 7 - Desempenho anual do volume de água, esgoto e custos, fonte COMPESA

A partir de 2022, observou-se uma redução abrupta de 49,9% no consumo de água (decréscimo para 19.703 m³), estabilizando-se em uma média de 16.546 m³ no biênio subsequente (2023–2024).

Um aspecto relevante observado neste estudo foi a divergência entre o volume de água medido no hidrômetro principal e o volume de esgoto faturado pela concessionária. Embora, em condições usuais, o volume de esgoto corresponda a uma fração da água consumida (fator de retorno), verificou-se que, a partir de setembro de 2021, o esgoto faturado passou a superar o consumo de água, alcançando diferença de 9,95% (1.959 m³) em 2022. Essa divergência é compatível com a utilização de fontes alternativas de abastecimento, como poços artesianos e caminhões-pipa destinados a setores críticos (como

Hemodiálise e CME), cujos efluentes são lançados na rede pública sem que a água correspondente seja registrada pelo hidrômetro principal. Esse cenário possui impacto para a governança contratual e tarifária do serviço de saneamento, justificando a implantação de hidrometria setorizada nas fontes alternativas e a revisão, junto à COMPESA, do fator de retorno de efluentes e dos critérios de faturamento do volume de esgoto, visando aprimorar a confiabilidade do balanço hídrico do hospital.

O desempenho hídrico também foi avaliado por meio dos indicadores L/leito-dia e m³/m²/ano. Como os dados de consumo referem-se à unidade consumidora nº 057774649 da COMPESA, enquanto a área construída (18.000 m²) e os 487 leitos correspondem ao complexo do HUOC, esses parâmetros foram utilizados como *proxies* institucionais. Embora a comparação dos indicadores normalizados entre as fases pré-pandêmica, crítica e pós-pandêmica seja desejável, a ausência de dados de consumo hídrico anteriores a 2020 impossibilitou o cálculo desses indicadores para a fase pré-pandêmica. Assim, a análise dos indicadores normalizados foi restrita ao período de 2020 a 2024. Na fase crítica da COVID-19, o consumo específico atingiu 558,48 L/leito-dia (2020), 961,99 L/leito-dia (2021) e 692,02 L/leito-dia (2022), evidenciando que o consumo hídrico não reduziu na mesma proporção da capacidade assistencial. O indicador de intensidade de consumo por área diminuiu de 2,078 para 0,940 m³/m²/ano entre 2020 e 2024, correspondendo a uma redução de 54,8%. Como a área construída permaneceu constante ao longo do período analisado, esse indicador mostrou-se mais apropriado para comparações temporais e para *benchmarking* com instituições que utilizem métricas padronizadas e critérios metodológicos comparáveis. Os resultados, entretanto, devem ser interpretados considerando as limitações inerentes ao uso de *proxies* institucionais.

Para avaliar a hipótese H1, investigamos o impacto da pandemia de COVID-19 sobre a carga operacional da infraestrutura hídrica hospitalar por meio da comparação do consumo mensal de água entre o período da pandemia (2020–2022; $n = 36$ meses) e o período pós-pandemia (2023–2024; $n = 24$ meses). A comparação das médias foi realizada utilizando o teste t de Welch, adequado para amostras independentes com variâncias potencialmente distintas. Os resultados evidenciaram diferença estatisticamente significativa entre os dois períodos ($t = 6{,}128$; gl = 43,11; $p < 0{,}001$), demonstrando que o consumo hídrico durante a pandemia foi substancialmente superior ao observado após a retomada das condições operacionais regulares. Esse comportamento é consistente com a intensificação dos protocolos de controle de infecção, ao aumento da frequência dos procedimentos de higienização, à ampliação temporária da capacidade assistencial e às adaptações operacionais impostas pelo enfrentamento da COVID-19. Diante disso, os resultados fornecem evidências quantitativas que corroboram a hipótese H1, indicando que a pandemia exerceu impacto significativo sobre a demanda da infraestrutura hídrica hospitalar.

Para testar a hipótese H2, a relação entre o consumo hídrico e os custos operacionais foi inicialmente avaliada por meio do coeficiente de correlação de Pearson, o qual revelou correlação linear positiva extremamente forte entre o volume de água consumido e o custo mensal correspondente ($r = 0{,}980$; $p < 0{,}001$). Embora esse resultado indique que o aumento do consumo está diretamente associado à elevação das despesas, a elevada correlação, isoladamente, não permite distinguir a contribuição dos reajustes tarifários ocorridos ao longo do período de estudo. Dessa forma, foi desenvolvido um modelo de regressão linear múltipla incorporando simultaneamente o consumo de água e os diferentes períodos tarifários estabelecidos pela concessionária. O modelo apresentou elevado poder explicativo ($R^2 = 0{,}993$), indicando que aproximadamente 99,3% da variabilidade observada nos custos foi explicada pelas variáveis independentes consideradas. A análise dos coeficientes indicou que tanto o consumo de água ($\beta = 21{,}17$; $p < 0{,}001$) quanto os reajustes tarifários permaneceram estatisticamente significativos, evidenciando que a evolução dos custos operacionais resulta da interação entre fatores físicos, representados pelo volume consumido, e fatores regulatórios, associados às alterações na estrutura tarifária. Esses achados confirmam a hipótese H2 e demonstram que o comportamento financeiro do sistema hídrico hospitalar não pode ser explicado exclusivamente pela demanda de água, sendo também influenciado pelas políticas tarifárias adotadas ao longo do período.

Para avaliar a hipótese H3, aplicamos inicialmente o Teste de Pettitt para identificar mudanças estruturais na série temporal de consumo hídrico. O teste detectou uma ruptura altamente significativa em maio de 2022 ($K = 864{,}0$; $p = 2{,}77 \times 10^{-9}$), evidenciando a transição para um novo regime estatístico de consumo. Embora o teste não identifique relações causais, o ponto de ruptura coincide temporalmente com a redução das medidas emergenciais implementadas durante a pandemia de COVID-19, sugerindo uma reorganização operacional da infraestrutura hospitalar.

A hipótese H3 foi avaliada por meio da combinação do teste não paramétrico de Pettitt e da Regressão Segmentada de Série Temporal Interrompida (ITS). O teste de Pettitt foi empregado exclusivamente para detectar a ruptura estatística, enquanto janeiro de 2023 foi definido *a priori* como marco operacional do período pós-pandemia.
O teste de Pettitt identificou uma mudança estrutural altamente significativa na série temporal ($K = 864{,}0$; $p = 2{,}77 \times 10^{-9}$), localizada na observação 29 (maio de 2022), indicando alteração da dinâmica do consumo hídrico antes do marco operacional adotado para a ITS. Considerando janeiro de 2023 como início do período pós-pandemia e marco operacional da intervenção na ITS, a regressão segmentada evidenciou tendência decrescente significativa no período pré-intervenção ($\beta_1 = -50{,}16$ m³/mês; $p = 0{,}001$). A mudança imediata no nível médio após a intervenção não foi estatisticamente significativa ($\beta_2 = -682{,}70$ m³; $p = 0{,}155$). Em contrapartida, observou-se alteração significativa da tendência temporal ($\beta_3 = 69{,}82$ m³/mês; $p = 0{,}023$), indicando mudança na dinâmica de consumo após a reorganização operacional. Adicionalmente, a análise restrita ao período de 2023–2024 evidenciou tendência de 19,66 m³/mês, sem significância estatística ($p = 0{,}456$),

caracterizando estabilização do consumo em um novo regime operacional.

IV. CONSIDERAÇÕES FINAIS

A análise integrada dos indicadores operacionais, assistenciais, financeiros e estatísticos demonstrou que as mudanças observadas no consumo hídrico acompanharam a reorganização da infraestrutura hospitalar e da capacidade assistencial ao longo do período investigado.

Os resultados confirmaram a hipótese H1, evidenciando que o período pandêmico apresentou consumo hídrico significativamente superior ao período pós-pandemia (teste *t* de Welch: $t = 6{,}128$; $p < 0{,}001$). Esse comportamento é consistente com a ampliação temporária da capacidade instalada, a intensificação dos protocolos de higienização, o aumento das internações relacionadas à COVID-19 e a maior utilização da infraestrutura hospitalar durante a emergência sanitária.

A hipótese H2 também foi corroborada. Embora tenha sido observada correlação linear extremamente forte entre consumo de água e custos operacionais ($r = 0{,}980$; $p < 0{,}001$), a regressão linear múltipla indicou que a evolução das despesas não depende exclusivamente do volume consumido. O elevado poder explicativo do modelo ($R^2 = 0{,}993$) evidenciou que tanto o consumo de água/esgoto quanto os sucessivos reajustes tarifários exerceram influência estatística sobre os custos, ressaltando que o planejamento orçamentário hospitalar deve considerar simultaneamente fatores operacionais e regulatórios.

Em relação à hipótese H3, o Teste de Pettitt identificou uma ruptura altamente significativa na série temporal em maio de 2022 ($K = 864{,}0$; $p < 0{,}001$), indicando a transição entre o regime operacional associado à pandemia e um novo padrão de funcionamento. A Regressão Segmentada forneceu evidências da redução imediata do nível médio de consumo após essa ruptura, enquanto a análise específica do período de 2023–2024 indicou ausência de tendência temporal significativa ($p = 0{,}456$), caracterizando a estabilização do consumo em um novo patamar operacional. Os resultados sugerem a consolidação de um novo padrão operacional no período observado (2023–2024).

Além dos aspectos quantitativos, a identificação de três estágios operacionais distintos do balanço hídrico evidenciou alterações relevantes tanto no comportamento do consumo quanto no método de faturamento dos serviços de água e esgoto. A divergência observada entre os volumes de água consumida e de esgoto faturado após 2021 sugere a necessidade de auditorias técnicas mais aprofundadas sobre os critérios de medição e cobrança adotados pela concessionária, bem como sobre possíveis fontes alternativas de abastecimento utilizadas pela instituição.

Do ponto de vista da gestão hospitalar, os resultados fornecem evidências que podem subsidiar estratégias de eficiência hídrica, planejamento orçamentário, auditorias operacionais e políticas institucionais de sustentabilidade, contribuindo para a otimização do uso dos recursos naturais em hospitais públicos de média e alta complexidade. As evidências produzidas também reforçam o alinhamento da gestão da infraestrutura hospitalar aos Objetivos de Desenvolvimento Sustentável, especialmente os ODS 3 (Saúde e Bem-Estar), ODS 6 (Água Potável e Saneamento) e ODS 12 (Consumo e Produção Responsáveis).

Como limitações, este estudo corresponde a um estudo de caso desenvolvido em um único hospital universitário, utilizando dados administrativos de faturamento e consumo. Embora os resultados apresentem consistência, sua generalização para outras instituições deve ser realizada com cautela. Pesquisas futuras poderão ampliar esta abordagem por meio de análises multicêntricas envolvendo hospitais de diferentes portes e perfis assistenciais, bem como incorporar indicadores de eficiência hídrica, *benchmarking*, técnicas de *Data Envelopment Analysis* (DEA), modelos de previsão por séries temporais e sistemas de monitoramento inteligente para apoiar a gestão da infraestrutura hospitalar.

***Resumo*—As cabines de segurança biológica (CSB) de Classe II são fundamentais para conter agentes biológicos e proteger os operadores, o ambiente e as amostras. O objetivo deste estudo foi avaliar, por meio de cultivo biológico, se existem pontos com maior potencial de contaminação na estrutura das CSBs, não apenas em áreas que são acessadas pelo usuário mas também por profissionais que realizam a manutenção destes equipamentos. A metodologia consistiu no mapeamento de 25 pontos, definidos com base na literatura, e na coleta microbiológica com placas de contato RODAC contendo Ágar Triptona de Soja, incubadas para fungos e bactérias. Foi utilizado como critério de indicação das superfícies contaminadas, um limite de crescimento de 2,5 UFC/cm^2. Dos 25 pontos avaliados, 10 apresentaram crescimento abaixo do limite, enquanto os 15 restantes apresentaram um crescimento desenfreado das colônias, impossibilitando a contagem. Estes resultados reforçam a hipótese de que alguns pontos são potencialmente mais contaminantes, e portanto seu mapeamento pode estabelecer as áreas que requerem maior atenção nos processos de descontaminação, aumentando a segurança ocupacional dos usuários e da equipe de manutenção.**

***Palavras-chave*—cabines de segurança biológica, biosegurança, microbiologia, engenharia clínica**

I. Introdução

Em ambientes laboratoriais nos quais há manipulação de agentes infecciosos capazes de representar risco ocupacional e ambiental, o conceito de biossegurança está relacionado à implementação de medidas de contenção destinadas a reduzir ou eliminar a exposição a esses agentes potencialmente perigosos. Nesse contexto, destacam-se três elementos fundamentais: a adoção de boas práticas laboratoriais, a seleção adequada de equipamentos de proteção e contenção, e o correto projeto das instalações, conforme o nível de risco envolvido. [1]

Entre os equipamentos de contenção, as cabines de segurança biológica (CSB) constituem o principal dispositivo destinado à proteção contra aerossóis e respingos gerados durante procedimentos laboratoriais. Essas cabines são classificadas em Classe I, II e III, sendo sua escolha determinada pelo tipo de procedimento realizado e pela classe de risco dos agentes biológicos manipulados. As CSB de Classe II possuem fluxo de ar controlado e filtros de alta eficiência (HEPA), responsáveis por reter partículas potencialmente contaminantes, protegendo simultaneamente o operador, a amostra e o ambiente [2].

No contexto da avaliação dos riscos associados ao uso deste equipamento, a literatura descreve pontos específicos para a verificação da eficácia da descontaminação ambiental. [3]–[11] Nesse sentido, o presente estudo tem como objetivo avaliar, por meio de cultivo biológico, se existem pontos com maior potencial de contaminação em áreas que são acessadas pelo usuário e por profissionais que realizam a manutenção destes equipamentos.

II. Materiais e Métodos

O presente trabalho apresenta a seleção do equipamento a ser avaliado, o levantamento e a avaliação dos pontos de interesse descritos na literatura. Adicionalmente, foi definido o protocolo de aplicação do meio para cultivo. Por fim, foi estabelecida uma metodologia para análise e quantificação dos dados obtidos, permitindo a avaliação objetiva dos resultados obtidos após incubação do material.

A. Delineamento do estudo e equipamentos utilizados

Para a identificação dos potenciais pontos de contaminação, foi realizada uma busca na literatura por estudos que abordassem procedimentos de descontaminação ambiental utilizando agentes químicos vaporizados, tais como formaldeído e peróxido de hidrogênio. Foram selecionados trabalhos que avaliassem a eficácia desses procedimentos por meio da utilização de indicadores biológicos posicionados em regiões previamente definidas dos equipamentos. Essas foram as regiões consideradas de interesse para o estudo.

Foi realizado o levantamento do parque de equipamentos de uma instituição pública com laboratórios em diversos estados do Brasil, com o objetivo de quantificar e caracterizar as

Cabines de Segurança Biológica (CSB) existentes. A coleta de dados abrangeu a identificação do setor, bem como a classe e o modelo de cada equipamento, utilizando-se uma planilha eletrônica para o armazenamento, análise e seleção dos atributos. Adotou-se como critério de inclusão exclusivamente os equipamentos de Classe II, visto que eles são maioria na instituição, e a literatura científica consultada fundamenta-se majoritariamente neste tipo [3]–[11]. Essa delimitação justifica-se, também, pela baixa prevalência de equipamentos da Classe I e III nos laboratórios locais. Da mesma forma, os sistemas de Classe III, além de incomuns, possuem estrutura totalmente enclausurada, característica que inviabilizaria a condução do experimento proposto. Além disso, utilizou-se como critério de exclusão os equipamentos que estivessem instalados fora do município do Rio de Janeiro.

A estrutura interna da CSB pode ser dividida em duas áreas: as áreas limpas e as áreas contaminadas (ou sujas). [3]–[11] As áreas limpas compreendem as regiões de circulação de ar, previamente submetido à filtragem por meio dos filtros HEPA, englobando os filtros de insuflação e exaustão. Por sua vez, as áreas sujas delimitam as regiões internas de trânsito do ar provido de carga biológica ou particulados.

B. Procedimento para detecção de microrganismos em superfície

Foi utilizado um meio específico para detecção e enumeração de microrganismos presentes em superfícies. Trata-se de uma placa de petri RODAC (do inglês *Replicate Organism Detection and Counting*), apelidada de ”carimbo”, de 65x6mm com inativante irradiada, para garantir esterilidade, contendo Ágar Triptona de Soja [12], como alternativa aos métodos tradicionais baseados na detecção de ATP por fluorescência.

A demarcação dos pontos na estrutura do equipamento foi realizada com o auxílio de marcador permanente. Com o uso de luvas estéreis, cada placa RODAC foi pressionada contra a sua respectiva área delimitada pelo período de 5 segundos, garantindo o alinhamento concêntrico entre a numeração registrada na superfície do equipamento e o disco de coleta para cultura. Para os pontos localizados nos filtros plissados, a identificação foi efetuada contornando, com caneta, a placa imediatamente após o posicionamento.

A Figura 1 retrata as placas numeradas pelas posições de coleta no equipamento. Após as medições, aplicação do ”carimbo” nas áreas identificadas, o material foi incubado em estufa à 22,5ºC por 5 dias para cultura de fungos, e 32,5ºC por 2 dias para cultura de bactérias. O processo envolve a contagem das colônias formadas após a incubação, e o resultado é expresso em unidades formadoras de colônias (UFC).

C. Análise dos dados obtidos

Considerando que para cada observação quantificou-se o número de UFC, a análise consistiu em verificar se alguma região ultrapassou limites recomendados de presença de microrganismos em superfícies. Embora não exista um limite universalmente aceito foi definido, baseado na literatura, que superfícies que registraram crescimento menor que 2,5 UFC/cm^2 estão em níveis aceitáveis, para isso o resultado obtido em UFC foi dividido por 25 que representa a área, em cm^2, da superfície de contato da placa RODAC [12], [13].

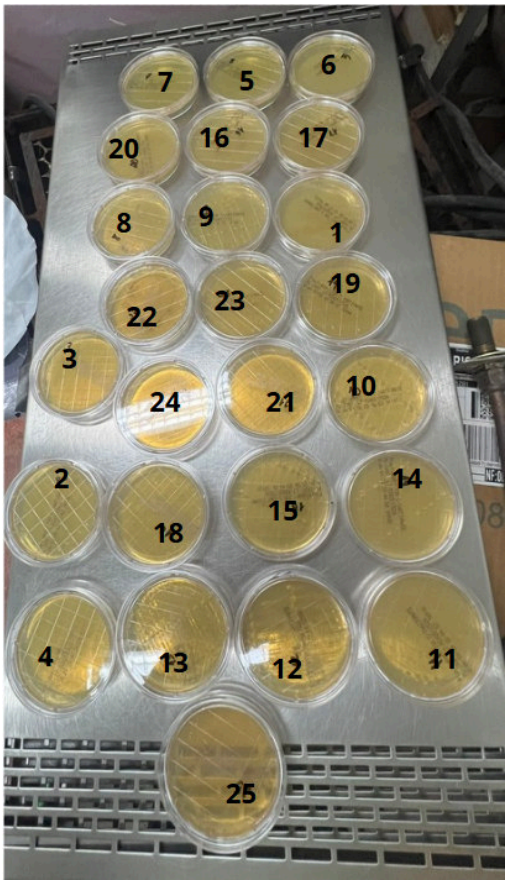

Figura 1. Placas RODAC identificadas pelas posições das superfícies coletadas.

III. Resultados e Discussão

As informações solicitadas referentes às quantidades, localização e características das CSBs foram disponibilizadas, pela instituição, por meio de uma planilha com 734 registros e 12 atributos categóricos. Dos 734 registros do banco de dados analisados, um total de 709 se tratavam de CSB, sendo 3 classificadas como Classe I, 705 como Classe II, sendo estas as de interesse do trabalho, e 1 como Classe III. Destas 709 CSBs, 490 unidades estavam localizadas no Rio de Janeiro. A distribuição quantitativa das 5 marcas com mais equipamentos encontram-se apresentadas na Tabela I.

Tendo em vista que os equipamentos da marca 1 representam mais de 50% do parque de Cabines de Segurança Biológica (CSBs) analisado, a avaliação dos pontos com maior potencial de contaminação concentrou-se nos modelos desta marca. A análise foi realizada em uma CSB de um laboratório que trabalhava com manipulação de Vírus da Imunodeficiência

24	Carcaça do exaustor
25	Meio da mesa de trabalho na parte do fundo

Para facilitar a visualização dos resultados, os pontos indicados na Figura 2 foram coloridos conforme a quantidade de UFC/cm^2 encontrada. As regiões com valores abaixo de $2,5$ UFC/cm^2 foram destacadas como hexágonos na cor verde. Nos casos em que não foi possível contabilizar as colônias formadas, utilizaram-se círculos na cor cinza. Além disso, os resultados visuais das colônias formadas em cada placa foram agrupados e divididos de acordo com a localização no equipamento: áreas limpas (Figura 3) ou áreas sujas (Figura 4).

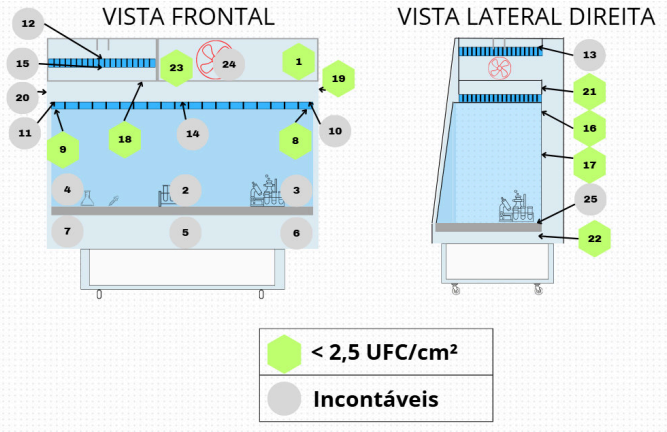

Figura 2. Mapeamento dos pontos de coleta representados nas posições do equipamento em vista frontal e vista lateral, os pontos com crescimento abaixo de 2,5 UFC/cm^2 estão pintados em verde, enquanto os pontos que representam incontáveis colônias formadas estão em cinza.

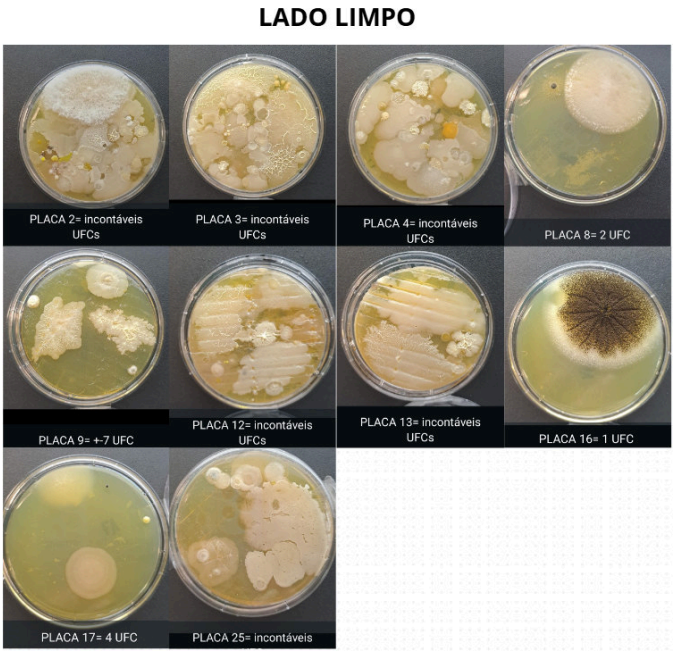

Figura 3. Resultado visual do crescimento de colônias após incubação agrupados por pontos que ficam localizados lado limpo. (Placas: 2, 3, 4, 8, 2, 9, 12, 13 ,15, 17 e 25 respectivamente da esquerda para direita de cima para baixo).

O padrão de crescimento dos microrganismos pode ser associado à forma como o ar circula na Cabine de Segurança Biológica (CSB). O ar do ambiente é puxado principalmente pelas frestas da mesa de trabalho em direção à bandeja de resíduos. Por causa da pressão negativa, ele corre pelo fundo do equipamento até o motor na parte superior, que sopra o ar para o pleno positivo, onde ficam os filtros HEPA. Como no pleno negativo o ar está sendo aspirado, é provável que não

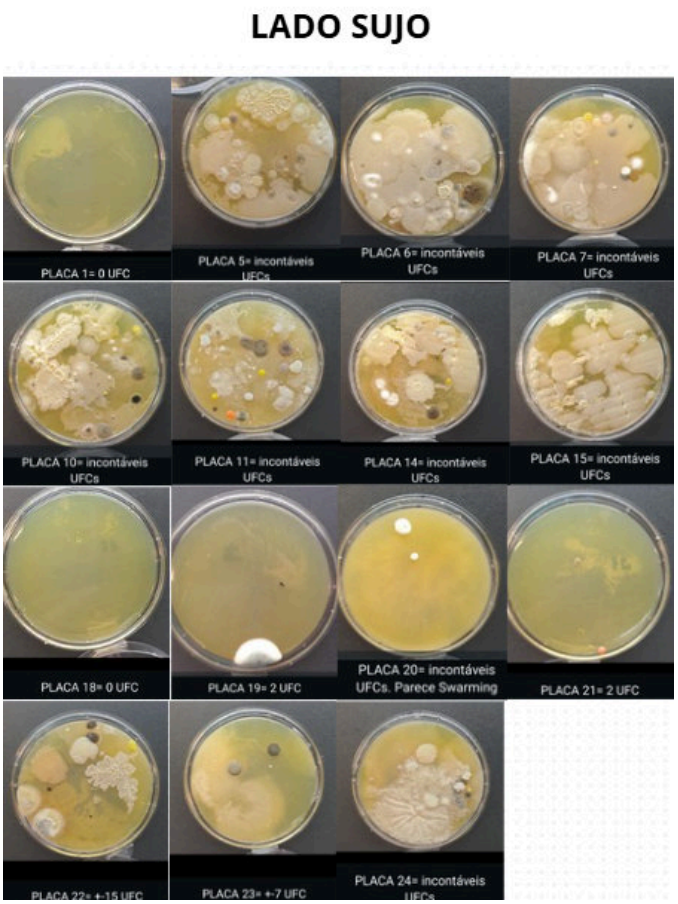

Figura 4. Resultado visual do crescimento de colônias após incubação agrupados por pontos que ficam localizados lado sujo (Placas: 1, 5, 6, 7, 10, 11, 14, 15, 18, 19, 20, 21, 22, 23 e 24 respectivamente da esquerda para direita de cima para baixo).

haja muita fixação nas suas superfícies, o que poderia explicar a ausência ou baixa quantidade de colônias nas regiões 1 e 23 (paredes laterais do pleno negativo superior).

Como era de se esperar, os pontos avaliados após o filtro de insuflação não apresentaram crescimento de UFC acima do limite. Por outro lado, no "lado limpo" do filtro HEPA de exaustão (ponto 12), houve um crescimento grande e diversificado de microrganismos, isto por que nesta região havia um acúmulo grande de poeira, o que pode justificar o grande crescimento de fungos.

A análise das imagens e dados mostraram ausência de crescimento nos pontos 1 e 18. Como mencionado, é provável que o resultado obtido no ponto 1 venha da própria característica construtiva das cabines, onde o fluxo de ar no pleno negativo é aspirado, e portanto haveria pouca aderência de aerossóis dos microrganismos nas paredes deste compartimento.

Já o ponto 18 fica no pleno positivo, no meio da chapa de cobertura e ao lado do difusor. Como essa é uma região de pressão positiva, onde há mais chance de turbulência do ar sobre as superfícies, o esperado era um crescimento acima do limite, porém não houve crescimento. É provável que o resultado nesse ponto tenha sido causado por uma aplicação do "carimbo" em uma pressão insuficiente para adesão dos microrganismos presentes na superfície ao meio TSA da placa ou o deslizamento da placa RODAC na hora da coleta. [12]

Também houve divergência entre pontos vizinhos. Nas laterais do pleno positivo, os pontos 19 e 20 tiveram comportamentos opostos: o ponto 19 apresentou formação de colônias abaixo do limite recomendado, enquanto no ponto 20 o crescimento foi tão denso que impediu a contagem (colônias incontáveis). Sendo que, o ponto 19 é o mais próximo da saída do motor de insuflação, e portanto deveria ter resultado semelhante ao 20 que fica mais distante.

De acordo com a norma ABNT NBR 17095: Cabines de segurança biológica classe II (CSB) - Projeto, características e ensaios de desempenho, [14] as superfícies da área limpa devem ser frequentemente descontaminadas com desinfetantes validado para o processo, portanto, a contaminação residual desses pontos deveria ser baixa. Porém, o resultado obtido foram incontáveis colônias em diversas placas, especialmente em regiões localizadas no lado superior das superfícies ou próximas a vértices, locais mais propensos a acúmulo de material particulado. Uma provável explicação pode ser o acúmulo de poeira, pois o equipamento estava fora de operação, em razão de uma necessidade de descontaminação ambiente para troca dos filtros. Também podem ter contribuído fatores como: distribuição dos materiais utilizados no interior do equipamento, turbulência gerada por movimentações realizadas pelo operador, procedimento inadequado de descontaminação, concentração e natureza dos agentes manipulados, posição do equipamento no layout do laboratório e frequência de uso do equipamento.

Após o isolamento microbiano nas placas RODAC, é possível identificar os microrganismos por diversas técnicas, que incluem a análise da morfologia da colonia formada, a técnica de coloração de Gram para bactérias e coloração por azul de lactofenol para fungos, a realização de provas bioquímicas e sequenciamento 16S para bactérias, e ITS para fungos. No trabalho só foi possível fazer uma análise morfológica visual, embora essa abordagem permita distinguir fungos de bactérias, ela não é suficiente para determinar a taxonomia exata das colônias. Apesar dessa limitação, a inspeção visual indicou que a maior parte do crescimento foi de fungos, identificados pelo aspecto cotonoso das colônias, que chegaram a dominar algumas placas. Além disso, observou-se a presença de bactérias pigmentadas que fica evidente na placa 11 da Figura 4.

O método utilizado traz algumas limitações que precisam ser consideradas. As placas RODAC são sensíveis e indicadas para avaliar superfícies limpas (pós-higienização) [15]. Quando usadas em superfícies sabidamente contaminadas, o crescimento de bactérias pode ser tão intenso que forma uma massa única (um "tapete"), dificultando a contagem individual das colônias.

Outro fator é que foi feita apenas uma coleta por ponto, o que impede uma análise estatística dos dados. Nos pontos onde não houve crescimento, fica a dúvida se a superfície estava realmente limpa ou se ocorreu algum erro na hora de

aplicar o ”carimbo” na superfície.

O cronograma também influenciou: para marcar os pontos, as tampas traseiras do equipamento precisaram ser abertas. Como houve um atraso de cerca de 5 dias até a chegada das placas RODAC, a cabine ficou destampada e exposta ao ambiente durante esse período. Por fim, a identificação se limitou à análise visual do cultivo; para maior precisão, seria importante realizar testes de coloração, provas bioquímicas ou sequenciamento genético (16S/ITS).

O procedimento com as placas RODAC será repetido logo após a descontaminação da cabine para se verificar a eficácia do processo e observar o desenvolvimento ou não de colônias. O protocolo será revisado a partir das limitações identificadas, prevendo, por exemplo, coletas em triplicata por ponto avaliado, para garantir uma melhor avaliação no processo aplicado a cada ponto, e a redução do tempo de abertura da cabine durante a marcação, a fim de minimizar a interferência do ambiente. Também está prevista a realização de sequenciamento molecular (16S/ITS) para identificar com precisão as espécies presentes nos pontos críticos, além da avaliação de CSBs que manipulam microrganismos patogênicos.

IV. Conclusão

Conclui-se que, embora as limitações metodológicas tenham gerado resultados parciais e, em alguns pontos, inconclusivos, este estudo foi capaz de descartar pontos com baixo potencial de contaminação, e alguns pontos que necessitam atenção, onde houve um crescimento desenfreado de colônias. Estes resultados indicam que há uma distinção de risco de contaminação entre algumas regiões do equipamento, oferecendo subsídios para adoção e revisão de práticas que possam aumentar a segurança ocupacional dos usuários e da equipe de manutenção.

Agradecimentos

Os autores agradecem as agências de fomento de pesquisa CNPq, CAPES e FAPERJ. Agradecemos também a Dra. Ana Paula Pereira Alcides do Setor de Produtos Estéreis do INCQS-FIOCRUZ, que nos auxiliou no processo de coleta do material e incubação das placas RODAC.

***Abstract*—Brazilian National Health Surveillance Agency (ANVISA) RDC No. 1,002/2025 establishes new Good Practice requirements for dental care services, mandating formal health technology management, medical device reprocessing, and risk management. Applying these requirements reveals technical and metrological challenges that remain scarcely described in the literature. This paper presents a practical pre-operational diagnostic and regulatory-adaptation guide developed by the Clinical Engineering team responsible for the Dentistry service at the Pernambuco Cancer Hospital (Hospital de Câncer de Pernambuco, HCP). This is a descriptive case study based on the systematic mapping of the requirements set out in the regulation as they relate to Clinical Engineering activities, encompassing a technology asset inventory, a gap-analysis matrix, and the need to redesign workflows, highlighting the regulatory decision to centralize sterilization at the hospital's Central Sterile Supply Department (CSSD) in light of local physical constraints. The results show that Clinical Engineering acts as an indispensable technical link in pre-operational planning, overcoming market bottlenecks such as the scarcity of metrological parameters from manufacturers and of accredited calibration laboratories. As its main contribution, this work provides a replicable implementation model to support transition and audit processes in other dental care services.**

I. Introduction

The publication of ANVISA Resolution RDC No. 1,002/2025 represents a regulatory milestone for dental services by consolidating requirements for good operating practices, biosafety, reprocessing of health technology and management of health technology [1].

Although many of these demands are already familiar to hospital facilities through technology management standards [2], applying them to the dental sector presents specific challenges, particularly for smaller facilities or those historically not integrated into formal clinical engineering structures.

This article presents a descriptive case study and a Framework for pre-operational diagnostic and regulatory compliance for the dental service of the Hospital de Câncer de Pernambuco (HCP) regarding ANVISA RDC No. 1,002/2025.

This study highlights the practical challenges encountered by the authors, who work at TECSAÚDE and provide Clinical Engineering services, including management and consulting of technological assets, to the hospital in question. The purpose of this paper is to present a compliance methodology to serve as a practical model/guide for dental services that must adapt to the new RDC regulations.

II. Regulatory and scientific background

ANVISA Resolution RDC No. 1,002/2025 establishes operational requirements for dental services and specifies obligations related to health technology management, medical device reprocessing, and patient safety [1]. In practice, the standard shifts dental compliance from an approach focused solely on physical infrastructure and biosafety to an integrated approach that includes equipment, documentation, traceability, and technical responsibility.

The requirements with the greatest impact on Clinical Engineering activities include: the development and implementation of a health technology management plan [2]; calibration and qualification of reprocessing equipment; equipment inventory; planned maintenance schedule for all equipment; evidence of preventive and corrective maintenance execution; mandatory equipment identification, among others.

In this scenario, clinical engineering plays a technical translation role: it transforms regulatory requirements into plans, schedules, acceptance criteria, execution records, and auditable evidence [3]. This role becomes even more relevant when manufacturers do not readily provide qualification parameters or when testing and calibration laboratories lack an accredited scope compatible with dental equipment.

III. Methodology

This work is a descriptive, applied, pre-operational case study conducted in the dental service of the Hospital de

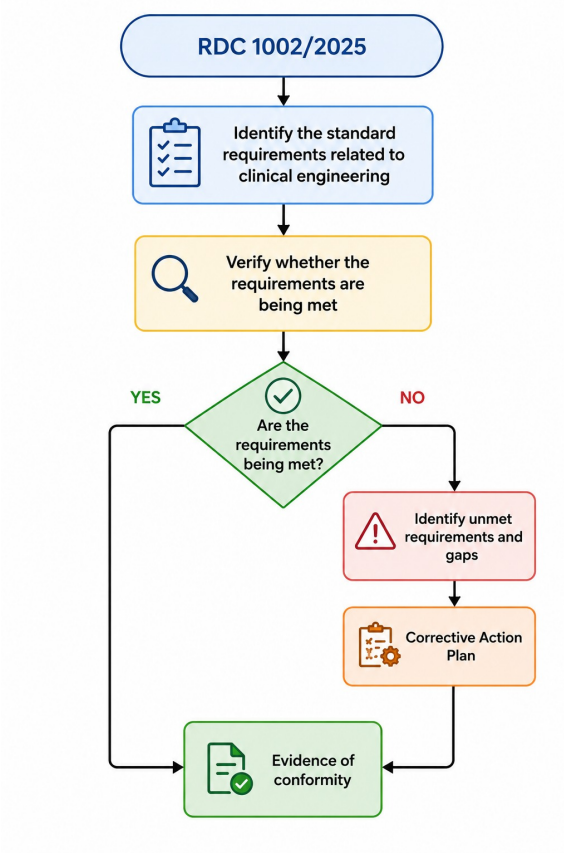

Fig. 1. Methodological design of the study

Câncer de Pernambuco (HCP) during its architectural and regulatory adaptation phase to ANVISA Resolution RDC No. 1,002/2025. This approach is justified by the opportunity to map and resolve—within a real hospital environment—the existing physical, metrological, and documentary constraints involved in the implementation of the new regulation.

The evaluation was conducted by the TECSAÚDE Clinical Engineering team working at HCP between March and May 2026, which included a documentary audit, an architectural project review and an inventory of existing technological assets.

The study was structured into four linked stages (Fig. 1):

- Normative Mapping and Structuring: systematic analysis of RDC No. 1,002/2025 and identification of requirements relevant to Clinical Engineering activities.
- Field Diagnosis and Audit: verification of compliance with the identified requirements.
- Gap Analysis Matrix [4]: identification of non-conformities and market constraints (such as the scarcity of manufacturer parameters and accredited calibration laboratories).
- Action Plan and Evidence of Conformity: formulation of corrective actions and workflow readjustments, where necessary, alongside the presentation of auditable evidence of conformity.

IV. HCP Case Study

A. Characterization Of The HCP Dental Service

Hospital de Câncer de Pernambuco (HCP) is a private, non-profit institution and a state reference center for the diagnosis and treatment of oncology patients within the Brazilian Unified Health System (SUS) [5]. The dental service constitutes an essential and mandatory stage in the care continuum, particularly for patients undergoing head and neck radiotherapy or chemotherapy.

The dental department is currently classified as a collective dental clinic, comprising: (i) three complete dental units; (ii) a dedicated room for medical device cleaning and reprocessing; and (iii) a reception area. Concurrently, the service is undergoing physical expansion to scale up patient care. The new facility will house a panoramic X-ray machine, an individualized office for patients requiring isolation, and the infrastructure for the future installation of a wall-mounted intraoral X-ray device.

Given the ongoing construction, an opportune moment to prevent regulatory non-conformities, the Clinical Engineering team performed a pre-operational diagnosis by auditing the architectural project, operational workflows, and existing assets. Mapping mandatory regulatory requirements and verifying compliance with ANVISA Resolution RDC No. 1,002/2025 was fundamental for adapting workflows and infrastructure, ensuring that once the department transitions to the new facility, it will operate in full compliance with health and legal standards.

B. RDC Compliance Experience

Given this scenario and following a detailed analysis of ANVISA Resolution RDC No. 1,002/2025, the Clinical Engineering team structured a regulatory diagnostic and gap analysis matrix. This tool correlates mandatory regulatory requirements with the findings from the pre-operational audit. In addition, it defines corrective actions, responsible personnel, legal grounds, and evidence verification methods [4], as presented in Table I.

V. Results and Discussion

Applying the regulatory diagnostic matrix enabled the Clinical Engineering team to map the operational status of the HCP dental care service during its pre-operational phase and guide targeted intervention actions. The primary findings and outcomes are detailed below.

A. Technical Inventory, HTMP, and Maintenance Schedule

The initial assessment confirmed that the Dentistry service was already covered by HCP's Health Technology Management Plan (HTMP), so no corrective action was required for this item.

After the sector inventory was formed, it was found that some existing equipment was not registered in the Clinical Engineering management software, nor was it included in the planned maintenance schedule. The updated inventory is shown in Table II.

TABLE I
GAP-ANALYSIS MATRIX AND ACTION PLAN FOR ADAPTATION TO ANVISA RDC NO. 1,002/2025

Axis/Requirement Assessed	Regulatory Basis	Current Situation	Corrective Action	Responsible Party	Evidence Method
Health Technology Management Plan (HTMP)	RDC 509/2021 [2] / Art. 131 RDC 1,002/2025 [1]	Compliant. The dental sector was already integrated into the institutional HTMP.	Maintain sector routines inclusion and periodically validate workflows.	Clinical Engineering	Current, approved institutional HTMP document.
Technology inventory	Art. 130 RDC 1,002/2025 [1]	Full integration of the dental technology park into the software was lacking.	Carry out a sector inventory and register the equipment not yet recorded in the management software.	Clinical Engineering	Inventory report in the management software and completed physical spreadsheet.
Planned Maintenance Schedule	Art. 130/134 RDC 1,002/2025 [1]	Equipment identified outside the planned maintenance routine.	Include the missing equipment and parameterize the scheduled preventive maintenance program.	Clinical Engineering	Issued service orders (SOs) and annual schedule.
Water Quality Control	Chapter III/IV RDC 1,002/2025 [1]	No sampling points mapped for microbiological control.	Add water sampling points in the sector for laboratory sampling and analysis.	Occupational Health and Safety Service (collection), Infection Control Committee, and Clinical Engineering (result evaluation)	Periodic physicochemical and microbiological analysis reports.
Asset Dimensioning	Art. 37 RDC 1,002/2025 [1]	Need for diagnostic expansion and isolation capability.	Map gaps and request acquisition of the necessary medical equipment.	Clinical Engineering, Dentistry, Management	Acquisition process and Technical Incorporation Report.
Qualification and metrology	Art. 130/134 RDC 1,002/2025 [1] / ISO 17665:2024 [6]	Lack of parameters in manuals and from local suppliers.	Contract external thermal qualification and calibration of peripherals.	Clinical Engineering	Metrological certificates and qualification reports.
Radiation Protection	RDC 1,002/2025 [1] / RDC 611/2022 [7] / RDC 50/2002 [8]	New panoramic and intraoral X-ray rooms under construction.	Design shielding and request a post-construction radiometric survey.	Maintenance (design), Clinical Engineering (imaging tests)	Radiometric survey report and imaging tests.
Continuing education	Art. 113 RDC 1,002/2025 [1]	No formal records of operational training.	Develop a continuing education schedule for care teams.	Continuing Education, Clinical Engineering	Training attendance records.

TABLE II
TECHNOLOGY INVENTORY OF THE HCP DENTISTRY SECTOR

Equipment / System	Qty.	Manufacturer/Model
Dental chair	04	Dentemed/Prime
Dental autoclave	02	Vitale 12/Cristófoli; Digitale/BS Equipamentos
Dental compressor	02	Motomil and FIAC
Micromotor	04	Marathon 3/Talmax
Dental laser	02	Laser duo/MM Optics
Vacuum pump	01	Suctron Eletronic/Schuster
Panoramic X-ray unit	01	Eagle 2D/Dabi Atlante
Ultrasonic bath	01	Cristófoli
Electrosurgical unit	01	HF120/WEM
Sealer	01	Cristófoli
Dental ultrasound scaler	01	Altsonic jet ceramic/Alt Equipamentos
Dental handpiece	02	Torque extra 605/Kavo
Contra-angle handpiece	01	Kavo
Negatoscope	01	Generic
Curing light	02	Bluestar/Microdent
Suction kit	04	Schuster

When integrating this equipment into the maintenance schedule, the team faced significant challenges due to the scarcity of technical data from the manufacturers and the broader market. The key parameters for calibration, thermal qualification, and performance qualification—particularly for sterilization equipment (autoclaves)—were omitted from the instruction manuals.

Although the documentation provided basic guidance on preventive and corrective maintenance, it omitted the metrological and validation requirements necessary for proper compliance with the sole paragraph of Art. 130 of RDC No. 1,002/2025 [1].

B. Metrological Gaps in the Local Market

In addition, a gap was identified in the local market for metrology service providers. The calibration providers consulted (such as LEMPE, Laboratório Medição, and Medserv) did not perform temperature calibration or performance qualification for dental equipment, which made it difficult to obtain the metrological evidence required by the regulation.

To gather more information and meet regulatory requirements, Clinical Engineering had to contact manufacturers and authorized factory representatives directly to build the updated planned maintenance schedule for the sector (Table III).

TABLE III
PLANNED MAINTENANCE SCHEDULE FOR THE HCP DENTISTRY SECTOR

Equipment	Maintenance Type	Frequency
Dental chair	Internal preventive; electrical safety	Annual
Dental autoclave; ultrasonic bath; sealer (decommissioned)	External calibration; external preventive	Annual or after corrective maintenance
Dental compressor	External preventive	Annual
Dental handpiece; contra-angle hand piece; micro motor; ultrasound scaler; curing light; laser	Internal preventive	Annual
Vacuum pump	External preventive	Annual
Panoramic X-ray unit	Image quality test; external preventive	Annual
Electro surgical unit	Internal preventive; internal calibration; electrical safety	Annual or after corrective maintenance

C. Adaptation of the Architectural Project and Centralization of Reprocessing

Before executing the action plan, Clinical Engineering met with a multidisciplinary hospital team (including Nursing, Architecture, Projects, Executive Board, Dentistry, and Civil Engineering) to evaluate and review the architectural design of the new area under construction. The sector's floor plan (Fig. 2) required adjustments to optimize equipment placement and functional area sizing, ensuring full compliance with regulatory requirements.

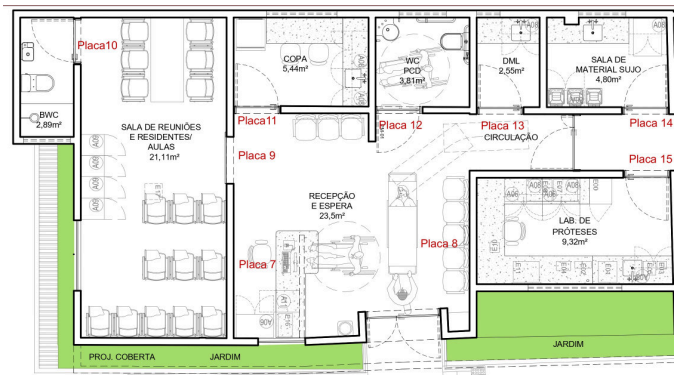

Fig. 2. Conceptual floor plan of the dental sector after architectural adaptation (simplified view)

Since the sector is configured as a collective dental practice, the area intended for medical device reprocessing had to comply with items II or III of Art. 25 of the regulation [1]. After reviewing the project, it was found that although a dedicated room for contaminated material (soiled utility room) was provided with a total area of 4.8 m² — which would strictly meet the lower limits of Item II, Art. 25 of the regulation [1] — the physical spatial arrangement presented severe operational constraints.

Specifically, the dimensions of the workbenches, the space required for existing equipment, and the mandatory regulatory distances between devices made it impossible to establish a compliant, unidirectional workflow from the soiled area to the clean/sterilized area.

Given these physical constraints, the sector's and HCP's management chose to centralize the disinfection and sterilization steps at the institution's Central Sterile Supply Department (CSSD), retaining only the pre-cleaning step within the dental sector, as a technical and regulatory safeguard measure.

Consequently, the sterilization equipment (autoclaves, ultrasonic bath, and sealer) mapped during the initial diagnostic phase were decommissioned from the sector's active maintenance schedule (Table III) and will be reallocated according to institutional workflows.

VI. FINAL CONSIDERATIONS

The adaptation of the Pernambuco Cancer Hospital's dental care service to ANVISA RDC No. 1,002/2025 demonstrates that compliance with the new regulatory requirements demands management-related technical competencies that go beyond the scope of traditional dental practice.

In this pre-operational scenario of sector expansion, Clinical Engineering established itself as a strategic agent for interpreting mandatory requirements, aligning infrastructure projects, and enabling engineering decisions — such as the decision to centralize material reprocessing at the hospital's CSSD to overcome the unidirectional-flow constraints required by the regulation.

The challenges identified throughout this case study—such as the scarcity of data in manufacturers' manuals and the lack of local laboratories with accreditation scope for the dental sector—indicate that while the new regulation promotes good practices and safe technology management, it also exposes market bottlenecks regarding technical reference materials and specialized service providers.

As a practical contribution, this work provides a methodological guide and a diagnostic matrix that can be replicated to assist other Clinical Engineering professionals, or even dental care services themselves, in adapting to the regulatory requirements.

Finally, since this intervention was carried out during the sector's physical restructuring phase, future work is recommended to monitor performance and operational-effectiveness indicators after the new HCP dentistry sector opens.

ACKNOWLEDGMENT

The authors would like to thank the Hospital de Câncer de Pernambuco (HCP) and the TECSAÚDE Clinical Engineering team for their institutional support and technical collaboration throughout the regulatory adaptation process.

***Abstract*— This study aims to perform a national exploratory mapping of the scope, practices, operational and professional perceptions within Brazilian Clinical Engineering. These empirical findings serve as a foundation for a critical conceptual discussion on the expansion and evolution of the profession's scope in the healthcare ecosystem. A descriptive and exploratory study was conducted using a mixed-methods approach (quantitative and qualitative). Data collection was carried out through an online questionnaire from August 2025 to April 2026, yielding a final sample of 84 professionals working in hospital Clinical Engineering departments across the country. The data reveal an expansion of the sector's scope. Although medical-assistive equipment accounted for 100% of managed assets, CE departments have absorbed the management of support equipment (91.38%), surgical instruments (44.83%), medicinal gases (36.21%), infrastructure (22.41%), and medical information technology systems (15.52%). The main challenges identified were equipment misuse by clinical staff (31.71%) and logistical dependency on manufacturers (18.29%). In light of these bottlenecks, the study proposes a conceptual redefinition of CE as an interdisciplinary, evidence-based field aimed at ensuring reliability, traceability, accessibility, and safety.**

Keywords—Clinical Engineering; Health Technology Management; Biomedical Engineering.

I. Introduction

Health technologies consist of devices, medicines, vaccines, procedures, and systems designed to address specific health problems and contribute to improving population quality of life [1]. As a result of growing technological incorporation, a proportionally greater number of professionals are required to carry out Health Technology Management (HTM) and to support safe and reliable use [2]. One of the fields that can contribute to the development, implementation, and monitoring of HTM programs in health services is Clinical Engineering (CE), a branch of Biomedical Engineering [1][3].

The participation of Clinical Engineering in the Health Technology Process (HTP) encompasses the application of knowledge across all lifecycle stages, contributing to effective and safe HTM in healthcare settings. The CE actions incorporated into the HTM process model of the Institute of Biomedical Engineering (IEB-UFSC) are based on three pillars: technology, human resources, and infrastructure. The interaction among these areas aims to improve the quality of health services through Clinical Engineering actions and the detection and analysis of HTP needs within each institution, thereby developing qualified human resources for the use of technological resources and adapting infrastructure more efficiently, with the objective of promoting reliability, effectiveness, and safety across health technology processes [4].

The definition of Clinical Engineering varies depending on the source, and is recurrently conceptualized based on the responsibilities of the clinical engineer. According to American College of Clinical Engineering (ACCE), this professional supports improvement in patient care by applying engineering knowledge and health technology management skills [5]. Bronzino characterizes the professional as responsible for applying technological and scientific expertise in healthcare environments to support clinical activities aimed at improving patient care [6]. The WHO, in one of its technical reports on medical devices, discusses the importance of updating this professional in light of the new competencies required in health systems. Clinical Engineering demands a more holistic approach, one that aims to support technology users by applying not only engineering knowledge but also

economic, communication, and managerial competencies involving health technologies [1].

There are many activities required of Clinical Engineering professionals; some of the main functions include: Health Technology Management, analysis and supervision of safety and performance testing; inventory management; economic and quality analyses; risk management; Health Technology Assessment (HTA); training; development and implementation of protocols, among others [6]. Given the growing presence of technology in healthcare settings, an HTM program aims to ensure availability, accessibility, cost reduction, and safety [1]. In Brazil, the management of these technologies in healthcare establishments is governed by a set of regulations, as presented in Table I.

TABLE I. ANALYZED REGULATORY AND NORMATIVE DOCUMENTS

Category	***Standard***
Health Technology Management	RDC 509/2021 - Provides for the management of health technologies in healthcare establishments.
	RDC 36/2013 - Establishes actions for patient safety in healthcare services and other provisions.
	ABNT NBR 15943:2011 - Guidelines for a management program for healthcare infrastructure equipment and medical equipment.
	ABNT NBR ISO 9001:2015 - Quality management systems.
	ABNT NBR ISO 14971:2020 - Medical devices – Application of risk management to medical devices.
	ABNT NBR ISO 7101:2025 - Healthcare organization management – Quality management systems in healthcare organizations.
	Law nº 14133/2021- Public Procurement and Administrative Contracts Law.
	Law nº 15210/2025 - Establishes requirements for the purchase of equipment intended for diagnostic or therapeutic procedures within the Brazilian Unified Health System (SUS).
	Portaria GM/MS n° 11694/2026 - Provides planning guidelines and recommendations for the acquisition of equipment intended for diagnostic or therapeutic procedures within SUS.
Infrastructure	RDC 50/2002 - Provides the Technical Regulation for planning, programming, design, and evaluation of physical projects for healthcare facilities.
	ABNT NBR 13534:2008 - Requirements for electrical installations in healthcare facilities.
	ABNT NBR 16651:2019 - Fire protection in healthcare facilities.
	ABNT NBR 12188:2016 - Centralized supply systems for medical gases, gases for medical devices, and vacuum systems for healthcare services.
	ABNT NBR 7256:2022 - Air treatment in healthcare facilities – Requirements for design and installation.
Medical Device Safety	RDC 751/2022 - Provides for risk classification, notification and registration requirements, and labeling and instructions for use of medical devices.
	RDC 579/2021 - Provides for the importation, commercialization, and donation of used and refurbished medical devices.
	ABNT NBR IEC 60601-1:2010 - Medical electrical equipment – Part 1: General requirements for basic safety and essential performance.
	ABNT NBR ISO 17025:2017 - General requirements for the competence of testing and calibration laboratories.
	ABNT NBR IEC 62353:2019 - Medical electrical equipment – Recurrent tests and tests after repair of medical electrical equipment.
	RDC 67/2009 – Provides technovigilance requirements applicable to medical device registration holders in Brazil.
	RDC 925/2024 – Provides requirements for the manufacture, commercialization, importation, and placing into use of personalized medical devices.
Specific Services	RDC 63/2011 - Provides requirements for good operating practices in healthcare services.
	RDC 07/2010 - Establishes minimum requirements for the operation of intensive care units and other provisions.
	RDC 15/2012 - Provides requirements for good practices in the processing of healthcare products and other provisions.
	RDC 611/2022 - Establishes sanitary requirements for the organization and operation of diagnostic and interventional radiology services and regulates the control of medical, occupational, and public exposures arising from diagnostic and interventional radiological technologies.
	RDC 11/2014 - Provides requirements for good operating practices in dialysis services and other provisions.
	RDC 222/2018 - Establishes good practices for the management of healthcare waste and other provisions.

Collegiate Board Resolution (RDC) nº509, of May 27, 2021, which governs health technology management in healthcare establishments, establishes a series of management procedures that are planned, developed, and implemented to ensure the traceability, quality, efficacy, effectiveness, safety, and performance of health technologies used in the provision of health services [7].

Collegiate Board Resolution (RDC) nº63, of November 25, 2011, which establishes Good Practice Requirements for Healthcare Services, also includes the need for technology management as one of the good practice requirements for health services [28]. Thus, the implementation of efficient management throughout the entire technology lifecycle constitutes an essential tool for safety and quality, leading to satisfactory outcomes in health systems [1].

The technology lifecycle encompasses all stages involving a technology, from initial innovation, research, and technological diffusion processes through incorporation, use, and obsolescence. HTM is responsible for developing, implementing, and monitoring management programs across these stages, covering activities such as planning, selection and incorporation, inventory, installation, training, technical interventions, and, finally, obsolescence assessment and final disposal. ABNT NBR 15943:2011 establishes guidelines for implementing equipment management programs for health services, in order to minimize risks associated with technologies in healthcare establishments [9].

There is a significant disparity in Clinical Engineering practice across different healthcare settings, both in activities performed throughout the technology lifecycle and in the profiles of professionals and the scope of internal versus outsourced services, among other factors. In this

context, this study aims to analyze the practice of Clinical Engineering in hospital settings across Brazil through the application of usability techniques in a questionnaire-based survey to identify, analyze, and propose improvements for Health Technology Management and patient safety. These empirical findings serve as a foundation for a critical conceptual discussion on the expansion and evolution of the profession's scope in the healthcare ecosystem.

II. Methodology

A quantitative and qualitative, exploratory and descriptive study with a cross-sectional design was conducted. The mixed-methods approach allowed for the descriptive characterization of structural scenarios in Clinical Engineering and the interpretation of professionals' perceptions and challenges through their written responses.

The target population consisted of professionals working directly in Clinical Engineering departments at hospital institutions in Brazil. The inclusion criterion was being a mid-level or higher-level professional (engineers, technologists, technicians, and managers) with an active role in hospital Clinical Engineering services. Responses with incomplete or duplicate data were excluded. The final valid sample consisted of 84 participants. Because institutional identifiers were not collected, it was not possible to determine whether more than one respondent belonged to the same institution.

Data collection took place from August 2025 to April 2026. A structured online questionnaire was used as the research instrument, developed and administered through an electronic research platform. The survey link was strategically disseminated through social media, professional networks, technical discussion forums related to Clinical Engineering and Biomedical Engineering at the national level, using a non-probabilistic recruitment strategy. As the questionnaire was publicly disseminated and the number of individuals reached could not be determined, a response rate could not be calculated. The instrument comprised blocks of multiple-choice questions (demographic data, team sizing, activities performed, use of computerized tools) and open-ended questions allowing investigation of daily challenges and priority actions to enhance the sector's recognition.

The collected data were exported and subjected to different processing workflows depending on the nature of the variable. Quantitative data were processed using simple descriptive statistics. No inferential statistical analyses were performed. Qualitative data pertaining to daily challenges and priority actions for sector recognition were subjected to content analysis and categorization. All responses to the open-ended questions were read and grouped according to thematic similarity. An initial categorization was performed by one researcher and subsequently discussed by two researchers. Responses containing more than one challenge or priority action could be assigned to more than one thematic category; therefore, the categories were not mutually exclusive. No inter-rater agreement statistic was calculated.

The research protocol was approved by the Research Ethics Committee of the Federal University of Santa Catarina (UFSC) under approval nº 7.706.804 (Nº CAAE 87849125.4.0000.0121). All participants expressly provided their free and informed consent on the initial page of the online platform before completing the questionnaire, ensuring respondent anonymity and the confidentiality of institutional information collected.

III. Results

Regarding the geographic distribution of the 84 respondents, participation was observed from all regions of Brazil. The Southeast region accounted for the highest proportion of responses (47.62%), followed by the Northeast (16.67%) and Center-West (15.48%) regions. The South and North regions corresponded to 13.10% and 3.57% of responses, respectively. Additionally, in 3.57% of cases it was not possible to identify the respondents' region of origin.

To understand the breadth of responsibilities held by hospital Clinical Engineering departments in Brazil, participants were asked about the types of assets under their teams' direct management. The consolidated results reveal that the sector's scope extends significantly beyond the exclusive management of medical equipment, as presented in Figure 1.

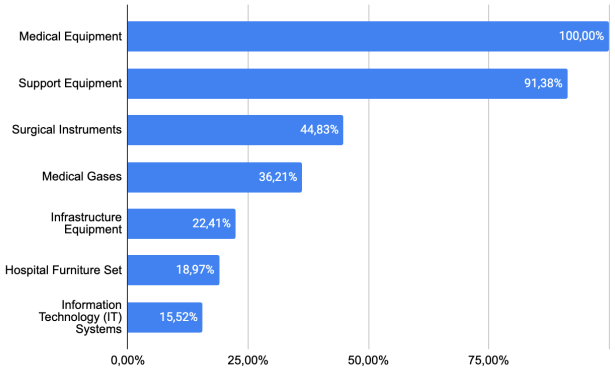

Fig. 1. Health technologies managed by Clinical Engineering departments in Brazil, as reported by participants

All Clinical Engineering departments reported managing Medical-Assistive Equipment. In parallel, the management of Support Equipment (91.38%) reinforces the role of Clinical Engineering as a key contributor to life-support and sanitary safety infrastructure. The expansion into Surgical Instruments (44.83%) and Medicinal Gases (36.21%) reflects a trend toward scope centralization by administrations seeking greater cost control and risk mitigation in high-financial-impact supplies. Finally, involvement in Infrastructure (22.41%) and IT (15.52%) outlines a trend toward integration across different areas.

Regarding the workforce contracting model, the results revealed a scenario distributed between in-house and outsourced service delivery. The in-house team model emerged as the most frequent in the sample, adopted by 42.8% of institutions (n=36), as illustrated in Figure 2.

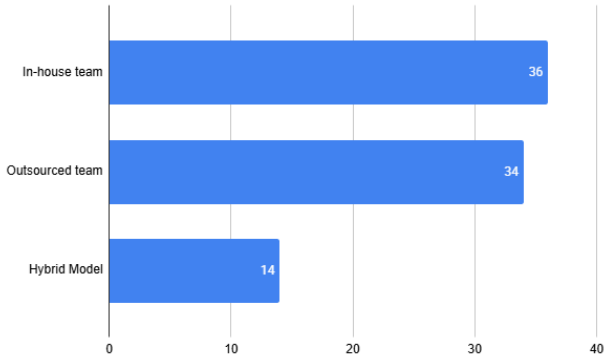

Fig. 2. Clinical Engineering team models in Brazil.

On the other hand, the full outsourcing model demonstrated strong market penetration in Brazil, accounting for 40.5% of the mapped cases (n=34). Finally, the hybrid model characterized by shared operational responsibilities between an in-house management core and companies contracted on demand was reported by 16.7% of respondents (n=14).

Regarding the sizing of Clinical Engineering departments, most institutions have up to 10 professionals, with a predominance of teams with 6 to 10 members (n=29). Next are teams composed of 11 to 20 professionals (n=20), 4 to 5 (n=13), and 1 to 3 professionals (n=12), as presented in Figure 3. Larger teams are less frequent, identified in only seven institutions with 21 to 50 professionals and in two institutions with more than 50 members (Figure 3).

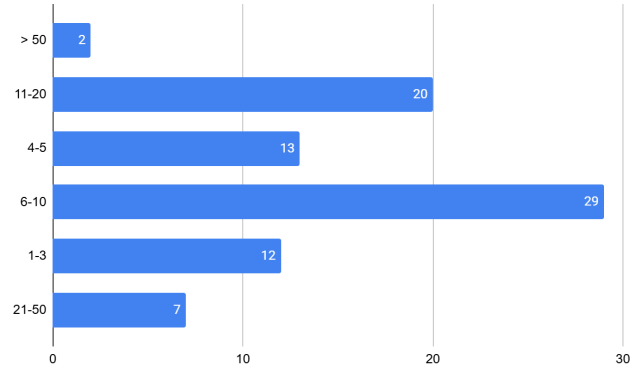

Fig. 3. Size distribution of Clinical Engineering teams in Brazilian hospitals.

Regarding team composition (Figure 4), technicians predominate, accounting for 54.6% of professionals, followed by engineers (22.1%). The category of other professionals, responsible for 18.8% of team composition, includes professionals from different fields, such as medical physicists, nursing technicians, interns, administrative staff, lawyers, advisors, and young apprentices. Technologists represent 4.4% of the total.

.

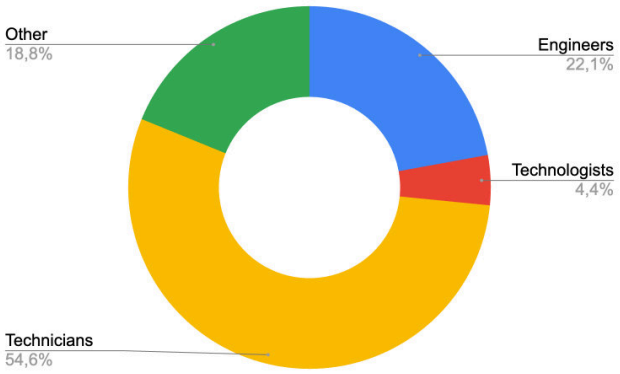

Fig. 4. Professional composition of Clinical Engineering teams

Analyzing the activities performed internally and externally (Figure 5), the results indicate a strong trend toward outsourcing most Clinical Engineering activities. Strategic functions, such as the incorporation of medical equipment (91%) and the implementation of maintenance programs (90%), operational activities such as equipment installation (89%), preventive maintenance (89%), and corrective maintenance (88%), as well as managerial functions such as risk management (66%), indicator analysis (65%), and adverse event management (61%), were predominantly performed in-house. This indicates that organizations maintain direct control over the day-to-day management of technologies.

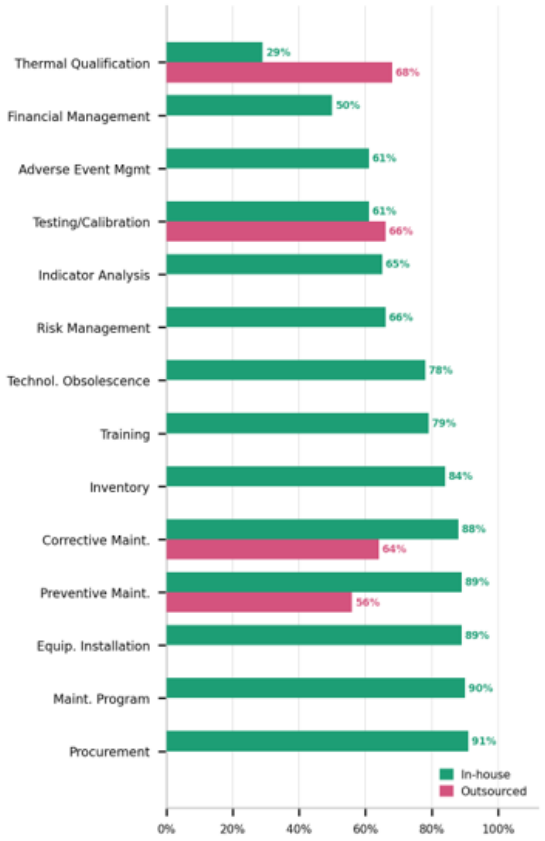

Fig. 5. Activities performed by Clinical Engineering departments in hospitals in Brazil.

In contrast, external activities were concentrated in areas such as thermal qualification, which showed the highest outsourcing rate (68%) and the lowest internal execution rate (29%). Testing and calibrations also showed a high frequency of external execution (66%), although 61% of institutions perform these activities in-house. Similarly, corrective maintenance (64%) and preventive maintenance (56%) present significant rates of external execution.

The overlap between internal and outsourced execution for maintenance and calibration highlights the adoption of a hybrid model, in which routine strategic and operational activities are maintained in-house, while outsourcing is selectively applied for specialized services requiring specific tools, mandatory certifications, or direct manufacturer support.

Regarding the adoption of computerized systems (maintenance/asset management software) by Clinical Engineering departments, results indicate strong consolidation of these digital tools, with 86.9% of institutions (n=73) using them actively for asset management.

Among the 84 participants included in the study, 82 provided valid responses to the question on daily challenges. The analysis of responses revealed a complex landscape of daily challenges faced in Clinical Engineering, highlighting that the greatest obstacles transcend the technical sphere and are concentrated in human and market factors (Table II). Within institutions, the interface with clinical staff emerged as the most frequently reported challenge, with 31.71% of mentions (n=26).

Reports consistently pointed to equipment misuse, difficulties in equipment handling, and low adherence to operational training. These internal challenges were accompanied by financial and budgetary constraints (15.85%) and workforce-related issues, including understaffing, limited availability of qualified professionals, and team turnover (20.73%).

TABLE II. CHALLENGES FACED BY CLINICAL ENGINEERING DEPARTMENTS

Challenge category	*Percentage of respondents (%)*	*Main evidence from reports (examples)*
Clinical Staff Interface / Equipment Misuse / Training	31.71%	Equipment misuse, low adherence to training, and user disorganization.
Spare Parts Logistics and Supplier Relationships	18.29%	Manufacturer delays, lengthy after-sales lead times, high spare-parts costs, and dependence on external technical support
Financial, Budgetary, and Infrastructure Issues	15.85%	Limited resources, insufficient budget for fleet renewal, outdated salaries, and inadequate tools.
Workforce, Staffing, and Team Turnover	20.73%	Chronic overload of beds per technician, lack of specialized staff, and high professional turnover.
Work Overload, High Demand, and Deadline Pressure	15.85%	Pressure to meet repair-time targets, a culture in which “everything is an emergency,” and growing corrective backlog.
Professional Recognition and Gender Challenges	13.41%	Lack of recognition of technical expertise, assignments outside the scope of practice, and gender bias in the field.
Administrative Bureaucracy and Public Management Issues	8.54%	Slow public procurement processes and delays in budget approval procedures.
Other General Operational Challenges	9.76%	Difficulty locating equipment, managing service reports, and surgical center routines.

On the other hand, in the external ecosystem, Clinical Engineering faces a logistical challenge in its relationship with suppliers and manufacturers (18.29%). Professionals reported slow after-sales services, long lead times, and high costs for acquiring spare parts, as well as commercial barriers limiting access to service software.

TABLE III. PRIORITY ACTIONS TO IMPROVE CLINICAL ENGINEERING IN BRAZIL

Priority action category	*Percentage of respondents (%)*	*Core themes identified in responses*
Compensation, Benefits, and Labor Rights	24.62%	Salary adjustments, inclusion of occupational allowances (hazard pay and unhealthy working conditions allowances), and compensation compatible with technical responsibilities.
Presentation of Performance Indicators and Financial Results	18.46%	Demonstrating financial return, savings in procurement processes, and costs avoided due to reduced equipment downtime.
Communication, Relationships, and Internal Dissemination	27.69%	Breaking the sector's isolation, improving dialogue with clinical teams, and providing effective feedback on service orders.
Technical and Operational Training	18.46%	Investment in training on emerging medical technologies and encouragement of continuous professional development.
Strategic Engagement and Integration with Senior Management	26.15%	Participating in decision-making processes, developing a holistic perspective, and aligning activities with hospital leadership.
Physical Infrastructure, Budget, and Resources	10.77%	Ensuring adequately equipped workshops, synchronization with building maintenance, and allocation of dedicated budgets.
Regulatory Oversight and Inspection	6.15%	Active supervision by professional councils regarding job positions, salaries, and irregular hiring practices in the hospital sector.

Among the 84 participants, 65 provided valid responses to the question regarding priority actions to promote the recognition and appreciation of Clinical Engineering. The responses revealed the need for structural labor reforms, combined with an urgent need to strategically reposition teams within the hospital environment.

When investigating priority actions to promote professional recognition of Clinical Engineering, results revealed the need for structural labor reforms, combined with an urgent need to strategically reposition teams within the hospital environment. Communication, relationships, and internal dissemination emerged as the most frequently identified category, with 27.69% of respondents (n=18) emphasizing the importance of strengthening dialogue with clinical teams, disseminating the activities and results of Clinical Engineering, and improving intersectoral relationships.

Strategic engagement and integration with senior management were also frequently identified (26.15%; n=17), particularly through participation in decision-making processes and the presentation of evidence and results to institutional leadership. Compensation, benefits, and labor rights were reported by 24.62% of respondents (n=16), highlighting salary adjustments, benefits, and recognition compatible with professional responsibilities. Additionally, respondents emphasized technical and operational training (18.46%; n=12), particularly continuous training and preparation for new technologies, as well as the presentation of performance indicators and financial results (18.46%; n=12) to demonstrate the economic contribution of Clinical Engineering. Physical infrastructure, budget, and resources (10.77%; n=7) and regulatory oversight and inspection (6.15%; n=4) were also identified as priority areas (Table III).

IV. Discussion

The results show that Clinical Engineering in Brazil constitutes an interdisciplinary structure. Although definitions frequently center the field on the clinical engineer as its central figure, the operational and strategic reality of Health Technology Management demands a shift from this paradigm toward a multiprofessional ecosystem model. In the interest of patient safety and risk mitigation, the analytical structure of contemporary Clinical Engineering is now composed of diverse competencies: engineers from various specialties, technologists, and technicians, health professionals and medical physicists, as well as administrators, lawyers, architects, among others. This convergence of knowledge demonstrates that technological safety in hospital environments is not the product of isolated engineering, but rather the result of collaborative and integrated governance across different sectors.

The unanimous convergence around the management of Medical-Assistive Equipment (100.00%) confirms the sector's identity; however, it is the significant management of Support Equipment (91.38%), Surgical Instruments (44.83%), Medicinal Gases (36.21%), Infrastructure (22.41%), and IT (15.52%) that redraws the boundaries of the sector's scope. However, it is important to emphasize that the fact that Clinical Engineering departments manage multiple asset types does not, by itself, prove an epistemological redefinition of the field. Rather than representing a planned strategic evolution, this expansion of scope may also reflect local administrative centralization, resource scarcity, or an accumulation of operational responsibilities due to institutional demands.

The distribution between in-house teams (42.8%), full outsourcing (40.5%), and the hybrid model (16.7%) indicates the coexistence of different organizational arrangements for Clinical Engineering service. Cruz and Rincon (2012), in a mapping review on the outsourcing of medical device maintenance, identified that the decision to internalize or outsource services is influenced by factors such as asset specificity, uncertainty, and transaction frequency [34].

The concentration of outsourcing in specific activities such as thermal qualification (68%), testing and calibrations (66%), and corrective maintenance (64%) suggests that outsourcing is selectively applied to activities that may require specific expertise, equipment, certification, or manufacturer support. However, Cruz and Rincon (2012) note that this decision frequently occurs without a consolidated methodological basis, given that no empirical model yet exists to integrally guide supplier selection and performance evaluation in the context of medical device maintenance [34].

The adoption of continuous training programs aimed at mitigating operational errors, the development of standard operating procedures (SOPs), the consolidation of performance indicators, and the transition to evidence-based management constitute fundamental technical-operational guidelines for Clinical Engineering, converging with the landscape discussed by Iadanza (2023). However, the results suggest that strengthening Clinical Engineering requires actions that extend beyond technical activities, including improved inter-sectoral communication, greater strategic engagement with senior management, recognition of professional responsibilities and compensation, and continued technical training. These priorities were reflected in the open-ended responses, particularly in relation to communication and relationships (27.69%), strategic engagement with senior management (26.15%), and compensation, benefits, and labor rights (24.62%). An analysis of the profile reveals a gap between traditional academic training and emerging market demands. It is recommended that continuing education programs be aligned with competencies in risk management, human factors engineering, and digital transformation.

Additionally, the need for more robust oversight by governmental bodies and professional councils is highlighted, consolidating a governance framework that integrates regulatory compliance and institutional recognition [35]. These results highlight the need for public policies aimed at strengthening Clinical Engineering, encouraging the creation of further national guidelines for Health Technology Management (HTM) and fostering continuous professional training aligned with regulatory and strategic demands. As main lessons learned, the study demonstrates that Clinical Engineering in Brazil operates under significant maturity heterogeneity across the public, private, and philanthropic sectors, revealing that while technical proficiency in medical equipment maintenance

and fleet management is well-established, a gap persists between traditional academic training and strategic management skills. Conversely, key research gaps were identified, underscoring the need for future studies that correlate Clinical Engineering maturity with patient safety indicators, evaluate the cost-effectiveness of HTM throughout the technology lifecycle, and investigate the impact of human factors engineering and usability on preventing use errors within the Brazilian healthcare context.

V. Conclusion

This study mapped the landscape of Clinical Engineering in hospital institutions in Brazil, revealing the structural, operational, and market complexity involved in the management of medical equipment. Based on a quantitative and qualitative approach with a sample of 84 professionals, the results provided an exploratory characterization of sector digitalization, and challenges that limit its full institutional recognition.

The high rate of adoption of computerized management systems (86.90%) and the significant rates of internal execution of strategic activities, such as maintenance program planning (90%) and the incorporation of new technologies (91%), suggest increasing involvement of Clinical Engineering in strategic activities. However, this technical advancement contrasts with severe behavioral and structural barriers. The interface with clinical staff emerged as the most prevalent challenge (31.71%), manifested through equipment misuse and low engagement with operational training, which may contribute to user-related failures and pose potential risks to patient safety. Additionally, the sector operates under multifactorial internal pressures, including chronic budgetary constraints and understaffed teams relative to bed volume, and external pressures driven by manufacturer dependency, which imposes high costs and long lead times for spare parts.

As a path to overcoming institutional invisibility, the Clinical Engineering community indicates that financial and salary recognition (24.62%) must be accompanied by a proactive change in posture from the teams themselves. This translates into the need for professionals to move beyond purely technical repair activities and to communicate with hospital senior leadership through quantifiable data, numerically demonstrating financial return (ROI), costs avoided through reduced equipment downtime, and the sector's direct impact on the micro- and macroeconomic sustainability of the health institution.

In this context, the findings reinforce the importance of implementing and systematically reviewing the Health Technology Management Plan (HTMP) as a strategic instrument for health technology governance. Its periodic updating enables the incorporation of improvement opportunities, supports the rapid technological evolution of the sector, and addresses changes in the population's epidemiological profile, thereby promoting greater operational efficiency, regulatory compliance, institutional sustainability, and strengthened patient safety.

Regarding limitations, the study was conducted through a self-administered questionnaire and voluntary public dissemination, making the results subject to respondent bias, which may lead to omissions or underreporting of failures in the health technology management process. Although the study achieved national coverage, the representativeness of the sample cannot be established due to the non-probabilistic recruitment and the uneven distribution of participants, with greater concentration in the Southeast region. Because institutional identifiers were not collected, it was not possible to determine whether more than one respondent belonged to the same institution, and the public dissemination of the questionnaire prevented the calculation of a response rate.

Furthermore, the descriptive nature of the study and the absence of inferential statistical analyses limited the investigation of associations between institutional profile, management model, and reported challenges. Stratified and inferential analyses using larger and more representative samples are suggested in future investigations to identify regional and institutional specificities. Nevertheless, this study provides exploratory national evidence on the landscape of Clinical Engineering in Brazil, contributing to discussions on public policies, professional development, and new scientific directions for the field.

These empirical findings serve as a foundation for a critical conceptual discussion on the expansion and evolution of the profession's scope in the healthcare ecosystem. Based on the evidence, a redefinition of the concept of Clinical Engineering is proposed, dissociating it from a purely technical, clinical engineer-centered view, to establish it as a holistic field oriented toward sustainability and safety in healthcare. Under this perspective, Clinical Engineering operates as an interdisciplinary link aimed at managing health technologies throughout the entire lifecycle, ensuring metrological reliability, asset traceability, accessibility, and safety for the mitigation of adverse events. Managing technology must therefore become more strategic and evidence-based.

In conclusion, this study provides important exploratory evidence that Brazilian Clinical Engineering increasingly operates as an expanded, interdisciplinary field encompassing management, risk, technology, infrastructure, and governance. However, a formal conceptual redefinition of the discipline requires future triangulation with institutional databases, formal consultation with professional societies and regulatory bodies, cross-national comparative studies, and empirical validation through larger, more representative, and stratified samples.

***Resumo*—Este estudo analisa a convergência técnica e normativa entre as diretrizes de biossegurança (RDC ANVISA n.º 222/2018 e Resolução CONAMA n.º 358/2005) e a estruturação dos instrumentos convocatórios para gestão de Resíduos de Serviços de Saúde (RSS) na rede pública estadual do Tocantins. Por meio de pesquisa documental qualiquantitativa centrada na análise de conteúdo, escrutinou-se o Termo de Referência do Pregão Eletrônico n.º 90147/2024, que rege a logística de 44 estabelecimentos assistenciais. O escopo restringe-se à avaliação do projeto do edital (*tender design*), não constituindo auditoria de execução prática nas unidades. Os resultados evidenciam alinhamento formal às normas federais, destacando-se a exigência de inativação microbiana de Nível III, incineração para partes anatômicas e requisitos de rastreabilidade digital (balanças calibradas pelo INMETRO, monitoramento via GPS e emissão do Manifesto de Transporte de Resíduos via SINIR). O Instrumento de Medição de Resultado (IMR) estabelece fórmula objetiva de glosa financeira baseada no Fator de Qualidade (FQ). Identificaram-se lacunas relacionadas à alta carga de auditabilidade e à dependência de autodeclaração das calibrações. Conclui-se que o desenho do edital fornece um arcabouço normativo estruturado para a fiscalização da engenharia clínica.**

***Index Terms*—Resíduos de Serviços de Saúde, Engenharia Clínica, Gestão Contratual, Rastreabilidade, Licitações Públicas.**

I. Introdução

O Estado do Tocantins administra uma rede de unidades hospitalares dimensionada para absorver demandas de média e alta complexidade. Polos estratégicos como o Hospital Geral de Palmas (HGP), o Hospital Regional de Araguaína (HRA) e o Hospital Regional de Gurupi (HRG) operam como geradores contínuos de Resíduos de Serviços de Saúde (RSS). A escala operacional dessas unidades implica a necessidade de rígido controle sanitário e ambiental para mitigar riscos à saúde pública.

O alicerce jurídico nacional é estabelecido pela Lei n.º 12.305/2010 [1], que institui a Política Nacional de Resíduos Sólidos (PNRS) e fixa a responsabilidade compartilhada do gerador. No plano operacional, a Resolução da Diretoria Colegiada (RDC) n.º 222/2018 da ANVISA [2] padroniza as etapas de segregação, acondicionamento e tratamento. Complementarmente, a ABNT NBR 10004:2004 [3] estabelece os parâmetros de classificação de periculosidade dos resíduos.

A proteção ambiental e a saúde ocupacional são regidas pela Resolução CONAMA n.º 358/2005 [4] e pelas Normas Regulamentadoras NR-9 e NR-32. A NR-32 estabelece diretrizes específicas para a segurança dos trabalhadores em serviços de saúde. Neste contexto, a Engenharia Clínica atua na interpretação, monitoramento e fiscalização dos fluxos contratuais, assegurando a aplicação dos parâmetros técnicos estipulados nos Termos de Referência (TR).

A investigação centra-se na análise do grau de convergência técnica entre a legislação sanitária vigente e o projeto instrucional do edital de licitação da Secretaria de Estado da Saúde do Tocantins (SES/TO). O presente trabalho avalia especificamente a estrutura normativa do instrumento convocatório (*tender design*), não abrangendo a verificação empírica da execução do serviço em campo.

II. Objetivos

A. Objetivo Geral

Analisar a convergência técnica e normativa entre as diretrizes da RDC n.º 222/2018 da ANVISA e as cláusulas estipuladas no edital público de gerenciamento de RSS da rede estadual do Tocantins para os Grupos A, B e E.

B. Objetivos Específicos

- Identificar as exigências normativas de segregação, acondicionamento e destinação dos Grupos A, B e E estipuladas na legislação federal [2].
- Mapear a estrutura contratual recente elaborada pela SES/TO para coleta e tratamento de RSS [7].
- Escrutinar o Termo de Referência, registrando o nível de detalhamento técnico frente aos requisitos normativos e classificando as provisões contratuais [2], [4].
- Avaliar a viabilidade dos mecanismos de fiscalização previstos no edital para atuação da engenharia clínica.

Os autores agradecem à Universidade Federal do Norte do Tocantins (UFNT) pelo suporte institucional e à Secretaria de Estado da Saúde do Tocantins (SES/TO) pela disponibilização dos documentos públicos que fundamentaram esta pesquisa documental.

III. Referencial Teórico

A. Arcabouço Normativo de Biossegurança

A RDC ANVISA n.º 222/2018 padroniza o gerenciamento de RSS e exige a elaboração do Plano de Gerenciamento de Resíduos de Serviços de Saúde (PGRSS) [2]. A norma impõe critérios para segregação na fonte, identificação e inativação de agentes patogênicos. Todos os normativos citados neste trabalho encontravam-se em plena vigência temporal durante a elaboração e publicação do certame analisado.

B. Rastreabilidade Eletrônica e Nova Lei de Licitações

A Portaria MMA n.º 280/2020 instituiu o Manifesto de Transporte de Resíduos (MTR) nacional via Sistema Nacional de Informações sobre a Gestão dos Resíduos Sólidos (SINIR) [8]. Paralelamente, a Lei Federal n.º 14.133/2021 (Nova Lei de Licitações) formalizou o uso do Instrumento de Medição de Resultado (IMR) para atrelar o pagamento ao cumprimento de metas contratuais objetivas [9].

C. Transporte Rodoviário de Cargas Perigosas

O transporte externo de RSS é regulado pela Resolução ANTT n.º 5.998/2022 [10]. Em nível estadual, a Resolução COEMA-TO n.º 07/2005 exige a Autorização de Transporte de Cargas Perigosas (ATCP) expedida pelo NATURATINS [11].

IV. Metodologia

A. Protocolo de Análise Documental e Fontes de Dados

Realizou-se pesquisa documental, descritiva e exploratória, com abordagem qualiquantitativa baseada em análise de conteúdo. A coleta dos documentos públicos ocorreu em 15 de abril de 2024 via Portal Nacional de Contratações Públicas (PNCP). O objeto de análise foi o Termo de Referência do Pregão Eletrônico n.º 90147/2024 (Processo Administrativo n.º 2023/30550/006554), promovido pela SES/TO para contratação de serviços em 44 estabelecimentos de saúde [7].

B. Unidades de Análise e Matriz de Codificação

O protocolo estruturou-se em quatro fases reprodutíveis:

1) Levantamento normativo: Mapeamento dos requisitos compulsórios das Resoluções RDC 222/2018 e CONAMA 358/2005.
2) Codificação contratual: Extração sistemática das cláusulas técnicas e operacionais contidas no Termo de Referência.
3) Categorização e vínculo: Classificação de cada cláusula em três categorias: (a) Provisão Compulsória Legal (exigência direta de lei ou resolução); (b) Prática Recomendada (especificação de boas práticas operacionais); e (c) Interpretação dos Autores (análise técnica sobre a aplicabilidade).
4) Avaliação do desenho do edital: Confronto estruturado entre os requisitos normativos e o texto contratual (*tender design*).

C. Delimitação do Escopo e Limitações

Este estudo limita-se estritamente à análise do texto e das especificações contidas no instrumento convocatório. A metodologia não inclui auditoria física nas 44 instalações de saúde, entrevista com gestores, nem coleta de dados operacionais passados de execução.

D. Aspectos Éticos e Transparência

Por utilizar dados secundários de acesso público, o estudo é isento de avaliação por Comitê de Ética em Pesquisa (CEP/CONEP). Informa-se que o modelo de inteligência artificial generativa Gemini (Google) foi utilizado exclusivamente para apoio na revisão gramatical, adequação ao estilo IEEE e formatação do código LaTeX. Os autores assumem responsabilidade integral pelo conteúdo, análises e conclusões do manuscrito.

V. Resultados e Discussão

A. Dimensionamento e Estruturação do Licitamento

O Pregão Eletrônico n.º 90147/2024 abrange a prestação de serviços de coleta, transporte, tratamento e disposição final de RSS em 44 unidades de saúde estaduais [7]. A demanda total prevista é de 17.420.400 kg ao longo de 60 meses de contrato, dividida no Lote 1 (Região Norte, 5,8 mil toneladas) e Lote 2 (Região Centro-Sul, 11,5 mil toneladas) [7]. O edital fixa frequências de coleta variáveis conforme a complexidade da unidade, variando de mensal para unidades ambulatoriais até três vezes por semana para hospitais de grande porte (HRA, HGP e HRG) [7].

B. Matriz Auditável de Conformidade do Desenho do Edital

A Tabela I apresenta a matriz de conformidade obtida pelo confronto entre a legislação vigente e as cláusulas do Termo de Referência.

Tabela I
MATRIZ AUDITÁVEL DE CONFORMIDADE DO DESENHO DO EDITAL (PE 90147/2024)

Grupo	Requisito Legal / Normativo	Especificação no Termo de Referência (TR)	Categoria de Análise
Grupo A (Infectante)	Inativação Nível III (A1/A2); Incineração compulsória para A3/A5 (RDC 222/2018 [2]).	Exigência de inativação Nível III e incineração para A3/A5, com Laudo de Queima Semestral (Cláusula 4.2 [7]).	Provisão Compulsória Legal
Grupo B (Químico)	Proibição de efluentes líquidos em aterros; Destinação em Aterro Classe I (RDC 222/2018 [2]).	Vedação de líquidos em aterro; exigência de neutralização prévia e descarte em Aterro Classe I (Cláusula 4.8 [7]).	Provisão Compulsória Legal
Grupo E (Perfurocortante)	Acondicionamento em recipiente rígido e estanque; Inativação compatível (RDC 222/2018 [2]).	Comodato de bombonas rígidas em PEAD e tratamento em Nível III prévio ao aterro (Cláusula 5.1 [7]).	Prática Recomendada / Legal

Fonte: Elaborado pelos autores (2026).

A especificação do TR exige que os subgrupos A3 (peças anatômicas) e A5 (suspeita de príons) sejam destinados estritamente à incineração, solicitando a apresentação semestral

de Testes de Eficiência de Queima emitidos por laboratórios credenciados, em conformidade com a Resolução CONAMA n.º 316/2002 [7].

C. Regras de Subcontratação

O edital estabelece limite máximo de 30% para subcontratação do objeto global, distribuído em até 25% para disposição final em aterro e até 5% para incineração dos subgrupos A3 e A5 [7]. O TR exige que as empresas subcontratadas apresentem Licença de Operação (LO) válida e comprovem regularidade ambiental perante os órgãos competentes [7].

D. Requisitos Metrológicos e Rastreabilidade Eletrônica

O TR exige que a empresa contratada forneça bombonas de polietileno de alta densidade (PEAD) em comodato e instale ao menos duas balanças digitais industriais calibradas por unidade hospitalar [7]. As balanças devem possuir capacidade mínima de 200 kg, plataforma de 60x60 cm, impressora de etiquetas integrada e certificação emitida pela Rede Brasileira de Calibração (RBC/INMETRO) [7].

O registro das pesagens fundamenta a emissão do Manifesto de Transporte de Resíduos (MTR) via sistema SINIR, atendendo à Portaria MMA n.º 280/2020 [8]. Para o transporte rodoviário, exige-se frota com baú estanque, sinalização conforme ABNT NBR 7500, licença ambiental ATCP e monitoramento por GPS [7], [10], [11].

E. Mecanismo do Instrumento de Medição de Resultado (IMR)

O modelo contratual adota a medição de desempenho por meio do Fator de Qualidade (FQ), calculated pela equação:

$$FQ = \left[\frac{(A - D) - C}{(A - D)} \right] \times 100 \tag{1}$$

Em que A representa o total de serviços avaliados, D indica os serviços dispensados ou não aplicáveis no período, e C representa o somatório de infrações técnicas ou operacionais registradas pela fiscalização.

O edital estabelece descontos faturados progressivos conforme o valor de FQ:

- $FQ \geq 90\%$: Pagamento integral (100% do valor mensal).
- $75\% \leq FQ < 90\%$: Glosa de 2% sobre a fatura mensal.
- $50\% \leq FQ < 75\%$: Glosa de 5% sobre a fatura mensal.
- $FQ < 50\%$: Glosa de 10% sobre a fatura mensal e abertura de processo administrativo de rescisão contratual.

F. Análise Crítica de Lacunas e Gargalos do Edital

Apesar da convergência formal identificada, a análise neutra do documento aponta limitações potenciais:

- Carga de auditabilidade: A fórmula do IMR exige verificação frequente de laudos de calibração, certidões ambientais e registros no SINIR. Sem dimensionamento adequado das equipes de fiscalização hospitalar, a identificação da variável C pode ser comprometida.
- Dependência de autodeclaração: O controle metrológico fundamenta-se no envio de certificados emitidos pela própria contratada ou por laboratórios por ela contratados, sem previsão expressa de aferição independente periódica por parte do contratante.

G. Requisitos de Saúde Ocupacional e Gestão do Fator Humano

Em conformidade com a NR-32, o TR exige que a empresa contratada ministre treinamento comprovado aos trabalhadores em até 20 dias após a emissão da Ordem de Serviço ou da contratação de novos funcionários [7]. É exigida a apresentação do Programa de Controle Médico de Saúde Ocupacional (PCMSO), do Programa de Gerenciamento de Riscos (PGR) e do Plano de Prevenção de Riscos de Acidentes com Materiais Perfurocortantes (PPRAMP), acompanhados das Anotações de Responsabilidade Técnica (ART) registradas nos conselhos de classe (CREA/CRM) [7].

VI. Considerações Finais

A presente investigação cumpriu o objetivo de analisar o alinhamento técnico e normativo do Termo de Referência do Pregão Eletrônico n.º 90147/2024 da SES/TO frente às diretrizes federais da RDC ANVISA n.º 222/2018, da Resolução CONAMA n.º 358/2005 e da Lei n.º 14.133/2021.

Os resultados demonstraram que o desenho do edital (*tender design*) apresenta elevado nível de convergência documental, incorporando requisitos metrológicos (balanças aferidas pelo INMETRO), rastreabilidade digital (MTR/SINIR) e critérios objetivos de glosa financeira previstos no IMR. Contudo, reforça-se que a conformidade instrucional do edital não assegura, por si só, a eficácia do cumprimento operacional nas 44 instalações assistenciais da rede estadual.

A. Limitações e Trabalhos Futuros

Por se tratar de uma pesquisa centrada no escrutínio documental do certame, identificam-se oportunidades de ampliação da investigação para trabalhos futuros:

- Auditorias operacionais *in loco*: Realização de inspeções físicas em campo para confrontar as cláusulas do edital com a prática diária de segregação, acondicionamento e frequência de coleta nas unidades de saúde.
- Análise da série histórica do IMR: Levantamento dos relatórios mensais de execução para mensurar a aplicação real das fórmulas de glosa (FQ) e quantificar a taxa de inconformidades operacionais ao longo da vigência contratual.
- Estudos comparativos multicêntricos: Aplicação da matriz de conformidade desenvolvida neste trabalho em editais de gestão de resíduos hospitalares de outros estados brasileiros, permitindo o *benchmarking* da governança pública em saúde.
- Desenvolvimento de ferramenta padronizada de *compliance*: Criação de um *framework* auditável e reprodutível que possa ser adotado por equipes de Engenharia Clínica para a fiscalização contínua de contratos de serviços de apoio hospitalar no Sistema Único de Saúde (SUS).

***Abstract*—Quality management in healthcare services depends on reliable records and indicators capable of supporting decision-making. This study evaluated the quality of data from closed corrective work orders extracted from a Computerized Maintenance Management System (CMMS) used in a multicenter healthcare network. A descriptive quantitative analysis of 82,431 work orders was performed in R, considering completeness, uniqueness, temporal consistency, informativeness, and the ability to support managerial indicators. Core administrative fields showed high completeness, and no duplicate values were identified in the main work-order identifiers. In contrast, downtime and return-to-operation data were missing in 80.6% of records. This high missingness persisted across the main priorities and periods evaluated and varied among equipment categories. Cost and release-for-clinical-use fields were formally completed but showed limited managerial interpretability. The database therefore provides adequate structural support for basic operational analyses, while limitations in critical managerial fields restrict the reliable generation of more advanced indicators. Effective CMMS use requires data governance, appropriate field definitions, validation rules, category standardization, user training, and continuous monitoring of data-entry quality.**

***Index Terms*—Clinical Engineering, CMMS, data quality, managerial indicators.**

I. Introduction

Quality management in healthcare services relies on documented processes, reliable records, and indicators capable of supporting decision-making. Continuous quality improvement, when applied to healthcare systems, requires structured models, monitoring tools, and the systematic analysis of care-related and support processes [1]. In this context, data availability alone does not guarantee improvement, since decision-making depends on the quality, completeness, and standardization of the available records [2].

In Brazil, RDC 63/2011 establishes good practice requirements for the operation of healthcare services, emphasizing the importance of qualified management and the reduction and control of risks to users [3]. In addition, RDC 509/2021 establishes requirements for the management of health technologies in healthcare facilities, reinforcing the need for structured processes throughout the technological life cycle [4]. More recently, the publication of the technical standard ABNT NBR ISO 7101:2025 reinforced the importance of quality management systems in healthcare organizations, oriented toward the delivery of timely, safe, effective, efficient, equitable, and people-centered care [5]. Furthermore, regulatory and standards-based frameworks establish criteria and guidelines for health technology management, with emphasis on quality, safety, and performance throughout the technological life cycle [4], [6].

In healthcare settings, Computerized Maintenance Management Systems (CMMS) can support the recording of work orders and maintenance histories by documenting failure causes, response times, costs, responsible technical personnel, execution status, and operational indicators [7]. These systems may contribute to equipment traceability, monitoring of corrective and preventive maintenance activities, resource planning, and performance assessment in Clinical Engineering services.

However, the mere existence of a computerized system does not ensure the generation of actionable managerial information. A CMMS may record a large volume of data and still present limitations for decision-making if its fields are incomplete or inconsistently completed. Therefore, the managerial usefulness of the tool depends on the quality of the data entered and on the ability to transform operational records into reliable indicators capable of adding value to the management process.

The publication of ABNT NBR ISO 7101:2025 expanded the possibilities and requirements applicable to management systems. Considering the relevance of corrective maintenance in the routine of healthcare facilities, records associated with these activities may represent an important source of information for assessing and improving management processes. Fields such as work order opening date (Abertura) and work order closing date (Fechamento) may allow, for example,

the calculation of the administrative cycle time of a work order. However, they do not necessarily indicate the actual downtime of the equipment. For this purpose, specific records of downtime (Parada) and return to operation (Funcionamento) would be required. Similarly, fields such as cause (Causa), occurrence (Ocorrência), cost (Custo), evaluation (Avaliação), and release for clinical use (Liberado para Uso) may exist in the database, but their analytical usefulness depends on the completeness and quality of the recorded data.

Thus, this study aimed to evaluate the quality of data recorded in corrective work orders extracted from a hospital CMMS used in a multicenter network, considering completeness, uniqueness, temporal consistency, informativeness, and the ability to support the generation of indicators in Clinical Engineering.

II. Materials and Methods

The study material consisted of a database of closed work orders extracted from a computerized hospital maintenance management system used in a multicenter hospital network. Data processing, organization, and analysis were performed using the R programming language, version 4.5.0 (R Foundation for Statistical Computing, Vienna, Austria), with support from the RStudio Desktop integrated development environment, version 2024.12.1.563 (Posit Software, PBC, Boston, MA, USA). The tidyverse, readxl, janitor, lubridate, xml2, writexl, and scales packages were used for data import, cleaning, transformation, analysis, and export [8].

A. Study Design and Data Source

An observational, descriptive, and quantitative study was conducted using a pre-extracted database of closed work orders obtained from the CMMS of a multicenter healthcare network. The dataset was provided to the authors as a spreadsheet export, with no intervention in care processes and no direct data collection from professionals or patients. The analytical sample corresponded to all records contained in the main work-order tab at the time the file was received. No row-level exclusions were applied to define the analytical sample. The original database query and any filtering procedures performed before delivery of the export were not available for independent verification.

The original spreadsheet contained four tabs: “Análise Fornecedores”, “Chamados Fechados”, “Chamados Corretiva Tempo Exec.”, and “Unidades”. The “Chamados Fechados” tab was used as the primary analytical dataset and contained 82,431 closed work orders and 64 original fields. The remaining tabs were used only for structural and consistency checks of the export and for auxiliary characterization and were not incorporated into the main analytical dataset.

The analysis was conducted at the network level. Individual healthcare facilities were not identified or compared, and unit-level characteristics such as care complexity, local versus centralized Clinical Engineering workflows, and installed-base criticality were not used for institutional stratification. The available organizational fields were therefore not interpreted as direct measures of healthcare-facility performance. The maintenance-type field classified the records into three CMMS categories: “corretiva”, “corretiva pro ativa”, and “corretiva de backup”. For the purposes of this study, these three system-defined categories were treated as corrective maintenance. No records classified in the analytical dataset as preventive maintenance, calibration, or electrical safety testing were identified. Accordingly, the scope of the study was restricted to closed corrective work orders.

The unit of analysis was the closed work order. For each record, administrative, operational, and managerial fields were evaluated, including work order number (OS), work order serial code (Código Serial OS), company (Empresa), maintenance shop (Oficina), maintenance type (Tipo de Manutenção), priority (Prioridade), work order status (Situação da OS), equipment (Equipamento), model (Modelo), manufacturer (Fabricante), department (Setor), cost center (Centro de Custo), opening date, closing date, occurrence, cause, work order notes (Observação), cost, asset tag (Patrimônio), evaluation, downtime, return to operation, and release for clinical use.

B. Data Quality Assessment and Statistical Analysis

Data quality assessment was structured into five main dimensions: completeness, uniqueness, temporal consistency, informativeness, and ability to generate managerial indicators. These dimensions were operationalized for CMMS work-order data considering general concepts used in secondary healthcare data quality assessment, including data presence, completeness, plausibility, and fitness for the intended use [9].

Completeness was assessed by calculating the absolute and relative frequencies of missing values for each variable. A value was considered missing only when it was null, an empty string, or contained only whitespace. Values that were formally present but carried limited analytical information were assessed separately under informativeness and were not counted as missing. For core work-order fields, completeness was used to assess the structural support provided by the database for operational characterization. For managerial fields, completeness was interpreted in relation to the feasibility of generating management indicators.

Uniqueness was assessed by checking duplicate values in the main work-order identifiers, particularly the work order number and the work order serial code. Temporal consistency was assessed from the opening and closing dates by identifying missing values and records outside a logical chronological sequence. Cross-field temporal plausibility was additionally evaluated for the downtime and return-to-operation fields by checking whether downtime preceded work-order opening, whether return to operation occurred after work-order closing, and whether return to operation preceded the recorded downtime.

Informativeness was evaluated separately from completeness. After normalization of case, accents, and excess whitespace, standardized entries corresponding to “Nao informado”, “Sem informacao”, “Nao se aplica”, “N/A”, “NA”, “NULL”,

"NULO", "Indefinido", and "Ignorado" were classified as non-informative. Zero values in the cost field were not considered missing but were analyzed separately because their economic interpretation could not be established from the database alone. Evaluation-note entries containing three or fewer characters were flagged as very short text entries for descriptive assessment. These classifications were performed using predefined computational rules rather than independent manual record-by-record judgment.

Semantic quality was assessed through the distribution and concentration of cause and occurrence categories. Absolute and relative frequencies were calculated for the most frequent categories. For normalization of compound entries, comma-separated terms were separated, whitespace was standardized, repeated terms were removed after text normalization, and the remaining terms were recombined while preserving their original categorical meaning.

To explore heterogeneity in data quality, missingness in the downtime, return-to-operation, and user-evaluation fields, as well as non-informative release-for-clinical-use entries and zero-cost records, were additionally stratified by year of work-order opening, work-order priority, and equipment type. For equipment-level interpretation, emphasis was placed on the 20 equipment categories with the highest number of work orders to reduce the influence of sparse categories. The stratified analysis remained descriptive and was intended to identify variation in completeness and informativeness across operational strata rather than to compare institutional performance.

Descriptive analyses were presented using absolute frequencies, percentages, means, medians, percentiles, and extreme values, according to the nature of each variable. Graphs were generated in the R environment and exported as image files for subsequent insertion into the manuscript.

III. Results and Discussion

A. General Analysis of the Database

The analyzed database consisted of 82,431 closed work orders and 64 original variables. The records had opening dates ranging from April 15, 2022, to June 4, 2025. The temporal analysis showed a higher density of records from 2024 onward, a finding that should be interpreted with caution because it may reflect implementation, migration, or consolidation of system use rather than an actual increase in maintenance demand.

The main identifiers showed good structural consistency. The work order number was filled in all records and showed no duplicates. A similar result was observed for the work order serial code, also with 82,431 unique values. At the identifier level, each row corresponded to a distinct work-order record, supporting the use of the closed work order as the unit of analysis.

The administrative opening and closing dates were filled in all records. The median time between opening and closing was 0.36 day, whereas the mean was 10.03 days. This difference between mean and median indicates an asymmetric distribution, with a large number of work orders closed within shorter intervals and a small set of records with prolonged duration. Fig. 1 shows the distribution of opening-to-closing time on a logarithmic scale for improved visualization.

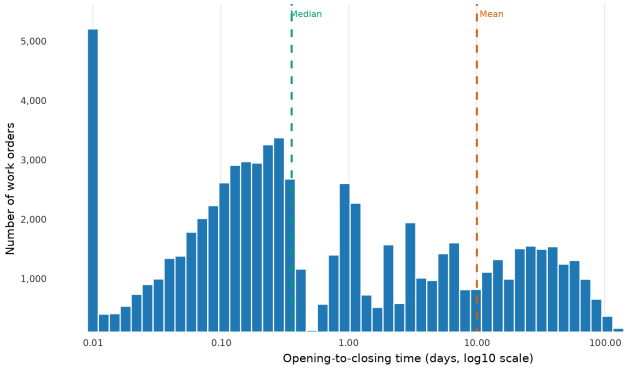

Fig. 1. Distribution of opening-to-closing time for corrective work orders on a logarithmic scale. Dashed lines indicate the median and mean values. Zero-day intervals were displayed as 0.01 day only for logarithmic visualization.

The results summarized in Table I indicate that the database has good structural quality for the operational recording of work orders. The absence of duplicate values in the main identifiers and the completeness of administrative dates allow descriptive analyses of volume, period, and administrative cycle time. Fig. 2 presents the five equipment types with the highest number of corrective work orders. However, this structural quality should not be confused with full capacity to generate advanced managerial indicators.

TABLE I
General Characterization of the Analyzed Service Order Database

Indicator	**Result**
Analyzed service orders	82,431
Original variables in the main tab	64
Opening period	15/04/2022 to 04/06/2025
Work order number filled	82,431
Duplicated work order	0
Duplicated work order serial code	0
Opening filled	100%
Closing filled	100%
Median opening-to-closing time	0.36 days
Average opening-to-closing time	10.03 days

B. Completeness of Core and Managerial Fields

The completeness assessment showed an important difference between core administrative fields and critical managerial fields. Variables such as work order number, work order serial code, company, maintenance shop, maintenance type, priority, work order status, department, cost center, opening date, closing date, occurrence, and cause showed high completeness. This result indicates that the CMMS is used consistently for the administrative and operational recording of work orders.

However, when fields required for management were evaluated, relevant gaps were observed. The overall percentage of empty cells in the main database was approximately 27.8%,

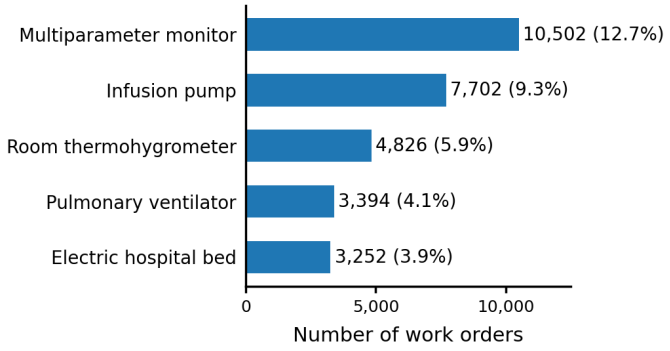

Fig. 2. Equipment types with the highest number of corrective work orders.

but this value should not be interpreted as a uniform property of the database because missingness varied substantially among variables. Missingness was particularly high in the closing-deadline and closing-justification fields and also affected evaluation notes, downtime, return to operation, and external service. Fig. 3 presents, in decreasing order, the percentage of missing records in critical managerial fields. Table II summarizes the managerial interpretation associated with the absence of data in these fields.

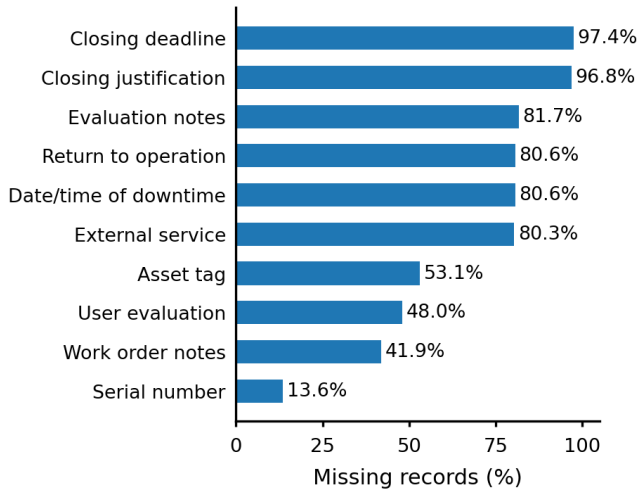

Fig. 3. Percentage of missing records in critical managerial fields of the work order database.

The stratified analysis showed that the high missingness of downtime and return-to-operation data was not restricted to a single work-order priority or period. Missingness in both fields was 81.1% for high-priority work orders, 79.8% for medium-priority work orders, and 85.6% for low-priority work orders. In 2024 and 2025, which together accounted for most of the analyzed records, the corresponding percentages were 79.9% and 82.0%, respectively. Greater variation was observed across the 20 equipment categories with the highest work-order volumes, for which missingness in both fields ranged from 71.0% to 92.5%. These results indicate that the limitation was present across the main operational strata evaluated,

TABLE II
COMPLETENESS OF SELECTED FIELDS FROM THE MAIN DATABASE

Variables	Missing	Interpretation
Serial Number	13.6%	Moderate loss for technical tracking
SO Notes	41.9%	Limited for qualitative text analysis
User evaluation	48.0%	Limited for perceived quality analysis
Asset tag	53.1%	Limited for individual tracking
External service	80.3%	Limited for third-party analysis
Date downtime	80.6%	Limited for unavailability calculation
Return operation	80.6%	Limited for usage return calculation
Evaluation notes	81.7%	Low availability for qualitative analysis
Closing justification	96.8%	Negligible for management analysis
Closing deadline	97.4%	Negligible for management analysis

although its magnitude varied among equipment categories. User-evaluation missingness also varied across the 20 most frequent equipment categories, ranging from 19.6% to 63.9%.

This finding does not mean that the database is unsuitable for analysis. Rather, it shows that the system is capable of recording work orders in a structured manner while also indicating that its use as a managerial intelligence tool depends on the completion of variables that go beyond the simple opening and closing of a work order.

C. Fields Formally Completed but with Limited Informational Value

Data quality analysis should not be limited to checking for empty fields. Some fields may be formally completed and still have limited analytical usefulness. This issue was observed particularly in the cost and release-for-clinical-use fields and, among completed entries, in evaluation notes.

The cost field was completed in all records. However, 75,968 work orders, corresponding to approximately 92.2% of the database, had a cost equal to zero. Only 6,463 records, equivalent to 7.8%, had a positive cost. Although the field showed formal completeness, its use for comprehensive cost analysis should be approached with caution. Without additional validation, it is not possible to determine whether zero values indicate an actual absence of cost, lack of cost entry, internally absorbed cost, non-applicable cost, or another operational criterion used by the institution.

From a managerial perspective, the predominance of zero values represents a loss of opportunity for maintenance cost monitoring, life-cycle cost assessment, replacement planning, and economic prioritization of maintenance actions. Nevertheless, this result should not be interpreted as evidence of absence of cost or as a management error without additional validation of the institution's costing rules and data entry practices.

The release-for-clinical-use field showed a similar pattern. Although formally completed, 98.3% of the records were classified as having limited informational value. This result limits the use of the field to assess the safe return of equipment to clinical use after maintenance.

The percentage of records affected by fields that were formally completed but had limited informational value is

shown in Fig. 4. The highest percentages were related to the release-for-clinical-use field with limited informational value and to zero cost. In addition, 12.0% of all records had very short evaluation notes. Considering that only 18.3% of records contained any evaluation-note information, very short entries represented a substantial proportion of the completed notes. This result should be interpreted together with the low completeness of this field, as shown in Fig. 3.

The stratified analysis also showed that limited informativeness was not confined to a single priority group. Non-informative release-for-clinical-use entries ranged from 97.8% to 98.4% across priority levels, while zero-cost records ranged from 91.9% to 96.1%. Greater heterogeneity was observed among the 20 most frequent equipment categories: non-informative release-for-clinical-use entries ranged from 95.6% to 99.6%, whereas zero-cost records ranged from 67.0% to 99.8%.

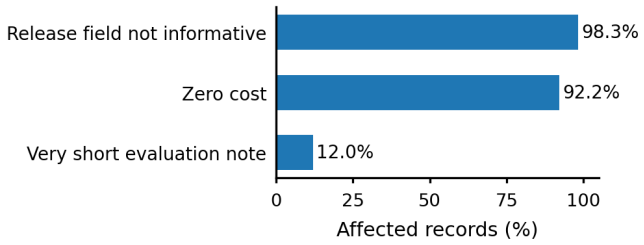

Fig. 4. Percentage of records with selected patterns of limited or uncertain managerial interpretability.

In addition to the fields shown in Fig. 4, the analysis of free-text fields indicated other limitations. The work order notes field was completed in 58.1% of the records, with a median of eight words. The service field was completed in 100% of records but had a median of only one word per completed record, indicating that descriptions were usually very short. The median was used because it is less sensitive to extreme values, since a small number of long texts could increase the mean without representing the predominant data entry pattern.

These results reinforce the need to distinguish formal completeness from analytical usefulness. The presence of a value in a given cell does not necessarily guarantee that the recorded information is sufficient to build reliable indicators. Therefore, data quality assessment should consider not only missing values but also the ability of the recorded content to support audits, managerial analyses for decision-making, and continuous process improvement.

D. Administrative Work Order Time Versus Actual Downtime

As shown in III-A, the database allows analysis of the administrative time between work order opening and closing. This interval was available for all records and showed no chronological inconsistency. This interval was not considered Time to Repair (TTR), because it does not necessarily represent the effective repair time or the actual equipment downtime. Therefore, the time between work order opening and closing should be interpreted as the distribution of the administrative work order cycle, not as the distribution of actual equipment downtime. This distinction is important for Clinical Engineering because opening and closing a work order may be influenced by administrative factors, spare-part availability, vendor availability, delays in data entry, process follow-up, or closure after the equipment has already returned to use.

To assess actual downtime, specific data on downtime and return to operation would be required. The latter was interpreted as the operational return of the equipment. These two fields showed identical availability patterns: both were completed in 15,991 records (19.4%) and both were missing in the remaining 66,440 records (80.6%), as shown in Fig. 3. No record had only one of the two fields completed.

Among the records in which the downtime and return-to-operation fields were completed, 863 cases had a downtime date earlier than the work order opening date. This condition may be operationally plausible, since the equipment may have been identified as unavailable by the care unit before the maintenance team formally opened the work order. In 326 cases, the return-to-operation date was later than the work order closing date, which may indicate a difference between administrative closure of the work order and the recorded operational return of the equipment. Among the completed records, there were no cases in which the return-to-operation date was earlier than the downtime date, indicating temporal coherence between these two fields.

These results show that the database adequately supports measurement of the administrative work order cycle, but it does not allow actual equipment downtime to be calculated for all records. Therefore, indicators such as Mean Time to Repair (MTTR) and operational availability should be considered weak when calculated exclusively from the fields available in the analyzed database.

E. Semantic Quality of Causes and Occurrences

The cause and occurrence fields were fully completed in the analyzed database. This is positive from a completeness standpoint. However, the semantic quality of these fields requires evaluation, since formal completeness does not guarantee sufficient granularity for more robust analysis.

After simple normalization, the most frequent causes were natural wear, equipment failure, damaged accessory, and operational error. These categories accounted for approximately 80.1% of the work orders. Fig. 5 shows the distribution of the most frequent causes.

The concentration of records in a few categories may be useful for Pareto analyses, as it allows the main groups of failures or demands to be identified. However, some categories are broad in nature. For example, the expression equipment failure indicates that a failure occurred, but it does not necessarily describe the mechanism involved, the affected component, or the root cause. Similarly, natural wear may represent an expected condition in some cases, but it may also include different situations that would require greater detail to

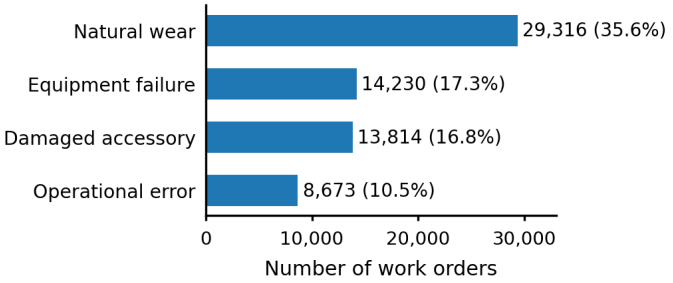

Fig. 5. Distribution of the four most frequent causes recorded in corrective work orders.

distinguish service life, usage pattern, preventive maintenance, and accessory condition.

In the occurrence field, the most frequent categories were third-party service, damaged accessory, malfunction, and alarming. These categories accounted for 64.5% of all occurrences. Fig. 6 shows the most frequent occurrences.

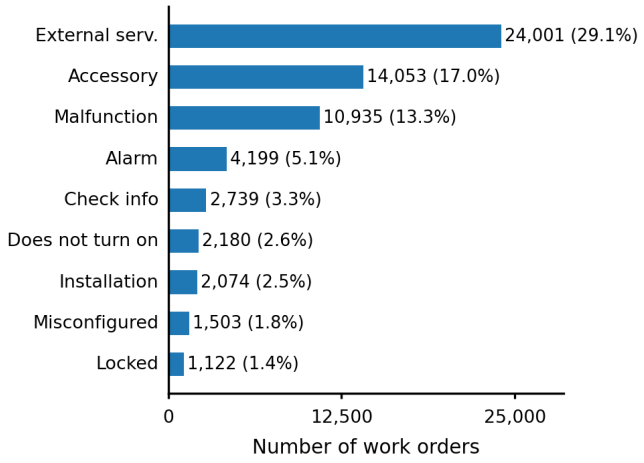

Fig. 6. Most frequent occurrences recorded in corrective work orders.

The predominance of third-party service as an occurrence suggests that the field may be used not only to record the technical symptom or observed problem but also to describe the operational workflow or routing of the work order. This mixture of different types of information in the same field limits more refined analyses, since it combines technical event, request, administrative condition, and operational routing.

Accordingly, the results indicate that cause and occurrence are complete fields, but they still require greater semantic standardization to support root-cause analysis, preventive actions, and evidence-based decision-making. One possible improvement would be to conceptually separate fields intended for observed symptom, probable cause, root cause, action performed, and need for third-party support.

F. Implications for Data Governance in Clinical Engineering

Based on the results obtained, the analyzed CMMS provides adequate structural support for the operational management of work orders. The database contains unique main identifiers, complete administrative opening and closing dates, and structured information that allows analyses of work-order volume, temporal distribution, equipment, departments, causes, occurrences, and cost centers. This operational structure, however, does not imply that all fields required for more advanced managerial indicators have the same level of completeness or informational value.

This distinction is particularly evident for downtime and return-to-operation data. These fields were available in only 19.4% of the work orders, and their missingness remained high across the main priorities and periods evaluated. Greater variation was observed among equipment categories. Therefore, estimates of downtime, MTTR, or related indicators calculated only from completed records may not adequately represent the entire set of work orders. The magnitude and direction of this possible distortion cannot be determined from the available database because the true values for records with missing information are unknown.

From a data-governance perspective, these results suggest that improving CMMS use depends not only on increasing data entry, but also on defining which information is required for each managerial purpose. Previous experience with CMMS database management in Clinical Engineering has also emphasized the need for data assessment, cleaning, validation, and organization before managerial use [10]. Fields such as downtime, return to operation, asset identification, and release for clinical use may require validation at work-order closure when they are applicable to the maintenance process. Controlled vocabularies could improve the consistency of cause and occurrence categories, while automated cross-field checks could identify implausible temporal relationships. Periodic dashboards could also monitor missing or low-information records over time and across relevant operational strata.

The dimensions considered in this study were applied to the structure and intended managerial use of the analyzed CMMS. They overlap with concepts used in broader healthcare data-quality frameworks, including completeness, consistency or concordance, plausibility or validity, uniqueness, timeliness, and accuracy [2], [9]. In the present study, these concepts were adapted to maintenance records, with additional emphasis on informativeness and fitness for managerial use. This suggests that the general assessment logic may be applicable to other CMMS environments, although the specific fields, validation rules, and thresholds would need to be adapted to the structure and operational workflow of each system.

Training, periodic review of field definitions, and monitoring of data-quality indicators may complement these controls. At the same time, making a large number of fields mandatory without considering their operational relevance may increase documentation burden without necessarily improving the analytical usefulness of the database.

Future analyses could extend the stratification to equipment criticality, department, cost center, unit profile, and institutional workflow when such descriptors are reliably available. This may help determine whether missing or low-information

records are concentrated in specific operational contexts or reflect broader network-wide data-entry patterns.

Table III summarizes the main managerial implications of the results. The analyzed database provides good support for basic operational indicators but presents relevant limitations for advanced indicators, particularly those dependent on downtime, cost, release for clinical use, and user evaluation.

TABLE III
COMPUTABILITY OF SELECTED MANAGERIAL INDICATORS

Indicator and rationale	Class.
Work order volume by period Work order ID and opening date were complete.	Computable
Opening to closing time Opening and closing dates were complete and temporally consistent.	Computable
Administrative SLA Depends on the institutional SLA rule and interpretation of related fields.	Caution
Equipment ranking by calls Equipment, model, and manufacturer fields were mostly available.	Computable
Real downtime Downtime and return to operation were missing in 80.6% of records.	Weak
MTTR Depends on downtime and return to operation, which were poorly completed.	Weak
Operational availability Depends on real downtime and a validated installed base.	Weak
Cost per work order or equipment Zero cost was recorded in 92.2% of records.	Weak
User perceived quality User evaluation and evaluation notes were incomplete or poorly informative.	Partial
Safe return to use The field was mostly filled with non-informative content.	Weak

IV. CONCLUSION

The analyzed database showed adequate structural quality for the operational recording of corrective work orders. The 82,431 records had unique main identifiers and complete administrative opening and closing dates, supporting analyses of work-order volume, temporal distribution, equipment, departments, causes, occurrences, and cost centers. These characteristics support the use of the CMMS for basic operational analyses, but they do not by themselves ensure that more advanced managerial indicators can be calculated reliably.

Relevant limitations remained in fields required for managerial interpretation. Downtime and return-to-operation data were missing in 80.6% of the records, and this high missingness persisted across the main priorities and periods evaluated, although its magnitude varied among equipment categories. Cost and release-for-clinical-use fields were formally completed but had limited interpretability, with 92.2% of cost records equal to zero and 98.3% of release-for-clinical-use records classified as non-informative. Cause and occurrence fields were complete, but broad or mixed categories limited more detailed root-cause analysis.

Because the analytical dataset contained only corrective work orders and no institutional or unit-profile stratification was performed, the results should be interpreted as an overall assessment of data quality within the analyzed network.

The results indicate that the managerial value of a CMMS depends not only on record availability, but also on data governance, field definitions, appropriate validation rules, category standardization, user training, and continuous monitoring of data-entry quality.

***Abstract*—This study describes the development of interactive Standard Operating Procedures (SOPs) and educational materials using H5P technology to support the implementation and promote standardized data-entry practices of a Computerized Maintenance Management System (CMMS) at the University Hospital of the University of São Paulo. The challenges encountered mainly involved the complexity and robustness of the CMMS and its non-standardized use by the technical team, which hindered reliable data analysis. To address this, flowcharts for critical procedures, such as equipment decommissioning and service requests, were created and integrated with custom video tutorials using an interactive educational content development software. These materials were exported as standalone HTML files to ensure offline access within the hospital environment, overcoming connectivity limitations. The resulting digital repository contains interactive SOPs and visual tutorials, organized by a centralized index that allows the maintenance team to access standardized instructions quickly. In the future, the use of interactive H5P tools can serve as both pedagogical support and a quality control mechanism for the CMMS database. However, the effect on data quality was not quantitatively evaluated. The framework employed may be replicable in other hospital CMMS implementations seeking to standardize local workflows.**

***Index Terms*—CMMS, Clinical Engineering, Standard Operating Procedures, H5P, Equipment Maintenance**

I. Introduction

The management of medical equipment represents one of the most critical dimensions of hospital administration. In the healthcare environment, ensuring that diagnostic and therapeutic devices operate reliably and safely is a prerequisite for quality patient care. According to the Brazilian Ministry of Health, the implementation of structured maintenance programs is fundamental to reduce accident risks, ensure device availability, and guarantee the effectiveness of clinical procedures [1].

Within the framework of hospital quality systems, performance indicators play a central role in guiding management decisions. Indicators such as equipment downtime rates, mean time between failures (MTBF), and mean time to repair (MTTR) allow clinical engineering teams to identify bottlenecks, allocate resources more efficiently, and demonstrate accountability to hospital administration. However, the validity of such indicators depends entirely on the quality and consistency of data recorded by maintenance technicians in every service interaction. When data entry is inconsistent or incomplete, the entire analytical framework built upon it loses its reliability, ultimately undermining the hospital's quality management system.

To support this data-driven approach, Computerized Maintenance Management Systems (CMMS) were developed. A CMMS is a comprehensive software platform that automates the full lifecycle of maintenance management and centralizes records [2].

Despite their benefits, modern CMMS platforms are complex systems with numerous data entry fields, configurable workflows, and interrelated modules, demanding a considerable level of training and familiarity from the technical staff. New users, and even experienced technicians adapting to a new system, face a steep learning curve that, if not adequately supported, can lead to non-standardized data entry and degraded database integrity over time [3].

A critical gap in current health technology management stems from commercial training resources: vendor-provided CMMS manuals and tutorials are inherently generic, covering general system functionality rather than the specific workflows adopted by individual institutions. As a result, they may include procedures that do not apply, omit steps that are locally relevant, or present sequences that differ from the actual

practice of the team. This gap between generic documentation and institutional reality creates a persistent training deficit that static manuals alone cannot bridge.

To bridge this gap, Standard Operating Procedures (SOPs), which have long been recognized as essential instruments for ensuring process consistency in regulated environments, can be combined with interactive digital formats, engaging users more effectively than traditional documents, facilitating knowledge retention and real-time consultation.

In this context, the open-source H5P (HTML5 Package) framework [4] emerges as a particularly suitable technology. H5P is an open-source framework that enables the creation of richly interactive content directly in the browser, without requiring specialized programming skills. Using tools such as an interactive content authoring software (ICAS) (Lumi Education UG, Germany) [5], H5P activities can be authored through an intuitive interface and exported in self-contained formats compatible with offline use.

The primary purpose of this work is to describe the development and implementation of interactive SOPs and educational materials using H5P technology to support the adoption of a specific CMMS at the University Hospital of the University of São Paulo (HU-USP) (Effort, GlobalThings, Brazil) [6]. The approach was designed with the usability needs of the Healthcare Technology Management (HTM) team in mind, prioritizing accessibility, contextual relevance, and independence from internet connectivity.

This study describes the development and implementation of institutional educational materials as part of standard quality improvement processes. All collaboration with the maintenance team occurred through routine institutional engagement. Although formal ethics approval was not sought, as this constitutes quality improvement rather than research, the technical team members were aware of and voluntarily participated in all development and validation activities.

II. Materials and Methods

The development process was guided by a user-centered design philosophy, placing the practical needs and daily workflow of the HTM team at the forefront of every decision. The methodology unfolded across several interconnected stages: observational assessment, procedural mapping, content production, iterative validation, and technical deployment.

A. Observational Assessment and Team Interaction

The first stage consisted of an observation period of two months, during which the actual use of the CMMS by the HTM team was monitored. This phase involved accompanying technicians during their routine activities, identifying the specific steps they performed in the system, and noting points of uncertainty, recurring errors, or inconsistencies in data entry.

Beyond simple observation, this stage also included informal consultations with team members, documented through field notes, to understand their prior experience with digital maintenance systems, their familiarity with the CMMS platform, and the difficulties they most frequently encountered.

These interactions were instrumental in establishing a shared understanding between the research team and the maintenance staff. Consequently, it became clear which procedures should be prioritized to establish a foundation for SOP development.

Two fundamental procedures were selected to be developed in detail as proof-of-concept: service request intake and equipment decommissioning. Notably, these processes do not possess complex, conditional steps or numerous decision points; instead, they are inherently simple. They were chosen because they effectively outline the boundaries of the maintenance workflow, acting as the logical initiation and a potential termination of a work order.

B. Procedural Mapping and Flowchart Development

Based on the insights gathered during the observational phase, detailed procedural flowcharts were developed collaboratively through discussions with two technical leads. Using a graph-diagramming tool (yEd, yWorks, Germany), the flowcharts were designed to represent not only the linear sequence of steps, but also the conditional branches and decision points inherent in each process. Special care was taken to ensure that the diagrams reflected the actual practice of the HU-USP HTM team, rather than a generic or idealized version of the procedure.

The flowcharts were subsequently reviewed in alignment meetings with the maintenance team, where all seven technicians commented and suggested modifications. These meetings proved particularly valuable for capturing tacit knowledge, procedural nuances that technicians perform automatically, but are rarely documented in official manuals.

Three rounds of revision were carried out based on team feedback. They resulted in changes such as the order and the terminology of the workflow, ensuring that the final flowcharts accurately captured the approved institutional workflow before any educational material was produced.

C. Video Recording and Content Production

With validated flowcharts in hand, the next stage involved producing custom tutorial videos tailored to the specific procedures adopted at HU-USP. As one of the experienced technicians executed each procedural step within the CMMS, the screen was captured using an open-source screen recording software (OBS Studio, OBS Project, USA). This approach was intended to produce content that was both authentic and directly applicable to the team's context, differing from the generic tutorials provided by the CMMS vendor.

The raw video recordings were subsequently edited using a video editing tool (Clipchamp, Microsoft, USA) to remove redundant segments, adjust pacing, and ensure that each clip corresponded precisely to a single step of the procedural flowchart. This segmentation was a deliberate pedagogical choice: by presenting each action in isolation, the tutorials allow the user to consult specific steps without navigating through lengthy recordings.

D. H5P Development and SOP Documentation

The edited video segments were then integrated into interactive H5P activities using the Lumi software. The "image hotspots" content type was selected as the primary format, as it allows users to interact with a visual representation of the procedural flowchart by clicking on individual steps to reveal the corresponding video tutorial.

This design directly mirrors the cognitive model of a technician consulting the SOP during task execution: they identify where they are in the process, access the relevant instruction, and proceed.

Concurrently, written SOPs were produced for each procedure. These documents provided a detailed narrative description of every step depicted in the flowchart, complemented by annotated screenshots extracted from the tutorial videos.

The combination of textual description and visual reference was intended to accommodate different learning preferences within the team and to serve as a printable fallback in situations where digital access might be unavailable.

E. Offline Deployment and Index Development

A critical constraint of the hospital environment is the limited or inconsistent internet connectivity in certain areas where maintenance activities are performed. To ensure that the educational materials could be consulted by technicians at the point of care, regardless of network availability, a technical solution was developed to package and distribute the H5P content as self-contained offline files.

Using the ICAS, each completed H5P activity was exported via the path: File → Export → All-in-one HTML file → Export Now. This process generated standalone HTML files capable of being executed directly in any browser without requiring an internet connection.

The resulting files were organized within a dedicated folder ("*fluxogramas*"), alongside the corresponding SOP documents (stored in a "*documentos*" folder).

To facilitate intuitive navigation across the growing collection of materials, a custom index site was coded in HTML. This interface presents all available procedures as interactive cards, organized alphabetically, with direct links to both the H5P interactive flowchart and the corresponding SOP PDF document.

Adding new procedures to the index requires only a straightforward editing step: duplicating the HTML card block (as illustrated in Fig. 1), adjusting the title, description, and file references, and saving the updated file.

This low-barrier update process was intentionally designed so that team members without advanced technical skills could independently maintain and expand the repository over time.

F. Final Validation

Upon completion of all materials, a final series of alignment meetings was held with the HU-USP HTM team. During these sessions, team members navigated the index interface, interacted with the H5P flowcharts, and reviewed the written SOPs. Feedback was collected regarding clarity, completeness, and usability, and minor adjustments were made accordingly.

```

    <!-- Card title -->
    <h3>Service Request Intake</h3>
    <!-- Brief card description -->
    <p>Critical analysis of service calls made by the University
        Hospital to the Equipment Maintenance Section.</p>
    <div class="button-group">
        <!-- link to flowchart -->
        <a href="fluxogramas/RequisicaoDeServico.html"
        target="_blank" class="btn btn-h5p">View Flowchart</a>
        <!-- link to SOP -->
        <a href="documentos/POP_RequisicaoDeServico.pdf"
        target="_blank" class="btn btn-pdf">View SOP (PDF)</a>
    </div>
</div>
```

Fig. 1. Structural HTML block for adding new H5P content to the index.

This validation step aimed to ensure that the materials were not only technically accurate but also genuinely accessible and useful to the intended audience in their day-to-day activities. Feedback was collected verbally during alignment meetings and documented in field notes. Although no standardized usability instruments or systematic usability metrics were applied, the overall response from the team was positive.

III. Results

Applying the described methodology, a total of two H5P interactive flowcharts and two written SOPs were successfully developed and validated, covering the two foundational procedures selected for the HU-USP HTM sector.

The development process resulted in clear flowcharts that map the straightforward nature of each procedure, capturing the essential, linear workflows that technicians follow to initiate and conclude a work order in practice.

Fig. 2 presents the flowchart for service request intake, which encompasses the steps from initial service demand identification through the proper registration of the service order in the CMMS.

Fig. 3 presents the flowchart for equipment decommissioning, a procedure of particular importance for maintaining an accurate active equipment inventory within the CMMS.

Each H5P activity was built around its respective flowchart, enabling users to click on individual steps to access the corresponding custom video tutorial.

The videos, recorded specifically for the HU-USP context, present the exact sequence of actions performed within the CMMS as practiced by the institutional team, making them immediately applicable rather than requiring adaptation from generic instructional content.

To consolidate all produced materials and provide an accessible query interface for the maintenance team, the index site was developed (Fig. 4).

The interface not only organizes the available procedure cards in alphabetical order, but also offers a search bar, allowing users to quickly locate the desired procedure and

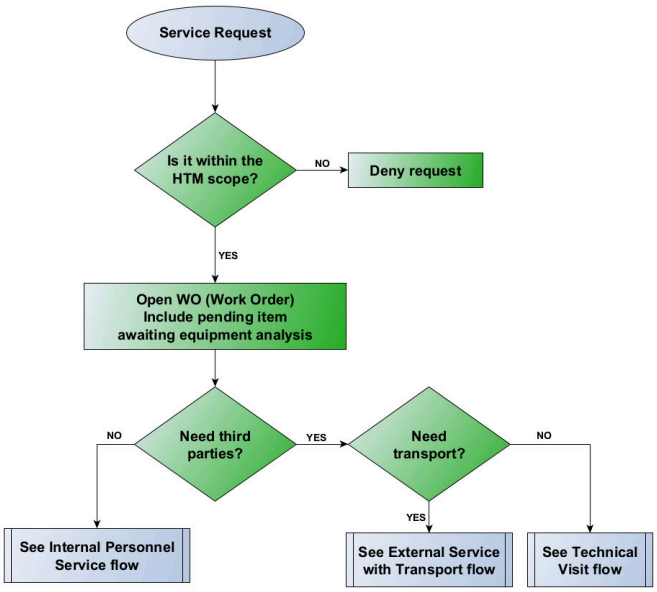

Fig. 2. Flowchart for service request intake.

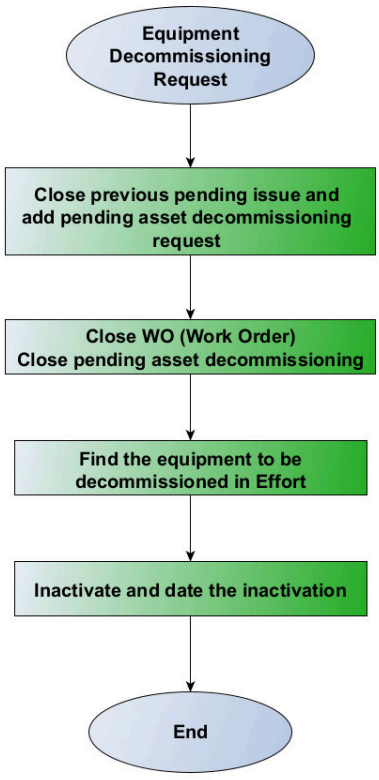

Fig. 3. Flowchart for equipment decommissioning.

open either the interactive H5P flowchart or the corresponding SOP document with a single click.

At the moment, the index is incomplete, with only the Equipment Decommissioning and the Service Request Intake procedures with both the interactive flowchart and SOP. However, all eight institutional CMMS procedures already have the flowchart (without the videos), providing a template for future expansion.

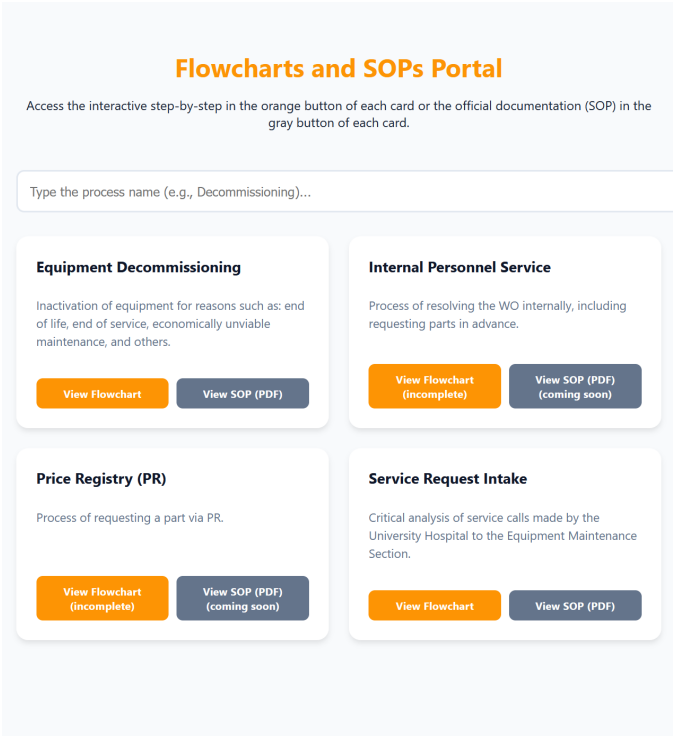

Fig. 4. Graphical interface of the developed index site.

The produced materials are available in Portuguese in the project's digital repository [7], organized as a compressed ZIP file containing the index, flowcharts, and SOP documents. For data protection and institutional privacy, the H5P videos in the shared repository have been replaced with example placeholder videos and the CMMS screenshots have been deleted from the SOPs. The full customized institutional versions are maintained locally within HU-USP systems.

Once the ZIP file is extracted, the entire collection is accessible by simply opening the index file in a browser, with no internet connection required.

This packaging strategy ensures that the full repository (including all interactive H5P content) can be distributed, stored locally, and consulted offline across different devices within the hospital environment.

Whenever new materials are added, updating the distributed folder ensures that all users have access to the most current version.

IV. Discussion

The Computerized Maintenance Management System represents, in contemporary clinical engineering, a management

tool of considerable scope and sophistication. Designed to integrate the full spectrum of equipment lifecycle activities into a single platform, a CMMS encompasses dozens of configurable fields, interrelated modules, and workflow dependencies that collectively demand a high level of familiarity from its users.

The process of adopting such a system in a hospital environment is not merely a technical transition, it is an organizational one, requiring that maintenance technicians internalize new data entry habits, adapt to structured workflows, and consistently apply procedures that may differ substantially from their previous informal practices.

This learning curve is well-documented in the literature and represents one of the primary barriers to successful CMMS implementation, particularly in public hospitals where training resources are often limited [2].

The experience at HU-USP highlighted this challenge. Through discussions with the HTM team, it was identified that the absence of clear, institutionally tailored guidelines contributed to variability in how maintenance records were entered. Different technicians interpreted the same fields differently, optional steps were inconsistently completed, and the classification of maintenance events lacked uniformity.

Over time, this variability accumulated into a database that, while voluminous, was insufficiently reliable for quantitative analysis, rendering performance indicators such as MTBF, MTTR, and preventive maintenance compliance rates either inaccurate or impossible to compute with confidence.

Most commercial CMMS vendors, including the provider of the HU-USP's platform, do supply their users with learning resources such as help menus, user manuals, and video tutorials. However, these materials are inherently designed for a general audience: they demonstrate system functionality in the abstract, without reference to the specific procedures, nomenclature, or institutional conventions of any particular hospital.

At HU-USP, this meant that available vendor tutorials contained steps not performed by the team, omitted institution-specific requirements, and followed sequences that diverged from locally approved workflows.

The generic nature of these resources, while understandable from a commercial perspective, makes them poorly suited as a sole training mechanism for teams with highly specific operational contexts.

By developing custom interactive materials anchored to the actual workflows of the HU-USP HTM team, this project aimed at addressing precisely that gap. The iterative process of observation, flowchart validation, and team alignment ensured that the produced SOPs and H5P tutorials reflected not a theoretical ideal, but the approved institutional reality.

Technicians consulting the materials encounter procedures that match their daily experience and expectations, which is expected to reduce the cognitive friction associated with adapting generic instructions to local practice.

The choice of H5P as the interactive content format brought additional pedagogical advantages beyond mere standardization. Interactive elements, such as the clickable flowchart hotspots linked to step-specific video demonstrations, were designed with the intent to promote active engagement rather than passive reading, supporting better knowledge retention. However, assessment of actual learning retention was outside the scope of this implementation study.

The visual and sequential structure of the materials also accommodates varying levels of prior CMMS experience within the team: newcomers can follow the tutorials step by step, while more experienced technicians can use the materials as a quick reference for less familiar procedures.

A critical technical challenge addressed during implementation was the limited internet connectivity available in several areas of the hospital where maintenance activities are performed. Exporting the H5P content as self-contained HTML files using the ICAS [5] provided an effective and low-cost solution to this constraint, enabling full offline access without requiring any server infrastructure or institutional IT investment. This portability makes the repository immediately deployable and maintainable by the team itself.

It is also worth noting that the optimization of tutorial video duration, achieved by recording procedure-specific clips rather than relying on the vendor's longer generic videos, had a direct impact on the practical viability of offline distribution. Shorter, targeted videos significantly reduced the total size of the compressed repository, making it feasible to store and share the complete collection via conventional digital media within the hospital.

One limitation of the current implementation relates to scalability: as the number of documented procedures grows, so does the volume of videos and PDF documents, and consequently the storage footprint of the standalone folder. This growth must be managed thoughtfully, with periodic reassessment of storage strategies and distribution mechanisms as the repository expands.

Technical limitations also include the lack of compatibility testing across different browsers (e.g., Chrome, Firefox, Safari) and operating systems (Windows, macOS, Linux), which is a critical requirement prior to broader deployment. Additionally, offline HTML distribution presents version control and content currency challenges, as the repository currently records only its last update date. To mitigate the security and reliability risks inherent to standalone files, future releases should incorporate: (1) explicit version numbering, (2) automated outdated-content warnings, (3) a centralized tracking system for active versions, (4) detailed change logs, (5) robust file integrity verification, (6) backup procedures, and (7) disaster recovery protocols. Finally, formal accessibility considerations were not incorporated; while video captions were unnecessary due to the absence of audio instructions, future iterations should include alternative text descriptions for all visual elements.

Another limitation of this study is that no logging or tracking of material utilization was performed, and no quantitative evaluation of CMMS data quality before and after implementation was conducted. Therefore, claims about improvements in database accuracy cannot be made. It can only be said that the implementation of this material was positively perceived by

the HU-USP's HTM team. Thus, comprehensive assessment of the impact of these materials on maintenance data quality and technician performance would require a more rigorous evaluation framework, including pre- and post-implementation data analysis and potentially a controlled comparison with alternative training approaches. Such evaluation is recommended as future work.

A critical aspect of long-term sustainability involves establishing explicit triggers for content review and updates. Specifically, whenever the CMMS interface undergoes significant updates (including new fields, modified workflows, or altered rules) or when institutional maintenance procedures are modified, the corresponding flowcharts and H5P tutorials should be reviewed and updated accordingly. This protocol ensures that the repository remains synchronized with actual institutional practice and continues to serve as an accurate reference over time.

Although this study was limited to a single institutional context and two detailed procedures, it is important to highlight the potential for broader applicability of the methodology developed in this work. The framework (observation, iterative procedural mapping, custom video production, H5P integration, offline packaging, and team validation) is not specific to the CMMS or to HU-USP. It is a potentially transferable framework that may be adapted to other settings; external validation is still required.

In contexts where inconsistent data entry compromises the quality of maintenance databases and, by extension, the reliability of clinical engineering performance indicators, this approach can offer a structured, low-cost pathway toward standardization.

The potential for application in other institutions suggests that this work, while grounded in a specific institutional experience, carries value beyond its original context, contributing to the broader goal of building robust, reliable health technology management systems across the Brazilian healthcare network.

V. Conclusion

This study describes a methodology for developing and implementing customized, interactive SOPs within institutional CMMS contexts. The framework integrating observational assessment, iterative flowchart development, custom video production, H5P-based interactive content, and offline deployment was designed to address known barriers to CMMS adoption in settings with limited connectivity.

While no quantitative evaluation of impact was performed in this work, the approach offers a template for other institutions seeking structured, low-cost solutions to standardize maintenance workflows.

Validation of the framework in another institutional context or department is recommended as future work to assess generalizability. Future work should also include systematic evaluation of adoption rates, database quality improvements, and maintenance performance indicators.

Conflict of Interest

The authors declare that they have no conflict of interest.

Acknowledgment

The authors would like to extend their gratitude to the entire team of the HTM Section of the HU-USP for their invaluable collaboration and assistance throughout the development of this work. This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brazil (CAPES) - Finance Code 001 and the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) (137972/2025-3 to SKH and 309464/2022-6 to HTM).

***Abstract*— The growing demand for home care programs and services has led to an increased incorporation of health technologies into the home environment, expanding care complexity and imposing new challenges related to technology safety and reliability, infrastructure adequacy, and user qualification. In this scenario, Clinical Engineering assumes a strategic role in managing these technologies throughout the technology lifecycle, from initial home assessment to continuous monitoring of home care conditions. This study proposes a home assessment tool for health technology management, grounded in the principles of Clinical Engineering, normative requirements, and the Medical-Hospital Technology Management model of the Institute of Biomedical Engineering of the Federal University of Santa Catarina (IEB-UFSC). The tool was developed through the integration of findings from a rapid literature review, normative requirements, and the IEB-UFSC conceptual model. It is organized into four progressive levels: initial home assessment (N1), multidisciplinary assessment of identified non-conformities (N2), installation and operational validation of health technologies (N3), and continuous care monitoring (N4). This structure integrates infrastructure, health technology, and human resource aspects, enabling a tiered approach. The proposal provides a structured framework for assessing and monitoring home conditions during the implementation and follow-up of home care.**

Keywords*— *home care, clinical engineering, health technology management, medical devices, home assessment

I. INTRODUCTION

The growing decentralization of healthcare has become increasingly established worldwide, and the home is one of the most important care settings. Driven by population aging, the increasing prevalence of chronic diseases, and the need for transition of care, this modality has emerged as a humanized alternative capable of reducing hospital costs and expanding continuity of treatment within the family context [1][2]. Simultaneously, there is a growing incorporation of health technologies in the home environment, including medical devices, life-support equipment, and monitoring systems, expanding care complexity and challenges related to the safety and management of these technologies [3][4].

Unlike healthcare facilities (HCF), homes are not designed to accommodate medical devices and may present limitations related to electrical infrastructure, physical space, environmental conditions, and user qualification [5][6]. Additionally, human factors represent critical challenges that require special attention from managers, particularly those related to user qualification, caregiver overload, and the lack of systematic monitoring and support mechanisms for the use of health technologies [7][8].

In this context, Clinical Engineering assumes a strategic role in managing health technologies used in the home environment, acting throughout the technology lifecycle and encompassing planning, acquisition, installation, training, monitoring, and maintenance processes. In recent decades, this field has evolved from an equipment maintenance-focused approach to a strategic model oriented toward quality, patient safety, and evidence-based decision-making [3]. In the home care context, this role becomes even more relevant due to the structural variability of homes, the use of devices by lay users, and the absence of continuous technical supervision [4][5].

Despite the growing incorporation of health technologies into home care and the existence of regulations such as Brazilian Health Regulatory Agency (ANVISA) Collegiate Board Resolution (RDC) number 11/2006, and ABNT NBR IEC 60601-1-11:2021, there is a limited availability of structured instruments to guide the systematic assessment of home conditions from a Clinical Engineering perspective [10][11][12]. The literature describes challenges associated with infrastructure, human factors, and the use of medical devices in the home, but lacks standardized methods capable of integrating these elements into an assessment process that supports decision-making regarding the installation, use, and monitoring of health technologies [3][9].

Existing approaches address specific aspects of home care, including the safe use and maintenance of medical devices [13] and the assessment of environmental barriers, adaptations, accessibility, and safety risks [14]. However, these approaches have different scopes and do not explicitly integrate technology, infrastructure, and human resources into a Health Technology Management process. The proposed tool seeks to address this gap through a progressive assessment structure encompassing initial screening, multidisciplinary analysis, installation and operational validation, and continuous monitoring.

In this sense, the present study proposes the development of a home assessment tool grounded in the principles of Clinical Engineering and Health Technology Management,

structured in four progressive levels. The tool integrates aspects related to infrastructure, health technologies, and human resources involved in care, providing a structured framework for the assessment and management of conditions associated with the use of health technologies in the home environment.

II. METHODS

This is an applied, qualitative, and descriptive study aimed at developing a home assessment tool for health technology management from the perspective of Clinical Engineering. The study was structured in two parts: the theoretical foundation of the tool, comprising a rapid literature review, normative analysis, and analysis of the conceptual model of the Institute of Biomedical Engineering of the Federal University of Santa Catarina (IEB-UFSC); and the elaboration and structuring of the tool, organized in four progressive assessment levels.

A. Tool Foundation

The rapid literature review was conducted based on the Methodological Guidelines of the Brazilian Ministry of Health for the development of systematic reviews [15] and reported following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) recommendations [16]. The review was guided by the research question: "What are the models, strategies, and outcomes reported in the literature regarding health technology management in the home care context?".

The searches were conducted in July 2025 in the PubMed, IEEE Xplore, Scopus, and SciELO databases. The search strategy applied to PubMed, IEEE Xplore, and Scopus combined the terms (“Home Care” OR “Home Health Care” OR “Home Health Services”) AND (“Health Technology Management” OR “Medical Devices” OR “Medical Equipment” OR “Clinical Engineering”). In SciELO, the strategy was adapted to Portuguese using (“assistência domiciliar” OR “atenção domiciliar”) AND (“tecnologia em saúde” OR “equipamento médico” OR “dispositivos médicos”). No publication date restriction was applied.

Eligibility criteria were defined prior to study selection. Studies were included when they addressed health technology management in the home care context and considered at least one of the three pillars adopted in this study: technology, infrastructure, or human resources related to health technology management in home care. Full-text studies were considered, including original and secondary research. Studies unrelated to the home care context, not addressing the proposed scope, unavailable in full-text, or duplicated were excluded.

The review did not include a formal methodological quality assessment. The included studies were instead characterized according to their objectives, context of application, methodological approach, and contribution to the three health technology management pillars.

All retrieved records were imported into Rayyan for reference management and screening. Duplicate records were automatically identified by Rayyan and subsequently checked manually. The screening process was performed by a single reviewer, initially through title and abstract assessment. A total of 1,260 records were identified, of which 907 remained after duplicate removal. Following title and abstract screening, 100 publications were selected for full-text assessment. After full-text screening, 42 studies were excluded because they did not meet the predefined eligibility criteria, resulting in 58 studies included in the qualitative synthesis. The complete process is presented in Figure 1.

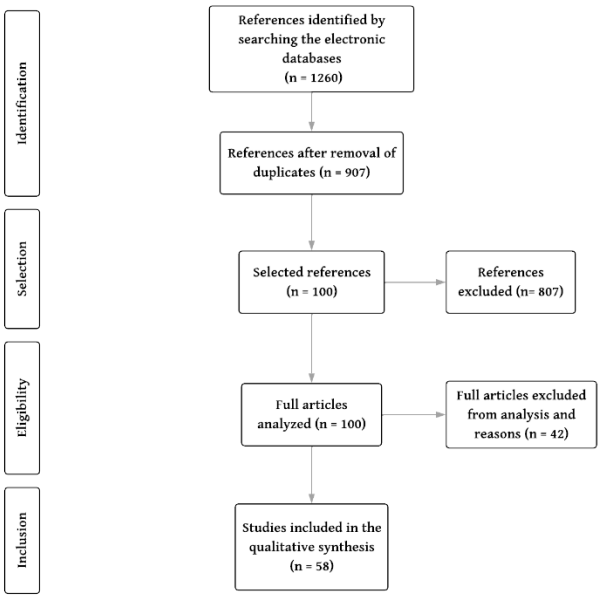

Fig. 1. Flow diagram of the study selection process for the rapid literature review.

The included studies were characterized according to their objectives, context of application, methodological approach, and relationship with the three health technology management pillars. The findings were synthesized into three analytical axes: technology, infrastructure, and human resources. Patient safety, adverse events, regulation, and related cross-cutting issues were considered throughout the synthesis and subsequently incorporated into the development of the assessment tool.

The normative analysis covered ANVISA regulations, national and international technical standards, and home care documents, with the objective of identifying technical and operational requirements for tool construction. Standards specifically related to home use were used as technical references and interpreted in relation to the characteristics of the home environment. Environmental parameters, including temperature, humidity, noise, and illuminance, were incorporated as reference criteria for assessing home conditions and identifying situations requiring further evaluation or corrective measures.

The analysis of the Medical-Hospital Technology Management model of IEB-UFSC, grounded in the pillars of technology, infrastructure, and human resources, was also conducted. This model seeks to promote safety, reliability, and effectiveness of health technology processes through integrated management of these three components

(Figure 2). Considering the particularities of home care, the pillars were adapted to this context and used as the basis for structuring the assessment criteria.

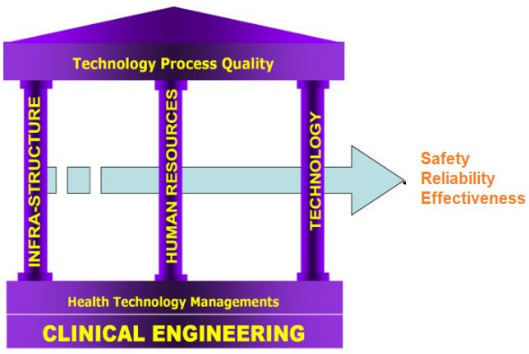

Fig. 2. IEB-UFSC health technology management process model.

B. Structuring the Home Assessment Tool

From the integration of literature findings, identified normative requirements, and the conceptual structure proposed by the IEB-UFSC model, the home assessment tool was developed. The assessment items were organized according to their role in the home care process, considering technology, infrastructure, and human resources, and structured into four progressive levels. This organization follows the sequence from initial assessment to implementation and continuous monitoring, allowing progression between levels according to the conditions identified at each stage.

The process begins at Level 1 (N1), intended for screening home conditions. When no non-conformities requiring further analysis are identified, the flow advances directly to Level 3 (N3). When restrictions or situations requiring further investigation are observed, Level 2 (N2) is triggered to support multidisciplinary assessment of the identified conditions. After defining the necessary adjustments, N3 covers the implementation of home care, including the installation, configuration, and validation of health technologies. Finally, Level 4 (N4) corresponds to the continuous monitoring of care and operational conditions, performed periodically or in response to events requiring reassessment.

The tool uses qualitative classifications rather than numerical weights or scores. Situations requiring further analysis are directed to N2, where the identified conditions can be considered according to the technology, infrastructure, and human resources involved.

III. Results

A. Tool Foundation

1) Rapid Literature Review

The rapid literature review resulted in the inclusion of 58 studies published between 1989 and 2025. The included publications used varied methodological approaches, predominantly observational and descriptive studies, such as case studies, descriptive analyses, and reviews. Results were organized around three analytical axes corresponding to the IEB-UFSC model pillars: technologies, infrastructure, and human resources.

In the technology axis, the literature highlights that the use of medical devices in the home presents challenges related to usability, especially due to operation by lay users and uncontrolled conditions. Issues such as unintuitive interfaces, inadequate instructions, and lack of standardization are pointed out as relevant challenges for safety in the use of these devices [17][18]. Clinical Engineering is identified as a strategic element, acting in device selection, installation, maintenance, and user training, with emphasis on the application of tools such as Failure Mode and Effects Analysis (FMEA) in improving management and safety of home devices [4][19]. Additionally, telemonitoring emerges as a promising alternative for remote monitoring and failure reduction, although challenges related to interoperability, regulation, and information security persist [20][21].

The most frequently reported equipment included mechanical ventilators, oxygen concentrators and cylinders, positive airway pressure devices (PAP/CPAP), infusion pumps, pulse oximeters, sphygmomanometers, multi-parameter monitors, and dialysis equipment [22]. Respiratory support, dialysis, and oxygen therapy devices are the most studied groups, present in 45%, 39%, and 29% of studies included in systematic reviews, respectively [23].

In the infrastructure axis, studies indicate that home adequacy is one of the main challenges of home care, since the residential environment is not designed for clinical purposes. Factors such as unsafe electrical installations, insufficient space, inadequate ventilation and lighting, and precarious hygiene conditions can compromise equipment operation and patient safety [24][25]. The reliability of electricity supply stands out as a critical factor for patients dependent on life-support equipment, with backup systems, contingency plans, and coordination with utility companies recommended for prioritizing these homes [26]. Home preparation should occur before hospital discharge through structured multidisciplinary planning [6].

In the human resources axis, training for the safe use of medical devices is recognized as an essential component of home care. It is noted that technologies originally developed for clinical environments are not always suitable for home users, making it necessary to develop training centered on tasks to be performed daily [7][8]. Family members and caregivers play a fundamental role in equipment operation but may face overload and operational difficulties in the absence of adequate support [27][28]. Management of this dimension also involves adverse event reporting systems and structured communication channels between professionals, patients, and caregivers [5][29].

2) Normative and Regulatory Analysis

The analysis of normative, regulatory, and technical documents aimed to identify relevant technical and operational requirements for tool construction. The analyzed documents covered ANVISA regulations, national and international technical standards, and home

care documents, as presented in Table I. It should be noted that some of these references were originally developed for healthcare facilities and were considered in relation to the specificities of the home environment, considering its structural variability and the absence of an original clinical design. Technical manuals for medical equipment commonly used in home care were also consulted to support operational, environmental, and electrical criteria.

TABLE I. NORMATIVE AND REGULATORY DOCUMENTS ANALYZED

Analyzed Documents		
Category	***Document***	***Contribution to the Tool***
Home Care	RDC 11/2006 [10]	Establishes technical operating regulations for home care services (N1, N4).
	Ordinance GM/MS nº 825/2016 [11]	Redefines Home Care within the Brazilian Unified Health System (SUS) and updates authorized care teams.
	Ministry of Health Home Care Handbook [30] [31]	References for patient eligibility, caregiver role, multidisciplinary work, follow-up, and monitoring of home care.
Health Technology Management	RDC 509/2021 [32]	Governs health technology management in healthcare facilities Reference for the health technology management block at N4.
	ABNT NBR 15943: 2011 [33]	Guidelines for management programs of healthcare infrastructure equipment and health equipment.
Electrical Infrastructure	ABNT NBR 13534:2008 [34]	Requirements for electrical installations in healthcare facilities, adapted for home electrical safety assessment.
	ABNT NBR 5410:2004 [35]	Low-voltage electrical installations; general home electrical safety criteria.
	ABNT NBR 14136:2012 [36]	Standardization of outlets and plugs used for electrical infrastructure assessment.
Environmental Condition	ABNT NBR 10152:2017 [37]	Noise level – reference: ≤ 35dB for healthcare environments; quantitative parameter for N1 and N3.
	ABNT NBR 16401-2:2024 [38]	Thermal comfort: temperature 20–24 °C, humidity 40–60%; quantitative parameters for N1 and N3.
	ABNT NBR ISO/CIE 8995-1:2013 [39]	Reference for illuminance assessment; adopted as a reference criterion in the home care context. Minimum illuminance of 100 lux; quantitative parameter for N1 and N3.
Medical Devices	ABNT NBR IEC 60601-1-11: 2021 [12]	Specific requirements for electro-medical equipment used in home environments, supporting compatibility assessment between technology, user, and environment.
Data Protection	Law nº 13.709/2018 (LGPD) [40]	Reference for evaluating privacy, security, and data processing aspects in telemonitoring technologies and home automation integrated into home care.

B. Development of the home assessment tool

The application of the IEB-UFSC conceptual model made it possible to organize the tool criteria around the technology, infrastructure, and human resources pillars. Adapting these components to the home care context allowed the incorporation of aspects related to environmental conditions, technologies used in care, and the actors involved in care. Figure 3 presents the operational structure of the assessment tool.

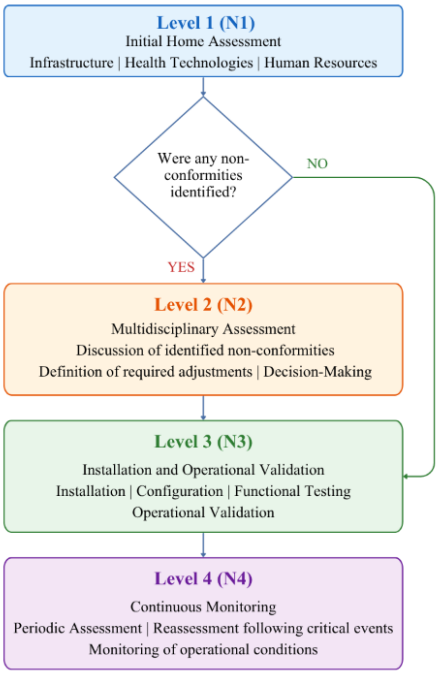

Fig. 3. Operational structure of the home assessment tool

N1 constitutes the initial screening stage and is applied to all homes prior to installation. It assesses physical infrastructure, health technologies, human resources, and quantitative environmental parameters, organized in four blocks (Table II). At the end of the assessment, the home is classified as adequate, with direct advancement to N3; deficient, triggering the N2 multidisciplinary assessment protocol; or critical, indicating the need to reassess the feasibility of implementation with N2. Conditions classified as critical are those with a potential to compromise the feasibility or continuity of care and therefore require immediate multidisciplinary assessment, whereas deficient conditions require corrective measures or further evaluation before progression.

Non-conformities are assessed qualitatively according to their potential to compromise the installation, operation, continuity of care, or safe use of the health technology. The tool does not use numerical scores or weighting; conditions requiring further analysis are directed to N2 for multidisciplinary assessment and definition of the appropriate course of action.

TABLE II. BLOCKS AND ITEMS ASSESSED AT LEVEL 1

Block	*Items to be Assessed*
Physical Infrastructure	Adequacy of physical space (RDC 11/2006); basic sanitation; outlets compliant with NBR 14136:2012; circuit breaker and surge protection device (SPD); electrical grounding; accessibility for wheelchair and stretcher; Wi-Fi or mobile network connectivity.
Health Technologies	Valid ANVISA registration; no active sanitary alerts; technical documentation available; compatibility of equipment with clinical profile and home conditions.
Human Resources	Patient's understanding of equipment use; physical or cognitive limitations of the caregiver; completion of formal training; availability of institutional training protocol.
Environmental Reference Parameters	Electrical voltage (V); reference temperature 20-24° C (NBR 16401-2:2024); reference relative humidity of 40-60% (NBR 16401-2:2024); reference noise level ⩽35 dB (NBR 10152:2017); reference illuminance ⩾100 lux (NBR ISO/CIE 8995-1:2013).

N2 is triggered when N1 identifies deficient or critical conditions requiring further assessment. It consists of a multidisciplinary assessment with mandatory participation from Clinical Engineering representatives, the care team, and service management. Operational responsibilities are shared among Clinical Engineering, the care team, and service management, with all parties participating in the assessment, discussion, decision-making, implementation, and follow-up of identified conditions according to their respective areas of expertise. The assessment is organized in three dimensions (Table III), resulting in a formal decision: installation authorized; authorized subject to adjustments; temporarily contraindicated; or contraindicated, with reassessment after corrective measures when required.

TABLE III. BLOCKS AND NON-CONFORMITIES ADDRESSED AT LEVEL 2

Block	*Non-Conformities Addressed*
Physical Infrastructure	Insufficient physical space; inadequate electrical installation; insufficient number of outlets; absence of grounding; power fluctuation; inadequate ventilation; humidity/infiltration; inadequate hygiene; access difficulties.
Health Technologies	Incompatibility between environment and technology; need for structural adjustment; risk to safe operation; need for complementary technology; risk of therapeutic interruption.
Human Resources	Family context for technology use; training needs; physical/cognitive limitations of the user; difficulty communicating in emergencies.

For example, if N1 identifies an electrical condition that may compromise the operation of a life-support device, the case is directed to N2 for multidisciplinary assessment and definition of corrective measures. After the required adjustments, the technology proceeds to N3 for reassessment and operational validation, while subsequent monitoring is performed through N4, with reassessment triggered when relevant changes or events occur.

N3 covers the installation, configuration, and validation of health technologies before the start of home care, structured in five assessment blocks (Table IV). In cases of home automation and telemonitoring, N3 also includes the assessment of sensors, connectivity, and the telemonitoring system. At the end of this stage, the home setup is classified as Validated, Pending, or Not Validated for service admission.

TABLE IV. BLOCKS AND ITEMS VERIFIED AT LEVEL 3

Block	*Items to be Assessed*
Physical Infrastructure – Physical Space	Room dimensions compatible with the planned technology; minimum clearance for installation and care; equipment access to the care environment.
Physical Infrastructure – Electrical Installation	Outlets near the installation site; voltage measurement per NBR 13534:2008; tested and documented energy backup with adequate autonomy; registration with the utility company as a priority customer; grounding verified; protection devices (SPD, RCD) installed.
Physical Infrastructure – Environmental Conditions	Reference temperature (NBR 16401-2); reference humidity 40–60% (NBR 16401-2); reference noise ≤ 35 dB (NBR 10152:2017); reference illuminance ≥ 100 lux (NBR ISO/CIE 8995-1); no electromagnetic interference identified.
Health Technology	Installation per manufacturer's technical specifications; clinical parameters configured and validated; alarm thresholds tested and documented; operation tested under real conditions; traceability recorded (serial number, date, initial configuration); contingency plan defined for life-support equipment.
Human Resources	Formal training completed for each device; practical competency assessed and recorded; educational materials available in the home; liability form signed by the responsible party.

N4 is intended for continuous monitoring after implementation and may be applied periodically or in response to events requiring reassessment of home conditions, technologies in use, or human resources involved. The assessment is organized in three blocks (Table V), and each item is classified as Compliant, Pending, or Non-Compliant, generating an action plan with responsible party, deadline, and priority.

TABLE V. BLOCKS AND ITEMS MONITORED AT LEVEL 4

Block	*Monitored Items*
Physical Infrastructure	General home conditions (space, hygiene, and ventilation); electrical installation without changes or damage; backup power system functional with maintained autonomy; correct disposal of healthcare waste.
Health Technologies	Equipment free of physical damage and in full operation; parameters and alarms configured per prescription; preventive maintenance performed according to the applicable maintenance program and manufacturer recommendations, with RDC 509/2021 used as a health technology management reference; accessories and supplies within expiration date; absence of recurring failures; no active sanitary alert or recall (ANVISA); adverse event records

Block	*Monitored Items*
	updated; telemonitoring functional (when applicable).
Human Resources	Caregiver present and without changes that compromise care; operational competence maintained; questions identified and clarified during the visit; communication channel with the care team active.

The developed tool integrates criteria related to infrastructure, health technologies, and human resources, organized in four progressive assessment levels. Grounded in the findings of the literature review, normative requirements, and the IEB-UFSC Clinical Engineering model, the tool organizes the assessment process from initial home screening to continuous monitoring of conditions relevant to the use of health technologies.

IV. Discussion

The transfer of technologies to the home environment introduces challenges related to safety, device performance, and the ability of both the environment and users to support their use. The literature indicates that physical infrastructure, environmental conditions, equipment usability, and user preparedness are important factors influencing the safety and effectiveness of home care [7][17][24][29]. In this context, the proposed tool seeks to systematize this assessment through criteria related to infrastructure, health technologies, and human resources.

Although the literature presents evidence on challenges related to infrastructure, medical devices, and human factors in home care, these elements are frequently addressed in isolation [6][7][17]. The findings of the review suggest that conditions affecting the safe use of health technologies may arise from the interaction among these components. For example, the availability of an appropriate technology does not by itself ensure safe care when structural limitations in the home compromise its installation or operation, or when caregivers lack the skills required for its use [28]. Therefore, the assessment tool was structured to consider technology, infrastructure, and human resources together, allowing conditions identified in one dimension to be considered in relation to the requirements of the others.

The tool was constructed by combining home care-specific documents, such as RDC 11/2006, with standards originally developed for healthcare facilities [10]. This approach was adopted because specific references for the technical assessment of home environments are limited, particularly regarding infrastructure and safety requirements. Requirements from these standards were considered as technical references and interpreted in relation to the structural variability of homes and the participation of non-professional users in care. For environmental conditions, the corresponding values were incorporated as reference parameters rather than rigid exclusion criteria. Deviations from these parameters are intended to indicate conditions requiring further assessment according to the technology involved, care requirements, and characteristics of the home.

This integrated approach is aligned with the principles of Clinical Engineering and Health Technology Management, fields that have been expanding their scope beyond traditional maintenance activities [4][9]. The Medical-Hospital Technology Management model developed at IEB-UFSC proposes a systemic view of health technology processes, considering the interaction between technology, infrastructure, and human resources as essential elements for the safety, reliability, and effectiveness of services [41]. Adapting this model to the home context allowed the incorporation of characteristics unique to this environment, such as the structural variability of homes, the active participation of patients, family members, and caregivers, and the limited availability of technical support [3][42]. These characteristics were incorporated into the proposed assessment structure, particularly through criteria addressing home infrastructure, technology–environment compatibility, caregiver competence, and conditions requiring reassessment. In this way, the IEB-UFSC model served as the conceptual basis for organizing the assessment criteria within the home care context.

Existing international approaches address several aspects of safety related to health technologies in the home. The Food and Drug Administration (FDA) provides guidance materials and checklists addressing the safe use and maintenance of medical devices, while Emergency Care Research Institute (ECRI) highlights risks associated with device use in home healthcare [13][43][44]. Other home assessment approaches focus on environmental hazards, functional performance, person-environment fit, and home modifications [14]. Home safety guidance also emphasizes continuous assessment, reassessment, and collaboration among patients, caregivers, and healthcare professionals [45]. Although these approaches address important components of home care safety, they differ in scope and in how assessment activities are organized.

In contrast, the proposed tool brings these dimensions together within a Health Technology Management process structured into four progressive levels. N1 performs initial screening of home conditions; N2 addresses conditions requiring multidisciplinary assessment; N3 focuses on installation and operational validation; and N4 establishes continued monitoring and reassessment. This organization links findings from infrastructure, technology, and human resources to successive decision and follow-up stages, providing an operational structure for documenting conditions and defining subsequent actions.

Despite its theoretical and normative foundation, the proposed tool has not yet undergone formal content validation or evaluation of reliability, usability, and operational applicability in real home care settings. The rapid review also did not include a formal methodological quality appraisal, which limits the assessment of the strength of the evidence synthesized. These aspects are important for determining whether the proposed criteria can be consistently interpreted and applied by different professionals and services. Existing home assessment instruments have been subjected to different reliability and validity assessments, demonstrating the relevance of these procedures for consolidating structured assessment tools

[46]. Therefore, future studies should include expert content validation, inter-rater reliability assessment, usability evaluation, and pilot application in home care services. These studies should also evaluate the time required for application, ease of completion, training needs, acceptability, and the tool's influence on the decision-making process among professionals from different home care services.

The proposed framework also incorporates elements that support future digital implementation, particularly through the assessment of sensors, connectivity, telemonitoring, alert management, and data protection. Future developments may include integration with electronic health records and decision-support platforms to expand data sharing and follow-up of home care conditions.

The development of the tool highlighted the importance of considering technological, environmental, and human factors together when assessing conditions for home care. Future research should expand the evidence base through multicenter studies and the development of indicators to evaluate the operational implications and potential clinical relevance of health technology management in the home environment.

V. CONCLUSIONS

This study aimed to develop a home assessment tool for health technology management from the perspective of Clinical Engineering. Grounded in scientific evidence, normative requirements, and the Medical-Hospital Technology Management conceptual model of IEB-UFSC, the tool was structured into four progressive assessment levels, encompassing aspects related to infrastructure, health technologies, and human resources involved in care.

The proposed tool organizes the assessment of home conditions throughout the implementation and follow-up stages of home care by integrating technology, infrastructure, and human resources into a single assessment structure. Its four progressive levels connect initial screening, multidisciplinary assessment, installation and operational validation, and continuous monitoring.

As a preliminary and theoretically grounded proposal, the tool has not yet undergone expert content validation, reliability or usability assessment, or application in real home care services. Therefore, future studies should include content validation, inter-rater reliability assessment, usability evaluation, and pilot application in real care settings to assess its applicability and operational performance. These studies may support the refinement of the assessment criteria and the further development of the tool for use in different home care contexts.

***Abstract*—This work presents an open-source software developed to automate the verification of infusion pump performance according to IEC 60601-2-24:2012. By integrating real-time data acquisition from an analytical balance with automated data processing, the software generates start-up graphs and trumpet curves, eliminating manual spreadsheet calculations. Key features include configurable sampling rates, automatic data storage, and adaptive visualization for flow rates with deviations exceeding the standard plotting range. Experimental validation demonstrated that the proposed system simplifies the testing workflow, reduces manual processing, and facilitates the analysis of infusion pump performance. The software provides a practical tool for post-market surveillance and research applications involving infusion pump accuracy.**

***Index Terms*—Infusion pumps, accuracy, post-market surveillance, automated testing, measurement uncertainty.**

I. Introduction

The accuracy of medical devices used in intensive care units (ICUs) is crucial for patient safety and treatment effectiveness. Therefore, robust regulatory systems and appropriate measurement capabilities are required to monitor the performance of medical devices throughout their operational lifetime.

Over the past decades, medical device regulation has evolved considerably [1], [2]. Regulatory authorities establish requirements that manufacturers must satisfy to demonstrate the safety and performance of medical devices before market authorization [2].

However, regulatory oversight does not end after market authorization. Medical devices must also be monitored during their use in real-world environments through activities commonly referred to as post-market surveillance (PMS) [1]. PMS includes the systematic collection and evaluation of information concerning device performance, safety, and potential failures.

The importance of PMS and maintenance of medical devices became particularly evident during the COVID-19 pandemic, which exposed vulnerabilities in the availability, maintenance, and performance monitoring of medical equipment. Regulatory authorities have consequently established specific requirements and recommendations for post-market surveillance activities [3], [4].

Medical device failures and inappropriate device use can contribute to adverse events in intensive and neonatal care. Reported problems include equipment failures, incorrect device settings, inadequate alarm configuration, and insufficient maintenance [5], [6]. A study conducted in the United Kingdom involving 1,021 incidents associated with medical equipment in an intensive care unit reported 537 incidents related to equipment failure and 358 associated with incorrect staff settings. Harm was reported in 26% of equipment-failure incidents and 39% of incidents involving incorrect settings [7].

Process improvement strategies may also contribute to reducing errors associated with infusion devices. In a study conducted in an intensive care department in the Netherlands, a Lean-based quality improvement approach involving 1,748 infusion pumps reduced reported infusion pump-related errors from 17.7% to 2.3% [8].

Although human errors can be addressed through appropriate training and awareness, device-related errors require appropriate maintenance, calibration, and performance verification. Regular verification is particularly important for infusion pumps because deviations in delivered flow may affect drug administration and consequently patient treatment.

Previous studies have demonstrated that infusion pump performance may depend on factors such as pump design, operating conditions, accessories, and flow rate [10]. Mechanical and electromechanical characteristics of the pumping mechanism can also affect the stability and accuracy of fluid delivery.

Infusion pumps are widely used in intensive care environments and are therefore required to provide safe, reliable, and sufficiently accurate fluid delivery. Over-infusion may result in excessive drug administration and potentially cause toxicity, whereas under-infusion may result in insufficient treatment [13]–[15].

TABLE I
SPECIFICATIONS OF THE ANALYTICAL BALANCE USED IN THE EXPERIMENTS.

Characteristic	Value
Maximum capacity	220 g
Readability	0.1 mg
Repeatability	±0.1 mg
Linearity	±0.2 mg
Stabilization time	approximately 2 s
Calibration	Internal and external
Pan diameter	80 mm
Operating temperature	15 °C to 30 °C

In this context, automated testing tools may facilitate the implementation of systematic post-market performance verification. Automation can reduce manual data processing, standardize calculations, and facilitate the analysis of a large number of devices.

Therefore, this article presents an open-source software developed to automate the acquisition, processing, and analysis of gravimetric measurements obtained during infusion pump accuracy tests according to IEC 60601-2-24:2012 [9]. The software integrates data acquisition from an analytical balance, automated calculations, spreadsheet generation, and graphical visualization of start-up behavior and trumpet curves.

The source code is openly available at:
https://github.com/Mathis-moiss/Infusion-pumps-testing-software.

II. MATERIALS AND METHODS

A. Experimental Setup

The experimental setup consisted of an infusion pump, an analytical balance, and the software developed in this study. The software was designed to support both volumetric infusion pumps using peristaltic mechanisms and syringe pumps.

1) Infusion Pump: A volumetric infusion pump equipped with a linear peristaltic mechanism (Infusomat Compact, B. Braun, Germany) was used to verify the functionality of the software.

2) Analytical Balance: An analytical balance (BP221S, Sartorius, Germany) with a maximum capacity of 220 g was used for the gravimetric measurement of the infused liquid. The balance has a readability of 0.1 mg and was operated according to the manufacturer's instructions.

The main specifications of the analytical balance are presented in Table I.

3) Software: The software was developed in Python version 3.12. It performs data acquisition, processing, analysis, visualization, and automatic storage of the experimental results.

The software communicates directly with the analytical balance through a serial communication interface and records the mass measurements at the selected sampling interval.

B. IEC 60601-2-24 Standard

The experimental procedure was based on IEC 60601-2-24:2012, which specifies particular requirements for the basic safety and essential performance of infusion pumps and controllers [9].

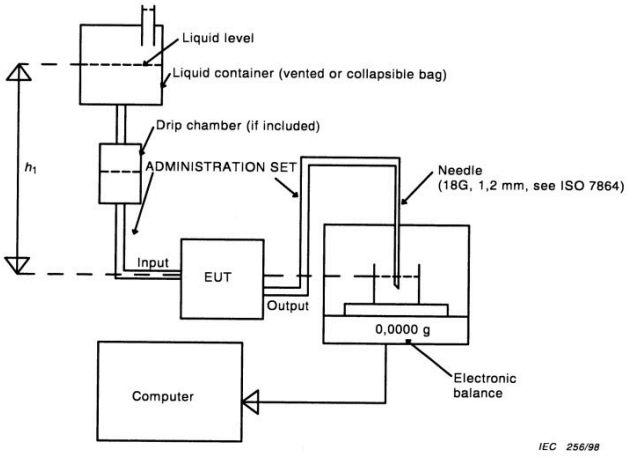

Fig. 1. Experimental apparatus for testing volumetric infusion pumps. Adapted from IEC 60601-2-24:2012 [9]. EUT: equipment under test.

The standard establishes requirements for the evaluation of flow accuracy and specifies the experimental arrangement, acquisition procedure, data analysis, and graphical representation of the results.

Figure 1 illustrates the experimental arrangement used for volumetric infusion pumps.

The software implements the calculations required to obtain the start-up graph, trumpet curves, and overall mean percentage flow errors.

1) Start-Up Graph: The start-up graph represents the flow-rate behavior throughout the initial period of the test.

For each sampling interval, the average flow rate Q_i is calculated from the difference between two consecutive mass measurements according to

$$Q_i = \frac{60(W_i - W_{i-1})}{Sd}(mL/h) \tag{1}$$

where Q_i is the calculated flow rate in mL/h, W_i and W_{i-1} are consecutive mass measurements in $T_x(g)$, S is the sampling interval in minutes, and d is the liquid density in g/mL.

The index i represents the sampling interval, with

$$i = 1, 2 \ldots T_0/S \tag{2}$$

For the start-up graph, the analysis period T_0 corresponds to the first 120 min of the test.

The graph axes follow the requirements of IEC 60601-2-24:2012. The flow-rate axis ranges from $-0.2r$ to $2r$, where r is the programmed flow rate, with increments of $0.2r$. The time axis ranges from 0 to 120 min, with increments of 10 min.

2) Trumpet Curves: Infusion pumps may deliver fluid in a pulsatile manner. Consequently, short-term flow-rate measurements may exhibit substantial deviations from the programmed flow rate, whereas longer observation periods generally provide more stable average values.

Trumpet curves represent the maximum positive and negative percentage errors obtained for different observation-window durations.

The observation-window durations considered:

$$P \in \{2, 5, 11, 19, 31\} \text{ min.} \tag{3}$$

Three analysis periods were considered when applicable: T_0, corresponding to the first 120 min; T_1, corresponding to the second hour of the test; and T_2, corresponding to the last hour of the test.

For an observation window of duration P, the number of windows within an analysis period T_x.

$$m = \left\lfloor \frac{T_x - P}{S} \right\rfloor + 1 \tag{4}$$

where m is the maximum number of observation windows, T_x is the analysis period specified as T_0, T_1, or T_2; P is the duration of the observation window, and S is the sampling interval in minutes.

The maximum positive percentage error:

$$E_{p(\max)} = \max_{j=1,\ldots,m} \left[\frac{S}{P} \times \sum_{i=j}^{j+\frac{P}{S}-1} 100 \times \left(\frac{Q_i - r}{r} \right) \right] (\%) \tag{5}$$

and the maximum negative percentage error:

$$E_{p(\min)} = \min_{j=1,\ldots,m} \left[\frac{S}{P} \times \sum_{i=j}^{j+\frac{P}{S}-1} 100 \times \left(\frac{Q_i - r}{r} \right) \right] (\%) \tag{6}$$

The overall mean percentage flow errors for the analysis period T_1 and T_2:

$$Q_a = \frac{60(W_j - W_k)}{T_1 d} (mL/h) \tag{7}$$

and

$$Q_b = \frac{60(W_j - W_k)}{T_2 d} (mL/h) \tag{8}$$

where W_j and W_k are the final and initial mass measurements of T_1, and T_2 respectively.

The corresponding overall mean percentage flow errors are

$$A = \frac{100(Q_a - r)}{r} (\%) \tag{9}$$

and

$$B = \frac{100(Q_b - r)}{r} (\%) \tag{10}$$

Here, r is the programmed flow rate in mL/h, while A and B are expressed as percentages.

For the trumpet curves, the standard graphical representation uses a vertical axis ranging from -15% to $+15\%$, with increments of 5%, and a horizontal axis ranging from 0 to 31 min.

C. Measurement Uncertainty

Measurement uncertainty was considered in the evaluation of the gravimetric flow-rate measurement. The primary measured quantity used to calculate the flow rate is the mass difference between two consecutive measurements.

For a single sampling interval, the flow-rate measurand:

$$Q = \frac{60(W_j - W_k)}{Td} (mL/h) \tag{11}$$

Assuming that the uncertainties associated with the two mass measurements are independent, the combined standard uncertainty of Q can be estimated using the law of propagation of uncertainty:

$$u^2(Q) = \left(\frac{\partial Q}{\partial W_k} u(W_k) \right)^2 + \left(\frac{\partial Q}{\partial W_j} u(W_j) \right)^2 \tag{12}$$

The corresponding sensitivity coefficients:

$$\frac{\partial Q}{\partial W_k} = -\frac{60}{Td} \qquad \frac{\partial Q}{\partial W_j} = \frac{60}{Td} \tag{13}$$

Assuming equal standard uncertainties for the two mass measurements:

$$u(W_k) = u(W_j) = u(W) \tag{14}$$

Eq. (12) becomes:

$$u(Q) = \frac{60\sqrt{2}}{Td} u(W) \tag{15}$$

The standard uncertainty associated with the balance measurement was obtained from its calibration certificate. The certificate reports an expanded uncertainty of 0.0002 g with a coverage factor of $k = 2$.

$$u(W) = \frac{U(W)}{k} = \frac{0.0002\,\text{g}}{2} = 0.0001\,\text{g} \tag{16}$$

Thus, the uncertainty associated with the analytical balance can be propagated to the calculated flow rate using Eq. (15).

The uncertainty analysis was restricted to the gravimetric flow-rate measurement for T_1 and T_2 and was not extended to the extremal values of the trumpet curves. Consecutive flow-rate estimates Q_i are calculated from overlapping mass measurements. For example, Q_i and Q_{i+1} share the mass measurement W_i and are therefore not statistically independent. Consequently, a rigorous uncertainty evaluation of $E_{p(\max)}$ and $E_{p(\min)}$ would require the consideration of covariance among the underlying measurements, as well as the statistical treatment associated with selecting the maximum and minimum values from multiple observation windows. This analysis is beyond the scope of the present software-development study.

The sampling interval was controlled by the data-acquisition software, and the liquid density was treated as a controlled input in the present simplified model. Therefore, timing and density contributions were not included in the uncertainty estimate reported here.

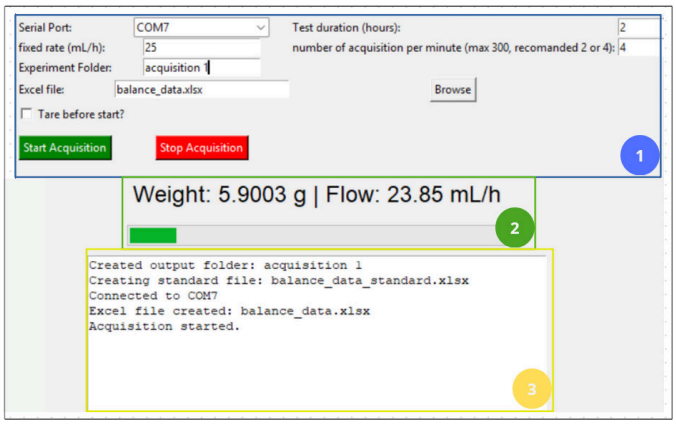

Fig. 2. Software graphical user interface.

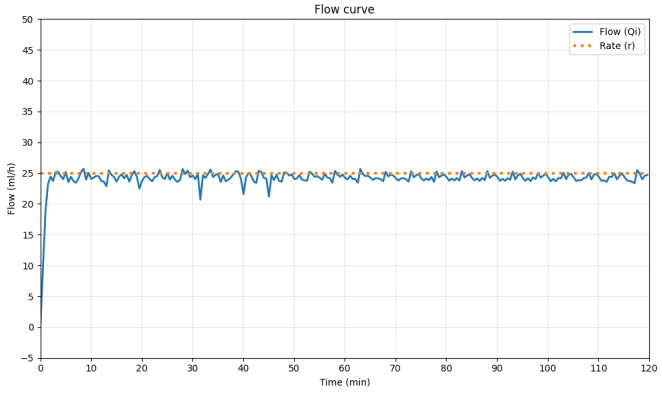

Fig. 3. Start-up graph generated by the software for a programmed flow rate of 25 mL/h.

III. Results

A. Graphical User Interface

Figure 2 presents the software graphical user interface. The interface comprises three main areas: (1) a configuration panel for defining the acquisition parameters; (2) a real-time monitoring area displaying the progress of the acquisition, the measured mass, and the calculated flow rate; and (3) a status window providing information concerning the acquisition process and potential errors.

B. Start-Up Graphs and Trumpet Curves

After completion of the acquisition, the software automatically calculates, plots, and saves the results.

The start-up graph generated by the software is presented in Fig. 3. The trumpet curves are presented in Fig. 4. The infusion pump was programmed at 25 mL/h during the test.

C. Spreadsheet Generation

The software automatically generates a spreadsheet containing the data acquired during each test.

The spreadsheet includes the following parameters: time in hours, time in minutes, mass W_i in grams, calculated flow rate Q_i in mL/h, and programmed flow rate r in mL/h.

The generated data provide a complete record of the acquisition and were used for software verification and validation. The files may also support subsequent verification activities and independent review of the calculations.

D. Sampling Rate Assessment

An excessively high sampling rate caused the data acquisition process to exceed the data transmission capability of the analytical balance. This resulted in intermittent zero readings and consequently generated unrealistic flow-rate values.

A dichotomy-based procedure was used to determine the maximum sampling rate that could be reliably handled by the communication interface. Tests were initially performed at high sampling frequencies and progressively reduced until continuous data acquisition was obtained.

A maximum operational acquisition rate of 300 samples per minute was identified for continuous data transmission without zero-value artifacts, as illustrated in Table II.

Although the communication interface allowed acquisition rates substantially higher than the sampling rate required for the standard analysis, very high sampling frequencies produced flow-rate values that were not representative of the pump's short-term delivery behavior. At very short intervals, the mass difference between consecutive readings approaches the resolution and repeatability limits of the balance, amplifying fluctuations in the calculated flow rate.

Therefore, although the software permits flexible sampling configurations, a sampling rate of two samples per minute was maintained for analyses following IEC 60601-2-24:2012. Higher sampling rates, such as four or six samples per minute, may be useful for exploratory or research applications, provided that their influence on the calculated flow-rate variability is considered.

Figure 5 illustrates the flow-rate behavior obtained with six samples per minute.

IV. Discussion

A. Analytical Balance Communication

The software successfully communicates with the analytical balance to acquire and record mass measurements. However, bidirectional communication was not implemented. Consequently, commands such as remote tare cannot currently be sent from the software to the balance.

The communication module was developed specifically for the balance model used in this study. Different balance models may employ different ASCII command sets or communication protocols. Therefore, modifications to the communication module may be required when another balance model is used.

Future development should include a configurable communication layer that allows the user to select the balance model and communication protocol without modifying the main software code.

B. Data Acquisition

Particular attention was given to the organization and accessibility of the acquired data. The software automatically

(b) Acquisition at 300 samples per minute.

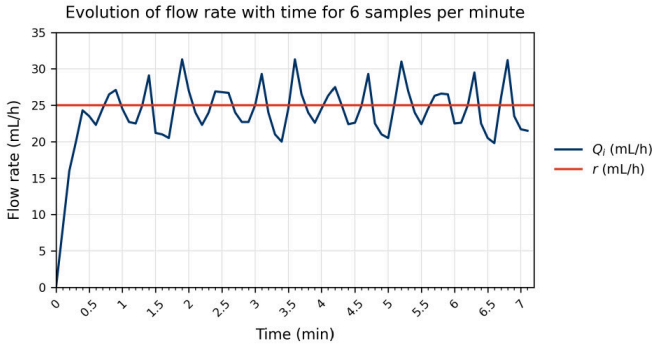

Fig. 5. Flow rate over time obtained with six samples per minute. Q_i represents the calculated flow rate, and r is the flow rate adjusted by the operator.

stores the measurements in spreadsheet format, including the acquisition time, mass measurements, programmed flow rate, and calculated flow rate.

The mass measurements are acquired directly from the analytical balance and timestamped by the acquisition software. The programmed infusion rate r is defined by the user, whereas the flow rate Q_i is calculated automatically according to Eq. (1).

After completion of the acquisition period, the spreadsheet is automatically saved and organized in a dedicated folder. This workflow reduces the amount of manual data handling required during infusion pump testing.

The software also allows the user to configure sampling rates according to the intended application. When a sampling rate different from the two samples per minute used in the IEC analysis is selected, the software can retain the complete data

set while also generating a data set adjusted to the standard sampling interval.

This feature allows the same acquisition to support both normative testing and exploratory research without requiring a new experiment.

C. Data Analysis

The calculations specified by IEC 60601-2-24:2012 were implemented directly in the software. These calculations generate the start-up graph, trumpet curves, and overall mean percentage flow errors.

The automated implementation reduces the possibility of transcription and spreadsheet-calculation errors and provides a consistent analysis procedure across tests.

An additional feature concerns the visualization of trumpet curves. IEC 60601-2-24:2012 specifies a fixed graphical range of $\pm 15\%$. However, experimental results may exceed this range, making part of the curve difficult to visualize.

For this reason, the software dynamically adjusts the vertical axis when the calculated errors exceed $\pm 15\%$. The scale is adjusted in increments of 5% according to the maximum absolute deviation.

When both $E_{p(\max)}$ and $E_{p(\min)}$ remain within $\pm 15\%$, the standard scale is maintained. When the deviation exceeds this range, the software expands the axis to the next appropriate multiple of 5%.

This adaptive visualization does not modify the calculated values; it only improves their graphical representation.

D. Measurement Uncertainty and Scope

The uncertainty analysis was intentionally limited to the gravimetric flow-rate measurement. The balance contribution was propagated to Q at T_1 and T_2 using the law of propagation of uncertainty, based on the expanded uncertainty reported in the calibration certificate.

The trumpet-curve analysis involves multiple overlapping observation windows. Since consecutive Qi values share mass measurements, their uncertainties cannot be treated as statistically independent without accounting for covariance. Furthermore, $E_{p(\max)}$ and $E_{p(\min)}$ are selected as extrema from a set of observation windows, introducing an additional statistical aspect to their uncertainty evaluation.

For these reasons, the present study does not report uncertainty values for the extremal trumpet-curve errors. This approach avoids assigning a simplified uncertainty value that would not adequately represent the correlation structure of the measurements and the statistical selection of the extrema.

A complete uncertainty evaluation of the trumpet-curve quantities may be addressed in future work using a covariance-based model and an appropriate statistical treatment of the extremum-selection process.

E. Software

The software was developed to simplify and accelerate infusion pump performance testing. The user can define important acquisition parameters, including the programmed flow rate, test duration, and sampling frequency.

The flexibility in sampling configuration was intentionally implemented to support future research applications in which higher temporal resolution may be desirable. Nevertheless, when the objective is strict compliance with the IEC 60601-2-24:2012 analysis procedure, the sampling configuration specified by the standard should be maintained.

The open-source nature of the software also allows researchers and clinical engineering laboratories to inspect, adapt, and extend the implementation according to their experimental requirements.

The source code is available at:
https://github.com/Mathis-moiss/Infusion-pumps-testing-software.

V. Conclusion

This work presented the development and experimental verification of an open-source software designed to automate the acquisition, processing, and analysis of infusion pump accuracy tests according to IEC 60601-2-24:2012.

The proposed system integrates communication with an analytical balance, automated data acquisition, flow-rate calculation, spreadsheet generation, and graphical visualization of start-up behavior and trumpet curves.

The implementation reduces manual data processing and provides a standardized workflow for infusion pump performance testing. The time saved by researchers using the program was approximately forty to sixty minutes per infusion pump tested, compared to the previous version of the program, which was built in LabVIEW, in addition to the convenience of being able to use the program on any computer. The software also allows flexible sampling configurations, making it suitable for both normative testing and exploratory research.

The current implementation is limited by the unidirectional communication with the analytical balance and by the dependence of the communication module on the specific balance model. Bidirectional communication, including remote tare and additional balance models, represents an important direction for future development.

The proposed software provides a practical tool for infusion pump performance verification and can support post-market surveillance activities in clinical engineering laboratories. The software is currently being used by the Normative Testing Division of the Biomedical Engineering Laboratory at the Escola Politécnica of the University of São Paulo (DEN–LEB/EPUSP).

***Resumo*—O mapeamento de parques tecnológicos e o acompanhamento do ciclo de vida de equipamentos médicos constituem atividades estratégicas da Engenharia Clínica para subsidiar o planejamento em saúde. Este trabalho apresenta uma investigação de diagnóstico estrutural e exploratório baseado em bancos de dados administrativos e parâmetros normativos do parque de radiodiagnóstico e medicina nuclear em Araguaína, Tocantins, contrapondo a capacidade instalada declarada aos parâmetros geodemográficos de acessibilidade assistencial das Portarias SAS/MS nº 1.101/2002 e nº 1.631/2015. A metodologia baseou-se na coleta de dados quantitativos (dezembro/2025) via Cadastro Nacional de Estabelecimentos de Saúde (CNES), validados junto à Comissão Nacional de Energia Nuclear (CNEN) para a modalidade de Gama Câmara, além de indicadores demográficos do IBGE. Os resultados evidenciam superávit quantitativo de equipamentos declarados frente às estimativas teóricas de planejamento para a cidade. Contudo, a análise geográfica revela que o fluxo macroregional captado pelo polo ultrapassa os raios de cobertura física idealizados. No panorama estadual, Araguaína centraliza 17,50% do inventário declarado do Tocantins, destacando-se na alta complexidade, na qual retém 31,25% dos mamógrafos, 25,00% dos densitômetros e 24,07% dos tomógrafos computadorizados. Sob o aspecto regulatório, identificou-se uma assimetria de informações: o CNES registra quatro dispositivos de Gama Câmara no município, enquanto a CNEN autoriza a operação de apenas uma instalação. Com isso, conclui-se que os dados coletados evidenciam um aparente excedente quantitativo de equipamentos em relação à população municipal. No entanto, esse achado pode ocultar pressões sobre o sistema de saúde associadas à função de Araguaína como centro de referência macrorregional. Nesse sentido, recomenda-se que estudos futuros incorporem indicadores capazes de avaliar se o aparente superávit de equipamentos se traduz, efetivamente, em maior acesso da população aos serviços de saúde.**

I. Introdução

A integração de métodos de diagnóstico por imagem é fundamental na prática médica contemporânea, possibilitando diagnósticos mais rápidos, precisos e a detecção precoce de diversas patologias, o que impacta diretamente na escolha terapêutica e na gestão de recursos em saúde [1], [2]. A disponibilidade e a distribuição adequada desses serviços, que utilizam tanto radiação ionizante (como raios-X, tomografia computadorizada, mamografia) quanto não ionizante (como ultrassonografia e ressonância magnética), são cruciais para garantir o acesso equitativo da população a cuidados de saúde de qualidade.

A relevância deste tema é validada por estudos que demonstram a radiologia diagnóstica como ferramenta indispensável na redução da mortalidade por doenças cerebrovasculares e neoplasias [3]. Nesse sentido, o mapeamento da distribuição geográfica e da infraestrutura declarada dos serviços de diagnóstico por imagem assume grande relevância para o planejamento em saúde pública. Autores demonstram a importância de conhecer a distribuição de equipamentos e a frequência de exames para analisar a adequação da oferta à demanda populacional, visto que esse tipo de levantamento permite identificar disparidades regionais, orientar investimentos, otimizar a alocação de recursos e avaliar a infraestrutura tecnológica disponível [4], [5].

No âmbito da Engenharia Biomédica, esse tipo de trabalho equipara-se a uma das principais atribuições do engenheiro clínico, que consiste em atuar diretamente na gestão do parque tecnológico institucional por meio do cadastro dos equipamentos existentes, mapeando informações essenciais como o custo de aquisição, o histórico técnico, a localização setorial, o registro de falhas e o tempo de utilização [6]. Ademais, a Engenharia Clínica acompanha o ciclo de vida dos equipamentos médico-assistenciais, atividade considerada determinante para garantir a segurança operacional e a otimização dos recursos hospitalares [7], [8].

Nesse sentido, estudos destinados ao mapeamento dos equipamentos de diagnóstico por imagem em regiões interioranas brasileiras constituem instrumentos relevantes para o planejamento da saúde pública, pois permitem caracterizar a distribuição territorial, a disponibilidade e a concentração do parque tecnológico. O levantamento sistemático do parque de diagnóstico por imagem fornece subsídios para reconhecer desigualdades de oferta, áreas potencialmente desassistidas, duplicidades de recursos e dependências intermunicipais. Constata-se, contudo, que a região Norte apresenta uma carência de tais estudos, em virtude da escassez de produção científica voltada para este campo de atuação, mesmo considerando o grande impacto social e econômico da matéria.

Diante desse panorama, a cidade de Araguaína, situada no Centro-Norte do estado do Tocantins, surge como um polo regional que transcende os limites municipais. Como sede

administrativa e centro de referência de alta complexidade, Araguaína recebe uma expressiva demanda por diagnósticos especializados proveniente de quase metade do território estadual, além de estados vizinhos [9]. Essa centralidade foi reforçada legalmente em 2026 com a institucionalização de sua Região Metropolitana, que estabeleceu uma estrutura de integração de larga escala abrangendo 65 municípios [10].

Portanto, o presente trabalho tem como objetivo realizar o levantamento e a classificação de dados referentes ao parque tecnológico de diagnóstico por imagem de Araguaína, avaliando sua infraestrutura face ao seu papel de polo na rede de saúde do Tocantins. Para tanto, realizou-se o mapeamento do contingente de equipamentos e instalações de Medicina Nuclear na modalidade de Gama Câmara em bases de dados federais — como o Cadastro Nacional de Estabelecimentos de Saúde (CNES) [11] e a Comissão Nacional de Energia Nuclear (CNEN) [12] —, seguido de uma análise comparativa entre os parâmetros estimativos teóricos demográficos e geográficos estabelecidos pelas Portarias SAS/MS nº 1.101/2002 e nº 1.631/2015 do Sistema Único de Saúde (SUS) [13], [14].

Cabe destacar que este trabalho não tem como objetivo interpretar os dados com base em indicadores como condição operacional, carga de trabalho, tempo de indisponibilidade, qualificação da equipe, infraestrutura física, manutenção e produção de exames. Tais aspectos deverão ser examinados em pesquisas posteriores, fundamentadas na análise espacial desenvolvida neste estudo. Desse modo, espera-se que a identificação realizada, em um contexto regional ainda pouco investigado, forneça subsídios iniciais para iniciativas voltadas ao desenvolvimento regional.

II. Objetivos

A. Objetivo Geral

Realizar uma análise da infraestrutura de serviços de diagnóstico por imagem na cidade de Araguaína, Tocantins, por meio do mapeamento sistematizado de parques tecnológicos declarados e regulamentados.

B. Objetivos Específicos

1) Mapear o inventário quantitativo e o perfil tecnológico dos dispositivos de diagnóstico por imagem declarados em Araguaína, contrapondo-os com o panorama geral do estado do Tocantins;
2) Aferir a adequação da capacidade instalada local frente às diretrizes geodemográficas das Portarias SAS/MS nº 1.101/2002 e nº 1.631/2015;
3) Avaliar a regularidade operacional das instalações de Medicina Nuclear com o equipamento Gama Câmara mediante o cruzamento de dados do CNES e da CNEN.

III. Materiais e Métodos

A presente investigação iniciou-se com um levantamento de dados quantitativos acerca dos equipamentos de diagnóstico por imagem e de medicina nuclear em Araguaína, estabelecendo uma análise comparativa com o panorama do estado do Tocantins. A coleta dos dados utilizou como fonte o Cadastro Nacional de Estabelecimentos de Saúde (CNES) [11], extraídos na competência de dezembro de 2025.

Visando correlacionar o número de equipamentos declarados pelas instituições de saúde com a realidade sociodemográfica a partir de parâmetros nacionais de cobertura assistencial, integraram-se indicadores extraídos do portal "Cidades" do Instituto Brasileiro de Geografia e Estatística (IBGE) [15]. Foram consideradas as projeções populacionais para o ano de 2025; contudo, para a análise da cobertura dos mamógrafos, utilizou-se o contingente de mulheres na faixa etária de 40 a 59 anos registrado no Censo de 2022, uma vez que não existem projeções oficiais para 2025 estratificadas simultaneamente por sexo e faixa etária no nível municipal. A utilização conjunta dessas bases, referentes a períodos distintos, constitui uma limitação metodológica decorrente da indisponibilidade de dados oficiais mais recentes com o nível de desagregação necessário.

Adicionalmente, realizou-se uma consulta ao guia de instalações autorizadas da Comissão Nacional de Energia Nuclear (CNEN) [12] para validar a regularidade dos serviços de Medicina Nuclear atuantes na região.

Para a classificação e sistematização do inventário, os dispositivos foram segregados nas categorias "Existentes", "Em Uso", "Existentes no SUS" e "Em uso no SUS", aplicando-se uma taxonomia adaptada de trabalhos anteriores [4]. Sob essa perspectiva, cumpre destacar que a classe "Existentes" representa o total de todo parque tecnológico mapeado, funcionando como o indicador bruto que engloba as demais categorias, as quais operam como subconjuntos analíticos. A classificação abrangeu as seguintes modalidades cadastradas no CNES:

- Raio-X: englobando equipamentos de "Raios X de até 100 mA", "Raios X de 100 a 500 mA" e "Raios X mais de 500 mA";
- Fluoroscopia: incluindo equipamentos de "Raios X com Fluoroscopia";
- Densitometria: incluindo equipamentos de "Raios X para Densitometria Óssea";
- Angiógrafo: incluindo equipamentos de "Raios X para Hemodinâmica";
- Mamógrafo: englobando aparelhos com "Mamógrafo com Comando Simples", " Mamógrafo com Estereotaxia" e "Mamógrafo Computadorizado";
- Ultrassonografia: englobando "Ultrassom Convencional", "Ultrassom Ecógrafo" e "Ultrassom Doppler colorido";
- Tomografia: incluindo equipamentos de "Tomografia Computadorizada";
- Ressonância: incluindo equipamentos de "Ressonância Magnética";
- Gama Câmara: dedicada à análise individualizada da infraestrutura de Medicina Nuclear, correlacionando os registros do CNES com as autorizações da CNEN.

Paralelamente, desenvolveu-se uma matriz de dados dedicada à estimativa teórica de equipamentos para o município de Araguaína conforme as diretrizes da Portaria SAS/MS nº 1.631/2015 [14] (para tomógrafo, ressonância magnética,

mamógrafo e ultrassom) e da Portaria SAS/MS nº 1.101/2002 [13] (para radiologia simples e densitometria óssea).

Sob a óptica metodológica, a Portaria SAS/MS nº 1.631/2015 representou um avanço substancial em relação à de 2002, visto que deixou de considerar apenas o cálculo numérico populacional para integrar critérios de regionalização e acessibilidade geográfica, tais como o raio de atendimento físico e o tempo de deslocamento espacial.

Todavia, a utilização combinada de ambas as normativas justifica-se pela ausência de parâmetros específicos para tecnologias de menor complexidade no documento de 2015. Assim, a incorporação da Portaria nº 1.101/2002 viabilizou a análise dos equipamentos de radiologia simples (Raios X) e da densitometria óssea, respaldando-se em sua relevância histórica e técnica. Para as modalidades não contempladas por ambos os documentos, não foram calculadas estimativas por ausência de parâmetros oficiais. Os modelos matemáticos e critérios geográficos aplicados para cada modalidade são descritos a seguir:

A. Tomógrafo Computadorizado

Conforme os parâmetros de planejamento da Portaria SAS/MS nº 1.631/2015 [14], o dimensionamento adota a modelagem demográfica de um equipamento para cada grupo de 100 mil habitantes, associado a um critério de regionalização que delimita um raio de atendimento de 75 km para o dispositivo. O modelo matemático é expresso por:

$$\mathrm{U}_{\text{Tomógrafo}} = \frac{\text{População Total}}{100.000} \tag{1}$$

B. Ressonância Magnética

Orientados pela Portaria SAS/MS nº 1.631/2015 [14], para os critérios de acessibilidade territorial impõe-se um raio de cobertura de até 30 km ou um tempo máximo de deslocamento de 60 minutos. Para a modelagem numérica, primeiramente é calculada a necessidade anual esperada de procedimentos (N_{RM}), considerando o indicador epidemiológico de 30 exames para cada 1.000 habitantes ao ano:

$$N_{\text{RM}} = \frac{\text{População Total} \times 30}{1.000} \tag{2}$$

A estimativa do contingente de equipamentos (U_{RM}) é obtida dividindo-se a demanda anual calculada pela produtividade média padrão estabelecida para o dispositivo, que é de 5.000 exames/ano:

$$U_{\text{RM}} = \frac{N_{\text{RM}}}{5.000} \tag{3}$$

C. Mamógrafo

De acordo com as diretrizes da Portaria SAS/MS nº 1.631/2015 [14], o planejamento geográfico dos equipamentos de mamografia estabelece uma distância de 60 km ou um tempo máximo de viagem de 60 minutos. Para a estimativa do número de equipamentos, inicialmente, efetua-se o cálculo do número de mamografias anuais necessárias (N_{M}) para a população de mulheres na faixa etária de 40 a 59 anos, conforme os seguintes critérios:

- Mulheres de 40 a 49 anos: 10% para indicação diagnóstica (D_1) e 10% para outras indicações (O_u);
- Mulheres de 50 a 59 anos: 50% para indicação de rastreamento (R_1) e $8,9\%$ para indicação diagnóstica (D_2).

$$N_{\text{M}} = D_1 + D_2 + R_1 + O_u \tag{4}$$

Assim, o número de equipamentos necessários ($U_{\text{Mamógrafo}}$) é determinado a partir da produtividade média anual de referência definida pela portaria, sendo 6.758 exames/ano:

$$U_{\text{Mamógrafo}} = \frac{N_{\text{M}}}{6.758} \tag{5}$$

D. Ultrassom

A estimativa fundamenta-se nos indicadores de produção da Portaria SAS/MS nº 1.631/2015 [14]. Diferente das modalidades citadas anteriormente, a normativa não estabelece um raio geográfico ou tempo de deslocamento padronizados para o ultrassom convencional. Desse modo, para a estimativa de equipamentos, primeiramente é calculada a necessidade anual de exames (N_{US}), que assume a razão de 150 exames para cada 1.000 habitantes ao ano:

$$N_{\text{US}} = \frac{\text{População Total} \times 150}{1.000} \tag{6}$$

Logo, a quantidade necessária teórica de equipamentos ($U_{\text{Ultrassom}}$) é calculada com base na produtividade anual de referência por dispositivo, estipulada em 3.024 exames:

$$U_{\text{Ultrassom}} = \frac{N_{\text{US}}}{3.024} \tag{7}$$

Nota-se que os parâmetros supracitados referem-se à modalidade de diagnóstico descrita como "Ultrassom Convencional", constando também no mesmo documento a categoria "Ultrassom Obstétrico" [14]. Porém, a base de dados do CNES estratifica os dispositivos de ultrassonografia em três categorias distintas: "Ultrassom convencional", "Ultrassom ecógrafo" e "Ultrassom com Doppler colorido". A aparente divergência de identificação do equipamento entre a Portaria SAS/MS nº 1.631/2015 [14] e a base de dados do CNES ocorre em função de abordagens distintas. Enquanto a Portaria [14] trata de parâmetros assistenciais e tipologia de exames, a base do CNES foca no inventário físico de equipamentos. Portanto, no presente trabalho, optou-se pela consolidação do contingente tecnológico em uma única categoria analítica de ultrassonografia, semelhantemente à metodologia adotada em levantamentos prévios [4].

E. Aparelho de Radiologia Simples (Raio-X)

O dimensionamento adota os critérios quantitativos da Portaria SAS/MS nº 1.101/2002 [13]. Por se tratar de uma normativa focada na relação demográfica, o documento não estabelece parâmetros geográficos de raio ou tempo de viagem. A proporção de cobertura estipula um equipamento para cada grupo de 25.000 habitantes, expressa por:

$$\mathrm{U}_{\text{Raio-X}} = \frac{\text{População Total}}{25.000} \tag{8}$$

F. Densitometria Óssea

Regulado de forma análoga pela Portaria SAS/MS nº 1.101/2002 [13], o planejamento quantitativo restringe-se a estimativas numéricas de capacidade instalada por volume populacional. A proporção estabelecida é de um dispositivo para cada 140.000 habitantes, portanto $U_{\text{Densitometria}}$ é obtido por:

$$\text{U}_{\text{Densitometria}} = \frac{\text{População Total}}{140.000} \tag{9}$$

Enfatiza-se que tais normativas constituem apenas um referencial teórico de planejamento, não correspondendo diretamente à capacidade operacional real, à produtividade efetiva dos equipamentos ou ao acesso geográfico concreto da localidade estudada.

Em suma, os dados de Araguaína foram consolidados e organizados para apresentação em quatro eixos analíticos sequenciais: o mapeamento quantitativo municipal e sua inserção no SUS, a análise comparativa frente ao contexto estadual, o confronto da capacidade declarada com os parâmetros assistenciais normativos do SUS e, por fim, a verificação do cadastro e da autorização dos equipamentos de Gama Câmara por meio do cruzamento das bases do CNES e da CNEN.

IV. Resultados e Discussão

Nesse tópico estão apresentados dados oriundos da investigação quantitativa realizada. Cabe destacar que tais resultados apresentam apenas um diagnóstico estrutural e exploratório baseado em bancos de dados administrativos e parâmetros normativos e não apresentam evidência de suficiência, equidade ou deficiência na assistência à saúde. Para conclusões a respeito da cobertura assistencial real, de gargalos e de necessidades tecnológicas efetivas é necessário a continuidade do estudo, com a expansão da análise e uso de dados reais como indicadores de produção, tempos de espera, origem dos pacientes, fluxos intermunicipais, dentre outros.

A. Mapeamento Quantitativo e Inserção no SUS

A Tabela I apresenta a distribuição quantitativa de todos os equipamentos de diagnóstico por imagem declarados em Araguaína na competência de dezembro de 2025, exceto os equipamentos de Medicina Nuclear - Gama Câmara - que serão analisados à parte, discriminados pelas categorias de existência e uso geral, bem como sua respectiva inserção no Sistema Único de Saúde (SUS).

Para fins de contextualização da composição tecnológica no município, a Fig. 1 foi gerada para segmentar a participação proporcional de cada modalidade diagnóstica frente ao montante de 172 dispositivos mapeados na base federal.

A análise combinada da Tabela I e da Fig. 1 expõe uma configuração tecnológica registrada fortemente dominada por tecnologias de média complexidade. A ultrassonografia assume a liderança correspondendo a 53,5% do inventário local (92 equipamentos), seguida pela radiologia convencional (Raio-X), que detém 22,1% (38 dispositivos). Somadas, ambas as modalidades representam mais de três quartos (75,6%) de toda a tecnologia de diagnóstico por imagem identificadas.

TABELA I
Número de Equipamentos de Diagnóstico por Imagem em Araguaína - TO (CNES, 2025)

Equipamento	Existentes	Totais em Uso	Existentes no SUS	Em Uso no SUS	% Em Uso SUS
Raio-X	38	35	27	24	68,57%
Fluoroscopia	1	1	1	1	100,00%
Densitometria	5	5	2	2	40,00%
Angiógrafo	2	2	1	1	50,00%
Mamógrafo	15	15	10	10	66,67%
Ultrassonografia	92	90	34	33	36,67%
Tomografia	13	13	9	9	69,23%
Ressonância	6	6	4	4	66,67%
Total	**172**	**167**	**88**	**84**	**-**
(%)	**100,00%**	**97,09%**	**51,16%**	**48,84%**	**50,30%**

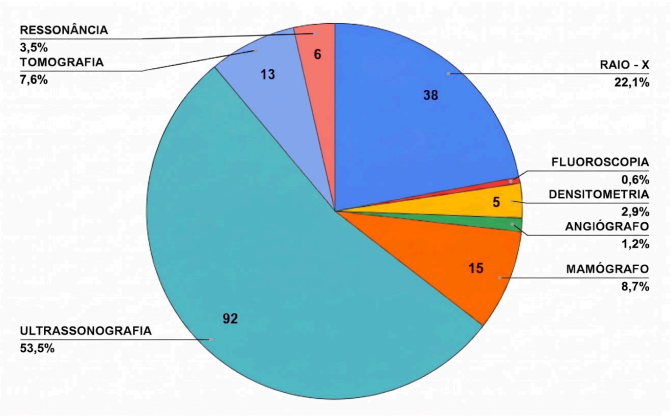

Fig. 1. Segmentos de equipamentos existentes no município de Araguaína - TO (CNES, 2025).

Em uma segunda análise, a Fig. 2 apresenta o quantitativo de equipamentos registrados que atende ao SUS em comparação com o total documentado. Esse comparativo revela a capacidade assistencial oferecida à população dependente da rede pública. O mapeamento dessas diferenças quantitativas constitui o passo inicial para a determinação da real cobertura assistencial. Sob a perspectiva da gestão pública de saúde, a mensuração do inventário tecnológico destinado ao SUS fundamenta as tomadas de decisão alinhadas aos parâmetros das Portarias SAS/MS nº 1.101/2002 [13] e SAS/MS nº 1.631/2015 [14].

Os resultados dispostos na Tabela I e graficamente mapeados na Fig. 2 revelam uma diferença no aproveitamento público de algumas tecnologias. Embora Araguaína possua um total de 172 equipamentos — dos quais 167 encontram-se declarados em uso efetivo (97,09%) —, pouco menos da metade do parque tecnológico atende diretamente à rede pública (48,84% em uso no SUS).

A maior assimetria localiza-se na ultrassonografia, onde, dos 90 dispositivos mapeados na cidade, apenas 33 realizam exames pelo SUS, representando uma retenção de 63,33% da capacidade para esse tipo de diagnóstico. Cenário similar observa-se na densitometria óssea, cuja vinculação pública é

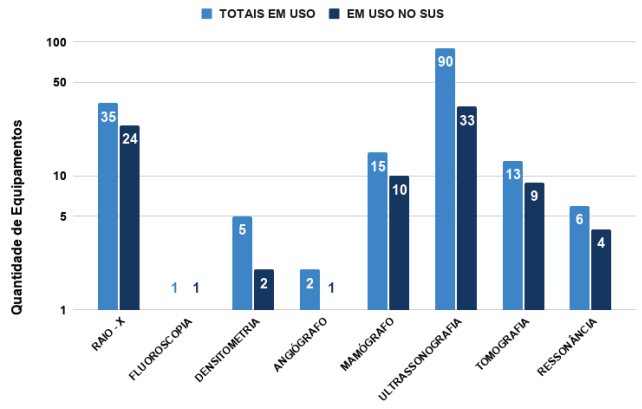

Fig. 2. Comparativo quantitativo de equipamentos em uso geral e em uso ativo na rede SUS em Araguaína - TO. (CNES, 2025)

de apenas 40,00%. Esse arranjo pode indicar um entrave no acesso público ao exame de densitometria óssea, indicativo que será melhor investigado na continuidade desse estudo.

Analisando isoladamente as demais modalidades, evidencia-se uma taxa de inserção no SUS superior a 60% para Raio-X, Mamógrafo, Tomografia e Ressonância. A Fluoroscopia se destaca com uma vinculação pública de 100% dos equipamentos identificados, contudo tal cenário pode mascarar uma vulnerabilidade estrutural, dada a existência de apenas um único aparelho de Fluoroscopia declarado em toda a extensão municipal.

Além disso, tendo em vista que o município se consolida como um polo de saúde macroregional, a aparente equidade observada nesses eixos de maior complexidade deve ser interpretada com cautela. A dispersão geográfica da demanda, que atrai pacientes de toda a região e de estados limítrofes [9], aponta para uma possível pressão de uso sobre a rede assistencial local, indicando a necessidade de maiores investigações acerca da demanda e fluxo intermunicipal.

B. Análise Comparativa Frente ao Contexto Regional

Para contextualizar a centralidade de Araguaína como polo de saúde, a Tabela II expõe a participação percentual do município em relação ao total de equipamentos registrados em todo o estado do Tocantins.

Com o intuito de visualizar essa dispersão, a Fig. 3 apresenta a composição percentual da capacidade instalada entre o polo municipal estudado e os demais municípios do território estadual.

Sob a perspectiva dos dados, a interpretação conjunta da Tabela II e da Fig. 3 contesta, à primeira vista, a expectativa para um polo de saúde, visto que Araguaína concentra apenas 17,50% do total geral de equipamentos de imagem inventariados do estado (172 de 983). Esse percentual relativamente baixo reflete as características geopolíticas do Tocantins: um estado jovem, de vasta extensão territorial e com uma rede urbana fracionada. Tal configuração geográfica impõe a necessidade de descentralizar dispositivos de menor custo

TABELA II
PARTICIPAÇÃO PERCENTUAL DE ARAGUAÍNA FRENTE AO INVENTÁRIO TECNOLÓGICO DO TOCANTINS (CNES, 2025)

Equipamento	Araguaína	Demais Municípios	Total no TO	% de Araguaína
Raio X	38	176	214	17,76%
Fluoroscopia	1	12	13	7,69%
Densitometria	5	15	20	25,00%
Angiógrafo	2	17	19	10,53%
Mamógrafo	15	33	48	31,25%
Ultrassom	92	487	579	15,89%
Tomografia	13	41	54	24,07%
Ressonância	6	30	36	16,67%
Total	**172**	**811**	**983**	**17,50%**

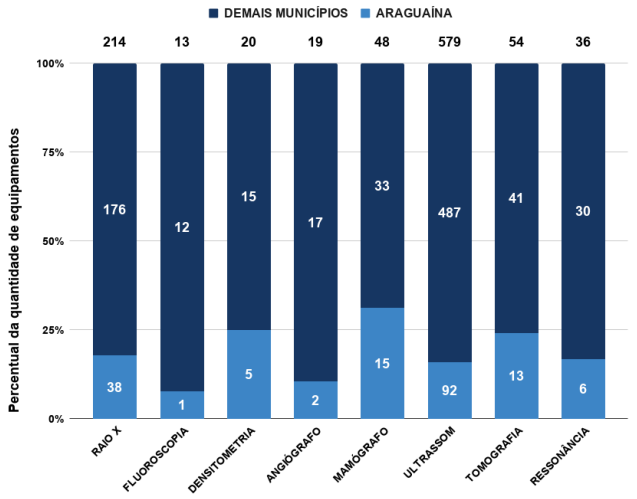

Fig. 3. Fração percentual e quantitativa de equipamentos existentes: Araguaína frente aos demais municípios do Tocantins (CNES, 2025).

— como Raio-X convencional e ultrassons, equipamentos mais numerosos no estado — pelas demais municipalidades, visando garantir a cobertura da atenção primária e evitar vazios assistenciais básicos.

Em contrapartida, o papel de Araguaína como polo regional se manifesta quando a análise é segmentada pelo nível de complexidade tecnológica. O município centraliza quase um terço dos mamógrafos estaduais (31,25%), um quarto de todos os densitômetros ósseos (25,00%), cerca de um quarto dos tomógrafos computadorizados (24,07%) e 16,67% dos equipamentos de ressonância magnética do Tocantins. Desse modo, esses índices revelam que as decisões de investimento tendem a se aglutinar no município quando se trata de alta densidade tecnológica.

Embora, em uma análise inicial, essa centralização indique uma otimização da viabilidade de operação, ela dificulta o acesso dos usuários de cidades periféricas que necessitam de diagnósticos especializados, impondo a necessidade de grandes deslocamentos. A análise espacial dessas distâncias geográficas, fundamentada nos raios normativos de acessibilidade dos equipamentos, será aprofundada na Seção C.

Diante disso, a aparente limitação do índice geral de 17,50% evidencia que a análise isolada dos limites político-administrativos da cidade mostra-se insuficiente para compreender a capacidade tecnológica local. Esse resultado atesta a necessidade de expandir o escopo analítico para além das fronteiras municipais, incorporando a dinâmica integrada de sua Região Metropolitana, instituída por lei estadual [10], ou de sua Região Geográfica Intermediária estabelecida pelo IBGE [16].

C. Aferição da Realidade Declarada com Parâmetros Assistenciais do SUS

A partir da aplicação dos modelos matemáticos determinados pelas Portarias SAS/MS nº 1.101/2002 [13] e nº 1.631/2015 [14], calculou-se a necessidade teórica de dispositivos para atender a população residente de Araguaína, estimada pelo IBGE em 183.024 habitantes para o ano de 2025 [15]. Pondera-se que o cálculo para os equipamentos de mamografia fundamentou-se especificamente no contingente de mulheres na faixa etária de 40 a 59 anos, compreendendo 12.470 mulheres entre 40 e 49 anos e 8.845 entre 50 e 59 anos, conforme o último censo de 2022 feito pelo IBGE [15].

Logo, a Tabela III confronta a necessidade normativa com o número total de equipamentos existentes no município, evidenciando um aparente cenário de superávit geral.

TABELA III
NÚMERO DE EQUIPAMENTOS ESTIMADOS A PARTIR DOS PARÂMETROS DE PLANEJAMENTO DO SUS DAS PORTARIAS DE 2002 E 2015

Equipamento	**N. Exames/Ano**	**N. Equip. Estimados**	**N. Equip. Existentes**
Tomógrafo	-	1,83	13
Ressonância	5490,72	1,10	6
Mamografia	7703,71	1,14	15
Ultrassom	27453,60	9,08	92
Raio X	-	7,32	38
Densitometria	-	1,31	5

Sob a óptica dos indicadores de planejamento, os dados dispostos na Tabela III revelam que o quantitativo de equipamentos ultrapassa as metas teóricas recomendadas pelas normativas do SUS para a população local. Uma ênfase maior se dá na ultrassonografia, cujo total existente (92 dispositivos) é mais de dez vezes superior à necessidade calculada (≈ 9). Variações semelhantes ocorrem nas modalidades de tomografia computadorizada (13 existentes frente a uma meta de ≈ 2) e na ressonância magnética (6 existentes frente a apenas ≈ 1 requerido). Esse fenômeno evidencia que as diretrizes baseadas estritamente na demografia não refletem a dinâmica real de mercado e de alocação de recursos tecnológicos em municípios que atuam como polos de atenção regional.

Diante desse cenário, o superávit observado corrobora as conclusões de estudos anteriores [9] de que Araguaína atua como o principal centro de referência assistencial da rede hospitalar com um raio de até 260 km de alcance. Configura-se, portanto, como um polo de saúde cuja infraestrutura atende a uma demanda que ultrapassa sua população residente e seus limites político-administrativos.

Sob a perspectiva da Portaria SAS/MS nº 1.631/2015 [14], o planejamento prevê raios de atendimento de 75 km para tomografia, 60 km para mamografia e 30 km para ressonância magnética. Para permitir uma visualização comparativa da abrangência do polo, dos limites normativos teóricos e das distâncias geográficas, a Fig. 4 foi elaborada no software QGIS [17], sobrepondo os raios de cobertura assistencial e de alcance da rede hospitalar à malha territorial da Região Metropolitana de Araguaína, composta por 65 municípios do norte tocantinense [10].

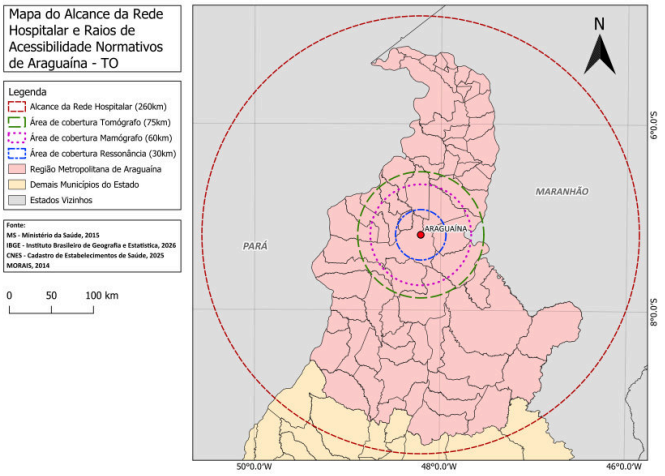

Fig. 4. Comparativo espacial entre os raios de cobertura normativos e o alcance real da rede hospitalar na Região Metropolitana de Araguaína-TO.

A análise da Fig. 4, em conjunto com os dados quantitativos discutidos nesta seção, permite concluir que o fato de o fluxo real captado pelo polo ultrapassar os raios de cobertura previstos normativamente atesta o fenômeno de concentração tecnológica municipal. Ademais, sugere que o município atua como retaguarda de alta complexidade para a região, embora a necessidade de grandes deslocamentos imponha possíveis restrições de acessibilidade aos serviços. Paralelamente, do ponto de vista mercadológico e de gestão, essa centralização indica o potencial econômico de investimentos e alocação de serviços na cidade.

D. Análise Comparativa CNES x CNEN para a Modalidade de Gama Câmara

Como eixo final desta análise, a Tabela IV apresenta o cruzamento de dados entre os diferentes sistemas regulatórios federais (CNES e CNEN) para o dispositivo de Gama Câmara, revelando uma assimetria nas informações cadastradas no âmbito da Medicina Nuclear.

A partir desse panorama, evidencia-se uma incoerência entre os registros do CNES e as autorizações vigentes da CNEN. Enquanto o sistema do Ministério da Saúde aponta a existência de 9 equipamentos de Gama Câmara no estado do Tocantins — sendo 4 deles localizados em Araguaína —, a base de dados da

TABELA IV
MAPEAMENTO COMPARATIVO DAS INSTALAÇÕES DE GAMA CÂMARA NAS BASES CNES E CNEN

Base de Dados	Araguaína	Demais Municípios	Total no Tocantins
Declarados pelo CNES	4	5	9
Autorizados pelo CNEN	1	1	2

Comissão Nacional de Energia Nuclear reconhece a operação de apenas duas instalações em todo o território estadual, com cada uma possuindo um equipamento, reduzindo o contingente do polo municipal a um único dispositivo autorizado.

Essa divergência estatística pode indicar diversas ocorrências, incluindo a existência de dispositivos em trâmite de certificação junto à CNEN. Contudo, sem uma validação em campo, essa diferença não deve ser interpretada automaticamente como indício de operação irregular, necessitando de investigações adicionais.

Desse modo, entende-se que assimetria de informações afeta de forma direta a gestão de tecnologias em saúde e a vigilância radiológica na região. Como a Medicina Nuclear lida com radioisótopos e exige que cada Gama Câmara ativa esteja vinculada a um serviço rigorosamente licenciado — envolvendo radioproteção, blindagem e gerência de rejeitos —, a inconsistência cadastral no CNES tem o potencial de comprometer o planejamento em saúde pública e ocasionar imprecisões na avaliação da distribuição de serviços no norte tocantinense. Reforça-se, portanto, a necessidade de mecanismos de interoperabilidade entre as bases federais, o que permitiria distinguir com clareza os equipamentos inoperantes ou obsoletos daqueles em processo de regularização normativa.

V. CONCLUSÃO

O trabalho apresentou uma investigação estrutural do parque tecnológico de diagnóstico por imagem e Medicina Nuclear no município de Araguaína, TO, fundamentada nos equipamentos declarados e autorizados nos bancos de dados do CNES e da CNEN, evidenciando as complexas dinâmicas entre a capacidade instalada e a cobertura assistencial teórica e efetiva.

Os resultados demonstram que, embora o município exiba um maior número de equipamentos em relação aos parâmetros demográficos teóricos recomendados pelas normativas do SUS para a população residente, potenciais gargalos de acesso para dependentes da rede pública podem estar ocultos e necessitam ser investigados por meio de dados adicionais sobre produção, demanda, deslocamento e utilização dos dispositivos.

Esse cenário decorre, principalmente, devido ao fato de a cidade se consolidar como um polo de saúde macrorregional, atraindo pacientes de uma rede de usuários distribuída em um raio de até 260 km. Essa dinâmica analítica ganha consistência ao se aplicar a abordagem geodemográfica, evidenciando que a demanda real captada pelo polo extrapola os raios de cobertura física e tempos de deslocamento previstos teoricamente para algumas modalidades.

Ademais, o confronto dos dados locais com os números estaduais revela que, embora Araguaína concentre apenas 17,50% do inventário mapeado do Tocantins, esse índice é atenuado pela possível dispersão de dispositivos de média complexidade em municípios vizinhos integrantes de seu fluxo territorial. Em contrapartida, o município se destaca na alta complexidade, com a segregação por densidade tecnológica demonstrando uma centralização de modalidades estratégicas, nas quais o polo retém até 31,25% da capacidade do estado.

No âmbito regulatório, a assimetria de informações identificada nos registros de Gama Câmara expôs uma lacuna na interoperabilidade entre diferentes bases de dados. Este panorama reforça a necessidade de auditorias cadastrais capazes de diferenciar erros operacionais no sistema e eventuais processos pendentes para licenciamento junto à CNEN, garantindo a fidedignidade dos registros nacionais e do próprio planejamento em saúde.

Por fim, ressalta-se que este estudo representa um diagnóstico estrutural inicial restrito à distribuição territorial e baseado exclusivamente em bancos de dados secundários e parâmetros normativos. Embora o objetivo de elaborar um inventário territorializado tenha sido alcançado, a ausência de validação em campo e a não contemplação de indicadores operacionais impedem afirmações definitivas sobre gargalos e necessidades tecnológicas efetivas. Desse modo, como desdobramento futuro, propõe-se a expansão do escopo analítico para o estado do Tocantins, aliada à apuração de dados reais de produção, tempo de indisponibilidade, tempos de espera, origem dos pacientes e fluxos territoriais intermunicipais. A incorporação de tais parâmetros é fundamental para confirmar se o aparente superávit de equipamentos mapeado se traduz, de fato, em um maior e efetivo acesso da população aos serviços de saúde.

VI. AGRADECIMENTOS

Agradecemos à Universidade Federal do Norte do Tocantins (UFNT) pelo apoio institucional e pelo incentivo à pesquisa científica. O desenvolvimento desta pesquisa contou com Apoio à Pesquisa e a Graduação da PROPI/UFNT, Edital n° 47/2026. Este trabalho foi desenvolvido no âmbito do Programa Institucional Voluntário de Iniciação Científica (PIVIC/UFNT), ao qual expressamos nosso reconhecimento pela contribuição à formação acadêmica e científica do estudante envolvido.

***Abstract*—Electrical energy consumption in Brazilian public hospitals represents a growing challenge to operational sustainability, due to their uninterrupted operation, high demand for air conditioning, and the use of high-power medical equipment. Although initiatives such as migration to the Free Energy Market contribute to cost reduction, the complexity of these environments demands more comprehensive energy management approaches. This study proposes an integrated methodology for monitoring, forecasting, and managing electrical energy consumption at the University Hospital of Brasília (HUB-UnB/HU Brasil), grounded in systematic data collection, Artificial Intelligence techniques, and data-driven strategies. The methodology encompasses a technical survey of the electrical installations, data acquisition and preprocessing, and predictive modeling of time series using statistical and machine learning methods. Expected outcomes include predictive models evaluated by RMSE, MAE, and R^2 metrics, identification of consumption patterns in critical hospital sectors, and data-driven energy efficiency strategies replicable across other HU Brasil network units, contributing to the digital transformation of energy management in the Brazilian hospital sector.**

***Index Terms*—Energy Efficiency, Public Hospital, University Hospital, Healthcare Facility**

I. Introduction

High energy consumption systems from continuous operations involving lighting, heating, ventilation, and air conditioning loads, as well as imaging equipment, operating rooms, and other facilities that must remain available at all times. In Brazil, although most federal university hospitals belong to a single centralized Federal Government network, HU Brasil, there are federal university hospitals with independent administrations, managed directly by their respective universities. These public hospitals simultaneously perform teaching, research, and healthcare functions. They also face the challenge of maintaining patient care amidst budget constraints, as they operate exclusively for the Unified Health System (Sistema Único de Saúde - SUS).

Aspects related to power quality and the quality of the electric power supply in hospital environments have direct implications for patient safety. Failures or instabilities in the power supply network can compromise the operation of life-support equipment as well as the infrastructure in critical areas, such as intensive care units and operating rooms. In this context, continuous monitoring of the electrical infrastructure is not merely a matter of energy efficiency but a requirement with significant operational impact.

The Child and Adolescent Unit (UCA) is the most recent building at the University of Brasília Hospital (HUB-UnB/HU Brasil); it has been in operation since 2023 but was officially inaugurated in 2024 and is managed by HU Brasil [11]. The building was designed to integrate a system for measuring electrical parameters with a photovoltaic generation system. This monitoring infrastructure features 21 installed electronic meters and a dedicated electrical substation, creating a favorable environment for implementing a supervisory system based on open SCADA technologies.

This paper presents a survey of the UCA's electrical monitoring infrastructure and a description of the healthcare services provided on each floor of the building, as well as a proposal for a continuous monitoring system based on the open-source SCADA-LTS software platform. Preliminary results from data collected at measurement points distributed throughout the unit are also presented. The technological development activities described herein aim to integrate the metering infrastructure with the implementation of a supervisory system and the design of hospital energy management models driven by energy consumption data.

II. General Description of Children and Adolescents Unit (UCA)

The UCA building has a capacity of 59 active beds and 80 specialized consultation rooms, distributed across a total area of 6,930 m². The care services provided include a pediatric ward, pediatric ICU, neonatal ICU, rooming-in unit, laboratories, and teaching areas. In total, 61 specialties and subspecialties are available: 37 focused on adult care and

24 dedicated to children and adolescents [11]. The building comprises four levels: a basement, a ground floor, and two upper floors. Each with a specific care-related purpose, as described in Table I.

TABLE I
DISTRIBUTION OF HEALTHCARE SERVICES OFFERED AT THE UCA BUILDING

Floor	Purpose
Basement	Adult Outpatient Clinic
Ground Floor	Outpatient Clinic and Pediatric Rehabilitation
1st floor	Pediatric Ward and Classrooms
2nd floor	Neonatal ICU (NICU), Pediatric ICU (PICU), Maternity Rooming-In Care

III. UCA Electrical Infrastructure

A. Distribution Topology

The UCA is supplied by a substation shared with two other buildings at the HUB-UnB/HU Brasil hospital complex. This substation houses the supply transformers for all three buildings, as well as the emergency generator sets serving the entire hospital, making it a strategic location within the complex's electrical network. HUB-UnB/HU Brasil is classified as a Group A4 consumer, with a supply voltage ranging from 2.3 kV to 25 kV, under the "Blue" three-phase tariff structure (time-of-use and seasonal pricing), operating within the Free Energy Market (Ambiente de Contratação Livre - ACL). Contracted demand levels are 1,090 kW during peak hours and 1,280 kW during off-peak hours [12]. Exceeding these limits results in significant additional charges on the energy bill, making the monitoring and forecasting of demand peaks a matter of direct economic importance.

B. Metering System

The UCA is equipped with 21 WEG electric meters (model MW03-CH [1]) located in distribution panels throughout the building. The MW03-CH is a multi-function energy meter that records electrical parameters such as voltage, current, active power, reactive power, power factor, and accumulated energy, among others. The meter's resolution is suitable for energy management applications in medium- and large-scale facilities.

Communication with the meters takes place via the Modbus TCP protocol over Ethernet and the RS485 serial interface; both are widely supported by industrial monitoring, supervisory, and energy management platforms [9]. The use of these industrial communication protocol standards is crucial to the strategy adopted in this work: fully leveraging the existing metering infrastructure without the need to replace equipment or adopt different protocols.

Due to healthcare service demands, patient care provided on each floor of the building is subject to frequent changes. Thus, it was not possible to associate the distribution of electrical panels with the type of care provided within the coverage area of each circuit. Consequently, it was only possible to determine which meters monitor each floor, as shown in Table II. It can be observed that the meter located in the rooftop panel corresponds to the building's photovoltaic solar generation system, while panels QD-AC-1, QD-AC-2, QD-AC-3, and QD-AC-4 contain the meters associated with the HVAC system. The remaining meters serve the other installed loads.

TABLE II
LOCATION AND IDENTIFICATION OF UCA METERS

Floor	Meter
Basement	QD-S1, QD-S2, QD-S3, QD-S4, QD-S5
Ground Floor	QD-T1, QD-T2, QD-T3, QD-T4, QD-T5, QD-T6
1st floor	QD-1-1, QD-1-2, QD-1-3, QD-AC-1, QD-AC-2, QD-AC-3
2nd floor	QD-2-1, QD-2-2, QD-AC-4
Rooftop	QDG-IT

C. Supervision System

The UCA has a commercial SCADA system responsible for integrating the meters into a single centralized platform. However, the SCADA system is currently inoperative. One of the purposes of this work is the recovery of the SCADA system through the use of the existing infrastructure, including all physical metering infrastructure, communication cabling, and data network, which has been fully preserved. This condition creates an opportunity to implement an alternative supervisory solution without the need for new hardware investments, leveraging the assets already installed. The adoption of an open-source platform, in addition to eliminating dependency on specific vendors, reduces the risk of discontinuation that compromised the legacy system.

IV. Proposed Supervisory System

A. SCADA-LTS Platform

The solution adopted to restore electrical monitoring at the UCA is SCADA-LTS, an open-source supervisory and data acquisition platform built on the Mango Automation architecture. The system runs in a web environment, operating on a Java server with a relational database, and exposes the collected data through a REST API, enabling integration with external analysis and visualization tools without dependence on proprietary software.

The choice of SCADA-LTS is based on three objective criteria. The first is native compatibility with the Modbus TCP protocol used by the WEG MW03-CH meters installed at the UCA, eliminating the need for protocol converters or hardware adaptations. The second is the absence of licensing costs, a factor in the context of a public hospital. The third important is long-term technical sustainability: being open source, the system can be maintained, modified, and expanded by the hospital's own technical team, removing dependence on an external vendor.

B. Architecture

The proposed architecture for the UCA monitoring system consists of three functional layers, illustrated in Fig. 1.

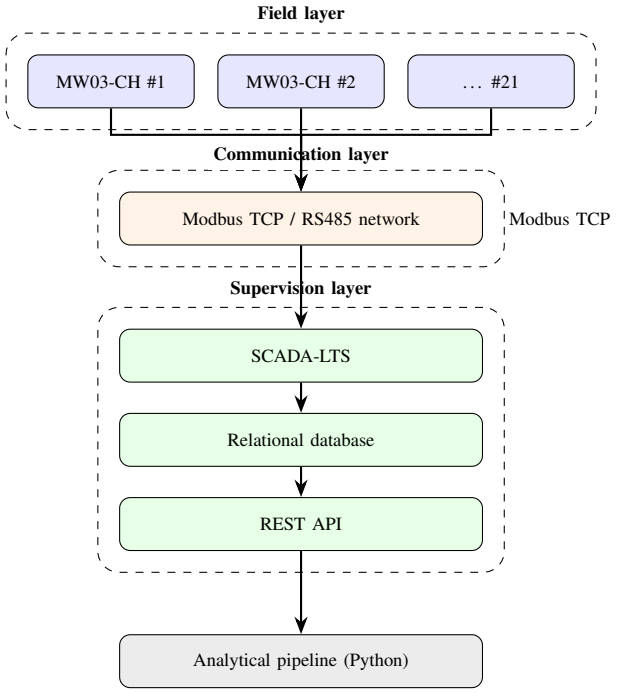

Fig. 1. Three-layer architecture of the proposed supervisory system for the UCA.

The field layer is formed by the 21 WEG MW03-CH [1] meters distributed across the distribution panels. Each UCA's meter operates as a Modbus slave, responding to requests from the supervisory server and providing records of electrical quantities.

The communication layer is formed by the data network already installed in the building, through which Modbus TCP traffic is routed between the meters and the SCADA-LTS server. The RS485 interface available on the meters is used at points where Ethernet communication is not available, routing this data to an RS485/Ethernet converter installed in the main panel on the UCA's ground floor.

The supervision layer is the SCADA-LTS server, responsible for periodically polling the meters, storing the data in a relational database, and making the historical series available through the REST API. The temporal resolution of acquisition is configurable per measurement point; for this work, a 15-minute interval is adopted as the minimum granularity, consistent with the resolution used in similar studies in the literature [2] and sufficient for detecting intraday demand patterns.

C. Data Pipeline and Analytical Integration

The data collected by SCADA-LTS are stored with a *timestamp* and a measurement point identifier, forming continuous time series for each monitored variable. Data extraction for analysis is performed via a REST API, which returns records in JSON format, that are processed directly by Python scripts within the analytical pipeline.

The data treatment pipeline comprises the following steps: identification and interpolation of communication failures; removal of documented maintenance periods; normalization of quantitative variables; and encoding of categorical temporal variables, such as day type and tariff period, are both described in [2]. The treated data feed, the demand forecasting models and the continuous monitoring system based on the CUSUM (*Cumulative Sum of Differences*) method, whose integration with SCADA-LTS constitutes the long-term goal of this work.

V. Results

A. Supervision Dashboard

Fig. 2 illustrates the main monitoring dashboard developed on the SCADA-LTS platform. The interface was designed to consolidate the electrical quantities collected by the 21 meters installed in the UCA (University Care/Health Unit — adjust acronym as needed). The meters were organized by floor, as described in Table II.

The main panel shows the total power of the whole hospital and allows to chose the building for a specific monitoring. Showing the total power of the building, the tension and the frequency measured, showing the limits established for a good energy quality, according to the regulatory standards [13].

In parallel with the integration between SCADA-LTS and the meters, a portable meter was installed at the substation as a strategy for collecting time-series consumption data, aiming at the construction of future data logging databases. This approach enables continuous recording of the electrical quantities across all distribution panels of the UCA over a predetermined period. This measurement aimed to anticipate the characterization of the facility's electrical profile and to provide a dataset with real measurements for validating the analyses proposed in this study, independently of the schedule for restoring the supervisory system.

The recorded quantities include current, voltage, power factor, and frequency, with a sampling granularity compatible with the analysis of intraday demand patterns. The objective was to verify the proper functioning of the meters, as well as to monitor the operation of the UCA from an electrical energy standpoint.

Fig. 3 and Fig. 4 present boxplots of the frequency and voltage values recorded across the 18 operational meters, respectively. The x-axis represents the individual meters, while the y-axis indicates the operational limits (upper and lower) established for each monitored quantity. Meters QD-T1, QD-T4, and QD-T6 were temporarily excluded from the system due to being out of service and were duly reported to the maintenance team.

In both cases, it is observed that frequency and voltage operate in compliance with the limits established by current regulatory standards [13]. For frequency, the values must be between 59.5 Hz and 60.5 Hz, for voltage, between 209 V and 231 V. Despite the presence of outliers, it is noteworthy that 100% of the collected data fall within regulatory limits, represented by the black lines above and under the figures, in-

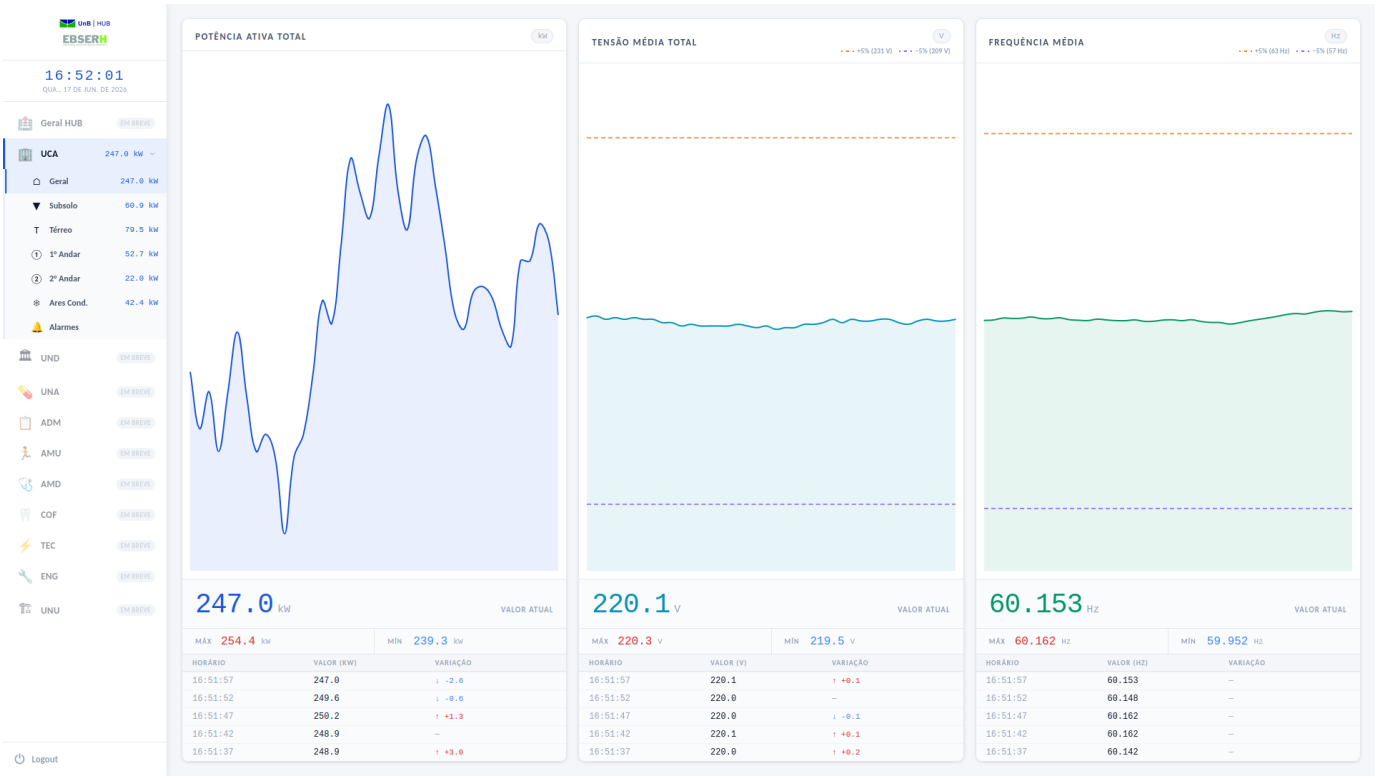

Fig. 2. SCADA-LTS platform main dashboard

dicating that the hospital's electrical system operated correctly throughout the monitored period.

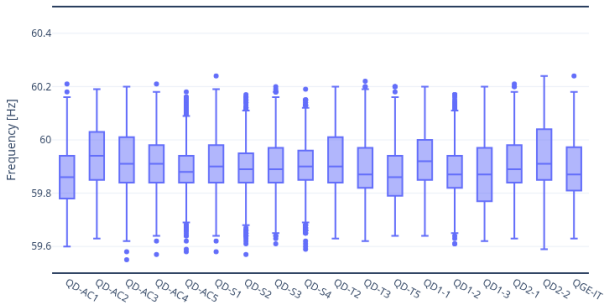

Fig. 3. Frequency monitoring of the UCA

In addition to these data, charts for energy recorded in 15 minutes per meter, system power factor, and average current per phase were generated, represented by Fig. 5, 6, and 7, respectively.

In 5 shows the energy consumption data for the seven monitored days. It can be observed that the meters showing the highest consumption are QD-AC1, QD-AC2, QD-AC3, QD-AC4, and QGE-IT. The first four are associated with the HVAC system distributed across the floors, while the last one

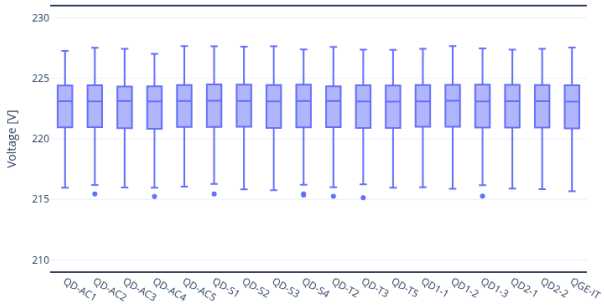

Fig. 4. Voltage monitoring of the UCA

is associated with the solar panel system.

As shown in Fig. 6, the power factor of the electrical installation is generally observed to be inductive (lagging). Given the presence of loads with varying technologies, operating profiles, and consumption patterns, it was to be expected that the electrical distribution system supplying the hospital would perceive it as a predominantly inductive load.

The behavior of the current values shown in Fig. 7 demnostratres that the UCA's electrical installation exhibits slight imbalances. However, from a general perspective, a balanced distribution of installed loads thoughout the building is still

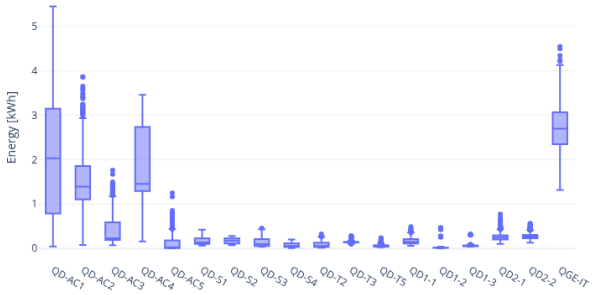

Fig. 5. Energy monitoring of the UCA

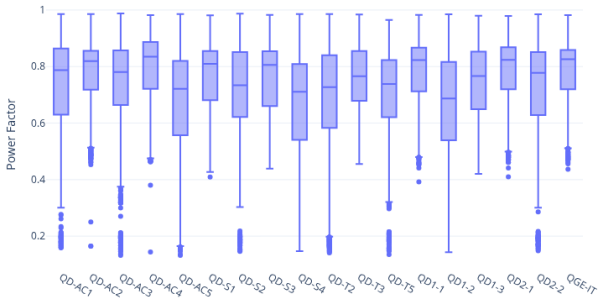

Fig. 6. Power factor monitoring of the UCA

maintained.

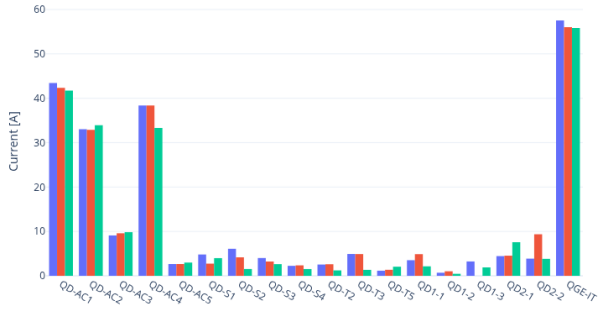

Fig. 7. Current monitoring of the UCA. Phase 1 (blue bar), Phase 2 (red bar) and Phase 3 (green bar)

VI. Conclusion

With full integration between the UCA meters and the SCADA-LTS server, continuous and automated collection of electrical quantities will become feasible. This integration will enable the enhancement of Modbus TCP communication at each measurement point, as well as the consolidation of a structured time-series repository covering the 21 meters installed in the UCA, with a minimum granularity of 15 minutes. Such granularity will allow the characterization of consumption profiles by circuit and by floor over complete seasonal cycles, as well as during sporadic events associated with increased patient flow throughout the year. Full operation of the SCADA-LTS system is further expected to cover broader seasonal variations and enable a more statistically robust characterization of the UCA's electrical profile.

Continuous monitoring of energy consumption and power quality will further enable the distinction between transient events and structural conditions requiring preventive, predictive, or corrective interventions. It is also proposed to evaluate the combined use of power quality monitoring and demand forecasting as inputs to a decision support system for the preventive maintenance of hospital electrical infrastructure, capable of anticipating failures before they compromise the continuity of patient care.

The development of electrical demand forecasting models based on the collected historical series is proposed, with performance evaluated using RMSE, MAE, and R^2 metrics, following the methodology validated in the literature for healthcare facilities [2], [3]. These models should be benchmarked against traditional statistical methods to determine the most suitable approach for each monitored variable. It is further proposed to apply the demand forecasting models already developed for HUB-UnB as a whole [2] to the specific context of the UCA, comparing the performance of statistical and machine learning models on the unit's electrical data. This is expected to validate the forecasting methodology at a more granular scale, per care unit, prior to its eventual expansion to the hospital's other units.

The implementation of a continuous monitoring system will enable the early detection of deviations in consumption patterns arising from operational failures, changes in hospital occupancy, or inefficiencies in HVAC systems.

Documentation of the proposed system will support its replication in other units of HUB-UnB, as well as in hospitals within the HU Brasil network.

Finally, the enhancement of data-driven energy infrastructure management is highlighted as a contribution stemming from the proposed approach, including the development of indicators based on the facility's electrical patterns, combined with other hospital logistics-related data, to support building administration.

For future works, is pretended to make a validation of anomaly detection algorithms, economic impact assessment and replication across mutiple hospital units, aiming to strengthen the scientific contribution and practical applicability of the proposed system.

Acknowledgment

The authors thank the Graduate Program in Biomedical Engineering, the National Council for Scientific and Tech-

nological Development (CNPq) and the University Hospital of Brasília (HUB-UnB/HU Brasil) for their collaboration and institutional support, which made this study possible.

“Estimated Annual Maintenance Cost of Life-Support Medical Equipment Registered in the Brazilian National Registry of Health Facilities” - Karin Moreira Santos; Harki Tanaka

Resposta aos/às revisores/as

Prezados/as, prezado/a editor/a,

Agradecemos a revisão atenta do nosso manuscrito, e os valiosos comentários para a complementação do documento, que certamente contribuirá à qualidade da versão final.

No que segue, iremos abordar as preocupações levantadas pelos/as revisores/as e indicar como contemplamos cada uma delas.

Revisor/a 1

O trabalho aborda um tema de grande relevância para a Engenharia Clínica e apresenta uma metodologia reprodutível, baseada em bases públicas (CNES e FNS), para estimar o custo anual de manutenção de equipamentos médicos de suporte à vida. O objetivo central busca contribuir diretamente para o planejamento orçamentário e a gestão de tecnologias em saúde. A metodologia é bem descrita e os autores deixam claras as limitações do estudo relativas às bases de dados, principalmente quanto ao caráter estimativo dos resultados.
Entretanto, o custo para manter a usabilidade, desempenho e a segurança de um equipamento médico não pode ser baseado somente no plano de manutenção. Ele é influenciado por diversos outros fatores, tais como: a tecnologia empregada, a necessidade de calibração, o uso de acessórios, a intensidade de uso, o modelo de manutenção (preventiva, corretiva ou contratual) e a disponibilidade de peças de reposição ou preço de mercado.
Nesse sentido, recomenda-se aprofundar a discussão como alerta ao leitor sobre os custos de calibração ou ensaios de desempenho, uma vez que esses componentes da manutenção apresentam características particulares, exigências regulatórias e periodicidades distintas entre as diferentes tecnologias médicas.

Agradecemos pela avaliação gentil do/a revisor/a, que levanta um ponto que de fato é essencial. Modificamos o nosso texto para contemplar essa ressalva importante. Mais especificamente, inserimos as seguintes frases no final da Introdução:

“Maintenance costs can be defined in several ways, and include or exclude expenses that are obviously related to the use of medical equipment, but for which, to our knowledge, no suitable database exists. Examples are the possible need of periodic calibration, accessories required for functioning, the variable cost of replacement of damaged parts, among other considerations that are hard to map, as these are extremely varied across different types of

medical equipment. There is no systematized database dedicated to these more specific costs of usage of medical devices, and we therefore present the data in this study noting first that these kinds of expenses are not considered in our estimates."

Como mencionado no próprio texto, "não existe hoje no Brasil uma base única consolidada que registre exclusivamente e diretamente o custo real executado de cada ordem de serviço ou manutenção técnica nacional". Contudo, o trabalho abre portas para que, em um futuro próximo, seja possível compor e validar esses custos por meio do cruzamento de dados oriundos de sistemas CMMS (Computerized Maintenance Management System). Esses sistemas registram o histórico real de cada equipamento, incluindo a quantidade de ordens de serviço, os custos de calibração, peças trocadas e acessórios, o valor da mão de obra (própria ou terceira), o tempo de parada (downtime), entre outros indicadores.
Portanto, nesse sentido recomenda-se discutir a utilização dos sistemas CMMS como ferramenta essencial para a coleta e a padronização de dados de manutenção nos estabelecimentos de saúde, permitindo futuramente confrontar os custos efetivamente realizados com as estimativas baseadas no valor de aquisição dos equipamentos.

Agradecemos o/a revisor/a por esta sugestão. De fato, a integração em maior escala de ferramentas digitais de acompanhamento de dispositivos do início até o final do ciclo da vida útil dos diversos equipamentos deve permitir um panorama bem mais acurado no que tange aos objetivos do nosso estudo, que é fornecer uma primeira estimativa do custo de manutenção do parque de equipamentos. É uma consideração importante para uma possibilidade que no entanto deve ser situada no futuro, já que a implementação deste tipo de sistema de acompanhamento ainda está em fase inicial na maioria das instituições. Contemplamos esta consideração através do seguinte novo trecho no manuscrito, alocado no final da seção III. Preliminary Results.

"Many institutions are starting to implement equipment management systems that register a broad set of operations related to the acquisition, functioning and maintenance of the devices that integrate the medical equipment park monitored by professionals of clinical engineering. To the extent these Computerized Maintenance Management Systems (CMMS) are adopted more widely, new methods for a much more accurate and systematized maintenance record will also allow to stipulate more reliable maintenance cost estimates. The implementation of CMM systems is gradual, and we expect this method of estimation to be available only at some point in the future."

Revisor/a 2

Agradecemos pela leitura atenta e pelas anotações do/a revisor/a; Tomamos a liberdade de itemizar os comentários levantados por este revisor para apresentar as respostas de maneira mais ordenada.

1. *Realizar uma análise de sensibilidade por tipo de equipamento e deixar ainda mais explícito que os valores representam cenários potenciais, não gastos reais.*

Entendemos que a possível falta de acurácia em alguns casos possa suscitar preocupações sobre o valor final das estimativas apresentadas. Na nossa análise, incluímos 15

dispositivos diferentes, e uma análise mais aprofundada nas estimativas de manutenção de cada um e os possíveis vieses associados para cada equipamento, individualmente, certamente receberá a atenção da nossa equipe de pesquisa futuramente. Para a finalidade do paper atual, da forma que o *scope* foi definido, acreditamos que este nível de detalhamento ocuparia um espaço desproporcional no texto, e preferimos deferir esta análise para posteriormente. Fizemos as devidas ressalvas no texto, no entanto, onde constam formulações como “The study is explicitly framed as an estimate of *potential* annual maintenance cost, not as a measurement of the real expenditure [...]” (com ênfase original), “exploratory and estimative approach based on open public data is the only viable path to a nationally representative study within the available timeframe” e “it does not report equipment age, usage frequency, failure history, whether preventive maintenance was actually executed and at what periodicity, maintenance contract terms, amounts paid, or equipment downtime. Consequently, the cost figures presented in this paper are best interpreted as an estimated potential maintenance cost associated with the registered park, computed from acquisition-value scenarios, and not as a measurement of real maintenance expenditure incurred by health facilities;”. Portanto, mesmo sem a apresentação de uma avaliação mais detalhada dos possíveis vieses nas estimativas por tipo de equipamento, que não conseguimos incluir no escopo do estudo atual, acreditamos que tenhamos enfatizado suficientemente junto aos interessados no manuscrito que as nossas estimativas não devem ser lidas como apresentando uma acurácia que não conseguimos oferecer ainda, a partir dos métodos utilizados.

2. *Também corrigiria o mapeamento CNES–FNS, pois o flowmeter foi associado ao preço de um Doppler vascular por ausência de correspondência exata, o que pode introduzir viés evitável na estimativa.*

O/a revisor/a certamente levanta um ponto importante, que é uma consequência do uso de referências de catálogo diferentes entre os sistemas existentes para o acompanhamento de aparelhos médicos em uso, que é um dos elementos mais pertinentes nas nossas conclusões. No caso do relacionamento do flowmeter com o Doppler vascular, fizemos uma tentativa para evitar uma lacuna no nosso levantamento através de uma associação que acreditávamos ser a mais plausível. Ao mesmo tempo, se o flowmeter corresponder a um equipamento distinto do equipamento de Doppler vascular, provavelmente seria um de menor complexidade e portanto menor valor do que o levantado no estudo. Como, pelos números que obtivemos, o valor do Doppler vascular só corresponde a 0,1% do valor total do parque de equipamentos médicos (v. Table III), o impacto de incluir ou excluí-lo da contabilização não deve produzir uma grande variação nas estimativas obtidas. Para permitir que os leitores façam uma avaliação deste ponto da relevância numérica limitada do flowmeter, incluímos, no texto, a seguinte frase, no final da Seção II: “According to the results obtained, presented below, the financial weight of the flowmeter in our estimates is minor (in the order of 0,1%), and we believe that alternative mappings have no significant impact on the aggregated numbers we present in this study. ” Nós mantivemos a intenção de produzir novas estimativas em trabalhos futuros quando os códigos forem harmonizados, como já citada no texto original: “this correspondence will be revisited as the FNS catalog is updated”.

3. *Além disso, monitores de pressão invasiva e não invasiva foram excluídos dos custos apesar de representarem aproximadamente 18,4% das unidades em uso, tornando o total uma estimativa inferior ao parque completo.*

Trata-se novamente de uma consequência da falta de harmonização entre os sistemas que usamos para realizar o trabalho. Infelizmente, diferente do caso do flowmeter, não teríamos embasamento para encontrar valores correspondentes. Concedemos que é uma limitação relevante do nosso estudo, e acrescentamos uma frase no final da Discussão para enfatizar que as estimativas, por esta lacuna na base da FNS, naturalmente seriam maiores se estes dispositivos forem incluídos:

“As the systems that can be consulted for the cost estimates currently do not allow for alternative estimates of the pressure monitors, one must consider that the values presented in this study would underestimate total maintenance cost in applications in which they are to be taken into account.” Furthermore, we added the comment “The invasive and non-invasive pressure monitors are set to zero in this graph because their average values are not available in the FNS system.” in the caption of Figure 2.

4. *Recomendo apresentar explicitamente o impacto dessas ausências e, se possível, acrescentar indicadores normalizados por população ou número de leitos para evitar que o ranking regional reflita predominantemente o tamanho dos estados.*

Agradecemos o/a revisor/a por este ponto, que contemplamos na versão atual do manuscrito, como ressalva: “As the maintenance costs are calculated proportionally to the value of the medical equipment park considering the life support items included in this study, the results per macroregion reflect the uneven distribution of both population and medical resources throughout Brazil. For example, using population estimates for july 2026 provided by the Instituto Brasileiro de Geografia e Estatística (IBGE), the maintenance cost according to the 7% benchmark amounts to R$9,95 per capita in the South, but only R$5,66 per capita in the North.”

Accumulated Dose Estimating to the Eye Lens in Fluoroscopic Procedures

Interventional radiologists receive large doses of radiation. The International Commission on Radiological Protection recommends an annual occupational dose of 20 mSv to the eye lens to prevent cataracts. We used a cumulative dose tracking system with real-time dosimeter surveillance to inform physicians about the risks of fluoroscopy table radiation. The present study deals with the real-time radiation exposure to the eyes of physicians who are standing 57 to 76 cm away from the primary beam of the fluoroscopy table during 8-, 12-, and 20-min procedures. Interventional radiologists perform 270 simulated procedures per year, exposing them to 8.68, 20.44, and 31.08 mSv at 57 cm and 6.44, 14.84, and 22.12 at 76 cm. We can protect interventional radiologists and their teams by considering the range and duration of the radiation beam. The estimated results are partly consistent with the ICRP criteria.

Keywords— Eye lens dose; Estimating Accumulated Dose; Interventional radiology.

I. INTRODUCTION

An interventional cardiologist uses X-rays all the time to see what's going on inside the body during procedures. Because they are constantly exposed to ionizing radiation, individuals are required to wear the appropriate radiological protection whenever they are near the X-ray beam. Excellent protection against ionizing radiation will prevent acute risks such as cataracts and skin lesions [1-5]. Additionally, long-term exposure can lead to chronic effects, including an increased risk of cancer. This is important for observing safety measures and monitoring radiation exposure during interventional procedures. The interventional physician receives high doses of radiation if his hands are in the region of the X-ray beam. The severity of side effects caused by radiation increases regarding the dose received, and this adaptation does not interfere with the dose, potentially leading to simple erythema or severe burns of the skin. This study shows how important it is to have adequate radiation protection, which minimizes these side effects. By implementing proper safety measures and using advanced shielding materials, we can significantly reduce the risk of exposure. Ensuring that both workers and patients are well-protected is essential for maintaining health and safety in environments where radiation is present. The Brazilian Institute for Radiation Protection and Dosimetry (IRD) has determined that when working with the dose received, and this adaptation does not interfere with ionizing radiation during a medical diagnosis, the occupational doses of radiation to which medical personnel are exposed should be controlled. According to Bingham, the IRD also advises keeping records so that clinicians can obtain a report of their interventional radiology-related activities. It also suggests that routines for measuring occupational doses for staff should be improved by frequent measurements of radiation doses on the hands and lenses, as well as in the assessment of recorded personal doses. Employees working in areas with ionizing radiation typically use thermoluminescence dosimeters (TLDs) in radiology-intensive hospitals. The short distance from the radiation source contributes to the staff's high radiation exposure during interventional work. Often, when working near the patient, it is difficult to use protective screens or even glasses, which are essential for protection against radiation exposure when working near the source. Unfortunately, the interventionist physician does not always use these tools properly, and many find them awkward and uncomfortable to use during long procedures [7]. The topic of ionizing radiation is especially relevant for interventionist physicians since the cumulative dose of interventionist radiography teams represents more than 90% of the collective dose of all radiology personnel. This emphasizes the significance of continual education and training to ensure that all team members are well-equipped to deal with radiation exposure successfully. Intervenors guaranty quality and safety. The dosimeter used by medical staff has the disadvantage of not immediately showing its cumulative dose, which is usually read one month after its use; so, a system for effectively measuring dose rates is essential for the safety of the medical staff. It is important that this system shows radiation doses in real time, as the information can help them be aware of protection against ionizing radiation and therefore lead to a

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

decrease in their personal doses [8]. The real-time system lets an interventionist doctor see the equivalent dose immediately. The information helps them stay away from the source of radiation and move to a position that exposes them to less radiation without affecting the performance of the intervention procedure. To obtain an equivalent cumulative dose real-time system [9], you need to know the factors about the ionization chamber's reference point and the dose rates around the fluoroscopy table, which are shown by the isodose map. The construction of the isodoses map is the result of the dose rate measurements of all points around the fluoroscopy table. The measured points with the same dose rates have adjusted the use of the interpolation technique to construct the isodoses. An ionization chamber located at a distance from the main beam records dose rates in real time. Real-time correction of measured values occurs through conversion factors in the isodose map, which displays dose rates and cumulative dose. The medical staff views these values numerically in relation to their position regarding the main beam. The medical staff [10-12] numerically views these values in relation to their position regarding the main beam. The software development project [13-14] aims to estimate equivalent doses in real time, as shown in figure 1.

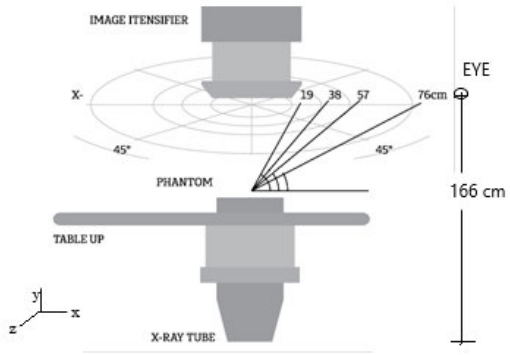

Fig. 1: Design of the development to estimate doses in real time.

The interventionist physician and their team will be able to verify radiation exposure in real time with the visualization system. By comprehending the consequences of ionizing radiation, medical professionals can modify their positions to reduce the dose they receive while maintaining the efficacy of the medical procedure. The annual occupational dose for the eye lens should be reduced from 150 mSv to 20 mSv, as per a recent statement from the International Commission on Radiological Protection (ICRP) [6]. The objective of this decrease in the cumulative dose limit is to mitigate the risk of cataracts after absorption. The main objective of this project is to develop a system that accurately estimates the equivalent dose to the eye lens in real time during interventional medical procedures that utilize fluoroscopy.

II. MATERIALS AND METHODS

The experimental setup consists of a cylindrical phantom (15 cm height, 30 cm width) to simulate the scattered radiation, a Ludlum 9DP ionization chamber connected to a computer using a Ludlum cable to measure the rate, and an automated fluoroscopy system, INNOVA. The real-time monitor is next to the fluoroscopy table. The algorithm estimates cumulative doses near the doctor's view. The real-time system's development was divided into two phases, as illustrated in Figure 2. The first step was a system linearity test. The system linearity test was a measurement of the dose rate as a function of the voltage, amperage, and exposure time. The current was kept constant at 30 mA, while the voltage was between 50 and 90 kV. Moreover, the voltage was constant (50 kV), and the current was changed from 5 to 30 mA. The exposure time was 10 s. Measurements were taken at a height of 166 cm above ground level, specifically at positions of 57 and 76 cm along the x and y axes from 45° to 45°. All measurements were conducted with a current of 30 mA, a voltage of 50 kV, an exposure time of 10 seconds, and 100 cm from the x-ray tube to the table. The ionization chamber was configured to gather continuous data at one-second intervals, aligned toward the center of the scattering object at all points on the plane. After data collection, an algorithm was developed to (1) eliminate data below 10 μSv/h, which identified the data for each position; (2) account for the ionization chamber's dead time by utilizing data above the average for each point; and (3) discard data that did not correlate. The Chauvenet criterion was applied to calculate the mean and standard deviation of the dose rate at each point [15]. We used interpolation techniques to determine isodoses based on data measured from scattered radiation points in each plan. The isodoses of interest corresponded to points (RangeDosesRatesInMap) at 38, 57, and 76 cm. These values were subsequently used to create a map of isodoses. A conversion factor was applied for the isodose on the map. The conversion factor isodose rate is 443 μSv/h. It is the dose rate at the reference point of Eq. (1).

$$\text{Factor}=\text{RangeDosesRatesInMap}/\text{DoseRateReferencePoint} \quad (1)$$

The second part, illustrated in Figure 2, pertains to the real-time system in which the ionization chamber was positioned at a fixed reference point. This system was designed to collect

data at specified intervals and transmit it to the 9DP Logging Spreadsheet software. The estimated real-time isodose rates indicate the dose rates measured at that specific location, where the conversion factor from Equation (2) is applied.

$$\text{Estimate} = \text{Factor} * \text{DoseRateReferencePoint} \quad (2)$$

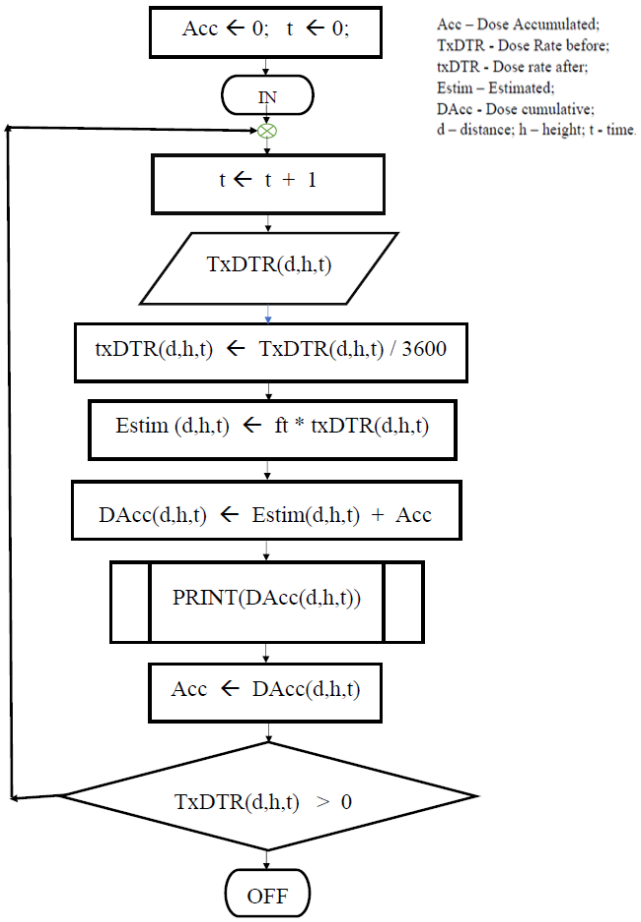

Fig. 2: Computational diagram of software development to estimate doses in real time [13].

The isodose rates (EstimateDoseRate) were initialized every time the x-ray system was triggered. Otherwise, the recording of dose rates referred to background radiation. Equation (3) calculated the estimated cumulative dose (EstimateAcc) for each isodose bin.

$$\text{EstimateAcc} = \text{EstimateAcc} + \text{Estimate} / 3600 \quad (3)$$

All interventionist procedures began with the readings for the accumulated dose of each isodose map at zero. The estimated cumulative dose is calculated in real time, and the results are displayed on a TV monitor for each corresponding radiation range when the fluoroscopy system is activated for a medical angiography procedure. This feature enables the physician to promptly make decisions, thereby ensuring the patient's safety in the vicinity of their eyes. Additionally, the system is designed to alert the physician to any substantial modifications in dose levels, allowing them to make immediate adjustments as required.

III. Results

The real-time dose system was validated from the interventional physician's perspective at distances of 57 cm and 76 cm from the primary beam, at a height of 166 cm from the floor to eye level, and at an angle of 45° from the fluoroscopy table. The system was tested with an irradiation duration of 10 seconds, as outlined in Table 1.

Table 1 - Dose rates were assessed at the interventional physician's position after a 10-second period. The primary beam was oriented at a 45° angle to the fluoroscopy table, and measurements were taken at distances of 56 cm and 76 cm.

Distance (cm)	Measured (µSv/h)	Estimated (µSv/h)	Deviation (%)
57	727,1	728,1	0,14
76	248,5	248,1	0,16

The interventional physician dose-rate tests and the estimated dose-rate tests yielded statistically significant agreement between the computed and measured values (p-values ranging from 0.05 to 0.025). Typically, the duration of an angiography procedure ranges from 30 minutes to 1 hour, contingent upon the examination's complexity. The voltage and current are automatically adjusted during the interventional procedure. The tests were administered for 8, 12, and 20 minutes. Real-time dose rates and accumulated doses in the physician's ocular region are estimated by the prototype for main beam distances of 57 cm and 76 cm. These were 31.20, 72.82, and 110.29 µSv at 57 cm and 22.54, 52.60, and 78.43 µSv at 76 cm per procedure with posteroanterior (PA) tube angles (figure 3-5). The estimated annual cumulative doses were determined by assuming that the physician conducted 270 interventional procedures annually [4]. The experimental conditions have been simulated. During these procedures, the medical professional is exposed to ionizing radiation. At a height of 57 cm, this professional receives 8.68, 20.44, and 31.08 mSv annually, while at 76 cm, they receive 6.44, 14.84, and 22.12. The data were collected

without the use of glasses. The results indicate that fluoroscopy suites are only used for interventional treatments. According to the findings, fluoroscopy allows devoted people to face higher amounts of radiation exposure when performing interventional operations.

to elevated levels of radiation exposure. Eye Protectors and Lead Aprons: provide protection against ionizing radiation. The doctor and their team should minimize the time in primary radiation to ensure their health and safety. However, at times, a brief exposure may be necessary to avoid interruptions during the interventional medical procedure.

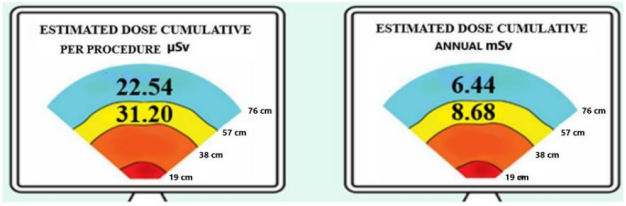

Fig. 3 – The estimate shows the distribution of cumulative fluoroscopy doses per procedure for a duration of 8 minutes. The annual accumulated dose for 270 procedures performed under the same conditions is also estimated.

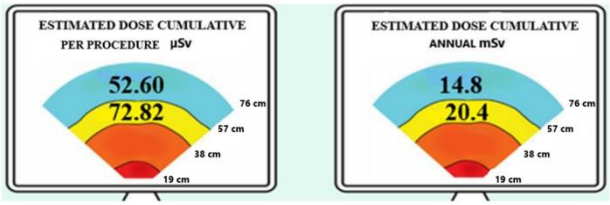

Fig. 4 –. The estimate shows the distribution of cumulative fluoroscopy doses per procedure for a duration of 12 minutes. The annual accumulated dose for 270 procedures performed under the same conditions is also estimated.

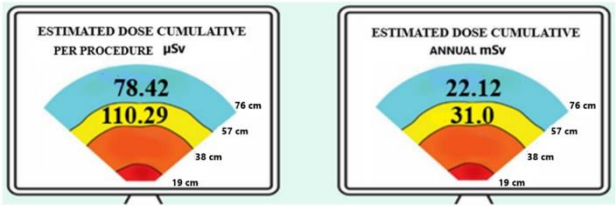

Fig.5 – The estimate shows the distribution of cumulative fluoroscopy doses per procedure for a duration of 20 minutes. The annual accumulated dose for 270 procedures performed under the same conditions is also estimated.

IV. Discussion

The aim of this study was to better understand settings at 8, 12, and 20 minutes, as well as at distances of the dispersion of to the physician's eye, which is particularly vulnerable to radiation exposure due to ocular malignancies. The International Commission on Radiological Protection (ICRP) recommended limiting radiation exposure to 20 mSv per year and the use of personal dosimeters, lead-lined eyeglasses, and other radiation protection measures. The prototype must display real-time estimates of cumulative doses per procedure setting at 8, 12, and 20 minutes, as well as at distances of the accumulated yearly dose on a TV for the interventional physician. In our work, we have studied the effect of ionizing radiation on X-ray generation. The interventional physician used automatic amperage settings at 8, 12, and 20 minutes, as well as at distances of 57 and 76 cm from the primary beam. We estimated 270 interventions per year and found that the physician's eye received the highest cumulative dose for estimated doses per procedure greater than 20 minutes of radiation exposure. The estimates are consistent with ICRP-103 [16-17] and use the same parameters at the various research stages.

V. Conclusions

Monitoring the estimates of cumulative doses during fluoroscopy can help the physician perform the angiography better by controlling the exposure to scattered radiation during the interventional procedure. A TV display is used to present real-time dosage estimates for radiation dispersion near the fluoroscopy table, both per procedure and annually. The results indicate that the best distance is between 57 and 76 cm, and fluoroscopy time beyond 20 minutes of estimated exposure exceeds the accumulated dose estimates of 20 mSv, raising serious concerns about the risk of exposure to the physician's ocular lenses causing cataracts. The fact that the results are partially consistent with the ICRP guidelines allows for considering the approach to the real-time visualization system, which is crucial and provides immediate responses for estimating accumulated doses.

ACKNOWLEDGEMENTS

The authors thank Dr Cesar A. Santos, from the Hospital University of the State University of Londrina, for his generous help and time for discussion.

CONFLICT OF INTEREST

The authors declare no conflict of interest.

Abstract: The growing incorporation of digital technologies into dentistry imposes new challenges on public procurement processes, since the performance of these solutions depends on the integration between equipment, software and technological infrastructure. This paper reports the application of a Proof of Concept (PoC) for the technical evaluation of a digital dental workflow intended for the production of prosthetic devices within the Brazilian Unified Health System (SUS). The PoC was used as an instrument for the analysis of the interoperability and operational performance of the components of the digital ecosystem, supporting decision-making in a specific context of technology acquisition. As a case study, an intraoral scanner, CAD software and their integration into the clinical-laboratory workflow were evaluated by means of document analysis and a practical demonstration conducted by a multidisciplinary team. The evaluation made it possible to identify aspects related to usability, compatibility, computational infrastructure and operational performance that would not be fully verified through the technical documentation submitted by suppliers alone. The results show that practical validation increases the safety of decision-making and contributes to more robust and better-grounded public procurement processes, as well as allowing better planning of the subsequent stages of the technological densification process. It is concluded that the evaluation of digital dental technologies must consider the technological ecosystem in an integrated manner, incorporating practical validation methods as a complement to documental analysis.

Keywords: Health Technology Assessment; Digital Dentistry; Device compatibility; Proof of concept; Public Procurement.

I. INTRODUCTION

Digital transformation has brought about significant changes in health care processes, driving the replacement of analogue workflows by automated and connected processes supported by integrated computational systems [1, 2]. In dentistry, this movement has become particularly evident in the field of prosthetic rehabilitation, in which the incorporation of digital technologies has profoundly transformed the way dental prostheses are planned, produced and delivered to the patient, increasing clinical accuracy, reducing production time and improving the predictability of rehabilitation treatments [3-5].

The growing incorporation of digital innovations into health systems increases the relevance of Health Technology Assessment (HTA) as a strategic tool to support decision-making processes related to technological densification. In the context of digital health technologies, HTA has taken on an increasing role in the assessment of the value, effectiveness and organizational impacts associated with the adoption of these solutions [6,7]. Traditionally, HTA is structured around the multidimensional analysis of specific technologies, assessing aspects related to safety, clinical effectiveness, technical performance, cost-effectiveness and organizational impacts associated with the adoption of medicines, equipment, medical devices or clinical procedures [6,7].

However, the recent evolution of digital health technologies has introduced challenges that go beyond conventional evaluation models. Unlike technologies assessed as isolated devices, the digital workflows applied to dentistry operate as complex technological ecosystems, in which clinical and operational performance does not depend exclusively on the individual characteristics of each item of equipment, but emerges directly from the functional interaction between multiple interdependent components. In such scenarios, technology assessment requires the verification of interoperability, functional integration and systemic performance along the entire digital workflow,

which are not fully captured by traditional models based on the isolated analysis of the components [7-10].

These workflows may be structured in open or proprietary architectures, integrating different equipment and software responsible for the acquisition, processing and fabrication stages of prosthetic devices [3-5]. In this model, the final outcome of the care process depends simultaneously on the coordinated functioning of the intraoral scanner, the digital planning software, the computational capacity available for processing, the automated manufacturing equipment and, above all, on the interoperability between technologies frequently developed by different manufacturers, a critical element in systems structured under an open architecture [9-10]. Consequently, the individual technical conformity of each component does not necessarily ensure the overall performance of the system when operating as an integrated workflow [9-11]. This characteristic becomes particularly relevant in public procurement processes, in which different technological components may be acquired separately on the basis of independent technical specifications and regulatory documentation. Although they individually meet the established requirements, their functional compatibility and the integrated performance of the system must be verified jointly [7,12].

From the perspective of Health Technology Assessment, this scenario reveals an important methodological gap: how can technological systems whose performance derives from the integrated behaviour of multiple interdependent components, and whose documentary evaluation is not sufficient to predict their performance under real conditions of use, be assessed in a robust manner applicable to public management? Recent discussions on HTA applied to digital technologies and medical devices point to the need for evaluative approaches capable of addressing aspects of interoperability, implementation and performance in real contexts of use [6, 7, 13].

In this context, it becomes necessary to adopt complementary mechanisms capable of assessing in advance the integrated performance of these complex ecosystems before their definitive incorporation. Because of this, carrying out Proofs of Concept (PoC) emerges as a methodological strategy capable of validating the compatibility between system components, reducing the technological risks associated with the public procurement process and producing more robust technical evidence to support incorporation decisions. In this context, the present study describes the application of a proof of concept carried out during the technical evaluation of a digital dental ecosystem intended for the Brazilian Unified Health System, discussing its potential as an instrument complementary to Health Technology Assessment in public procurement processes [11, 14].

II. CASE STUDY

A. Context

Expanding access to oral rehabilitation and modernizing oral health care processes are priorities of the public policies aimed at strengthening Primary Health Care (PHC) within the Brazilian Unified Health System (SUS). In this context, a national strategy for the incorporation of digital technologies was designed with the objective of qualifying care, increasing the resolution capacity of services and promoting greater efficiency in the production of dental prostheses. This initiative is part of the effort to strengthen Primary Health Care, oriented towards expanding the resolution capacity of services and the technological qualification of Basic Health Units (UBS) and Dental Specialty Centres (CEO), in accordance with national guidelines for the modernization of care infrastructure. As part of this strategy, a procurement process was conducted for the implementation of a digital workflow for the fabrication of dental prostheses in public health services. Unlike traditional acquisitions centred on isolated equipment, the contract awarded had as its object the implementation of a complete technological ecosystem, structured to support all stages of the digital prosthetic workflow, from the acquisition of intraoral images to the manufacture of the final prosthetic device. This contracting model introduces additional challenges to technical evaluation, since the individual conformity of the components does not in itself ensure the integrated performance of the system under real conditions of use.

The technological ecosystem comprised intraoral scanners, specialized software for acquisition, planning and digital modelling (CAD/CAM/CAI), compatible computational infrastructure, additive manufacturing equipment, post-processing devices and specific consumables, constituting a complete digital workflow for the production of dental prostheses and configuring a sociotechnical system whose performance depends on the interaction between technological, operational and human factors.

Although each component of the solution individually met the technical requirements set out in the contracting documentation, the adoption of an open architecture made it necessary to verify the functional compatibility between equipment, software and computational infrastructure when operating in an integrated manner. In this context, a Proof of Concept (PoC) was conducted as a complementary stage of technical evaluation, aimed at producing evidence on the compatibility and the performance of the technological ecosystem under conditions representative of use.

It is important to highlight that the acquisition was structured under an open solution model (open ecosystem), in which the different technological components that make up the production workflow do not necessarily belong to the same manufacturer, thereby increasing technological flexibility and competition among suppliers. This architecture, however, transfers to the technological densification process the challenge of ensuring functional compatibility and full compatibility between all the components that make up the system.

B. B. Motivation for developing the Proof of Concept

Although public procurement processes traditionally rely on the documentary analysis of technical specifications, regulatory certifications and demonstrations of conformity of the products offered, this model has limitations when applied to the evaluation of technological ecosystems, whose performance depends on the interaction between multiple components. In the specific case analysed, it was found that the individual technical conformity of the components alone was not sufficient to ensure the performance of the digital workflow when operating in an integrated manner. The quality of the solution depended on the interaction between equipment, software, computational infrastructure and digital files throughout the entire production process.

In addition to compatibility aspects, the evaluation took into account that the different components of the digital workflow were subject to distinct regulatory requirements, which limits the exclusive use of sanitary documentation as sufficient evidence to attest to the performance of the technological ecosystem in an integrated manner, especially in scenarios involving multiple suppliers and interoperable solutions.

The analysis of the technical report prepared by the Federal University of Uberlândia (UFU) showed that factors such as computational capacity, compatibility between software packages, performance of CAD systems and operator experience directly influenced the performance of the digital workflow, confirming that such variables constitute critical determinants of performance and cannot be fully assessed by means of isolated technical documentation. This finding revealed the inadequacy of an evaluation based on the expectation of complete proprietary solutions, reinforcing the need to consider hybrid configurations based on complementary software that is already available and has been functionally tested.

Moreover, it was found that certain native software packages originally supplied by the manufacturers presented functional limitations regarded by the UFU team as relevant to the full execution of the prosthetic workflow, making it necessary to additionally use specialized external software in order to enable specific stages of digital modelling and planning. This observation reinforced the understanding that the isolated evaluation of each component would not be sufficient to predict the overall performance of the system after its implementation in a real environment of use.

On the basis of the integrated analysis of the technical documentation, the evidence presented in the technical report and the statements submitted by the supplier, it was concluded that uncertainties remained regarding the integrated performance of the proposed solution. In view of these limitations, a Proof of Concept (PoC) was planned as a strategy to support administrative decision-making under conditions of greater technical safety, reducing the uncertainties associated with the implementation of the solution. It was conceived as a process of assisted practical demonstration in a controlled environment, conducted with the joint participation of the institutional technical team, academic specialists and representatives of the suppliers, with the objective of validating the compatibility between the acquired components, verifying the operational feasibility of the complete digital workflow and reducing the technological risks associated with the incorporation of the solution in the context of the SUS.

The PoC therefore represented a stage complementary to the traditional process of documentary evaluation, making it possible to increase the technical robustness of the decision-making process and to produce additional evidence capable of supporting the safe incorporation of a complex technological ecosystem on a large scale in the public health system. Furthermore, it made it possible to compare the documentary evidence with the performance observed in an environment representative of use, allowing the empirical validation of the critical aspects identified in the preliminary analysis, especially those related to compatibility, operational performance and infrastructure requirements.

The authors declare that they have an institutional affiliation with the Brazilian Agency for Support to the Management of the SUS (AgSUS), the institution responsible for the acquisition of the equipment and for conducting the proof of concept presented in this study. However, they have no financial or commercial ties with the manufacturers or suppliers of the technologies evaluated. The institutional affiliation did not influence the analysis of the results, their interpretation or the decision to publish.

III. METHODOLOGY

The present study is characterized as a descriptive case study that systematizes the technical evaluation process employed during the analysis of a digital dentistry solution undergoing public procurement. It is an applied study with a qualitative approach, oriented towards the analysis of a real decision-making process in a context of technological densification within the Brazilian Unified Health System (SUS). The evaluation was conducted sequentially, integrating document analysis, specialized technical analysis, statements by the supplier and practical demonstration, thus making it possible to consolidate different sources of evidence to support the administrative decision regarding the technical feasibility of the solution.

Initially, an analysis was carried out of the technical documentation made available during the contracting process, including equipment specifications, the requirements of the tender documents and the technical report prepared by the Federal University of Uberlândia (UFU), which assessed the performance of intraoral scanners and CAD software in the context of the digital prosthetic workflow, applied to the fabrication of single crowns, occlusal splints and complete dentures.

In the following stage, a critical analysis was made of the results presented in the report, considering aspects related to the performance of the equipment, the quality of the digital models produced, the required computational infrastructure, usability, processing time, learning curve and clinical applicability of the digital workflow. The analysis considered technical criteria previously defined on the basis of parameters usually employed in health technology assessment and clinical engineering, focusing on the identification of critical factors of system performance. The technical statements submitted by the supplying company were also assessed, with the aim of identifying complementary elements and possible divergences in relation to the technical evidence previously gathered that might support the analysis of the proposed solution.

Owing to the limitations inherent in an exclusively documentary evaluation, a complementary stage of assisted practical demonstration was carried out in a controlled environment and monitored by a multidisciplinary team composed of representatives of the Brazilian Agency for Support to the Management of the SUS (AgSUS), the Ministry of Health and specialists from the Federal University of Uberlândia (UFU) and the University of Brasília (UnB). The participants in the evaluation performed complementary roles throughout the PoC. The institutional team was responsible for the document analysis, the verification of adherence to the contracting requirements and the consolidation of the evidence to support the decision. The academic specialists contributed to the technical evaluation of the digital workflow, the interpretation of the results and the analysis of the clinical

and laboratory applicability of the solution. The suppliers' representatives carried out the operational demonstration of the equipment and software evaluated, as well as providing the technical support required for the execution of the planned tests. The practical demonstration was structured as a Proof of Concept (PoC), with the objective of assessing the integrated performance of the technological ecosystem under conditions representative of use.

During the practical demonstration, the following were evaluated: the performance of the intraoral scanner, the native software, the integration with complementary CAD software, the required technological infrastructure and the applicability of the digital workflow in different clinical scenarios, including the fabrication of single crowns, occlusal splints and complete dentures. The evaluation covered technical criteria related to the quality of digital image acquisition, interoperability between systems, operational stability of the workflow, usability, computational infrastructure requirements, processing time, reproducibility of results and adherence of the workflow to the care needs of the Brazilian Unified Health System.

The analysis adopted acceptance criteria related to the feasibility of executing the digital workflow, the capacity to exchange files between the different stages of the process, the operational stability of the systems and the clinical adequacy of the devices produced. Whenever applicable, aspects such as marginal fit, the possibility of completing the proposed workflow and the need for corrective interventions to enable the final result were also considered.

The digital models generated during the evaluation were exported, transferred and processed in STL format, used as the reference file for the subsequent stages of CAD modelling, dimensional assessment and fabrication of the prosthetic devices. The compatibility of the workflow was verified through the capacity to exchange these files between the different components of the technological ecosystem evaluated.

The table below presents the technical characteristics assessed and the evaluation matrix.

TABLE I. TABLE I. PROPOSED EVALUATION MATRIX

Characteristics	**Evaluation matrix**	**Evaluation matrix**
Characteristics	Indicator	Evaluation Method
Interoperability	Capacity for transfer between systems	Verification of the export, transfer and import of the files
Integrity of the information	Changes in the geometry of the scanned mesh; fit of the final product	Final product's adaptation
Time	Acquisition time	Timing
Time	Processing time	Timing
Efficiency	Total workflow time	Timing
Infrastructure	Adequacy of the computational requirements	Comparison between requirements and available infrastructure
Compatibility	Opening/import of files	Export, transfer and import test

[a.] Note: The proposed matrix represents an evaluation model applicable to different technological ecosystems. In the case studied, some of the indicators were employed in a qualitative and observational manner, owing to the characteristics of the demonstration carried out.

For the operationalization of the Proof of Concept, the criteria presented in the matrix were applied by means of structured observation of the complete digital workflow, covering tests of file export, transfer and import, verification of the execution of the clinical and laboratory stages, assessment of the operational stability of the systems, analysis of the adequacy of the computational infrastructure and appraisal of the clinical applicability of the devices produced.

Finally, the evidence obtained in all stages was consolidated into an integrated technical analysis, making it possible to compare the documentary results with the observations obtained in the practical demonstration and to substantiate the assessment of the technical feasibility of the solution from the perspective of technological densification within the Brazilian Unified Health System. The methodological sequence employed in the case studied was systematized in an evaluation framework (Fig. 1), structured so as to allow its adaptation to different technological ecosystems while maintaining the stages of analysis, definition of tests, evaluation, recording of results and decision-making. The indicators, test scenarios and acceptance criteria may be adjusted to the characteristics of each solution.

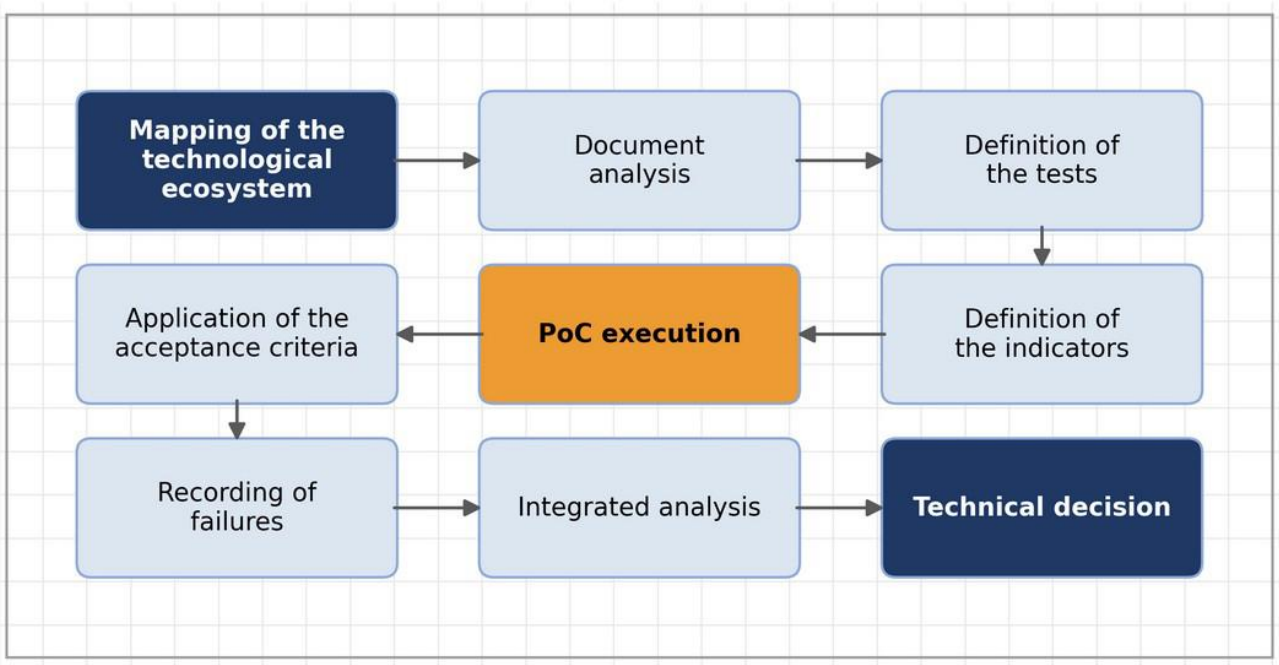

Fig. 1. Fig. 1.Evaluation Framework

This stage allowed for the empirical validation of the main critical factors identified in the preliminary analysis, especially those related to interoperability, systemic performance and operational requirements.

IV. RESULTS AND DISCUSSION

The PoC was conducted in a controlled technical environment with the objective of validating the operational feasibility of the digital dental prosthesis workflow acquired in the public contracting process. The validation focused mainly on assessing the integrated performance of all the technological components under conditions representative of operation, simulating the complete production workflow expected during the implementation of the solution in public health services.

Three levels of interpretation of the findings should be distinguished. At the level of documentary conformity, the components met the specifications of the tender documents and presented the appropriate regulatory documentation. At the level of observed technical behaviour, integrated execution revealed that the native software required external software, and that this software presented relevant limitations of reproducibility, operational stability and dependence on a continuous internet connection. The future organizational consequences discussed below, relating to contracting models, team training, centralization of digital planning and the role of clinical engineering, should be read as hypotheses to be tested.

The evaluation included interoperability tests between the intraoral scanner, the CAD/CAM/CAI software environment, the computational infrastructure, the three-dimensional printing system, the printing software, the post-processing equipment (washing and curing) and the consumables required for production, including dental resins and pigmentation kits. Execution was carried out jointly by technical representatives of the contracting institution, academic specialists, supplying companies and professionals experienced in digital workflows applied to dentistry. This multidisciplinary approach enabled an integrated analysis of the technical, operational and clinical aspects of the system evaluated.

The results showed that, although all the components individually met the technical specifications previously established in the procurement process, relevant operational limitations were identified during the integrated execution of the workflow. Variations in performance were observed, especially in relation to the interaction between different software environments, compatibility between exported and imported digital files, the computational requirements needed for processing the digital modelling stages and dependencies related to the functional limitations of the native software originally supplied by some manufacturers. These findings confirm that individual technical conformity is not sufficient to guarantee the systemic performance of the technological ecosystem when operating in an integrated manner, especially in scenarios dependent on interoperability between heterogeneous systems and on the structured exchange of information between different platforms [8], [10], [11], [15].

TABLE II. TABLE II. ASPECTS EVALUATED AND OBSERVATIONS RECORDED DURING THE POC

Aspect evaluated	Observation recorded during the PoC
Interoperability between components	Workflow executed with integration between scanner, CAD software and digital manufacturing
Native software	Limitations for the complete execution of the prosthetic workflow
Complementary software	Required for certain stages of the process
Dependence on connectivity	Identified in part of the solutions evaluated

Aspect evaluated	Observation recorded during the PoC
Computational infrastructure	Direct influence on stability and performance
Usability	Variable according to the software and the operator's experience
Complete denture	Greater operational complexity and dependence on specialized software

The findings made it possible to distinguish two complementary levels of interoperability. The first corresponds to syntactic interoperability, related to the capacity to export, transfer, import and use the files along the different stages of the digital workflow. The second refers to the preservation of the relevant characteristics of the transferred information, including the quality of the digital mesh, the continuity of the surfaces, the geometry, the spatial alignment of the records and other information necessary for the clinical use of the digital models. It was thus found that the mere possibility of exchanging files does not in itself constitute sufficient evidence of satisfactory performance of the technological ecosystem.

It should be noted that the present protocol does not replace interoperability standards or norms used in health care. Its purpose was to verify the practical operation of the digital dental workflow under conditions representative of use, assessing the interaction between equipment, software, computational infrastructure and digital files. Accordingly, the proposed approach should be understood as complementary to consolidated interoperability references such as HL7 FHIR, DICOM and IHE profiles, since it seeks to verify, in an operational context, aspects related to implementation, functional integration and the behaviour of the technological ecosystem. Within the scope of this study, formal conformity or certification of the systems in relation to these standards was not assessed.

The validation process also showed that certain stages of the workflow required complementary adjustments that could not be identified solely through the document analysis carried out during the contracting phase. In particular, it was found that more advanced digital planning activities require the use of specialized external software in addition to that originally provided with the equipment. This finding reinforces the limitations of evaluations based exclusively on documentary and regulatory conformity for complex digital technologies, in which factors related to implementation, integration between systems and context of use directly influence the observed performance [6], [7], [13], [16].

Despite the interoperability challenges observed, the PoC demonstrated that the proposed technological architecture was operationally feasible when appropriately configured, allowing the successful execution of the digital workflow from the acquisition of intraoral images to the final fabrication of the prosthetic device. The process generated relevant technical evidence confirming the possibility of implementing an open solution model for the digital production of prostheses in the context of the public health system, provided that minimum requirements related to interoperability, technological infrastructure and the use of specialized complementary software are observed [9,11].

The results obtained reinforce a methodological challenge that is increasingly present in contemporary processes of technological densification in health care: the growing mismatch between traditional models of technology assessment and the complexity of the new digital ecosystems applied to care delivery. Recent studies show that digital technologies require evaluative models capable of addressing aspects related to interoperability, implementation, usability, technological integration and value generation under real conditions of use [6, 13, 16].

Historically, public procurement and technology assessment processes have been structured on the basis of the individual analysis of discrete technologies, in which each component is assessed in isolation from technical specifications, regulatory documentation, certifications and its own performance criteria. However, the case analysed showed that, when health technologies operate as interconnected technological ecosystems, the individual conformity of the components ceases to be a reliable predictor of the operational performance of the integrated system. This finding is consistent with recent studies on digital health ecosystems, which identify interoperability and the capacity for integration between systems as critical factors for successful technological implementation [8, 10, 15].

The digital prosthetic workflow evaluated in this study represents a typical example of a multilayer technological ecosystem, in which clinical and operational performance does not derive from the isolated functioning of the individual devices, but from the dynamic interaction established between software, computational infrastructure, compatibility between hardware, compatibility between digital files, manufacturing processes, properties of the consumable materials and the coordinated execution of the clinical and production workflow. This characteristic is consistent with contemporary models of digital health ecosystems, in which the value generated depends on the interaction between multiple technological and organizational components [8,15].

This result reveals an important limitation of the models traditionally employed in the field of Health Technology Assessment, historically oriented towards the evaluation of medicines, isolated medical devices, diagnostic tests or specific therapeutic procedures. In contrast, the growing digitalization of health services requires evaluation approaches at a systemic level, capable of incorporating criteria of interoperability, technological integration and operational performance in a real context of use [6,7,13,16].

The adoption of a contracting strategy based on an open solution further increased this complexity. Although open architectures offer important advantages in terms of competition between suppliers, technological flexibility, lower dependence on single manufacturers and greater sustainability in public procurement processes, this model transfers to the Public Administration the responsibility for ensuring functional compatibility and compatibility between heterogeneous components. Recent studies indicate that medical device procurement processes still face relevant challenges in adequately incorporating aspects related to

interoperability, implementation and organizational impacts into decision-making [12].

From the perspective of engineering applied to health care, the results show that technological densification processes should not be restricted to the individual evaluation of devices when the object under analysis involves integration between hardware, software, digital workflow, additive manufacturing, compatibility between platforms/devices and operational dependence between multiple suppliers. In addition to clinical and economic aspects, the evaluation of such systems requires consideration of organizational and operational factors and of factors related to the interaction between technology and user, particularly in contexts of greater technological complexity [7,17].

In this context, the use of PoC methodologies proved to be a relevant complementary strategy for reducing technological uncertainties in public procurement processes, especially in scenarios involving complex and interdependent technological ecosystems whose overall performance cannot be adequately predicted solely by means of technical documentation or conventional regulatory analysis. In addition, the PoC made it possible to empirically validate critical criteria previously identified, strengthening the robustness of administrative decision-making.

This result reinforces the potential of proofs of concept as complementary instruments for the evaluation of complex technologies prior to their large-scale implementation, contributing to the analysis of interoperability, operational feasibility and the risks associated with technology adoption [9,11]

V. LIMITATIONS

The present study has limitations that should be taken into account when interpreting its results. It is a single case, conducted within a specific public contracting process, which partly restricts the generalization of its results to other institutional contexts. Moreover, the evaluation carried out in this article did not compare different ecosystems and was predominantly qualitative and observational. For this reason, some of the indicators presented in Table I could not be fully measured.

Although the technical reports used in the evaluation stage included specific measurements related to dimensional accuracy, processing times and operational performance of the equipment assessed, these results were not produced in a standardized manner within the context of the present Proof of Concept, and for this reason they were not used as comparable quantitative outcomes in this study.

The demonstration of the operation of the equipment took place in a controlled environment, with on-site support from the suppliers, a condition that does not faithfully reproduce the different realities of the Brazilian Unified Health System. In addition, the demonstration was carried out by professionals already familiar with the equipment. Under these conditions, execution times, the quality of the models and the capacity to solve software-related problems tend to represent a

performance scenario superior to that expected in routine operation. Accordingly, the findings of this article should be interpreted as indicative of the potential performance of the solution, provided that favourable conditions for its operation are in place. Finally, no post-implementation follow-up was carried out, so the longitudinal performance of the solution remains to be assessed.

VI. CONCLUSION

The present study suggests that the incorporation of complex digital health technologies, especially those structured as technological ecosystems made up of multiple interdependent components, may involve challenges that go beyond conventional models of technology assessment and the models traditionally employed in public contracting processes, particularly in the context of administrative decision-making. In the experience analysed, it was observed that the individual technical conformity of the equipment, compliance with regulatory requirements and conventional document analysis are not, in isolation, sufficient to ensure the operational performance of the solution, given its dependence on compatibility between different hardware and software components. These findings must, however, be interpreted in the light of the specific characteristics of the case studied and do not allow fully generalizable conclusions to be drawn for other technology implementation processes.

The results observed in this context indicate the relevance of considering digital health technologies not only as isolated devices, but also as integrated systems in which technological, operational and clinical aspects interact. The use of PoC methodologies made it possible to clarify technological uncertainties, compatibility aspects and operational issues before definitive implementation, producing complementary technical evidence capable of supporting safer and more robust decisions aligned with the real conditions of use in health services. In addition, the approach made it possible to identify and characterize challenges associated with the subsequent stages of incorporating the digital prosthesis workflow, under conditions close to those of its practical application.

A central aspect observed throughout the process was the interdisciplinary character required for the adequate validation of the solution evaluated, involving clinical, technological and management knowledge in the assessment of digital health solutions. The conduct of the PoC relied on the articulation between universities responsible for the production of technical and scientific knowledge and methodological support, dental surgeons responsible for the clinical validation of the digital workflow, supplying companies in charge of providing the technological infrastructure and operational support, and biomedical engineers, whose work contributed to the systemic analysis of the solution, the technical evaluation of the equipment, the verification of compatibility between components and the management of the technological risks associated with the incorporation process.

The experience provides preliminary evidence that the growing incorporation of digital technologies in the health sector may require approaches capable of integrating clinical knowledge, applied engineering, technology assessment, regulatory aspects, digital systems architecture and innovation management, especially in complex care environments. However, the applicability of this approach to other scenarios still requires validation in different institutional, care and technological contexts.

In addition, the results point to the need for the future development of more standardized methodological protocols for conducting PoC processes in public procurement

involving complex technological ecosystems, allowing greater reproducibility and the reduction of uncertainties during technological densification processes, especially in the context of solutions based on open architecture and multiple suppliers. Likewise, it becomes relevant to carry out longitudinal studies capable of assessing the behaviour of these solutions after their implementation in different realities of the Brazilian Unified Health System, considering factors such as operational sustainability, learning curve, clinical performance and technological maintenance over time.

Finally, the experience presented here shows that, in the context of technological densification, the work of Biomedical Engineering contributed to the integration of technical aspects, infrastructure, compatibility, technology assessment and management of technological risks. In this context, the integration between engineering, technology management and health technology assessment proved relevant in supporting the safe and sustainable implementation of the solution evaluated. Nevertheless, considering the specific characteristics of the case, further studies are proposed to assess the applicability of this approach to the contribution of Biomedical Engineering in different contexts of technology acquisition and health care delivery.

VII. FUTURE PERSPECTIVES

The results presented highlight opportunities for improving evaluation methodologies applied to the acquisition of technological ecosystems in health care. As a future perspective, it is recommended that standardized protocols for conducting Proofs of Concept (PoC) be developed and validated in multicentre settings, allowing greater reproducibility and comparability between different technological solutions.

Future studies may incorporate quantitative indicators related to interoperability, integrity of information, operational performance, usability, computational infrastructure and organizational impact, thereby increasing the robustness of the evaluation processes. In addition, it is relevant to investigate the application of the proposed methodology in other public procurement contexts and in different care realities of the Brazilian Unified Health System.

Longitudinal evaluations after the implementation of the solutions are also recommended, covering aspects such as the users' learning curve, operational sustainability, technological maintenance, clinical performance and the evolution of digital workflows over time. Finally, the integration of the proposed methodology with formal models for the evaluation of interoperability may contribute to the development of more comprehensive frameworks for the analysis of digital health ecosystems.

ACKNOWLEDGEMENTS

The authors thank the University of Brasília (UnB) for providing the infrastructure and physical space that made it possible to carry out the Proof of Concept (PoC) and the experimental activities of this study. They also thank the Federal University of Uberlândia (UFU) for the technical collaboration and scientific support provided during the process of evaluating and validating the digital dental workflow.

The authors further acknowledge the institutional partnership established with the Ministry of Health, through the Secretariat of Primary Health Care (SAPS) and the General Coordination of Oral Health (CGSB), which was essential for enabling the activities related to the development of the project.

Finally, the authors thank the Brazilian Agency for Support to the Management of the Unified Health System (AgSUS) for its institutional partnership, support, and encouragement in carrying out this research.

***Abstract*— Clinical Engineering (CE) plays a relevant role in the safety and reliability of medical equipment. However, constant challenges persist, such as metrological control. An example is the assessment of Non-Invasive Blood Pressure (NIBP) modules, particularly in acceptance testing for new equipment and post-corrective maintenance. This descriptive case study evaluated 87 performance test reports of 53 multiparameter monitors across two Emergency Care Units (ECUs) and two hospitals over a three-year period. The analysis revealed that only 20% of the tested devices were fully compliant with normative limits. Notably, none of the 23 tests performed after corrective maintenance achieved full compliance, indicating vulnerabilities in traceability and quality control. Focusing on the 120/80 (93) mmHg reference point-the threshold for hypertension screening 14 out of 33 new devices and 15 out of 23 post-maintenance devices exceeded the ±3 mmHg maximum permissible error. These results suggest that the release of equipment without metrological verification may introduce hidden deviations, thereby reducing diagnostic accuracy. The study advocates for the systematic integration of metrological testing throughout the technology's life cycle as a viable Health Technology Management (HTM) tool to mitigate clinical risks, highlighting the need for future multicenter and inferential studies.**

Keywords—Clinical Engineering, Health Metrology, Metrological Testing, Quality Control, HTM.

I. INTRODUCTION

Metrology in the healthcare sector has gained significant prominence over the years, becoming essential for patient safety and the quality of medical procedures, as evidenced by performance testing. Medical Hospital Technologies (MHT) that perform measurements have been used in medicine for many years; however, it was only a few decades ago that legal metrological control, combined with the quality policies of ISO/IEC 17025 (General requirements for the competence of testing and calibration laboratories), established MHT performance testing as an integral part of medical technology management. Performance test reports facilitate the interpretation and evaluation of the reliability of technologies used in Health Care Facilities (HCF) [1]. Clinical Engineering (CE) serves as the cornerstone for fostering metrological awareness and technovigilance within HCFs, bridging the gap between technical oversight and patient safety [2], aligning with technovigilance principles (a post-market surveillance system designed to identify and evaluate adverse events and technical complaints) among all healthcare professionals. Performance testing is a key indicator of safety for both patients and operators; if equipment does not perform adequately, misinterpretations and diagnostic errors may occur, compromising the therapy or procedure to which the patient is subjected.

One of the most common medical technologies found in HCFs is the non-invasive blood pressure (NIBP) monitor. These devices can be analog (using an aneroid sphygmomanometer and stethoscope), semi-automatic, or automatic. Currently, many HCFs, including those in primary care, utilize automatic equipment, a practice protocolized by the Brazilian Society of Hypertension (SBH). It is important to highlight that while these devices provide static readings, facilitating the operator's task, minor deviations in measurement results can impair equipment performance and compromise the correct approach to treatment or the classification of the patient being attended.

The 2025 Brazilian Guideline on Arterial Hypertension (AH), in chapters 3 and 5, recommends "classifying pre-hypertension," encompassing systolic blood pressure (SBP) values between 120-139 mmHg or diastolic blood pressure (DBP) between 80-89 mmHg in clinical settings, with the goal of early identification of at-risk individuals and encouraging proactive, non-pharmacological interventions to prevent progression to AH [3]. Furthermore, it recommends pharmacological treatment after 3 months for individuals with BP of 130-139/80-89 mmHg and high cardiovascular (CV) risk. The threshold differences between classifying a patient as pre-hypertensive versus hypertensive with CV risk are minimal. The summation of minor procedural and equipment measurement errors can lead to a misdiagnosis when the patient's BP is in the "borderline risk" zone between normal and established hypertension [3]. According to statistics from the Brazilian Ministry of Health, nearly 30% of the adult population in Brazil is hypertensive.

The objective of this article is to demonstrate not only the well-established importance of performance testing but also the critical need for its correct interpretation, specifically emphasizing tests conducted after corrective maintenance and during the acceptance phase for new equipment. This approach aims to strengthen the "safety layer" in the performance and operation of MHT.

II. Materials and Methods

This study was conducted at the Health Metrology Laboratory of the Biomedical Engineering Institute at the Federal University of Santa Catarina (IEB-UFSC), which maintains various protocols for evaluating the performance and safety of diverse Health Technologies (HT). Among these is the Internal Testing Procedure PE-209 - Non-Invasive Blood Pressure Monitor Performance Test (a test validated and audited by INMETRO), which evaluates non-invasive blood pressure (NIBP) measurement technologies, generating the reports of interest for this study.

PE-209, like the laboratory's other procedures, is based on validated protocols from the Emergency Care Research Institute (ECRI). For NIBP specifically, it follows the 454-0595 "Blood Pressure Monitors, Electronic Indirect" and 454-20130812 "Health Devices Inspection and Preventive Maintenance System" guidelines, as well as the technical standard ABNT NBR IEC 80601-2-30 - Particular requirements for the basic safety and essential performance of automated non-invasive sphygmomanometers.

The procedure consists of a qualitative evaluation of the equipment under test, subjecting it to a comprehensive visual and operational inspection of items such as the power cord, housing, cuff, software, and battery, among other elements that could compromise measurement results. It also includes a quantitative evaluation (calibration), which compares the blood pressure (systolic, diastolic, and mean) in millimeters of mercury (mmHg) measured by the equipment with the corresponding blood pressure values selected on a calibrated patient simulator. The test includes 7 adult pressure simulation presets and 4 neonatal pressure simulation presets:

TABLE I. Simulated Adult Parameters

Preset	Blood pressure (mmHg) systolic/diastolic (average)
1	120 / 80 (93)
2	150 / 100 (116)
3	200 / 150 (166)
4	255 / 195 (215)
5	60 / 30 (40)
6	80 / 50 (60)
7	100 / 65 (76)

TABLE II. Simulated Neonatal Parameters

Preset	Blood pressure (mmHg) systolic/diastolic (average)
1	35 / 15 (22)
2	60 / 30 (40)
3	80 / 50 (60)
4	100 / 70 (80)

The tests are conducted under the following environmental and mains voltage conditions (for mains-powered equipment) [6]:

- Temperature: 15°C to 35°C.
- Relative Humidity: 45% to 75%.
- Atmospheric Pressure: 860 hPa to 1060 hPa.
- Mains voltage: V_{mains} (V) ±10 %.

All auxiliary instruments used to verify the test conditions, humidity, temperature, barometric pressure, and mains voltage, as well as the patient simulator, are calibrated with valid traceability as established by the applicable technical standard [7]. The tests take place either at the Healthcare Facility (EAS) or at the IEB-UFSC metrology laboratory. Environmental and mains conditions are measured at the test site before the start and at the end of the test using auxiliary equipment, recording the corresponding values on the datasheet for subsequent inclusion in the test report. The report presents the data and measurements collected and processed according to the procedure, formatted as tables. The qualitative evaluation table uses the concepts of Compliant, Non-compliant, or Not Applicable. "Compliant" indicates that the evaluated item meets the recommendations outlined in PE-209; "Non-compliant" indicates that the equipment does not meet the recommendations; and "Not Applicable" indicates that the equipment lacks the item or the item cannot be evaluated, in which case the reason must be stated in the remarks field. The calibration table includes the measurement average (mean of three readings), the error (E), the uncertainty (U), and the coverage factor (k) [4].

In metrology, the concepts of error, uncertainty, and coverage factor complement measurement reliability, as equipment exhibiting high dispersion correlated with usage time may suggest the need for replacement. By definition, the test report is not "conclusive" [6]; that is, it does not state whether the equipment is "approved" or "rejected." This determination is a subsequent step, falling under the responsibility of the Clinical Engineering (CE) team in conjunction with the clinical staff. The objective of the report is to provide qualitative and metrological data, leaving the decision-making to the end user. When applicable, specific technical standards may be included in this decision. Therefore, as an interpretation aid, the normative limits for NIBP are provided at the end of the report, as established by INMETRO's legal metrology in standards NIT-SEFIQ-026 (verification of electronic sphygmomanometers) and NIT-SEFIQ-025 (verification of mechanical sphygmomanometers). Under these guidelines, the maximum permissible error is ±4 mmHg for periodic testing (equipment in use, voluntary verification) and ±3 mmHg for testing new equipment or post-repair [5].

The case study presented herein results from the analysis of performance test reports of NIBP modules integrated into multiparameter monitors from two Emergency Care Units (ECUs) and two hospitals in the metropolitan region of Florianópolis over a three-year period. Authorization to access the reports was granted by the metrology laboratory, adhering to confidentiality and impartiality policies [6].

The analyzed sample consisted of 53 multiparameter monitors encompassing 9 distinct brands. To preserve the study's commercial neutrality, the manufacturers were not nominally identified. Out of the total equipment, 18 are domestically manufactured and 35 are imported. Regarding technological age and usage time, the sample comprises 33 new devices (subjected to acceptance testing), 9 devices with up to 5 years of use, and 11 devices operating for over 5 years in the healthcare environment.

The objective of the study focuses on the NIBP measurement results from the reports that are used to proactively identify individuals predisposed to arterial hypertension (AH) [4]. Serving as an aid in clinical decision-making for adult patients, these involve measurements close to 120–139 mmHg for systolic BP and 80–89 mmHg for diastolic BP. Within the report, the measurement of interest is the simulated measurement in preset 1 for adult patients: 120/80 (93) mmHg — systolic/diastolic (mean). The selection and prioritization of this preset are justified as it represents the borderline reference value in clinical guidelines for hypertension screening and classification, where metrological deviations may contribute to inadequate classification. The CE database was also accessed to verify, within each equipment's history, the occurrence or absence of performance test requests during equipment incorporation, post-corrective maintenance, and/or on a periodic basis.

III. Results and Discussion

The sample used in the case study comprised a total of 87 performance test reports conducted on equipment belonging to two Emergency Care Units (ECUs) (35 tests) and two medium-complexity hospitals (52 tests) in the metropolitan region of Florianópolis. The sample consists of tests on new equipment, periodic tests, and post-corrective maintenance tests, as presented in the tables below:

TABLE III. Distribution of tests across ECU and Hospitals

Test Type	ECU	Hospitals
Acceptance Testing (New)	3	30
Post-Corrective Maintenance	12	11
Periodic Testing	20	11

Over the three years comprising the sample, some devices naturally underwent more than one test. The number of registered devices in the two ECUs is 12, and in the two hospitals, it is 41, totaling 53 multiparameter monitors. The sample encompasses devices from 9 distinct brands (18 domestically manufactured and 35 imported). Regarding technological age and usage time, the baseline consists of 33 new devices, 9 devices with up to 5 years of use, and 11 devices operating for more than 5 years.

Upon analyzing Table 3, considering the number of registered devices versus the number of tests, subtle divergences in the technological management methodology among the Healthcare Facilities (EAS) become apparent. While the ECUs conducted a higher number of post-corrective maintenance and periodic tests, testing during equipment incorporation (commissioning) showed low adherence. In contrast, the hospitals exhibited a significant number of incorporation tests, but the frequency of periodic and post-maintenance testing was low. This difference does not necessarily prove the existence of distinct institutional "cultures" or negligence; rather, it indicates varying levels of maturity in local protocols and points to a vulnerability in quality control throughout the technology's life cycle.

The reality in the ECUs demonstrates that, of the 12 registered devices, 3 underwent testing upon incorporation, 8 were incorporated without testing, and 1 was already in the unit prior to the analyzed period. Although the volume of post-corrective tests in primary care appears high, these analyses were concentrated on only 4 devices, as they required the most interventions according to the CE history. It was observed that 6 devices were never tested, and there were 4 records of corrective maintenance where the equipment was returned to clinical use without metrological evaluation.

In the hospitals, out of 41 devices, 30 were tested upon receipt. However, 33 devices did not undergo periodic testing during the period, indicating a departure from the guidelines of the NBR IEC 62353 standard, which recommends recurrent and post-repair testing [7]. The 11 post-corrective tests were concentrated on 8 devices, and, similar to the ECUs, there were 13 recorded instances of post-repair return without testing. Another detail found in the database: in one of the hospitals, there were 2 occurrences of periodic testing without linkage to a service order in the history, evidencing flaws in documentary traceability.

The overall approval results for the 87 reports are detailed in Table 4, specifying compliance with the PE-209 parameters:

TABLE IV. OVERALL RESULTS OF THE TESTS IN THE TWO ECUS (EMERGENCY CARE UNITS) AND TWO HOSPITALS

Test Type	Number of Tests	100% Compliant
Acceptance Testing (New)	33	12
Post-Corrective Maintenance	23	0
Periodic Testing	31	7

In Table 4, the operational definition of "approved" requires the absence of qualitative non-conformities and errors strictly within normative limits [6], resulting in an overall compliance rate of only 20%. It is emphasized that the metrological report does not impose automatic rejection; the final decision lies with the CE and the clinical staff. For example: if a device allocated to an Adult ICU presents a failure only in the neonatal simulation, the CE, evaluating

demand and criticality, may keep it in use restricted to adults. However, if this same scenario occurs during the acceptance of a new device, it must be returned to the supplier. From the perspective of operational and economic impact, the systematic adoption of these tests demonstrates viability, given that the cost of a test is lower than the costs associated with the possibility of maintenance rework, equipment downtime, institutional attrition, or the potential for interference in clinical management and complementary exams.

The metrological focus of the study centers on preset 1 of PE-209 for adult patients: 120/80 (93) mmHg - systolic/diastolic (mean). This choice is based on the borderline reference value in the guidelines for arterial hypertension (AH) screening [4]. For the measurement result to be compliant, a maximum permissible error of ±3 mmHg [6] is considered for new and post-maintenance equipment; the sample results are presented in Tables 5 and 6:

TABLE V. OVERALL RESULT: PRESET 1, ADULT, NEW EQUIPMENT

Measurement mmHg	Compliant	Non-compliant
120 systolic	33	0
80 diastolic	19	14
93 average	25	8

TABLE VI. OVERALL RESULTS FOR PRESET 1: ADULT EQUIPMENT POST-MAINTENANCE

Measurement mmHg	Compliant	Non-compliant
120 systolic	10	13
80 diastolic	10	13
93 average	12	11

Consolidating the measurement results for preset 1 from each report, 19 were compliant while 14 exceeded the error limit; for the results in post-corrective test reports, 8 were compliant while 15 exceeded the error limit. Evaluating the magnitude of the deviations, the maximum error found in the systolic measurement was +7 mmHg (post-corrective), in the diastolic measurement +7 mmHg (post-corrective), and in the mean measurement -8.67 mmHg (new). To exemplify the potential interference, an undetected error of +7 mmHg in a clinically borderline patient (e.g., 135/85 mmHg) could result in an inadequate classification for the hypertension stage, potentially leading the medical team to unnecessary pharmacological intervention. Although there are no documented harms to patients in this study, the data substantiate the clinical risk.

The overall total for the measurement results in preset 1 was 45 compliant tests and 42 exceeding the error limit. Isolating only the systolic and diastolic pressures (the primary metrics for AH diagnosis), the number shifts to 64 compliances and 23 exceeding the error limit. Non-compliance in the mean pressure measurement should not be underestimated, as it indicates the effectiveness of blood flow to vital organs (perfusion), which could interfere with the management of critical patients [8].

A limitation identified in the documentary analysis is that the reports certify non-compliance but do not discriminate the root cause (such as failures in the piezoelectric transducer, pneumatic leaks, or component fatigue). The absence of this differentiation in the reports restricts deeper predictive analyses.

Finally, the concern regarding NIBP monitors is validated on a national level. According to INMETRO, periodic inspections are essential to ensure reliability and prevent health impacts [8]. In the latest national action in April 2026, out of 1,994 inspected instruments, 116 presented irregularities [8], corroborating the relevance of the constant vigilance demonstrated in this local case.

IV. CONCLUSION

The primary contribution of this study consists of the integrated analysis of the metrological performance of multiparameter monitors from the perspectives of acceptance, post-corrective maintenance, and periodic monitoring. NIBP measurement technology is constructively complex, encompassing mechanical, pneumatic, and electronic components that require constant vigilance [9], whether by Clinical Engineering (CE) or testing laboratories. Furthermore, the predominance of digital equipment in healthcare facilities may create a false sense of security, given that metrological defects in these devices are not visually apparent unlike the deviation of a pointer in a mechanical sphygmomanometer making the execution of performance testing even more indispensable.

The analysis revealed a high percentage of non-conformities across the three tested conditions. The most sensitive finding points to metrological deviations precisely at the pressure levels used to classify the stages of hypertension. Although this descriptive study does not document adverse events, such errors signal a potential clinical risk, as they may induce diagnostic inaccuracies and undesirably influence therapeutic management.

As the main lesson learned, the study highlights the vulnerability of commissioning based solely on the presumption of factory conformity. Within the scope of this work, the non-conformity of an entire batch comprising 10 new units was observed. Consequently, formal notification to the manufacturer and regulatory agencies (such as ANVISA) is recommended. A preventive action is also recommended for CE: during the incorporation of new technologies, the technical specifications in the bidding process [10] can stipulate the requirement of a performance test report, to be included in the documentation upon delivery as a binding criterion for final acceptance.

The case study evidences subtle variations in institutional metrological awareness. While in some situations metrology is well integrated into Health Technology Management (HTM), in others, a fragility in traceability and quality control is observed. The evolution of this technical culture should be fostered starting from professional training to mitigate risks. It is also noteworthy that hidden failures can stem not only from

the equipment itself but also from the incorrect choice of accessories or patient conditions, demanding a systemic view from the healthcare team.

Finally, the limitations of this research are acknowledged. Among the remaining research gaps, future studies are suggested to investigate the root causes of the non-conformities, conduct multicenter validation of the findings, and apply inferential statistical analyses. The development of economic impact studies will also be fundamental to demonstrate the operational viability of metrology as an essential pillar for patient safety.

CONFLICT OF INTEREST

The authors declare that they have no conflict of interest.

***Abstract*—Performance indicators and quality management tools are widely used in maintenance assessment; however, their integrated application to support evidence-based decision-making in Clinical Engineering remains limited. This study presents an integrated framework combining performance indicators and quality management tools to transform routine corrective maintenance records into strategic information for healthcare technology management. A retrospective, documentary, observational, and quantitative study was conducted using maintenance records from a Brazilian federal university hospital. During April 2026, the institution recorded 1,349 maintenance work orders, of which 239 corresponded to corrective maintenance and were included in the analysis. Maintenance performance was assessed using the Mean Time to Repair (MTTR), which was 1.92 days. Repair times were characterized using a histogram, followed by Pareto analysis to identify the equipment contributing most to cumulative corrective maintenance time. Five prioritized prolonged-repair cases were investigated using Ishikawa cause-and-effect diagrams, and improvement actions were structured according to the Plan–Do–Study–Act (PDSA) cycle. Recurrent factors associated with prolonged repair times included equipment aging, limited availability of replacement components, administrative process constraints, lack of standardized maintenance procedures, and insufficient technology renewal planning. Within the scope of this single-center, one-month analysis, the workflow demonstrated its potential to organize maintenance information and support prioritization and improvement planning; longitudinal evaluation is still required to determine whether the proposed actions reduce MTTR or improve maintenance performance over time.**

***Index Terms*—Clinical Engineering, Performance Indicators, Mean Time to Repair (MTTR), Quality Management Tools, Decision-Making**

I. Introduction

The increasing incorporation of medical technologies into healthcare systems has substantially increased the complexity of hospital services, making equipment availability, reliability, lifecycle management, and evidence-based decision-making essential components of safe and efficient patient care. In this context, Clinical Engineering has evolved from a predominantly technical support function into a strategic discipline responsible for managing healthcare technologies throughout their entire lifecycle, including planning, acquisition, installation, maintenance, performance evaluation, obsolescence management, and technology replacement [1]–[3].

The widespread implementation of computerized maintenance management systems (CMMS) has enabled the systematic collection of operational information generated during routine maintenance activities. Consequently, maintenance work orders have evolved beyond administrative records to become valuable sources of evidence capable of supporting performance assessment, maintenance planning, resource allocation, risk management, and strategic decision-making in Clinical Engineering [4]–[6]. Among the indicators used to evaluate maintenance performance, the Mean Time to Repair (MTTR) is one of the most widely adopted measures of maintainability.

MTTR estimates the average time required to restore equipment to operational condition following a failure and reflects not only the efficiency of technical repair activities but also organizational factors such as spare-part availability, administrative workflows, logistics, technical support, and maintenance planning [7], [8]. Consequently, MTTR should be interpreted as a system-level maintenance performance indicator rather than simply a measure of repair duration. Despite its broad applicability, MTTR alone does not explain why repair times vary among equipment or which factors contribute most to maintenance delays.

Performance indicators therefore require complementary analytical approaches capable of identifying priority equipment, investigating potential contributing factors, and supporting continuous quality improvement initiatives. In this context, quality management tools—including histograms, Pareto charts, Ishikawa cause-and-effect diagrams, and the Plan–Do–Study–Act (PDSA) cycle—provide complementary perspectives that facilitate systematic analysis of maintenance processes and support evidence-based quality improvement [9]–[12].

Although performance indicators and quality management tools are individually well established, studies integrating these approaches into a structured analytical workflow for

Clinical Engineering remain limited, particularly those based on routinely collected maintenance data from university hospitals. Bridging this gap may enhance the analytical value of maintenance records by transforming operational data into strategic information capable of supporting maintenance management, technology renewal planning, and evidence-based decision-making [2], [4], [5].

Therefore, this study proposes an integrated analytical framework combining the Mean Time to Repair (MTTR), histogram analysis, Pareto charts, Ishikawa cause-and-effect diagrams, and the Plan–Do–Study–Act (PDSA) cycle to evaluate corrective maintenance performance in a Brazilian federal university hospital. By integrating complementary analytical tools into a sequential decision-support workflow, the proposed approach demonstrates how routinely collected maintenance data can be transformed into actionable information to support evidence-based decision-making and continuous improvement in healthcare technology management.

II. Material and Methods

A. Study Design

This retrospective, documentary, observational, and quantitative study was conducted using maintenance records from the Clinical Engineering Department of a Brazilian federal university hospital. The analyses were based on data extracted from the institution's computerized maintenance management system (CMMS), including all maintenance work orders registered during April 2026. During the study period, a total of 1,349 maintenance work orders were recorded. Among these, 239 corresponded to corrective maintenance and were included in the analysis. Preventive maintenance, calibration activities, inspection records, duplicated entries, incomplete work orders, and administrative records without corrective interventions were excluded.

B. Maintenance Performance Indicator

Corrective maintenance performance was evaluated using the Mean Time to Repair (MTTR). In this study, MTTR was operationally defined as the mean elapsed time between the Service Order Request (SOS), which marks the beginning of the corrective repair process, and the Work Order Ready/Completed status (OSP), which marks its completion in the CMMS. This definition encompasses the complete corrective repair process recorded by the institution rather than only hands-on technical intervention time. Individual Time to Repair (TTR) values were expressed in days, and MTTR was calculated for the 239 corrective maintenance work orders included in the final analytical dataset.

Because repair-time distributions may be asymmetric, MTTR was complemented by the median, interquartile range (IQR), 90th and 95th percentiles, observed range, skewness, and a 95% bootstrap confidence interval for the mean. MTTR was retained as the principal maintenance indicator, whereas prioritization was interpreted from the combined distributional and Pareto analyses rather than from the mean alone. MTTR was calculated as

$$\mathrm{MTTR} = \frac{\sum_{i=1}^{N} \mathrm{TTR}_i}{N}, \tag{1}$$

where MTTR is the Mean Time to Repair (days), $\sum \mathrm{TTR}_i$ is the sum of the individual SOS–OSP intervals for all corrective maintenance work orders, and N is the number of corrective maintenance work orders in the final analytical dataset ($N = 239$).

C. Analytical Workflow

The analytical workflow was designed to progressively characterize, prioritize, investigate, and address factors associated with prolonged corrective maintenance times. Initially, the distribution of individual Time to Repair (TTR) values was examined using a histogram to characterize variability and asymmetry. Descriptive statistics were calculated to complement the graphical assessment, including the median, IQR, percentiles, observed range, skewness, and a 95% bootstrap confidence interval.

For equipment prioritization, "SUPPORT" work orders, representing miscellaneous technical services such as accessory replacement, were excluded without affecting the 239 records used to calculate overall MTTR. Among the remaining records, TTR values above the overall MTTR formed an exploratory screening set ranked in descending order. This step was not interpreted as a validated clinical or engineering criticality threshold. A Pareto chart examined the screened records' contribution to cumulative corrective maintenance time [12]. The five highest-ranked cases were selected for qualitative investigation using Ishikawa cause-and-effect diagrams and are reported in Table I. Potential contributing factors were organized into the categories Equipment, Parts and Materials, Methods, Workforce, Management, and Suppliers [9], [10].

The diagrams were developed from information available in the maintenance records and were subsequently reviewed by five Clinical Engineering professionals (three technicians and two clinical engineers) to assess the technical plausibility and operational relevance of the mapped factors. This expert review supported the qualitative interpretation of the diagrams but did not constitute quantitative causal validation. Based on the potential contributing factors identified, improvement actions were structured according to the Plan–Do–Study–Act (PDSA) cycle as a planning framework [11].

In the present study, the PDSA actions were proposed from the analytical findings; their longitudinal implementation and post-intervention effect on MTTR were not evaluated. Therefore, no claim of intervention efficacy was made.

III. Results and Discussion

A. Maintenance Performance

During the study period, 239 corrective maintenance work orders, extracted from a total of 1,349 maintenance records, were analyzed. The calculated Mean Time to Repair (MTTR) was 1.92 days. The median TTR was 1.0 day (IQR: 0–2 days), the 90th and 95th percentiles were 5 and 7 days,

respectively, and the observed range was 0–27 days. The distribution was markedly right-skewed (skewness = 3.98). The 95% bootstrap confidence interval for the mean was 1.56–2.33 days. These statistics demonstrate that the mean was influenced by a relatively small number of prolonged repair intervals and should therefore be interpreted together with robust distributional measures.

In this study, MTTR represents the complete SOS–OSP interval recorded in the CMMS, from the service request that initiates the corrective repair process to the work-order ready/completed status. Accordingly, the indicator reflects the institution's operational repair process rather than only hands-on technical intervention time. This operational definition should be considered when comparing the present MTTR with indicators derived from other maintenance systems or definitions. This broader interpretation extends the analytical value of MTTR beyond repair efficiency alone.

By reflecting the overall performance of the maintenance management system, the indicator provides evidence to support decisions related to resource allocation, technology renewal planning, obsolescence management, and maintenance strategy. Recent studies have similarly emphasized that maintenance performance indicators constitute essential components of evidence-based maintenance management in healthcare institutions [5], [8]. Nevertheless, although MTTR objectively quantifies maintenance performance, it does not explain the factors responsible for prolonged repair times. Therefore, complementary analytical tools were required to characterize repair-time distribution, prioritize critical equipment, investigate potential contributing factors, and structure improvement actions, justifying the integrated analytical workflow adopted in this study.

B. Repair Time Distribution

The distribution of individual Time to Repair (TTR) values was examined using a histogram (Fig. 1), providing an overview of repair-time variability in relation to the calculated MTTR and complementary descriptive statistics. The histogram revealed a pronounced right-skewed distribution, consistent with the numerical skewness of 3.98.

The median TTR (1.0 day) was substantially lower than the mean (1.92 days), while the 90th and 95th percentiles reached 5 and 7 days, respectively. Thus, a relatively small number of prolonged repair intervals exerted considerable influence on the overall MTTR. This finding supports reporting the mean together with median- and percentile-based measures rather than interpreting MTTR in isolation [8], [12]. Beyond describing repair-time variability, the histogram served as an exploratory analytical tool that facilitated the identification of atypical repair durations prior to equipment prioritization. This preliminary assessment provided the basis for the subsequent Pareto analysis.

C. Prioritization of Critical Equipment

The Pareto analysis showed that corrective maintenance time was concentrated in a subset of equipment records (Fig. 2),

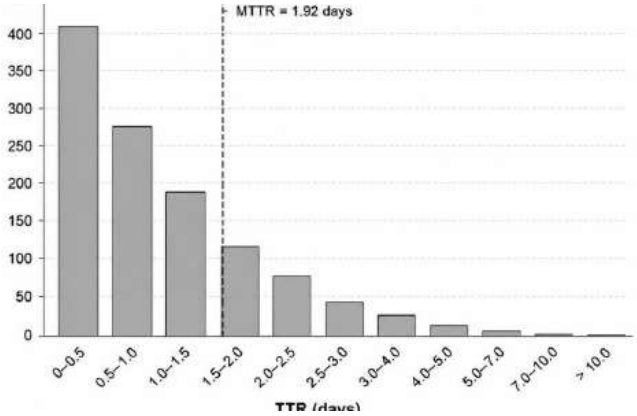

Fig. 1. Distribution of repair times for corrective maintenance work orders.

supporting descriptive prioritization of prolonged repair cases. Given the marked asymmetry of the TTR distribution, the overall MTTR was not interpreted as a validated cutoff for defining equipment criticality. Instead, the Pareto chart was used to visualize the relative contribution of repair intervals to cumulative corrective maintenance time. After excluding SUPPORT work orders from equipment prioritization, records with TTR above the overall MTTR were screened and ranked in descending order.

The five highest-ranked records were selected for qualitative investigation (Table I): three multiparametric monitor cases and two ophthalmic tonometer cases, with TTR values of 27, 17, 17, 8, and 8 days. Prioritization was based on this exploratory screening set; the mean was not interpreted as a validated criticality threshold. Rather than establishing a clinical or engineering criticality threshold, the TTR $>$ MTTR step was used only as an exploratory screening rule. Within that screened set, descending TTR ranking and the Pareto chart provided a descriptive means of concentrating attention on prolonged repair intervals.

This distinction is important because the mean of a markedly right-skewed distribution is not, by itself, a validated cutoff for prioritization. The Pareto stage therefore supported exploratory prioritization for subsequent investigation of potential contributing factors [4], [8]. The Pareto analysis complemented the MTTR and distributional statistics. While MTTR quantified average maintenance performance and the median and percentiles characterized the asymmetric distribution, the Pareto chart visualized the concentration of cumulative repair time, establishing the basis for the subsequent qualitative Ishikawa analysis.

D. Investigation of Potential Contributing Factors

To investigate factors potentially associated with prolonged repair times, Ishikawa cause-and-effect diagrams were developed for the five cases taken forward from the prioritization stage (Figs. 3–5). This qualitative approach organized potential contributing factors into six analytical categories: equipment characteristics, spare parts, maintenance methods, workforce, management practices, and supplier-related factors.

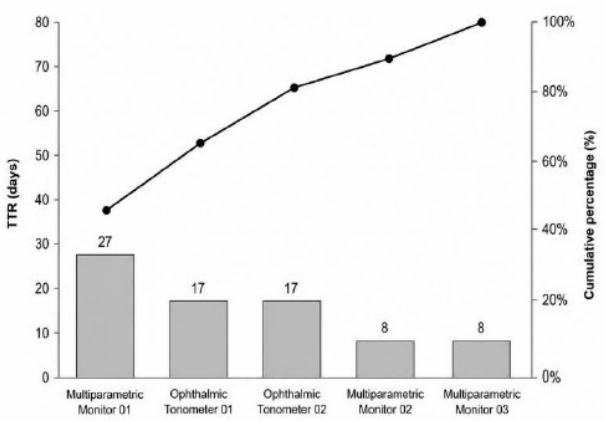

Fig. 2. Pareto chart of the equipment contributing most to cumulative corrective maintenance time.

TABLE I
EQUIPMENT PRIORITIZED FOR INVESTIGATION OF POTENTIAL CONTRIBUTING FACTORS

Equipment	TTR (days)	Main identified factor
Multiparametric Monitor 01	27	Equipment lifecycle limitations and replacement component unavailability
Ophthalmic Tonometer 01	17	Discontinued equipment and spare-part supply restrictions
Ophthalmic Tonometer 02	17	Discontinued equipment and spare-part supply restrictions
Multiparametric Monitor 02	8	Electronic failures associated with administrative constraints
Multiparametric Monitor 03	8	Equipment lifecycle limitations and insufficient spare-part inventory

Across the diagrams, the maintenance records suggested recurrent potential contributing factors, including equipment obsolescence, limited availability of replacement parts, discontinued manufacturer support, incomplete diagnostic procedures, deficiencies in maintenance documentation, communication failures between technical and administrative sectors, and institutional management constraints. These factors should be interpreted as hypotheses generated from the available records rather than as independently verified causes. Among the potential factors represented in the diagrams, equipment obsolescence and discontinued manufacturer support were considered plausible contributors to prolonged downtime.

The mapped factors were reviewed by three technicians and two clinical engineers from the Clinical Engineering team, providing an expert-based assessment of their technical plausibility and operational relevance. Nevertheless, no formal consensus method, independent documentary confirmation of every mapped factor, or quantitative causal assessment was performed. The diagrams should therefore be interpreted as expert-reviewed exploratory tools for hypothesis generation and improvement planning [1], [4].

The Ishikawa diagrams also highlighted potentially modifiable organizational factors, including diagnostic protocols, maintenance procedure standardization, spare-parts inventory, communication between technical and administrative departments, workforce training, and documentation practices [5], [8]. These factors require prospective verification before their effect on MTTR can be established. Taken together, the Ishikawa diagrams suggest that maintenance performance may be influenced by interactions among technical, organizational, and managerial processes. This systems perspective is compatible with the operational definition of MTTR adopted in this study, which covers the complete SOS–OSP repair interval.

The potential contributing factors mapped through the Ishikawa analysis subsequently served as the foundation for structuring proposed improvement actions using the PDSA cycle.

E. Integration of Performance Indicators and Quality Management Tools

The integrated analytical workflow showed that maintenance performance indicators and quality management tools provide complementary descriptive information when applied sequentially. MTTR quantified average performance; the median, IQR, percentiles, confidence interval, and histogram characterized the asymmetric repair-time distribution; the Pareto chart supported descriptive prioritization; and the Ishikawa diagrams organized potential contributing factors. Finally, the PDSA cycle translated these findings into proposed improvement actions. The workflow therefore supports structured decision-making but does not, in the present cross-sectional analysis, demonstrate improvement efficacy.

The proposed workflow illustrates how maintenance records generated during routine hospital activities can support operational maintenance control and decision-making in Clinical Engineering. Its principal contribution is the sequential application of complementary tools to real CMMS records, allowing descriptive performance measurement, prioritization, exploratory cause mapping, and improvement planning within a single analytical process [4], [5], [8]. Several limitations should be considered when interpreting these findings.

The analysis was conducted at a single university hospital and covered only one month, limiting generalization to institutions with different equipment inventories, maintenance structures, and operational characteristics. The study focused exclusively on corrective maintenance and therefore did not permit comparison with preventive or predictive maintenance. The CMMS field for equipment criticality was incomplete in the analytical dataset, preventing a valid stratified analysis by criticality, and no dedicated variable quantified waiting time for spare parts. Consequently, spare-part waiting time could not be analyzed independently and was outside the scope of this study. Equipment-type stratification was also limited by small numbers within several categories.

The analytical dataset comprised completed corrective work orders; consequently, no right-censored observations were present among the 239 analyzed records. Nevertheless, restricting the analysis to completed work orders may introduce selection effects because repairs that remained open beyond the observation window were not represented in the final analytical dataset. Furthermore, the PDSA cycle was used to structure proposed actions rather than to evaluate longitudinal implementation. Although the Ishikawa factors were reviewed by three technicians and two clinical engineers, this validation remained qualitative and did not establish causality.

No direct comparison was performed with predictive-maintenance, machine-learning, or multicriteria decision-support approaches, as such a comparison was outside the scope of this study. Future studies should include multicenter and longitudinal datasets, explicit tracking of spare-part waiting time, more complete equipment-criticality fields, preventive and predictive maintenance indicators, reliability measures, utilization, lifecycle costs, and prospective assessment of PDSA interventions.

IV. Conclusion

This study showed that integrating MTTR with complementary descriptive statistics and quality management tools provides a structured approach for analyzing corrective maintenance in Clinical Engineering.

Using 239 corrective maintenance work orders from routine CMMS records, the mean SOS–OSP repair interval was 1.92 days, while the median was 1.0 day (IQR: 0–2 days), confirming a markedly right-skewed distribution. Histogram and Pareto analyses characterized variability and supported descriptive prioritization, Ishikawa diagrams organized potential contributing factors, and the PDSA cycle was used to structure proposed improvement actions. Within the scope of this single-center, one-month study, the contribution of the work lies in the sequential application of these tools to real maintenance records as a decision-support workflow.

The findings demonstrate descriptive prioritization and structured improvement planning, not proven improvement in maintenance outcomes. Future multicenter and longitudinal studies are required to evaluate generalizability and to quantify the effect of proposed interventions on MTTR and other maintenance outcomes.

***Resumo*—A crescente incorporação de tecnologias nos serviços de saúde tem ampliado a necessidade de métodos estruturados para o gerenciamento dos equipamentos médico-hospitalares, especialmente em instituições que ainda não possuem setores formalizados de Engenharia Clínica. A literatura aponta que a ausência de inventários atualizados e de sistemas de gestão tecnológica compromete a rastreabilidade dos ativos, dificulta o planejamento da manutenção e impacta diretamente a disponibilidade operacional. Nesse contexto, o presente trabalho apresenta o desenvolvimento de um inventário estruturado do parque tecnológico de um hospital público municipal da região Agreste de Alagoas, como etapa inicial para a implantação da Engenharia Clínica institucional. A pesquisa, caracterizada como estudo de caso, envolveu o levantamento físico dos equipamentos, a transição dos dados para um sistema informatizado de gerenciamento de manutenção (CMMS) e a estruturação de Ordens de Serviço (OS) com protocolos de segurança elétrica. Os resultados evidenciaram que o hospital operava sob um modelo de manutenção predominantemente corretivo e terceirizado, sem cronogramas preventivos. A informatização do inventário e a gestão via OS permitiram organizar o acervo, criando condições para a rastreabilidade das intervenções e para a mitigação de riscos, estabelecendo as bases para a extração futura de indicadores de desempenho, como o Tempo Médio Entre Falhas (Mean Time Between Failures - MTBF), o Tempo Médio de Reparo (Mean Time to Repair - MTTR) e a disponibilidade operacional. Conclui-se que o inventário estruturado e informatizado representa o pilar fundamental para práticas modernas de Engenharia Clínica em hospitais públicos interioranos, promovendo a transição para a cultura preventiva, o aumento da segurança assistencial e a otimização dos recursos em saúde.**

***Palavras-chave*—Engenharia Clínica, Gestão de Tecnologias em Saúde, Manutenção de Equipamentos Hospitalares, Sistemas de Gestão de Manutenção (CMMS).**

I. Introdução

Os Equipamentos Médico-Hospitalares (EMH) constituem elementos essenciais para a assistência moderna à saúde, participando diretamente dos processos de diagnóstico, monitoramento e tratamento dos pacientes. O aumento da complexidade tecnológica dos hospitais exige métodos estruturados para controle, rastreabilidade e manutenção desses ativos, garantindo maior segurança ao paciente e eficiência operacional dos serviços de saúde [1]–[3].

A Engenharia Clínica surge nesse contexto como área estratégica responsável pelo gerenciamento do ciclo de vida das tecnologias em saúde, abrangendo atividades relacionadas à aquisição, instalação, inventário, manutenção, avaliação de desempenho e descarte. Estudos demonstram que hospitais com processos estruturados de Engenharia Clínica apresentam maior disponibilidade tecnológica e redução dos custos associados à manutenção corretiva [4]–[6].

Pesquisas recentes evidenciam que a implantação de práticas formais de gestão tecnológica promove melhorias significativas na redução de falhas operacionais e no planejamento das intervenções técnicas [7]. Constata-se, contudo, que a ausência de sistemas estruturados de gerenciamento tecnológico e de informações organizadas sobre o acervo constitui uma das principais barreiras para o desenvolvimento da área em hospitais públicos brasileiros, impactando diretamente a eficiência assistencial [8], [9].

No cenário nacional, Cardoso e Waqued [7] observaram que a Engenharia Clínica deixou de atuar apenas como setor de oficina para assumir um papel estratégico, incorporando o gerenciamento de riscos e o controle do ciclo de vida dos equipamentos. Essa evolução reforça a urgência da implantação de sistemas organizados de inventário. Além disso, a experiência observada durante a pandemia da COVID-19 demonstrou a criticidade de informações confiáveis. Segundo Toscas *et al.* [8], dificuldades relacionadas ao controle patrimonial comprometeram a rápida mobilização de ventiladores

pulmonares e outros suportes de vida em diversas regiões do país.

A literatura aponta que a etapa fundamental para a consolidação da Engenharia Clínica é a elaboração de um inventário estruturado. A ausência de dados unificados sobre localização, estado operacional, fabricante e histórico de manutenção inviabiliza a tomada de decisão técnica [3], [10], [11]. Em hospitais localizados em regiões interioranas, os desafios tornam-se ainda maiores devido à limitação financeira, escassez de profissionais especializados e alta dependência de assistências técnicas sediadas em grandes centros urbanos. Essa realidade gera um aumento do tempo de indisponibilidade dos equipamentos, forçando a predominância de ações corretivas em detrimento das preventivas [6], [12].

A integração entre logística hospitalar e manutenção também se mostra determinante. A localização física dos equipamentos, o controle das movimentações internas e o acompanhamento dos fluxos de Ordem de Serviço (OS) influenciam diretamente a prontidão tecnológica das instituições [13]. Para sanar essas lacunas, a utilização de sistemas informatizados de gerenciamento de manutenção (CMMS) tem sido destacada na literatura. A consolidação de bancos de dados estruturados permite identificar padrões de falhas, embasar decisões e gerar indicadores de desempenho confiáveis para os gestores [6].

Diante desse cenário, o presente trabalho tem como objetivo apresentar o desenvolvimento de um inventário estruturado dos equipamentos médico-hospitalares de um hospital público municipal localizado na região Agreste do estado de Alagoas, atuando como etapa inicial para a implantação da Engenharia Clínica institucional. O estudo busca evidenciar como esse mapeamento fornece suporte para a transição de um modelo de controle informal para um sistema informatizado, podendo subsidiar o planejamento da manutenção, estabelecer uma base para a rastreabilidade dos ativos e criar condições para práticas modernas de gerenciamento de tecnologias em saúde.

II. Referencial Teórico

A Engenharia Clínica é definida como a aplicação dos conhecimentos de engenharia, gestão e ciências da saúde para garantir a utilização segura, eficaz e economicamente viável das tecnologias empregadas nos serviços assistenciais. Seu principal objetivo consiste em assegurar que os equipamentos médico-hospitalares mantenham desempenho adequado ao longo de todo o seu ciclo de vida [1], [2].

Segundo Wang [4], a gestão tecnológica hospitalar deve contemplar atividades integradas de planejamento, aquisição, inventário, manutenção, monitoramento e substituição de equipamentos. Essas ações permitem reduzir falhas operacionais e ampliar a confiabilidade dos sistemas utilizados na assistência aos pacientes [4], [5]. No Brasil, a regulamentação relacionada à gestão de tecnologias em saúde é fortalecida pela Resolução da Diretoria Colegiada (RDC) nº 509/2021 da Agência Nacional de Vigilância Sanitária (ANVISA), que estabelece diretrizes rigorosas para o gerenciamento de equipamentos e infraestrutura tecnológica em estabelecimentos assistenciais de saúde [14].

Complementando essa visão regulatória, pesquisadores do Hospital das Clínicas da Universidade de São Paulo (USP) [15] demonstraram que a formalização dos fluxos de trabalho da Engenharia Clínica proporciona maior eficiência na comunicação entre os setores assistenciais, a equipe de manutenção e a administração hospitalar. O mapeamento desses processos operacionais permite identificar gargalos e otimizar significativamente o gerenciamento das tecnologias em saúde.

A Organização Mundial da Saúde (OMS) considera o inventário de equipamentos como a primeira etapa, inegociável, para a implementação de um programa de gerenciamento tecnológico. O inventário fornece a base de dados primária sobre quantidade, localização, características técnicas, fabricante, estado de conservação e criticidade do acervo institucional [10], [11]. De acordo com Calil e Teixeira [3], um inventário adequadamente estruturado permite que os gestores conheçam a real situação do parque tecnológico hospitalar, subsidiando decisões estratégicas relacionadas à manutenção, aquisições e desativações.

A literatura reforça que a inexistência de inventários atualizados inviabiliza a rastreabilidade tecnológica e suprime a capacidade de planejamento das unidades de saúde. Em contrapartida, a implantação de inventários devidamente informatizados destaca-se como um dos principais fatores responsáveis por um avanço significativo na qualidade da gestão de equipamentos [7]. Além do mero controle patrimonial, essa ferramenta fornece suporte para a avaliação de riscos tecnológicos e no planejamento de investimentos futuros, conferindo maior eficiência operacional [6], [16].

A implantação da Engenharia Clínica em hospitais públicos ocorre, habitualmente, de forma gradual, tendo o levantamento físico e patrimonial como o ponto de partida para a construção de um ecossistema de gestão eficiente [7], [15]. Estudos de caso realizados em hospitais brasileiros evidenciam que a ausência dessa base de dados dificulta o planejamento da manutenção preventiva, infla os custos operacionais e prolonga o tempo de indisponibilidade de máquinas vitais. Por outro lado, a implantação de rotinas sistematizadas contribui para a redução das ocorrências de falhas severas, impacto que se torna ainda mais relevante em hospitais interioranos, onde os recursos técnicos e financeiros são frequentemente escassos e a dependência de terceiros é alta [2], [5], [12].

A partir da consolidação do inventário e do histórico de intervenções técnicas (Ordens de Serviço), o referencial contemporâneo aponta para a adoção de sistemas informatizados de gerenciamento de manutenção (CMMS). Pesquisas voltadas para estratégias baseadas em dados [6] demonstraram que a utilização de registros estruturados permite extrair indicadores de desempenho robustos e confiáveis.

Segundo os princípios da Engenharia Clínica contemporânea, a extração de métricas como o MTBF, o MTTR, a disponibilidade operacional e a taxa de manutenção preventiva torna possível identificar tendências de depreciação, estabelecer prioridades de manutenção e otimizar, de forma fundamentada, a alocação de recursos financeiros e humanos da instituição [1], [4], [16].

III. Materiais e Métodos

A pesquisa caracteriza-se como um estudo de caso, de natureza aplicada, com abordagem mista (qualitativa e quantitativa) e objetivos descritivos. O estudo foi desenvolvido em um hospital público municipal localizado na região Agreste do estado de Alagoas, que presta atendimento de média complexidade a diversas cidades circunvizinhas. A instituição possui um parque tecnológico diversificado, englobando setores de urgência, internação, centro cirúrgico, laboratório e diagnóstico. Para preservar a confidencialidade institucional, a identificação do hospital foi suprimida, visto que a pesquisa aborda aspectos sensíveis relacionados à gestão tecnológica e aos processos de manutenção.

Inicialmente, realizou-se uma revisão da literatura nacional e internacional sobre Engenharia Clínica, gerenciamento de tecnologias em saúde, inventário hospitalar, gestão do ciclo de vida dos equipamentos e indicadores de desempenho. Essa etapa forneceu a fundamentação teórica necessária para o delineamento dos procedimentos experimentais. O plano de trabalho contemplou o mapeamento dos setores a serem visitados, a definição das variáveis a serem coletadas e o cronograma de atividades.

A coleta de dados ocorreu por meio de visitas técnicas quinzenais, nas quais procedeu-se ao levantamento físico dos equipamentos. Registrou-se, para cada ativo, informações como localização, patrimônio, fabricante, modelo, número de série, estado de conservação, condição operacional e características técnicas relevantes. Paralelamente, foram realizadas entrevistas técnicas com os gestores da manutenção para compreender o fluxo atual de atendimento. O diagnóstico inicial abrangeu a análise de contratos com empresas terceirizadas, a verificação de cronogramas de manutenção preventiva e a análise da resposta à manutenção corretiva.

Após a coleta, os dados foram processados e inseridos em um sistema informatizado de gerenciamento de manutenção (CMMS), utilizando a plataforma Arkmeds em ambiente educacional. O banco de dados foi estruturado para organizar o parque tecnológico por setor, registrar o histórico de intervenções e permitir a geração de Ordens de Serviço (OS).

Por fim, os dados foram analisados por meio de estatística descritiva e análise qualitativa, buscando identificar o perfil do parque tecnológico e as principais fragilidades na gestão. Os resultados foram confrontados com a literatura especializada para subsidiar a proposta de implantação gradual da Engenharia Clínica, incluindo a padronização das ordens de serviço, a criação de indicadores de desempenho, como MTBF e MTTR, e o estabelecimento de um plano anual de manutenção preventiva.

IV. Resultados e Discussão

A inspeção visual permitiu registrar as características físicas e o estado de conservação do parque tecnológico. Conforme ilustrado na Fig. 1, o painel evidencia a diversidade de ativos críticos presentes na instituição, englobando desde equipamentos de suporte à vida e terapia, como incubadoras de transporte, ventiladores pulmonares e bombas de infusão, até sistemas radiológicos de diagnóstico por imagem, como mamógrafos. Ademais, o registro fotográfico de etiquetas de teste e calibração em equipamentos específicos, observado na Fig. 1(h), reforça a necessidade prática de rastreabilidade técnica.

Com base nessa inspeção física, o inventário estruturado resultou na catalogação de 40 equipamentos médico-hospitalares, destinados ao atendimento básico e de média complexidade. A totalidade do parque tecnológico inventariado encontrava-se com status operacional ativo (operante) no momento da coleta. A distribuição desses ativos revela uma concentração em setores críticos, como Centro Cirúrgico e Estabilização, conforme evidenciado na Tabela I.

Tabela I
Distribuição dos Equipamentos Inventariados por Setor Hospitalar

Setor / Unidade	Quantidade	Status Operacional
Centro Cirúrgico	12	Operante (100%)
Estabilização	12	Operante (100%)
Unidade Mista (UMNSG)	6	Operante (100%)
Maternidade	5	Operante (100%)
Clínica Médica	2	Operante (100%)
Esterilização (CME)	2	Operante (100%)
Radiologia	1	Operante (100%)
Total	**40**	**Operante (100%)**

Além da localização espacial, o mapeamento evidenciou os principais tipos de tecnologias disponíveis na instituição. A compilação quantitativa por categorias de equipamentos é apresentada na Fig. 2.

Durante o levantamento, observou-se que a instituição não possuía histórico consolidado de manutenção nem sistema informatizado para gestão dos equipamentos, evidenciando limitações no controle das atividades de manutenção e na rastreabilidade das intervenções técnicas. Durante as entrevistas realizadas com o responsável pela manutenção dos equipamentos, foi informado que o hospital possui um acordo firmado com uma empresa especializada localizada na capital do estado, Maceió, responsável pela execução dos serviços de manutenção. Entretanto, a instituição não dispõe de informações detalhadas sobre o conteúdo desse contrato.

Quando questionado sobre a existência de um calendário de manutenção preventiva dos equipamentos médico-hospitalares, o responsável informou desconhecer sua existência, afirmando não possuir acesso a qualquer cronograma ou planejamento formal das intervenções preventivas. Curiosamente, o levantamento físico e fotográfico revelou a existência de etiquetas de teste e calibração em ativos específicos, como observado na bomba de seringa (Fig. 1h), o que evidencia um grave descompasso entre as rotinas de campo e o controle administrativo da instituição. Essa situação evidencia fragilidades na gestão tecnológica do hospital, dificultando o acompanhamento das ações de manutenção e o controle da disponibilidade dos equipamentos.

Em relação ao fluxo de atendimento das manutenções corretivas, foi relatado que, quando ocorre uma falha em algum equipamento, o hospital entra em contato com a empresa

(a) Monitor multiparamétrico (Fabricante: COMEN; Modelo: STAR8000E; Localização: Estabilização; Patr.: 20211897; Nº Série: S/N; Condição: Operante).

(b) Incubadora neonatal (Fabricante: Olidef; Modelo: RWT PLUS; Localização: Maternidade; Patr.: 3697; Nº Série: S/N; Condição: Operante).

(c) Ventilador pulmonar (Fabricante: Magnamed; Modelo: OxyMag; Localização: Estabilização; Patr.: 20222181; Nº Série: S/N; Condição: Operante).

(d) Mamógrafo com console (Fabricante: Aurora; Localização: Maternidade; Patr.: S/N; Nº Série: S/N; Condição: Operante).

(e) Bomba de infusão volumétrica (Fabricante: Não ident.; Modelo: SAM-6003; Localização: Centro Cirúrgico; Patr.: 2025005436; Condição: Operante).

(f) Detalhe do gantry do mamógrafo Aurora catalogado na Maternidade (Ativo vinculado à Fig. 1d).

(g) Configuração clínica do ventilador Magnamed OxyMag interligado ao cilindro de oxigênio (Ativo vinculado à Fig. 1c).

(h) Bomba de seringa (Fabricante: CMOS Drake; Modelo: Yonah; Localização: Estabilização; Patr.: 20242504003; Nº Série: 0408006; Condição: Operante).

Figura 1. Painel ilustrativo do parque tecnológico catalogado, apresentando a compilação final dos dados de rastreabilidade extraídos durante o inventário físico institucional, em conformidade com as variáveis definidas no método. Na coluna esquerda: (a) Monitor multiparamétrico de sinais vitais; (b) Incubadora neonatal de transporte; (c) Ventilador pulmonar; e (d) Sistema de mamografia. Na coluna direita: (e) Bomba de infusão volumétrica; (f) Detalhe do sistema de compressão do mamógrafo; (g) Detalhe de instalação do ventilador pulmonar; e (h) Bomba de seringa evidenciando etiqueta de rastreabilidade de manutenção.

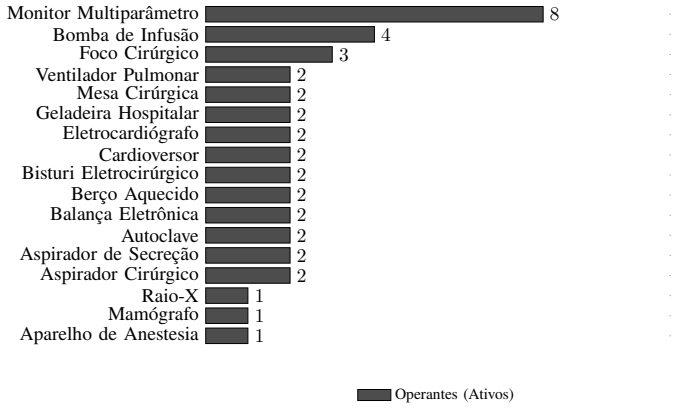

Figura 2. Distribuição quantitativa das categorias de equipamentos médico-hospitalares identificados no inventário. O levantamento constatou que 100% (40) dos ativos registrados encontram-se em status operacional operante (ativos), sem incidência de equipamentos inoperantes ou sucateados.

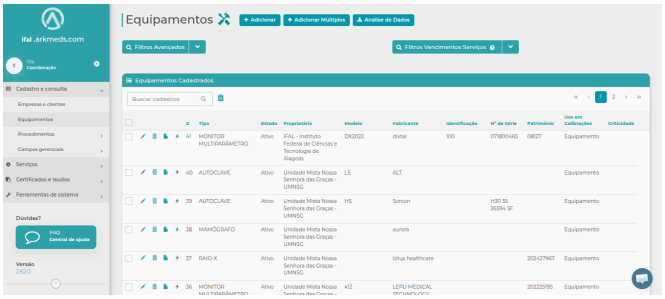
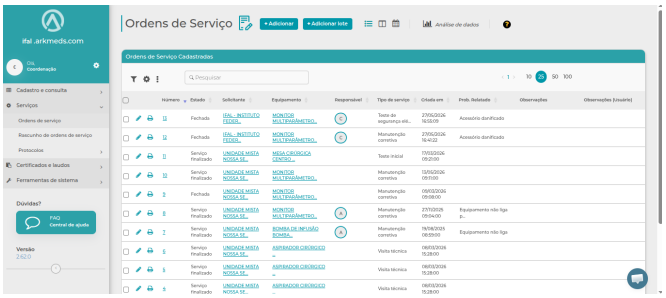
contratada, que estabelece um prazo de até dez dias para atendimento da solicitação. Esse intervalo pode comprometer significativamente a disponibilidade operacional de equipamentos essenciais de suporte à vida e diagnóstico por imagem, a exemplo dos ventiladores pulmonares e sistemas de mamografia identificados no inventário, sobretudo em hospitais de pequeno porte e localizados no interior, onde a dependência de assistência técnica externa tende a aumentar o tempo de resposta às ocorrências.

Esses achados corroboram a literatura, que aponta que a ausência de um sistema estruturado de Engenharia Clínica, aliado à inexistência de registros organizados de manutenção preventiva, contratos tecnicamente gerenciados e indicadores de desempenho, favorece a predominância de ações corretivas, eleva os custos operacionais e aumenta o tempo de indisponibilidade dos equipamentos médico-hospitalares [6], [7], [12]. A implantação de um sistema informatizado de gestão, associada à formalização dos processos de manutenção e ao acompanhamento sistemático dos contratos de assistência técnica, estabelece uma base para o aumento da confiabilidade tecnológica da instituição.



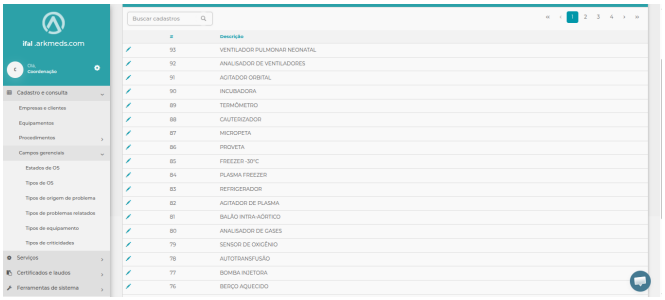
A implantação do inventário estabelece a base para a organização patrimonial dos ativos e cria condições para a rastreabilidade tecnológica, a identificação rápida da localização dos equipamentos, o registro padronizado das características técnicas, a criação de histórico para futuras análises de manutenção e a implementação de indicadores de desempenho, como o MTBF, o MTTR, a disponibilidade operacional e o índice de manutenção preventiva.

Como desdobramento prático do inventário físico, procedeu-se com a inserção dos dados em um software de gerenciamento de manutenção informatizado (CMMS), cuja interface é ilustrada na Fig. 3.



Para demonstrar a aplicabilidade do sistema e exemplificar a execução dos protocolos de qualidade, realizou-se um ensaio prático de segurança elétrica em um dos equipamentos críticos inventariados (Monitor Multiparamétrico Dixtal DX2022). O teste foi parametrizado com base nos limites normativos de aceitação estabelecidos pela norma ABNT NBR IEC 60601-1:2010 (incluindo Emenda 1:2016) para a segurança geral e pelos critérios de ensaios recorrentes de campo preconizados pela ABNT NBR IEC 62353:2019. Para as medições das correntes de fuga (do equipamento e do gabinete), o analisador de segurança elétrica aplicou o Método de Medição Direto. O monitor ensaiado possui classificação geral de proteção contra choque elétrico de Classe I (com aterramento de proteção), e suas partes aplicadas possuem classificações distintas a depender do parâmetro (Tipo BF para PNI e SpO2, e Tipo CF para o canal de ECG). Para a simulação física das correntes de fuga das partes aplicadas registradas na Ordem de Serviço nº 13, conectou-se ao analisador o cabo paciente de ECG de 5 vias, avaliando-se o limite para partes aplicadas Tipo BF/CF.

Os parâmetros coletados durante a intervenção foram inseridos diretamente na plataforma Arkmeds. A Tabela II apresenta os resultados qualitativos e quantitativos do ensaio de segurança. É importante destacar que o monitor foi adequadamente caracterizado como um equipamento de Classe I com partes aplicadas flutuantes, utilizando-se o cabo paciente de ECG como a parte aplicada ativa para o teste físico de corrente de fuga de paciente. Os valores medidos de corrente de fuga do equipamento, do gabinete e das partes aplicadas mantiveram-se significativamente abaixo dos limites de aceitação impostos pelas normas vigentes ABNT NBR IEC 60601-1 e ABNT NBR IEC 62353, o que garantiu a aprovação técnica integral do ativo.



Com base nos resultados obtidos, propõe-se a implantação gradual da Engenharia Clínica por meio da consolidação contínua do inventário no CMMS. A adoção dessa ferramenta viabiliza a estruturação do banco histórico de falhas e a implantação formal do sistema de ordens de serviço. Por fim, o desenvolvimento de Procedimentos Operacionais Padrão (POPs) garantirá a organização e padronização de todos esses processos.

Corrente Funcional (A)	0.04	N/A	Conforme
Potência aparente (VA)	8.52	N/A	Conforme

V. Conclusão

O desenvolvimento do inventário estruturado permitiu estabelecer as bases técnicas necessárias para a implantação da Engenharia Clínica na instituição estudada. Os resultados evidenciaram que o inventário não se limita ao controle patrimonial, constituindo uma ferramenta estratégica para a gestão tecnológica hospitalar. Sua implementação, aliada ao levantamento físico e visual em campo, forneceu suporte para a organização das informações dos equipamentos, para a futura rastreabilidade dos ativos e para a criação de mecanismos visando o acompanhamento sistemático da manutenção.

Além disso, o estudo demonstrou que a transição de um modelo de manutenção predominantemente corretivo e dependente de assistência técnica externa para uma abordagem preventiva exige a formalização de processos e o engajamento contínuo da gestão hospitalar. A adoção de um sistema informatizado de gerenciamento revelou-se indispensável para a centralização dos dados e para a futura geração de indicadores de desempenho, os quais serão fundamentais para embasar decisões estratégicas e avaliar a eficácia dos contratos de prestação de serviços.

Como trabalhos futuros, recomenda-se a consolidação das ordens de serviço digitalizadas, a elaboração de um plano anual de capacitação contínua para a equipe assistencial e a implantação de um programa de gerenciamento de riscos tecnológicos. Conclui-se, portanto, que a estruturação inicial desse inventário representa o primeiro passo decisivo para a consolidação de práticas modernas de Engenharia Clínica em hospitais interioranos, com potencial para contribuir diretamente para a melhoria da qualidade assistencial, a otimização dos recursos públicos e a construção de uma base sólida para o aumento da confiabilidade tecnológica e da segurança do paciente.

Agradecimentos

Os autores agradecem ao Instituto Federal de Alagoas (IFAL) pelo suporte acadêmico e institucional, bem como à gestão do hospital parceiro pela abertura e colaboração fundamentais para a realização do levantamento de campo e para a execução dos testes de segurança elétrica que viabilizaram este estudo.

Abstract* — This study evaluated the level of knowledge and application of the ABNT NBR IEC 62353:2019 standard among Clinical Engineering professionals in Brazil. The research was conducted using a structured questionnaire administered to 45 professionals from 18 Brazilian states. Results indicate that only 22.2% of participants reported in-depth knowledge of the standard. Regarding test execution, the rates for performing the complete protocol prescribed by the standard (visual inspection, functional testing, and electrical safety tests) were low: 22.2% reported conducting all tests at equipment reception, 31.1% after repair, and 48.9% on a recurrent basis. It was also observed that most participants who perform tests use ABNT NBR IEC 60601-1:2022 as their reference, which is not the most appropriate standard for post-market testing, since ABNT NBR IEC 62353:2019 is specifically designed for this purpose. Larger institutions and those with quality certifications demonstrated higher levels of knowledge and greater adherence to the standard guidelines.

Keywords* — ABNT NBR IEC 62353:2019, electromedical equipment, electrical safety, clinical engineering.

I. Introduction

The interaction of electrical current with the human body can result in irreversible health damage and even death. Medical electrical equipment (ME Equipment) represents a potential source of electrical energy that may interact with the body during normal use; therefore, these risks must be managed throughout the devices' entire service life [1], [2].

The ABNT NBR IEC 62353:2019 standard establishes guidelines for conducting pre-service, recurrent, and post-repair testing on ME Equipment, aiming to ensure electrical safety and functional performance throughout their lifecycle [1], [3]. Despite its relevance, the adoption of this standard within Brazilian healthcare institutions remains poorly characterized.

Clinical Engineering (CE) departments are responsible for managing the performance of medical equipment inventories in hospitals. Activities such as acceptance testing, preventive and corrective maintenance, and periodic safety inspections comprise the core functions of these departments [4]. The inclusion of a specific standard for these tests within hospital routines represents a significant advancement for the sector. Previously, only the ABNT NBR IEC 60601-1:2022 series standards were available [2]; however, these standards focus on equipment manufacturing and require testing in environmentally controlled laboratories [5].

The first edition of IEC 62353 was published in 2007. However, national adoption in Brazil only occurred 12 years later, with the publication of ABNT NBR IEC 62353:2019 [1].

A study conducted at a large public hospital in Curitiba demonstrated the practical importance of these tests: out of 393 tests performed, failures were identified in 9.3% of cases, all of which had the potential to compromise patient and operator safety [6].

The present work aims to characterize, at a national level, the degree of knowledge and application of ABNT NBR IEC 62353:2019 among CE professionals, as well as to identify the main barriers to its implementation in Brazilian healthcare institutions.

II. Methodology

A. Study Design and Participants

This cross-sectional study involved CE professionals working in Brazilian healthcare institutions. The questionnaire was distributed electronically, and responses were collected anonymously and voluntarily. Participants working at more than one institution were instructed to respond based on their primary workplace. The study was approved by the Research Ethics Committee (CEP) of UTFPR (CAAE Nº. 84255024.2.0000.0177, Report Nº. 7.226.777).

Of the 47 responses received, two were excluded: one from a participant outside Brazil (Angola) and one without state-of-practice identification. The final sample comprised 45 valid responses from professionals in 18 of Brazil's 26 states.

B. Questionnaire Structure and Analysis

The structured questionnaire addressed five main areas, as illustrated in Fig. 1. Institutional characterization collected data on the total inventory of ME Equipment, the funding model (public, private, or philanthropic), quality certifications (e.g., ONA, JCI, or equivalent), and the state in which the participant operates. The self-reported knowledge level was assessed by asking participants to rate their familiarity with the ABNT NBR IEC 62353:2019 standard using a proficiency scale. Reference standards mapped the specific technical guidelines that professionals adopt in their daily work routines. Types of testing performed included detailed safety practices across three critical stages of the equipment lifecycle: acceptance (incoming inspection), post-repair, and recurrent testing. Finally, the identified implementation challenges highlighted the primary technical, financial, and cultural barriers to adopting the standard. Responses were analyzed descriptively, and subgroup analyses were conducted to identify correlations among institutional

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

characteristics, knowledge of the standard, and actual testing practices.

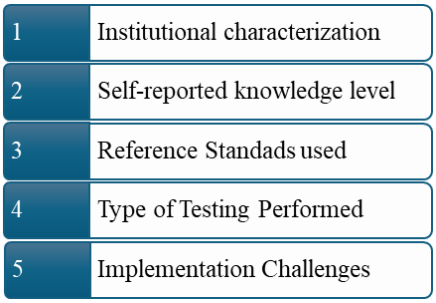

Fig. 1. Main topics addressed in the structured questionnaire.

III. Results and Discussion

A. Participant Characterization

Regarding the number of ME Equipment (institutional size), 66.7% of respondents (*n*=30) worked in hospitals with more than 1,500 ME Equipment, 15.6% (*n*=7) in medium-sized institutions with 501 to 1,500 devices, and 17.8% (*n*=8) in establishments with fewer than 500 ME Equipment. As for the funding model, 53.3% (*n*=24) worked in public institutions, 24.4% (*n*=11) in private ones, and 22.2% (*n*=10) in mixed institutions. Regarding quality certification (ONA, JCI, or equivalent), 35.6% (*n*=16) worked in certified institutions, while 64.4% (*n*=29) did not. Responses were received from 18 states, with the highest concentrations in the Southeast (19 participants), the Northeast (9), and the South (8). Table I summarizes the characterization of the study participants.

TABLE I. Characterization of Survey Participants

Variable	Category	n	%
Institution size	> 1,500 ME Equipments	30	66.7
	501 to 1,500 ME Equipments	7	15.6
	< 500 ME Equipments	8	17.8
Funding model	Public	24	53.3
	Private	11	24.4
	Mixed	10	22.2
Quality certification	Certified	16	35.6
	Not certified	29	64.4
Region	Southeast	19	42.2
	Northeast	9	20.0
	South	8	17.8
	Other regions	9	20.0

B. Knowledge Level of ABNT NBR IEC 62353:2019

The survey results reveal that knowledge of the ABNT NBR IEC 62353:2019 standard among CE professionals in Brazil is still in its early stages.

Of the 45 participants, only 22.2% (n=10) stated that they know the content of the standard deeply, while another 42.2% (n=19) have only superficial knowledge of it.

The most concerning data is that 35.6% of the participants have never heard of the standard or have only heard of it but are unfamiliar with its content, highlighting a significant dissemination gap for a regulation published more than five years ago.

These results may be partially explained by the recent history of CE in Brazil, which is still a maturing field. As the survey itself indicates, IEC 60601-1 remains the most widely used reference for routine testing: 30.6% of participants' institutions use it exclusively, while only 11.1% use IEC 62353. An additional 16.7% reported using both. According to Nascimento *et al.* [10], the IEC 60601 series does not encompass post-market testing, as it was designed to qualify equipment for commercialization in certified laboratories under conditions that are often destructive and incompatible with hospital routines. Laferrara *et al.* [5] corroborate this distinction by identifying IEC 62353 as the most appropriate standard for monitoring ME Equipment service life in hospital maintenance environments. Furthermore, testing according to IEC 62353 requires less time than testing per IEC 60601 [11].

Table II presents the level of knowledge regarding the IEC 62353 standard by institutional size. In institutions with more than 1,500 ME equipment, 76.7% of professionals reported familiarity with the standard, either superficially or in depth, with 30.0% claiming comprehensive knowledge. In medium-sized institutions (501 to 1,500 devices), this rate drops to 57.1%, whereas in institutions with fewer than 500 ME equipment, it reaches only 25.0%, with no participants reporting in-depth knowledge. This gap of over 50 percentage points between the extremes is unsurprising: services managing a higher volume of equipment tend to face greater operational complexity and, consequently, increased pressure to standardize technical processes. Miniati *et al.* [4] point in the same direction, observing that the formal structuring of CE processes generally scales with the institution's operational capacity. In other words, a larger equipment inventory drives a greater need and internal pressure for teams to understand and comply with existing regulatory frameworks.

TABLE II. Knowledge Level of ABNT NBR IEC 62353:2019 By Institution Size

Knowledge Level	> 1,500 MEE (*n*=30)	%	501–1,500 MEE (*n*=7)	%	< 500 MEE (*n*=8)	%
In-depth knowledge	9	30.0	0	0.0	1	12,5
Superficial knowledge	14	46.7	4	57.1	1	12,5
Heard of it, does not know	6	20,0	1	14,3	5	62,5
Does not know	1	3,3	2	28,6	1	12,5
Knows (superf. + in-depth)	**23**	**76.7**	**4**	**57.1**	**2**	**25.0**

The comparison between professionals working in hospitals with and without quality certifications presents even more significant differences, as shown in Table III. Among professionals from certified institutions (ONA, JCI, or similar), 87.5% stated they knew the standard superficially or deeply. In non-certified institutions, this rate drops to 51.7%. Deep knowledge was reported by 37.5% of professionals at certified institutions, compared with only 13.8% at non-certified institutions. This pattern is consistent with the

findings of Costa *et al*. [7], who demonstrated that accredited hospitals present higher operational efficiency and greater compliance with quality standards. Silva *et al*. [12] complement this perspective by highlighting that accreditation improves hospital infrastructure and constitutes an effective strategy to raise the quality of processes related to healthcare equipment. Within the scope of CE, Oliveira *et al*. [8] found that professionals from certified institutions report greater clarity in protocols and a higher perception of workplace safety. From an international perspective, Stern [9] described how JCI-regulated environments favor the systematic implementation of recurring electrical safety testing programs. This result aligns directly with the observations in this study.

TABLE III. KNOWLEDGE LEVEL OF ABNT NBR IEC 62353:2019 BY QUALITY CERTIFICATION

Knowledge Level	Certified (*n*=16)	%	Not Certified (*n*=29)	%
In-depth knowledge	6	37.5	4	13.8
Superficial knowledge	8	50.0	11	37.9
Heard of it, does not know	1	6.3	11	37.9
Does not know	1	6.3	3	10.3
Knows (superf. + in-depth)	**14**	**87.5**	**15**	**51.7**

The results, therefore, indicate that low familiarity with the ABNT NBR IEC 62353:2019 standard, especially in smaller and non-certified institutions, poses an obstacle to its practical adoption. Knowledge of the standard is a necessary condition for testing to be properly structured. Without this foundation, teams will find it difficult to develop internal protocols that comply with regulatory guidelines, thereby directly compromising the quality and traceability of tests performed on ME Equipment.

C. Tests Performed at Healthcare Institutions

The ABNT NBR IEC 62353:2019 standard defines three moments at which tests must be performed: upon receipt of new equipment (before entering service), after any repair, and on a recurrent basis as part of the preventive maintenance program [1]. The survey results indicate that none of these stages fully adheres to the protocol required by the standard, which includes visual inspection, functional testing, and electrical safety.

Upon receipt of the ME equipment, as presented in Table IV, visual inspection and functional testing are widely adopted practices, with 97.8% and 95.6% adherence, respectively. However, when it comes to electrical safety testing, only 22.2% of participants reported performing all three tests together, which is the complete protocol required by the standard. This data is noteworthy because receipt is, by definition, the equipment acceptance stage, and at this point, the device is verified as safe for use. Performing only visual inspection or functional testing, without electrical testing, means approving equipment without a complete functional evaluation under actual conditions of use. The discrepancy between certified and non-certified institutions reinforces this point: while 43.8% of professionals from accredited institutions perform the complete protocol upon receipt, this rate drops to 10.3% among those from non-certified institutions.

TABLE IV. TESTS PERFORMED ON ME EQUIPMENT AT RECEPTION INTO SERVICE (*N*=45)

Test type	Responses	%
No tests performed	1	2.2
Visual inspection	44	97.8
Functional test + Visual inspection	43	95.6
Functional test + visual inspection + electrical safety	10	22.2

Post-repair tests (Table V) follow a similar pattern. Visual inspection and functional testing are performed by 86.7% and 97.8% of respondents, respectively, but the complete protocol is adopted by only 31.1%. This result warrants particular attention: it is precisely at this stage that the risk of electrical failure is greatest, as the device has often been disassembled and reassembled. IEC 62353 [1] is explicit about the mandatory nature of post-repair tests, and data from Nunes et al. [6] reinforce this requirement. 23.7% of devices evaluated after repair did not meet the normative requirements. It was also observed that certified institutions show nearly twice the adherence rate of non-certified ones at this stage: 43.8% versus 24.1%.

TABLE V. TESTS PERFORMED ON ME EQUIPMENT AFTER REPAIR (*N*=45)

Test type	Responses	%
No tests performed	1	2.2
Visual inspection	39	86.7
Functional test + visual inspection	44	97.8
Functional test + visual inspection + electrical safety	14	31.1

Recurrent testing, shown in Table VI, presents the highest adherence rate to the complete protocol among the three stages (48.9%). This is expected, as recurrent tests are performed as part of preventive maintenance, an activity already well established in the routine of most CE departments. Even so, just over half of the participants still do not include electrical safety testing in this stage.

TABLE VI. RECURRENT TESTS PERFORMED ON ME EQUIPMENT (*N*=45)

Test type	Responses	%
No tests performed	5	11.1
Visual inspection	41	91.1
Functional test + visual inspection	41	91.1
Functional test + visual inspection + electrical safety	22	48.9

Table VII shows adherence to the complete protocol by stage and certification status. Certified institutions display higher adherence across all stages, with differences ranging from 20 to 33 percentage points. This outcome aligns with the observed levels of knowledge regarding the standard, suggesting that quality certification not only demands regulatory compliance but also establishes organizational

conditions that foster practical implementation and more structured protocols [7–9].

TABLE VII. ADHERENCE TO FULL PROTOCOL (ALL THREE TESTS) BY STAGE AND CERTIFICATION

Stage	Certified (*n*=16)	%	Not certified (*n*=29)	%
Reception	7	43.8	3	10.3
After repair	7	43.8	7	24.1
Recurrent	10	62.5	12	41.4

D. Challenges to Implementation

Participants were asked to indicate the primary difficulties encountered in implementing the ABNT NBR IEC 62353:2019 standard at their institutions, with multiple-choice options. The results are presented in Figure 2.

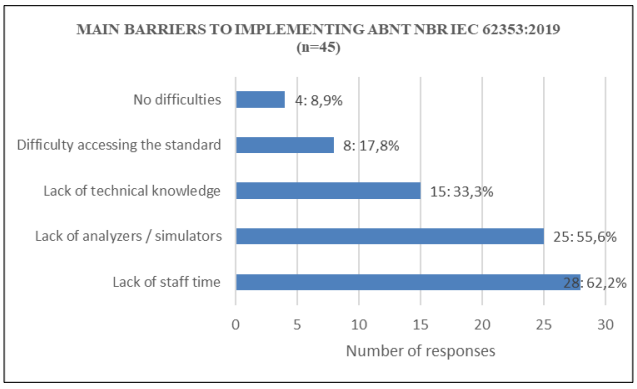

Fig. 2. Main barriers to implementing ABNT NBR IEC 62353:2019 (*n*=45).

The most frequently reported barrier was the lack of time among the technical staff, cited by 62.2% of the respondents. As a reference, Nunes et al. [6] reported a mean execution time of 5.34 ± 1.71 minutes per test (n = 363), measured with a calibrated stopwatch in a large public hospital. That interval corresponds to the complete protocol and not only to the electrical safety measurements: it covers the preparation of the equipment for testing, the visual inspection, the protective earth bond resistance measurement, the leakage current measurements, the functional test, and the completion of the test record form. This value, however, was obtained in a single institution that already had a consolidated CE team, its own analyzers, and a standardized internal operational procedure, and it should therefore be taken only as an order-of-magnitude reference, not as a parameter directly transferable to the heterogeneous institutional realities identified in the present survey, in which staff sizing, inventory size, and degree of process standardization vary widely. In addition, the time per test represents only part of the effort required by the standard, which also demands scheduling, training, metrological traceability, record keeping, and the incorporation of a new activity into an already saturated workload. The lack of time reported by the participants should thus be understood as a real structural barrier, associated with team sizing and work organization, rather than a difficulty relativized by the execution time measured in a specific study.

The lack of analyzers and simulators was reported by 55.6% of participants. This represents a concrete infrastructure barrier, as it is impossible to perform the electrical safety tests required by the standard with metrological traceability without the proper equipment. Campbell [13] lists electrical safety analyzers as essential items for the operation of a CE department, and ANVISA [14] emphasizes that the physical infrastructure of healthcare technology management services must be compatible with the activities performed.

A lack of technical or managerial knowledge was indicated by 33.3% of the participants, which aligns with the low levels of familiarity with the standard observed in this study. Lastly, 17.8% reported difficulties in assessing the standard due to its high acquisition cost, while only 8.9% reported no difficulties implementing it.

IV. CONCLUSION

The results of this study indicate that the ABNT NBR IEC 62353:2019 standard has not yet been fully incorporated into the practices of Brazilian CE departments. Only 22.2% of professionals possess in-depth knowledge of the standard, and adherence to the complete testing protocol remains low across all stages. Furthermore, the persistent reliance on the ABNT NBR IEC 60601-1:2022 series as a reference for routine testing underscores that this gap is not merely operational but also technical.

Larger, quality-certified institutions consistently demonstrated superior results, suggesting that more structured organizational environments facilitate the adoption of technical standards.

The primary barriers identified were a lack of time, the absence of analyzers, and insufficient technical knowledge. These findings demonstrate that widespread implementation of the standard requires targeted training, infrastructure investment, and the formalization of internal protocols. Ultimately, the data from this study fills a critical gap in national characterization and can support capacity-building initiatives and strategic incentives for standard adoption, particularly within smaller institutions.

ACKNOWLEDGMENT

The authors would like to thank the Federal Technological University of Paraná (UTFPR) for providing all resources for project development, and the Fundação Araucária (FA) & Superintendência de Ciência, Tecnologia e Ensino Superior (SETI) for the conference grants to H. C. C. and F. S. B.

***Abstract*—Administration of parenteral medications requires strict adherence to aseptic techniques and technical procedures to minimize the risk of microbiological contamination and ensure patient safety. Among the potential sources of contamination, manual contact with the syringe plunger during the preparation of parenteral solutions has been identified as a possible risk factor. This study aimed to evaluate the occurrence of microbiological contamination associated with this practice. An experimental, descriptive and analytical study was conducted under controlled laboratory conditions. Different handling conditions were established, including non-hygienized hands, hands disinfected with soap and water or 70% alcohol, and the use of procedure and sterile gloves. Samples collected from the syringe plunger and the aspirated solutions were inoculated onto Brain Heart Infusion (BHI) agar supplemented with defibrinated sheep blood and incubated at 35°C for 48 hours. No microbial growth was observed in the aspirated solutions under any of the experimental conditions. However, microbiological growth was detected in samples obtained by direct inoculation of the syringe plunger surface, indicating the presence of microorganisms on this structure. These findings suggest that, under the conditions evaluated, manual contact with the syringe plunger did not promote the transfer of microorganisms to the parenteral solutions, although the plunger may serve as a microbiological reservoir. These results reinforce the importance of maintaining aseptic techniques during the preparation and administration of parenteral medications in clinical practice.**

***Index Terms*—nursing, microorganisms, syringe plunger, healthcare-associated Infections (HAIs), aseptic Technique**

I. Introduction

Parenteral medication administration is one of the most frequent and critical procedures in nursing practice, requiring strict adherence to technical standards and aseptic practices to ensure patient safety. As an invasive procedure, failures during medication preparation or administration may contribute to the occurrence of Healthcare-Associated Infections (HAIs), compromising the quality of care and increasing morbidity, mortality, length of hospital stay, and healthcare costs [1].

In this context, the proper handling of devices used during medication administration represents an essential measure for preventing contamination and reducing infection risks. The hands of healthcare professionals are recognized as one of the main routes of microorganism transmission, harboring both resident and transient microbiota that may contaminate surfaces, equipment, and materials used in patient care [2]. Therefore, appropriate hand hygiene and strict adherence to aseptic technique are fundamental practices for maintaining microbiological safety throughout the preparation and administration of medications.

Among the devices used in parenteral therapy, syringes play a central role and require specific precautions to preserve sterility. During nursing education and clinical training, one of the most emphasized recommendations is to avoid direct contact with the syringe plunger, based on the assumption that manual manipulation may facilitate the transfer of microorganisms to the internal components of the syringe and subsequently contaminate the medication solution administered to the patient [1].

Although this recommendation is widely incorporated into healthcare protocols, experimental evidence demonstrating that contact with the syringe plunger effectively results in microbiological contamination of parenteral solutions remains limited. Previous studies have reported conflicting findings, suggesting that the presence of microorganisms on a surface does not necessarily result in their transfer to another environment, as microbial transmission may be influenced by factors such as microbial load, contact time, applied pressure, environmental conditions, and characteristics of the microorganisms involved [3], [4].

Microbiological evaluation of surfaces and medical devices is therefore essential for understanding potential contamination pathways. Culture media capable of supporting the recovery of clinically relevant microorganisms, such as Brain Heart Infusion (BHI) agar supplemented with sheep blood, are

widely used for microbiological investigations due to their high nutritional capacity and ability to support the growth of microorganisms with complex nutritional requirements. Additionally, blood supplementation enables the observation of hemolytic patterns, which may contribute to the preliminary characterization of bacterial isolates [5].

Considering the importance of maintaining sterility during medication preparation and the limited experimental evidence regarding microbial transfer associated with syringe plunger manipulation, further investigations are necessary to evaluate this potential contamination pathway. A better understanding of the mechanisms involved in microbial transmission may contribute to the improvement of medication preparation practices and support evidence-based approaches to patient safety.

Therefore, the present experimental study was conducted to investigate the risk of microbiological contamination associated with manual contact with the syringe plunger during the preparation of parenteral solutions. By comparing different manipulation conditions, this study aimed to evaluate whether contact with the plunger could compromise the sterility of aspirated solutions and provide scientific evidence to support safe medication preparation and administration practices.

II. Materials and Methods

An in vitro experimental study with a qualitative, descriptive, and analytical approach was conducted. The methodological design was structured as a pilot study to evaluate the feasibility of the experimental protocol and generate preliminary data on the investigated phenomenon.

A. Study Setting and Period

The experiment was carried out at the Chemistry and Biosciences Laboratory of the National Institute of Telecommunications (INATEL), in a controlled laboratory environment. All sample handling procedures were performed inside a previously disinfected and sterilized vertical laminar airflow cabinet (Pachane, Brazil) on March 6, 2026. The incubation period lasted 48 hours, and microbiological analyses were performed on March 9, 2026. The laboratory environment was maintained under standardized hygiene and temperature conditions to minimize the influence of external factors on microbial growth.

B. Materials

The following materials were used in the experiment: sterile disposable 5-mL syringes; 25 × 7 mm hypodermic needles; sterile distilled water; sterile swabs with Stuart transport medium; sterile Petri dishes; Brain Heart Infusion (BHI) agar supplemented with defibrinated sheep blood; defibrinated sheep blood (Nova Lab, Brazil); 70% ethanol; vertical autoclave (Prismatec CS-18, 18 L); vertical laminar airflow cabinet (Pachane, Brazil); and bacteriological incubator (Mylabor, 11 L).

C. Culture Medium Preparation

Brain Heart Infusion (BHI) agar supplemented with sheep blood was used as the culture medium. Eighteen Petri dishes were prepared, with three replicates for each experimental condition. Dehydrated BHI agar was weighed according to the manufacturer's recommendations, dissolved in distilled water, and heated under constant stirring until complete homogenization. The culture medium, together with the Petri dishes previously packed in surgical-grade paper envelopes, was sterilized in an autoclave at 121°C for 15 minutes.

After sterilization, the medium was allowed to cool inside the previously sterilized laminar airflow cabinet until it reached a temperature between 45 °C and 50 °C. Defibrinated sheep blood was then added at a final concentration of 5% (v/v), followed by gentle homogenization. Finally, the medium was poured into sterile Petri dishes and allowed to solidify, forming a uniform agar layer.

D. Experimental Design

Six experimental conditions were established to simulate different handling practices during the preparation of parenteral solutions:

- Sterile gloves;
- Examination (non-sterile nitrile) gloves;
- Hands washed with soap and water;
- Hands washed with soap and water followed by 70% alcohol disinfection;
- Unwashed hands;
- Samples obtained by direct inoculation of the syringe plunger surface.

E. Experimental Procedures

Initially, the workbench, supporting tray, and all materials were disinfected with 70% ethanol to minimize environmental contamination. Sterile distilled water was then aspirated into syringes to simulate the preparation of parenteral solutions. During the experiment, intentional manual contact with the syringe plunger was performed under each experimental condition to reproduce different clinical handling practices, including situations with and without aseptic technique. All samples were appropriately labeled for subsequent microbiological analysis.

F. Sample Collection

Following syringe manipulation, samples were collected from the plunger surface using sterile swabs containing Stuart transport medium. In addition, 0.1-mL aliquots of the aspirated solutions were collected and inoculated onto the culture medium. An additional sample obtained by direct inoculation of the syringe plunger surface was prepared under the same experimental conditions. However, instead of sampling the aspirated solution, the plunger surface was directly inoculated after completion of all five experimental handling conditions in order to assess possible microbial contamination of the plunger during the experiment.

G. Microbiological Analysis

Samples were inoculated onto BHI agar plates using the spread plate technique. The plates were incubated in a bacteriological incubator at 35°C for 48 hours. After incubation, microbiological evaluation included the following parameters:

- Presence or absence of microbial growth;
- Number of colonies;
- Macroscopic characteristics of the colonies;
- Presence of agar aggregates.

H. Data Analysis

The collected data were organized into spreadsheets and analyzed descriptively. Comparisons were performed among the experimental groups to identify potential differences in the pattern and frequency of microbiological contamination under the evaluated handling conditions.

I. Ethical Considerations

Because this was an experimental laboratory study that did not involve human participants or identifiable personal data, approval by a Research Ethics Committee was not required according to the applicable national regulations. Nevertheless, all applicable biosafety standards were strictly followed throughout the experimental procedures to ensure researcher safety and the reliability of the study findings.

III. RESULTS AND DISCUSSION

Brain Heart Infusion (BHI) agar was selected because it is an enriched culture medium widely used in microbiology due to its high nutritional capacity. Its composition includes infusions of animal brain and heart tissues, as well as peptones, which provide amino acids, peptides, vitamins, and essential minerals required for bacterial growth.These characteristics support the cultivation of a wide variety of microorganisms, including fastidious (nutritionally demanding) species of clinical and environmental importance, such as bacteria belonging to the genera Streptococcus, Staphylococcus, and Enterococcus [5], [6].

When supplemented with sheep blood, BHI agar becomes even more versatile. Sheep blood provides additional nutrients, such as iron and hemin, which are essential for the growth of many fastidious microorganisms. In addition, it enables the assessment of hemolysin production, as some bacteria produce enzymes capable of lysing the red blood cells (erythrocytes) present in the culture medium. This phenomenon, known as hemolysis, is an important characteristic for the preliminary identification of several bacterial pathogens [7].

Hemolysis may occur in three distinct patterns. Alpha hemolysis is characterized by the partial lysis of red blood cells, resulting in a greenish halo surrounding the bacterial colonies due to the oxidation of hemoglobin. Beta hemolysis corresponds to the complete lysis of red blood cells, producing a clear, transparent zone around the colonies. Gamma hemolysis indicates the absence of red blood cell lysis, with no visible changes observed in the culture medium surrounding the colonies [5].

Because of these characteristics, BHI agar supplemented with sheep blood is widely used in both clinical and experimental microbiology. This medium is employed for the primary isolation of microorganisms from a variety of biological specimens, including blood, secretions, tissues, and other clinical samples. It is also extensively used in scientific research, microbiological contamination studies, and microbiological quality control [8].

After 48 hours of incubation, no microbiological growth was observed in the parenteral solutions (10 mL of sterile distilled water) under any of the experimental conditions evaluated. Regardless of the manipulation strategy employed, including contact with unwashed hands, hands sanitized with soap and water, hands sanitized with 70% alcohol, the use of sterile gloves, or procedure gloves, the samples showed no evidence of bacterial or fungal growth Figs.[1 - 5].

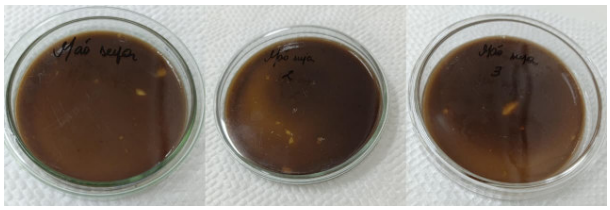

Fig. 1. Absence of microbiological growth in samples obtained under the unwashed hands condition.

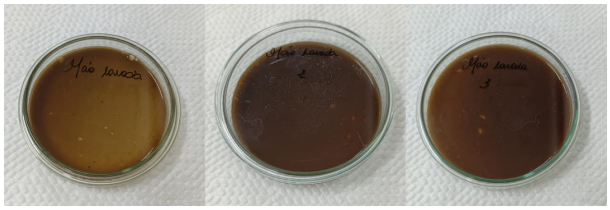

Fig. 2. Absence of microbiological growth in samples obtained after hand hygiene with soap and water.

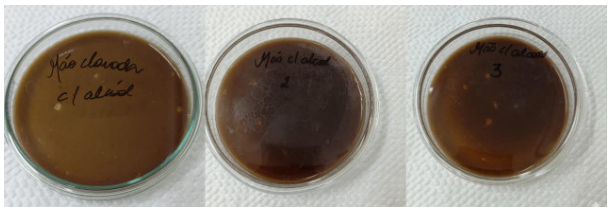

Fig. 3. Absence of microbiological growth in samples obtained after hand hygiene with 70% alcohol. The isolated structure observed was not consistent with microbial colony morphology.

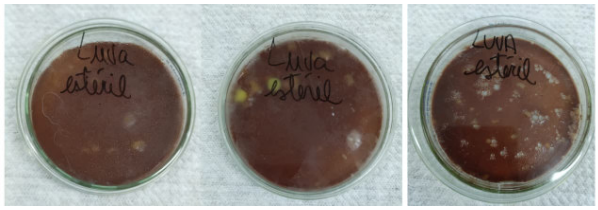

Fig. 4. Absence of microbiological growth in samples handled using sterile gloves.

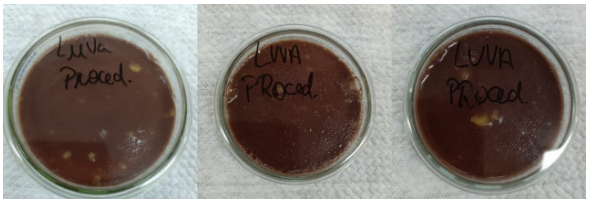

Fig. 5. Absence of microbial growth in samples handled using examination gloves.

Therefore, under the experimental conditions established in this study, manipulation of the syringe plunger did not result in detectable microbial transfer to the aspirated solution, and no differences were observed among the evaluated groups.

During the analysis of the culture plates, some structures with coloration ranging from white to yellowish and irregular morphology were observed. However, these structures did not present characteristics compatible with microbial colonies and were considered aggregates derived from the culture medium itself. Unlike bacterial or fungal colonies, these structures did not exhibit progressive growth, defined edges, spreading patterns, or typical hemolytic characteristics, indicating that they did not represent microbiological growth.

The absence of microbial growth in the parenteral solutions demonstrates the importance of differentiating the presence of microorganisms on device surfaces from the actual contamination of the medication. Surface contamination, such as that occurring on the syringe plunger, represents a potential microbiological risk; however, the transfer of microorganisms to a sterile solution depends on several factors related to the interaction among the microorganism, the contaminated surface, and the receiving environment. Therefore, the mere presence of microorganisms in a specific location does not necessarily imply their transfer to another substrate.

Microbial transfer is a complex process influenced by factors such as the initial microbial load, cellular adhesion capacity, contact time, pressure applied during manipulation, surface moisture, characteristics of the materials involved, and environmental conditions [9]. Thus, even when a device presents microbiological contamination, the migration of microorganisms to a parenteral solution may not occur or may occur at levels below the detection capacity of the analytical method employed.

Similar results were reported by Ferreira et al. (2007) [3], who evaluated contamination associated with syringe handling and observed that contact with the plunger did not necessarily result in significant microbiological contamination of solutions, particularly when basic aseptic conditions were maintained.

Likewise, Bucholz (2019) [4], in an experimental study involving devices used for medication administration, demonstrated that the presence of microorganisms on manipulated surfaces does not necessarily result in their transfer to sterile solutions or culture media, supporting the findings observed in the present study. However, although the parenteral solutions remained sterile under the evaluated conditions, samples obtained by direct inoculation of the syringe plunger surface showed significant microbiological growth Fig 6.

Fig. 6. Microbial growth in samples obtained by direct inoculation of the syringe plunger surface.

This result highlights a fundamental difference between surface contamination and medication contamination, demonstrating that the syringe plunger may act as a reservoir of microorganisms after manual manipulation, even when detectable transfer to the aspirated solution does not occur.

In the samples obtained directly from the plunger, multiple colonies with different macroscopic characteristics were observed, including variations in size, white, yellowish, and gray pigmentation, as well as cottony or velvety structures, compatible with different microbial groups, including possible fungi. However, definitive identification of the microorganisms was not performed, since morphological characterization alone does not allow taxonomic confirmation.

The recovery of microorganisms from the plunger surface reinforces that devices manipulated during medication preparation may act as microbiological reservoirs, representing a potential source of contamination under certain clinical conditions [10]. Nevertheless, these findings should not be interpreted as evidence that all surface contamination will necessarily result in medication contamination, but rather as evidence of the importance of maintaining strict aseptic practices.

From the perspective of nursing practice, the results obtained do not invalidate the recommendation to avoid direct contact with the syringe plunger. On the contrary, they reinforce the need to understand the mechanisms involved in microbial transfer and to maintain preventive measures aimed at interrupting potential contamination pathways. Aseptic technique remains essential to ensure patient safety, particularly in clinical situations where small microbial loads may represent significant risks, such as in immunocompromised patients or those undergoing intravenous therapies [11].

IV. Conclusion

The results of this study demonstrated that, under the experimental conditions evaluated, manual contact with the syringe plunger did not result in detectable microbiological contamination of the parenteral solutions, regardless of the manipulation condition employed. The absence of bacterial or fungal growth in the aspirated solutions indicates that the transfer of microorganisms from the plunger surface to the liquid medium did not occur at a significant level in this experimental model.

However, the recovery of microorganisms from samples obtained by direct inoculation of the syringe plunger surface demonstrates that this component of the syringe may act as a microbiological reservoir after manual manipulation. These findings reinforce the importance of distinguishing surface contamination from actual medication contamination, as the presence of microorganisms on a device does not necessarily imply their transfer to a sterile solution.

Although the results obtained did not indicate impairment of the sterility of the evaluated solutions, they do not eliminate the importance of strict adherence to aseptic practices during the preparation and administration of parenteral medications. Prevention of contamination remains essential in nursing care, particularly considering that clinical, environmental, and microbiological factors may influence the potential for microbial transfer under different healthcare settings.

As a pilot study, this investigation contributes to expanding the understanding of the mechanisms involved in microbial transfer during syringe manipulation and provides evidence to support future research with larger sample sizes, identification of isolated microorganisms, and more comprehensive control of experimental variables. Further studies are required to deepen knowledge regarding the microbiological risks associated with the handling of devices used in parenteral therapy and to strengthen evidence-based practices in healthcare.

V. Future Studies

As a contribution to future studies, the description and monitoring of laboratory environmental conditions will be expanded, specifying the instruments and methods employed, including the use of data-logging thermometers, hygrometers, and microbiological air monitoring techniques through passive and/or active sampling methods. Considering the experimental nature of the study and its focus on the assessment of microbiological contamination, the systematic characterization of environmental conditions and the establishment of quality control procedures may contribute to enhancing the reliability, reproducibility, and validity of the results obtained.

Mitigando e Caracterizando Relativamente EMI Radiadas em Salas Cirúrgicas de Alta Complexidade

Anderson Alves dos Santos*, William Knob de Souza*, Gabriel Fallavena Chaves*, Rodrigo Lopes Rezer*
*Engenharia Clínica, Hospital Moinhos de Vento, Porto Alegre, RS, Brasil
{anderson.santos, william.knob, gabriel.chaves, rodrigo.rezer}@hmv.org.br

***Resumo* — A incorporação de tecnologias de maior sensibilidade em salas cirúrgicas de alta complexidade reduz a margem de imunidade eletromagnética do ambiente construído. Manifestada a interferência, o serviço de engenharia clínica não dispõe de meio acessível para localizar a fonte, dimensionar a intervenção e comprovar a correção. Propõe-se um ciclo de mitigação — detecção, localização, intervenção e verificação — executável pela equipe própria com analisador portátil de US$ 170, sem câmara anecoica e sem rastreabilidade a padrões nacionais. A grandeza é a elevação do ruído eletromagnético ambiente radiado sobre a condição de referência da própria sala, obtida por subtração pareada: medição relativa, que reduz a dependência de calibração absoluta. O ciclo foi aplicado a uma sala de hemodinâmica com artefato de imagem intravascular (IVUS) e perda de conexão do sistema de reserva de fluxo fracionada (FFR) associados ao acionamento da iluminação LED. A detecção registrou 13,23 dB de elevação em 30 a 150 MHz, e a amostragem em sete pontos indicou emissão distribuída pelo circuito. Após a substituição dos drivers das luminárias, a elevação caiu para 1,04 dB — redução de 12,19 dB no indicador relativo, aprovada segundo o critério interno nos sete pontos; duas salas de referência sem intervenção, medidas no mesmo dia, mantiveram 12,40 e 12,68 dB, fortalecendo a atribuição do fenômeno ao circuito de iluminação e à intervenção realizada. Emergiu um achado metodológico: a faixa de 225 a 575 MHz indicou 2,94 dB e sugeria conformidade operacional, contra 13,01 dB no mesmo ponto e dia sob a faixa crítica. A faixa de análise determina a conclusão e deve ser fixada por caracterização inicial do próprio ambiente.**

***Index Terms* — compatibilidade eletromagnética, mitigação de interferência, emissão radiada, medição relativa, engenharia clínica, salas cirúrgicas, ultrassom intravascular, iluminação LED**

I. INTRODUÇÃO

A prática cirúrgica e intervencionista incorpora, de forma progressiva, tecnologias de maior resolução e sensibilidade. Sistemas de ultrassom intravascular (IVUS) e de reserva de fluxo fracionada (FFR) operam com sinais de amplitude reduzida conduzidos por cateteres de pequeno diâmetro; navegação eletromagnética e plataformas robóticas dependem de sensores igualmente suscetíveis. Cada geração de equipamento amplia a informação disponível ao operador e, ao mesmo tempo, *reduz a margem de imunidade eletromagnética disponível* no ambiente em que opera.

O arcabouço normativo acompanhou essa evolução no que diz respeito ao equipamento. A IEC 60601-1-2 [1] estabelece ensaios de imunidade e limites de emissão para o equipamento eletromédico, verificados pelo fabricante antes da colocação no mercado. A CISPR 15 [2] regula a perturbação radioelétrica de equipamentos de iluminação, e a versão brasileira da norma colateral [3] reproduz esse escopo. Todas atuam sobre o produto isolado, em condição de ensaio, antes da instalação.

O ambiente construído permanece fora desse escopo, e a consequência é operacional antes de ser conceitual. Quando a interferência se manifesta em uma sala em uso, o serviço de engenharia clínica precisa responder a quatro perguntas em sequência — existe interferência? de onde vem? o que substituir? a substituição resolveu? — e não dispõe de método acessível para nenhuma delas. Na ausência de medição, a investigação recai sobre o equipamento médico, que é o elemento visível da cadeia: trocam-se cabos e módulos, o quadro não se altera, e o custo da tentativa se acumula sem que a fonte seja alcançada. A mitigação, quando ocorre, é conduzida por presunção.

A literatura sobre compatibilidade eletromagnética em ambiente hospitalar concentra-se em levantamentos de campo e em fontes móveis. Ishida et al. [4] caracterizaram os campos eletromagnéticos de um hospital antes e após a ocupação, concluindo pela conformidade aos limites normativos sob condições normais de uso. Estudos de caso em unidades de terapia intensiva seguem abordagem semelhante, comparando os campos medidos aos limites da IEC [12]. A iluminação como fonte foi investigada por Ishida et al. [13], que avaliaram a interferência radiada por foco cirúrgico LED sobre sistema de navegação eletromagnética e concluíram por interferência improvável naquele arranjo.

Três aspectos permanecem pouco explorados, e todos os três bloqueiam a mitigação. Primeiro, esses trabalhos medem o *nível absoluto* de campo e o comparam a limites normativos, ao passo que a degradação relatada na prática decorre da *elevação relativa* do ruído eletromagnético ambiente sobre a condição de referência da própria sala — grandeza que um limite absoluto não captura. Segundo, avaliam a sala em um instante, sem tratar a instalação como algo que se altera por reformas ao longo da vida útil. Terceiro, os arranjos empregados dependem de instrumentação e de *expertise* raramente disponíveis ao serviço de engenharia clínica, o que impede a reexecução da medida depois da intervenção — e sem medição posterior não existe mitigação comprovada, apenas serviço executado.

O objetivo deste trabalho é propor e aplicar um ciclo de mitigação eletromagnética de salas de alta complexidade que seja (i) executável pela própria equipe de engenharia clínica, (ii) exequível sem câmara anecoica e sem rastreabilidade a padrões nacionais, (iii) capaz de orientar o escopo da intervenção a partir da medição, (iv) encerrado por critério objetivo de aceitação e (v) de custo compatível com a realidade das instituições brasileiras.

Um resultado colateral mostrou-se tão relevante quanto a proposta: a faixa de análise escolhida pode inverter o veredito sobre uma mesma sala, medida no mesmo dia (Seção V-D, Fig.

4). A faixa é parte do critério, não um parâmetro de configuração.

II. CASO MOTIVADOR

Em fevereiro de 2026, a equipe de engenharia clínica foi acionada para investigar e mitigar artefato de imagem no sistema de orientação multimodal AVVIGO+ (Boston Scientific) [14] de uma sala de hemodinâmica: granulação na imagem IVUS e perda intermitente de conexão do FFR Link. A iluminação não era suspeita; chegou-se a ela por eliminação.

A etapa inicial foi a anamnese técnica junto à equipe assistencial, que delimitou as condições de ocorrência. Como conduta primária, o equipamento foi conectado a ponto de energia isolado do sistema IT médico e o artefato persistiu; a substituição de cabos e módulo também não alterou o quadro. O elemento decisivo veio do relato de que o mesmo equipamento operara sem falha em sala adjacente: confrontadas as duas instalações, identificou-se que a única diferença fora de procedimento era a iluminação, desligada onde o teste fora bem-sucedido. Desligado o circuito de iluminação da sala com a anomalia, a interferência cessou de imediato; religado, retornou. Estabeleceu-se assim que o artefato decorria de ruído eletromagnético originado nas luminárias do ambiente — e nada havia sido medido: nenhum desses passos produz número que justifique intervir na instalação predial, e é essa lacuna que o método a seguir pretende fechar.

III. MATERIAIS E MÉTODOS

A. Instrumentação

Todas as campanhas foram realizadas com o analisador de espectro portátil TinySA Ultra (modelo ZS405, firmware 1.4-104), com antena telescópica na entrada de baixa frequência. O instrumento dispunha de calibração de fábrica — ajuste de nível do fabricante, exatidão de amplitude declarada de ±1 dB [20] —, porém sem rastreabilidade a padrões nacionais (Seção III-D). O ZS405 saiu de linha após as campanhas; o modelo atual, TinySA Ultra+ (ZS406), executa o mesmo procedimento por US$ 170 — custo de referência para quem reproduza o protocolo. A escolha da classe de instrumento é deliberada: a proposta perde sentido se depender de equipamento inacessível ao serviço, porque é a própria equipe que reexecuta a medida após a intervenção.

Os parâmetros de varredura, mantidos constantes em todas as campanhas, estão na Tabela I. Nenhuma calibração de nível absoluto foi aplicada; as amplitudes em dBm referem-se à entrada do analisador e destinam-se exclusivamente à comparação relativa entre condições, conforme discutido na Seção VI-D.

Tabela I
PROTOCOLO DE MEDIÇÃO

Parâmetro	**Configuração**
Instrumento	TinySA Ultra ZS405 (atual: Ultra+ ZS406, ordem de US$ 170)
Infraestrutura	nenhuma — sem câmara nem laboratório
Faixa	0 a 350 MHz, 450 pontos
RBW / VBW	850 kHz
Atenuação	0 dB, nível de referência 0 dBm
Protocolo	A/B — luminárias acesas × apagadas
Amostragem	7 pontos por sala
Execução	equipe própria, ≈ 2 h por sala
Critério	elevação ≤ 3 dB em 30 a 150 MHz (critério interno)

B. Protocolo A/B de detecção

O elemento central do método é a comparação pareada entre duas condições que diferem exclusivamente pelo estado da iluminação. Para cada ponto de medição registra-se uma varredura com as luminárias acionadas e outra com as luminárias apagadas, sem deslocar a antena entre as duas aquisições e mantendo inalterado o estado de todos os demais equipamentos da sala.

A grandeza de interesse é a *elevação*, definida como a diferença ponto a ponto entre as duas condições:

$$\Delta(f) = A_{\text{acesa}}(f) - A_{\text{apagada}}(f) \tag{1}$$

onde A(f) é a amplitude em dBm na frequência f. Por ser uma razão entre potências, Δ é expressa em dB — e não em dBm, unidade reservada às amplitudes absolutas dos eixos.

A subtração pareada reduz a dependência de calibração absoluta: contribuições comuns às duas condições — radiodifusão, telefonia, demais equipamentos — cancelam-se, restando a parcela atribuível à iluminação. Essa propriedade é o que torna o método executável em sala assistencial, sem desmontar a instalação nem interromper o serviço. A Fig. 1 situa a cadeia causal que o protocolo isola dentro da sequência de investigação que a produziu.

Cabe delimitar a grandeza medida. Com antena no interior da sala, o arranjo caracteriza a componente *radiada* da perturbação. A emissão conduzida pela rede, também regulada pela CISPR 15, exigiria rede fictícia de acoplamento e interrupção do circuito — inviável em sala em operação. Ambas compartilham a origem no chaveamento do driver, de modo que a componente radiada serve como indicador acessível do fenômeno.

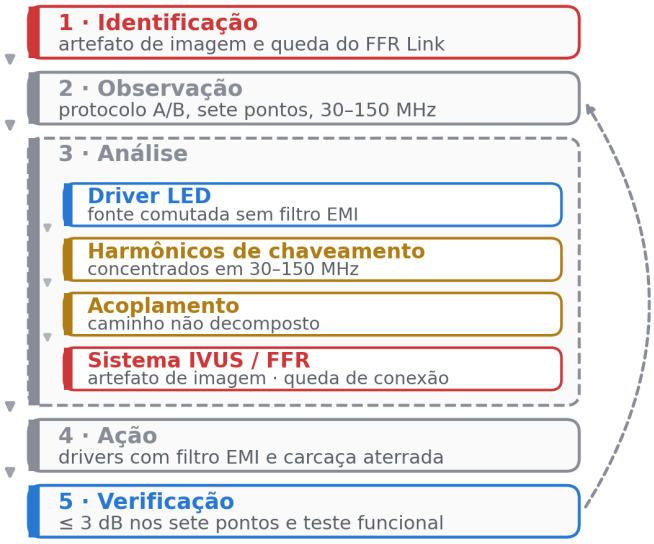

Figura 1. Sequência de investigação em cinco fases e a cadeia causal que a terceira delas isola — produto da análise, não premissa. O protocolo A/B opera sem desmontar a instalação, condição para execução em sala assistencial, e a verificação realimenta a observação: reprovar um único dos sete pontos reabre o ciclo. O caminho de acoplamento não é decomposto entre as componentes conduzida e radiada (Seção VI-D).

C. Amostragem espacial e localização da fonte

Cada sala foi amostrada em sete posições: entrada, centro e fundo de ambos os lados da mesa cirúrgica, além do ponto central. A amostragem atende a dois propósitos, e o primeiro é o que dimensiona a intervenção: a dispersão entre pontos distingue emissão *localizada* — compatível com luminária ou driver individual defeituoso — de emissão *distribuída*, que aponta o circuito de iluminação como um todo. O segundo é assegurar que a aprovação da sala segundo o critério interno não dependa de um ponto favorável.

A distinção tem consequência direta de escopo e de custo. Diagnosticada emissão localizada, a substituição pontual resolve; diagnosticada emissão distribuída, a substituição pontual consome recurso sem alterar o resultado, e o escopo precisa abranger o conjunto.

D. Situação de calibração e rastreabilidade

O analisador empregado **não dispunha de calibração vigente rastreável** durante as campanhas — a calibração de fábrica declarada na Seção III-A não constitui rastreabilidade —, e não houve janela de calibração disponível antes das medições. A condição é declarada aqui, e não apenas na seção de limitações, porque condiciona a leitura de todos os resultados.

Cabe distinguir o que essa ausência afeta. O ILAC-G24/OIML D 10 [5] não estabelece intervalo universal de recalibração: o intervalo deve ser definido e justificado pelo usuário a partir do histórico de deriva, da intensidade de uso e da consequência de um resultado fora de tolerância. A ISO/IEC 17025 [19] exige que exista programa de calibração, sem fixar periodicidade. Não há, portanto, um prazo normativo que tenha sido descumprido — há uma lacuna de rastreabilidade, que é coisa distinta.

Para a grandeza medida neste trabalho, a consequência é limitada por construção. Sendo Δ uma diferença entre duas leituras tomadas com o mesmo arranjo, separadas por segundos e sem deslocamento da antena, os erros sistemáticos comuns às duas leituras cancelam-se:

$$\Delta_{\text{med}} = (A_{\text{acesa}} + e_{\text{sist}}) - (A_{\text{apagada}} + e_{\text{sist}}) = \Delta_{\text{real}} \quad ($$

onde e_sist agrega ganho de antena, perda de cabo, resposta do pré-amplificador e desvio absoluto de calibração. O que *não* se cancela é tratado na Seção VI-D.

Uma tabela de correção será acrescentada ao repositório de dados tão logo o instrumento seja calibrado, permitindo reprocessar as varreduras brutas e avaliar a repetibilidade das medições aqui apresentadas (ver *Disponibilidade dos Dados*).

E. Critério de aceitação

Adotou-se como critério que a elevação média em 30 a 150 MHz não ultrapasse 3 dB em nenhum dos sete pontos. A reprovação de um único ponto reprova a sala. A faixa foi delimitada empiricamente, pela caracterização inicial: é onde a elevação se concentrou e onde ela acompanha o acionamento da iluminação. Não decorre de especificação de suscetibilidade publicada para os sistemas envolvidos — os fabricantes não a disponibilizam em forma de faixa — e essa delimitação empírica é parte do que o trabalho propõe como método.

Em consequência, a faixa não é transferível sem reexame: outra sala, com outras tecnologias instaladas, exige nova caracterização inicial para fixá-la.

Trata-se de critério operacional interno de triagem e aceitação. O valor de 3 dB corresponde à paridade entre a contribuição acrescentada e o ruído de fundo preexistente: duas potências não correlacionadas de igual magnitude somam-se em 3,01 dB ($10 \log_{10} 2$) — a mesma relação que leva o método de medição invocado pela CISPR 15 [2] a exigir margem mínima de 6 dB sobre o ambiente [8]. Não constitui limite normativo de emissão ou de imunidade, nem se propõe como limiar universal de interferência: os limites da CISPR 15 são absolutos, em dBμV/m, e não se aplicam a uma grandeza relativa. Corroboram a escolha a repetibilidade do arranjo (desvio-padrão de 0,89 dB entre as cinco varreduras sucessivas da campanha inicial; o critério equivale a cerca de 3,5 vezes esse valor) e o desfecho clínico.

Distinguem-se dois planos, mantidos separados em todo o texto: **conformidade normativa** — atendimento a limite absoluto de norma, verificável apenas em ensaio acreditado com instrumento rastreável — e **conformidade operacional** — atendimento ao critério interno de 3 dB sobre a grandeza relativa Δ. Toda "aprovação" neste trabalho é do segundo plano (redução relativa aprovada segundo o critério interno), e as conclusões limitam-se à triagem, à orientação da intervenção e à verificação relativa.

Um instrumento sem rastreabilidade não deve comunicar resultado com aparência de valor metrológico. Adotou-se, por isso, uma **classificação ordinal de severidade** sobreposta à medida, com limiares ancorados em referências deste trabalho e

não arbitrados: **Classe 0**, não detectável ($\Delta \leq 1$ dB, dentro da repetibilidade do arranjo); **Classe I**, detectável e conforme o critério interno (1 a 3 dB); **Classe II**, não conforme o critério interno (3 a 10 dB); e **Classe III**, não conformidade severa ($\Delta >$ 10 dB, o dobro da incerteza que a CISPR 16-4-2 [6] admite em ensaio acreditado). A classe é o que se comunica ao corpo clínico; o valor em dB é o que se registra e reprocessa.

IV. PROTOCOLO DE MITIGAÇÃO

A medição orienta a intervenção, mas não a substitui. Esta seção descreve como o resultado da detecção se converte em escopo de serviço executável e verificável.

A. Hierarquia de intervenção

A ordem de intervenção segue o princípio de atacar a fonte antes do acoplamento. Quatro níveis, em ordem de precedência:

1. **Supressão na fonte** — substituição dos drivers por modelos com filtragem EMI integrada. É o único nível que reduz a emissão gerada, e não apenas o quanto dela alcança o equipamento suscetível.
2. **Aterramento funcional** — conexão das carcaças metálicas à barra de terra da sala, fornecendo caminho de retorno para as correntes de modo comum.
3. **Roteamento** — separação física entre o cabeamento de alimentação das luminárias e o cabeamento de sinal.
4. **Blindagem** — último recurso, por custo e por interferir na manutenibilidade da instalação.

No caso relatado, a dispersão espacial reduzida indicou emissão distribuída por todo o circuito, e o escopo foi definido no primeiro nível, com o segundo e o terceiro executados como medidas associadas. Cabe registrar o limite dessa evidência: os níveis não foram comparados isoladamente entre si, de modo que a hierarquia é derivada do padrão espacial medido e do princípio de supressão na fonte, e não de contraste experimental entre alternativas.

B. Especificação por desempenho

A especificação do componente substituto foi redigida por requisito de desempenho, não por marca: filtro EMI integrado com emissões dentro dos limites da CISPR 15; conformidade declarada às normas EN 55015 [18], EN 61000-3-2 Classe C [16] e EN 61547 [15]; carcaça metálica com ponto de aterramento funcional; fator de potência superior a 0,95; distorção harmônica total inferior a 10 %.

A forma da especificação não é detalhe editorial. Redigida por marca, ela restringe a concorrência e não é utilizável em processo de compra pública ou regulado; redigida por desempenho, admite equivalente técnico de qualquer fabricante mediante laudo comprobatório, e transfere ao fornecedor o ônus de demonstrar conformidade.

C. Aceitação vinculada à verificação

O recebimento do serviço foi condicionado a nova medição, nos mesmos sete pontos e com os mesmos parâmetros, com aprovação segundo o critério interno exigida em todos eles. Essa vinculação é o elemento que converte a medição em instrumento contratual: sem ela, o serviço é aceito por execução e não por resultado, e a persistência da interferência após a intervenção não gera consequência para o fornecedor.

O ciclo completo — detectar, localizar, especificar, intervir, verificar — encerra-se apenas quando a verificação aprova. A Tabela II e a Fig. 2 documentam esse fechamento no caso relatado.

V. RESULTADOS

A. Detecção e caracterização

A campanha de fevereiro de 2026 registrou, com as luminárias acionadas, elevação média de 13,23 dB na faixa de 30 a 150 MHz. O piso de ruído eletromagnético da sala subiu de −87,6 dBm para −79,1 dBm na média de 5 a 350 MHz. O maior pico da faixa de análise atingiu −61,0 dBm em 77,2 MHz — elevação de 25,3 dB.

Doze máximos locais excederam a média da banda em mais de um desvio-padrão, distribuídos entre 60,8 e 130,2 MHz, o maior deles em 77,2 MHz. Os espaçamentos entre eles são irregulares (5,4 a 16,4 MHz), o que não caracteriza série harmônica resolvida — e não poderia: uma fonte comutada de driver LED opera com fundamental de dezenas a centenas de kHz [11], de modo que as ordens situadas em 60 a 130 MHz distam entre si menos que a largura de banda empregada, e cada *bin* integra dezenas delas. A estrutura observada é, portanto, envelope de emissão, não espectro de raias.

A atribuição da fonte ao circuito de iluminação não decorre dessa estrutura, e sim do protocolo A/B: a emissão aparece e desaparece com o acionamento, no mesmo ponto e no intervalo de segundos.

B. Mitigação e verificação

A intervenção consistiu na substituição dos drivers das luminárias por modelos atendendo à especificação da Seção IV, com aterramento funcional das carcaças e revisão do encaminhamento do cabeamento de alimentação. A ação determinante foi a substituição do driver; aterramento e roteamento acompanharam-na como boas práticas de instalação, e não como variáveis ensaiadas isoladamente.

Os componentes são descritos por características técnicas, não por marca. O driver original, conforme a etiqueta do componente inspecionado, era de 36 W e 425 mA, com entrada de 100 a 250 VAC em 50/60 Hz, fator de potência declarado superior a 0,99, distorção harmônica total inferior a 10 %, eficiência de 92 % e saída aproximada de 84 V/425 mA, alojado em carcaça polimérica ventilada sem ponto de terra identificado. O substituto é fonte de corrente constante com ajuste de corrente, em carcaça metálica com terra funcional e com especificações formais de emissão e imunidade declaradas pelo fabricante.

Esses números excluem uma explicação: o componente original já apresentava fator de potência e distorção harmônica dentro dos valores tidos como adequados, de modo que a qualidade de energia não explica a emissão observada. A diferença plausível está na arquitetura construtiva — filtragem de EMC, caminhos de retorno e de terra, controle de emissões do estágio chaveado —, que este trabalho não isolou: a substituição coincidiu com a redução do indicador relativo e com a resolução

funcional do artefato, sem que se atribua o efeito a um elemento interno específico.

A verificação pós-intervenção, realizada em julho de 2026 nos sete pontos, registrou elevação média de 1,04 dB — redução de 12,19 dB no indicador relativo em relação à campanha inicial, com valores individuais entre 0,34 e 1,73 dB — todos abaixo do critério interno. Nenhum dos máximos anteriores permanece destacado: aplicado o mesmo critério de seleção à condição posterior, nenhum ponto da faixa excede a média em mais de um desvio-padrão. A Fig. 2 apresenta a comparação espectral.

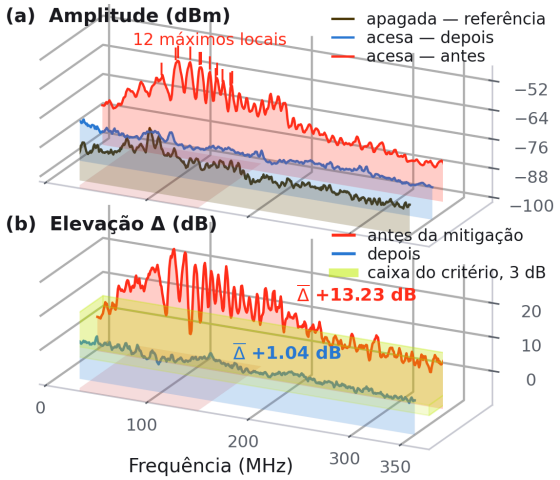

Figura 2. Sala 3 antes e depois da mitigação, em vista isométrica — a profundidade separa condições que em duas dimensões se sobrepunham. (a) Amplitude absoluta: ao fundo a campanha inicial, ao centro a de verificação, à frente a referência com as luminárias apagadas; as hastes assinalam os máximos locais que excedem a média da faixa em mais de um desvio-padrão. (b) Elevação Δ(f) nas duas campanhas, com o critério marcado no eixo e Δ̄ indicando média da faixa. Os primeiros 2 MHz foram omitidos por conterem vazamento de oscilador local, artefato do instrumento.

C. Salas de referência sem intervenção

Duas salas do mesmo serviço, sem qualquer intervenção, foram medidas no mesmo dia, com o mesmo instrumento, os mesmos parâmetros e o mesmo protocolo. Os resultados constam da Tabela II e da Fig. 3.

Tabela II
ELEVAÇÃO POR SALA EM 30 A 150 MHZ

Sala	Elevação média (dB)	DP (dB)	Faixa (dB)	Classe
3 — após mitigação	+1,04	0,52	0,34 – 1,73	I
3 — antes	+13,23	0,89*	—	III
2 — referência	+12,40	1,74	9,24 – 14,32	III
1 — referência	+12,68	0,70	11,62 – 13,77	III

Elevação média: média das elevações dos sete pontos (21 pares de varreduras por sala). DP: desvio-padrão espacial entre os sete pontos — dispersão entre posições de medição, calculada dos dados brutos; não corresponde à incerteza metrológica do instrumento, tratada na Seção VI-D. (*) Campanha inicial, ponto único: DP de repetibilidade entre as cinco varreduras sucessivas no mesmo ponto. Salas 1 e 2: referência, sem intervenção. Classes da Seção III-E (critério interno).

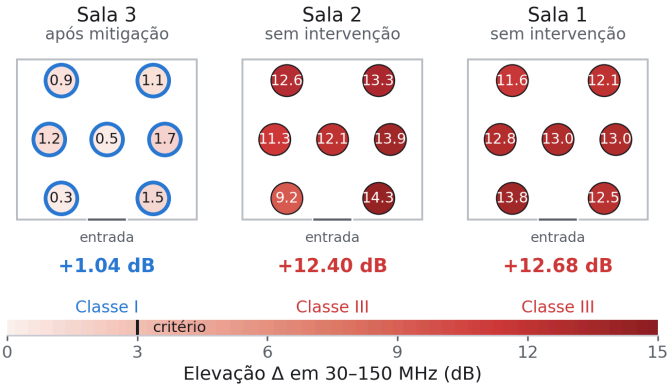

Figura 3. Elevação nos sete pontos de cada sala, em esquema de planta com a entrada ao pé. Cada marcador é uma amostra, não um campo interpolado: sete posições não sustentam reconstrução espacial contínua. Contorno azul indica ponto dentro do critério interno.

Estas salas não constituem controle experimental no sentido clássico — não houve alocação nem intervenção parcial —, mas referência contemporânea: permaneceram sem intervenção e mantiveram elevação acima de 12 dB, enquanto apenas a sala submetida à substituição dos drivers caiu abaixo do critério operacional adotado. A comparação simultânea é relevante para a inferência: não se trata apenas de comparação temporal — sujeita a mudanças não registradas no ambiente — mas de contraste entre salas medidas nas mesmas condições instrumentais, diferindo quanto à intervenção realizada. Um desvio instrumental afetaria as três salas igualmente e não produziria essa separação.

A dispersão entre pontos também informa o escopo das intervenções pendentes. Na Sala 1 a variação é de 2,1 dB — entre 11,62 e 13,77 dB, desvio-padrão de 0,70 dB —, padrão de emissão distribuída que indica substituição do conjunto. Na Sala 2 a variação alcança 5,1 dB, com desvio-padrão de 1,74 dB e o pior ponto na entrada, compatível com contribuição localizada somada à distribuída. Medidas apenas no ponto central, as duas salas apresentariam valores próximos — 13,0 e 12,1 dB — que ocultariam essa diferença de escopo.

D. Efeito da faixa de análise

Uma medição preliminar da Sala 1, restrita à faixa de 225 a 575 MHz, indicou elevação média de 2,94 dB — abaixo do critério de 3 dB e, portanto, sugestiva de conformidade operacional. Tomada no mesmo ponto central e no mesmo dia, a faixa de 30 a 150 MHz devolveu 13,01 dB: subestimação de 10,07 dB sob confronto pareado por posição, ilustrada na Fig. 4. Considerada a média dos sete pontos, a sala reprova com 12,68 dB.

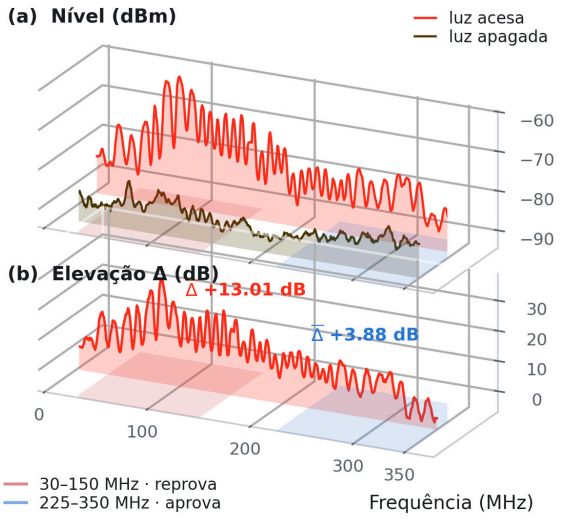

Figura 4. A faixa de análise decide o resultado. Vista isométrica do ponto central da Sala 1 sem intervenção: em (a) os níveis absolutos com a iluminação acionada e apagada, em (b) a elevação Δ(f) daí resultante. A projeção no piso assinala as faixas de análise, e o veredito de cada uma contra o critério de 3 dB consta da legenda. A barra superior, $\bar{\Delta}$, declara média da faixa e não pico, conforme ISO 80000-2 [9] e GUM [10]: bins isolados na faixa crítica chegam a 30,5 dB, mais que o dobro. A projeção é ortográfica: sem perspectiva, a mesma distância mede igual em qualquer profundidade.

A comparação retrospectiva confirma o padrão: na campanha de fevereiro, com o fenômeno clinicamente ativo, a faixa de 225 a 350 MHz registrava apenas 3,93 dB, enquanto 30 a 150 MHz indicava 13,23 dB. A faixa inadequada subestimou o fenômeno em 9,3 dB.

A consequência para a mitigação é direta: a faixa inadequada não produz apenas imprecisão, mas inversão de decisão. Em classe de severidade, a sala migra de III — não conformidade severa — para I — detectável e conforme o critério interno. A investigação teria sido encerrada com a sala liberada e a interferência intacta.

Este resultado alterou a evolução do próprio trabalho: a faixa de análise deixou de ser parâmetro de configuração e passou a integrar o critério de aceitação (Seção III-E); a caracterização inicial tornou-se etapa obrigatória do ciclo — é ela que fixa a faixa — e a declaração da faixa junto ao resultado converteu-se na recomendação metodológica central do artigo (Seção VII). Por documentar uma decisão que seria invertida, o resultado figura nesta seção.

VI. DISCUSSÃO

A. Por que a mitigação falha sem medição

A medição altera três decisões que, sem ela, são tomadas por presunção: onde intervir — ambiente e não equipamento; *quanto* intervir — conjunto e não luminária isolada, conforme o padrão espacial; e quando encerrar — por critério verificado e não por serviço executado. Nenhum protocolo vigente de liberação de área teria detectado a condição, porque nenhum a verifica.

O contraste com [13] é instrutivo e não contraditório. Naquele estudo, Ishida et al. mediram o ruído radiado por focos cirúrgicos LED sobre um sistema de navegação cirúrgica eletromagnética — acoplamento indutivo em baixa frequência — e concluíram por interferência improvável. Seu impacto aqui é duplo: legitima a iluminação LED como hipótese de fonte desde a anamnese do caso motivador, e mostra que a mesma classe de fonte produz desfechos opostos conforme a tecnologia exposta — a susceptibilidade observada neste caso situa-se em 30 a 150 MHz e afeta a cadeia de recepção de sinais de cateter. Isso reforça o argumento central: a verificação ambiental precisa ser referida ao que está instalado naquela sala, e não a um limite único.

B. Relação com o problema clínico original

O ciclo foi desencadeado por um problema clínico concreto — granulação na imagem IVUS e perda intermitente de conexão do FFR Link — e a relação dos resultados com a sua solução deve ser caracterizada com precisão. A cadeia de evidência: a anamnese estabeleceu correlação temporal reprodutível (Seção II); o protocolo A/B a converteu em grandeza medida — 13,23 dB em 30 a 150 MHz, coincidente com o acionamento; a intervenção removeu a causa proposta e a verificação mediu a remoção (1,04 dB, com as salas de referência sem intervenção acima de 12 dB); após a intervenção, não houve novos relatos de artefato nem de queda de conexão até o fechamento deste texto.

O alcance tem limite declarado: o desfecho clínico é observação qualitativa, sem registro sistematizado de eventos, e a verificação funcional prolongada não havia sido concluída. Os resultados demonstram a remoção verificada da causa ambiental identificada e corroboram, pela cessação dos relatos, a resolução do problema original — não constituem demonstração definitiva de causalidade clínica, que exigiria a relação dose–resposta apontada na Seção VI-D como trabalho futuro.

C. Generalização do protocolo

Propõe-se a incorporação do ciclo de mitigação aos procedimentos de engenharia clínica em três momentos: na liberação inicial da sala, como linha de base contra a qual medições futuras serão comparadas; após qualquer reforma que altere iluminação, cabeamento ou aterramento; e na investigação de falhas recorrentes não explicadas pelo equipamento.

A linha de base na liberação inicial é o elemento de maior retorno e o de menor custo: sem ela, toda medição posterior compara a sala apenas consigo mesma no estado atual; com ela, torna-se possível atribuir uma degradação à reforma que a introduziu. O protocolo é compatível com essa aplicação: dispensa laboratório e executa-se em cerca de duas horas por sala com equipe própria.

D. Limitações

As amplitudes registradas em dBm na entrada do analisador permitem comparação relativa entre condições, mas não constituem medida de conformidade normativa à CISPR 15, que estabelece limites em dBµV/m com antena calibrada e distância normalizada. A CISPR 32 [17], por exemplo, fixa a emissão radiada Classe B em 30 dBµV/m na faixa de 30 a 230 MHz a 10 m — valor com o qual os resultados aqui apresentados não podem ser confrontados. A proposta não substitui ensaio acreditado; destina-se à triagem, à orientação da intervenção e à veri-

ficação relativa de rotina, contextos em que o ensaio acreditado é economicamente inviável.

Conforme a Seção III-D, a subtração pareada cancela os erros sistemáticos comuns às duas leituras. Resta, porém, um termo que ela não elimina: a **não linearidade de amplitude** do instrumento. Como as duas condições são lidas em níveis distintos — −73 dBm com as luminárias acionadas contra −86 dBm com elas apagadas —, sobrevive na diferença o desvio de linearidade ao longo desse intervalo:

$$\Delta_{\text{med}} = \Delta_{\text{real}} + \left[\, e(A_{\text{acesa}}) - e(A_{\text{apagada}}) \,\right] \qquad (3)$$

A exatidão de amplitude declarada pelo fabricante é de ± 1 dB [20], o que limita o termo residual a cerca de 2 dB. Para referência, a CISPR 16-4-2 [6] atribui a uma medição radiada *acreditada* incerteza de instrumentação de 4,95 dB a 3 m. A elevação observada, de 12 a 13 dB, excede essa incerteza em duas vezes e meia — margem que sustenta a conclusão sob a hipótese mais desfavorável quanto ao instrumento.

Para uma diferença tomada no intervalo de segundos, a grandeza relevante não é o intervalo de calibração, mas a estabilidade de curto prazo do arranjo, caracterizada por desvio-padrão de 0,89 dB entre as cinco varreduras sucessivas da campanha inicial — cerca de um décimo quinto do efeito medido. A repetibilidade pós-intervenção não foi caracterizada por varreduras sucessivas (a verificação registrou um par por ponto); o indicador disponível — desvio-padrão de 0,52 dB entre os sete pontos — é compatível com a repetibilidade do arranjo, e a caracterização direta, pendente, será depositada no repositório de dados.

Permanece fora de alcance a equivalência metodológica com a norma: o instrumento não dispõe de detector de quase-pico nem das larguras de banda normativas de 200 Hz, 120 kHz e 1 MHz exigidas pela CISPR 16-1-1 [7], e analisadores sem pré-seleção não são admitidos em medição de conformidade. Literatura de referência em diagnóstico de EMI [11] situa instrumentação dessa classe como adequada à localização de fontes e à verificação relativa, e explicitamente não à medição de nível para fins de conformidade — delimitação que este trabalho adota.

O critério de 3 dB é operacional. Foi estabelecido a partir da repetibilidade do arranjo e apoiado pelo desfecho — ausência de novos relatos da equipe assistencial após a mitigação, observação qualitativa sem registro sistematizado — mas não decorre de relação dose–resposta estabelecida entre elevação do ruído eletromagnético ambiente e degradação mensurável do sinal clínico. Não existia registro sistematizado dos eventos clínicos e nenhum foi instituído durante o estudo; o estabelecimento dessa relação, com registro estruturado de eventos clínicos como desfecho, constitui trabalho futuro.

O caminho de acoplamento não foi decomposto. Mediu-se a componente radiada; a componente conduzida pela rede de alimentação, que compartilha a mesma origem no chaveamento do driver, não foi caracterizada por indisponibilidade de rede fictícia de acoplamento e pela impossibilidade de interromper o circuito de uma sala em operação. Como a intervenção realizada atua sobre ambas — filtro integrado ao driver, aterramento de carcaça e roteamento —, o desfecho não discrimina qual caminho predominava no acoplamento ao equipamento suscetível. Para o objetivo de mitigar, a indistinção é aceitável; para atribuir mecanismo, não é, e o trabalho não faz essa atribuição.

Uma observação de alcance decorre da faixa em que o fenômeno se concentrou. O ensaio de imunidade a campos de RF radiados da IEC 60601-1-2 [1] inicia-se em 80 MHz; abaixo dessa fronteira, a imunidade do equipamento é qualificada por ensaio de perturbações conduzidas induzidas por RF, com o cabeamento como caminho de acoplamento. Dos 154 pontos espectrais de 30 a 150 MHz da campanha inicial, 64 (42 %) situam-se abaixo de 80 MHz. Não se conclui daí violação de requisito — as amplitudes são relativas e não admitem confronto com limites em V/m —, mas apenas que parte do fenômeno recai em região cuja qualificação de imunidade não se dá por ensaio radiado. Registre-se ainda que não há, em norma alguma, limite para o ruído eletromagnético ambiente da sala: o critério de aceitação ambiental é lacuna a preencher na liberação da área, não requisito a transcrever de norma existente.

A hierarquia de intervenção da Seção IV não foi submetida a contraste experimental entre níveis: apenas o primeiro foi exercido, com o segundo e o terceiro como medidas associadas, de modo que a contribuição individual de cada um permanece não quantificada. A campanha inicial não incluiu amostragem espacial, o que impede reconstruir a distribuição da emissão anterior à mitigação. A verificação funcional prolongada do equipamento sob iluminação acionada, embora prevista, não havia sido concluída até o fechamento deste texto.

VII. CONCLUSÃO

Demonstrou-se que a interferência eletromagnética radiada de origem predial em sala de hemodinâmica é detectável, localizável, corrigível e *verificável* por medição relativa, com instrumentação de custo da ordem de US$ 170 operada pela própria equipe de engenharia clínica. A mitigação reduziu a elevação do ruído eletromagnético ambiente de 13,23 para 1,04 dB na faixa crítica — redução de 12,19 dB no indicador relativo —, aprovada segundo o critério interno nos sete pontos, enquanto duas salas de referência sem intervenção mantiveram valores superiores a 12 dB — resultado que fortalece a atribuição do fenômeno ao circuito de iluminação e à intervenção realizada.

Quanto ao problema de origem, os relatos de artefato IVUS e de queda do FFR cessaram após a mitigação e não haviam retornado até o fechamento deste texto — remoção verificada da causa ambiental e corroboração da resolução, não demonstração definitiva de causalidade clínica (Seção VI-B).

O ciclo proposto contribui em três pontos além da detecção. A amostragem espacial converte a medição em escopo de serviço, distinguindo emissão distribuída de localizada. A especificação por desempenho torna a intervenção executável em processo de compra, sem restringir a concorrência. E a vinculação do recebimento à verificação transfere o ônus do resultado ao fornecedor, o que distingue mitigação comprovada de serviço executado.

O achado metodológico mais transferível é que a faixa de análise determina a conclusão: restringir a medição a frequências inadequadas produziu aparente conformidade operacional e subestimou o fenômeno em cerca de 9 dB — não uma imprecisão, mas uma inversão de decisão. Qualquer protocolo de mitigação eletromagnética ambiental deve, portanto, fixar a faixa por caracterização inicial do próprio ambiente, e declará-la junto ao resultado.

Recomenda-se a incorporação da verificação eletromagnética aos procedimentos de liberação e de manutenção de áreas cirúrgicas de alta complexidade, à medida que a sensibilidade das tecnologias incorporadas reduz a margem de imunidade disponível no ambiente construído. Os resultados aqui relatados permanecem no plano da triagem, da orientação de intervenção e da verificação relativa — não substituem ensaio EMC acreditado.

DISPONIBILIDADE DOS DADOS

As 52 varreduras brutas que sustentam este trabalho — 42 da campanha de verificação (três salas, sete pontos, duas condições por ponto), seis da campanha inicial e quatro que documentam o falso negativo por faixa — estão depositadas em repositório público de acesso aberto, sob licença CC BY 4.0, com os parâmetros de aquisição, o protocolo de amostragem e o código que reproduz todas as tabelas aqui apresentadas:

https://github.com/DiyMV/emi-iluminacao-led-salas-cirurgicas

O repositório inclui caderno de verificação executável em navegador (Colab), que recalcula cada valor publicado a partir dos CSV brutos. As amplitudes são publicadas exatamente como saíram do instrumento, sem fator de antena, perda de cabo ou correção de calibração. O conjunto não contém dado de paciente — as medições são de emissão ambiente, em salas sem procedimento em curso — nem identificador de instituição, pessoa, ativo ou documento administrativo; a declaração de anonimização acompanha um verificador executável.

Conforme a Seção III-D, o analisador não dispunha de calibração vigente durante as campanhas. Assim que a calibração for realizada, a tabela de correção e o respectivo certificado serão acrescentados à pasta calibracao/ do mesmo repositório, com o recálculo de todas as tabelas lado a lado com os valores publicados. Uma calibração posterior não torna estas medições retroativamente rastreáveis — a rastreabilidade é propriedade da medição no momento em que é feita —, mas permitirá caracterizar a resposta do instrumento, limitar sua deriva e verificar se a correção desloca de forma material as conclusões relativas.

DECLARAÇÃO DE USO DE INTELIGÊNCIA ARTIFICIAL

Em atendimento à Portaria CNPq nº 2.664, de 6 de março de 2026, declara-se o uso de ferramenta de inteligência artificial generativa (Claude, Anthropic) nas seguintes finalidades: elaboração dos programas de processamento das varreduras e de geração das figuras; elaboração e revisão do texto; e levantamento de referências normativas.

Todo o material assim produzido foi submetido a revisão criteriosa pelos autores. Cada valor publicado foi reconferido contra as varreduras brutas por rotina de verificação independente, depositada no repositório de dados; as divergências identificadas nesse processo foram corrigidas antes da submissão. O texto reproduz com fidelidade os achados de medição e as interpretações formuladas pelos autores, a quem pertencem a concepção do estudo, a execução das campanhas, a condução da intervenção e as conclusões. A responsabilidade pela exatidão dos dados, das referências e de todas as afirmações é integralmente dos autores.

AGRADECIMENTOS

À equipe de Hemodinâmica, pela disponibilização das salas para as campanhas de medição, e à equipe de Manutenção Predial, pela execução da intervenção.

***Abstract*—Hospital maintenance records accumulated in CMMS systems represent an underused information asset in decision-making in Clinical Engineering. The present investigation structured an analytical framework applied to the operational history (2020 to 2025) of five categories of medical-hospital equipment, prioritized through multi-criteria selection (CAPEX impact, maintenance volume, and clinical criticality), to support health technology management. The reliability and maintainability assessment, conducted through the application of the Kruskal-Wallis test, Kaplan-Meier estimators, and the Cox proportional hazards model, indicated the manufacturer as a performance predictor with significantly greater statistical weight than cumulative equipment usage (Age Proxy). In the Electric Bed samples, the variance explained by the asset brand reached Eta^2 = 0.3787 for repair time (MTTR). The technical weight of this variable provides quantitative support for the design of new institutional guidelines for the acquisition and renewal of the technology inventory. Time-series modeling based on STL decomposition mapped seasonal behaviors inherent to each technology category. The maintenance volume follows regular care and epidemiological cycles, measured by a Seasonal Index (SI) of 231.8 for Pulmonary Ventilators in June and an SI of 158.3 for Electric Beds in September. The proposed incorporation of large language models (LLMs) adds a semantic processing layer to the numerical indicators. Textual analysis of the work orders generated during seasonal peak months is proposed to classify and detail the root causes and failure modes of the equipment. The proposed integration between stochastic modeling and natural language interpretation constitutes a replicable analytical framework aimed at transforming data generated in the hospital environment into operational intelligence to support decision-making.**

***Keywords*—healthcare asset management, CMMS, reliability, seasonality, language model, clinical engineering.**

I. Introduction

The management of medical-hospital equipment inventories plays a central role in the quality and safety of care provided in healthcare facilities. Over the years, computerized maintenance management systems (CMMS) have become substantial repositories of operational information, recording not only failure events but also response times, mobilized resources, and recurring patterns of technical intervention throughout the life cycle of each technology [1], [2].

In practice, however, these databases are limited to storing operational records, without fully exploring the analytical potential of data regarding the general or specific behavior of assets. Even when some type of analysis is incorporated, which is not the most common situation, Clinical Engineering and Health Technology Assessment (HTA) tend to explore them in a segmented manner: either focusing on reliability and maintainability indicators [1], [3], [6], or analyzing temporal demand patterns [4], [5], without articulating the multiple analytical dimensions that the same database can reveal simultaneously. This fragmentation limits synthesis capacity and reduces the use of the operational knowledge available in historical maintenance records.

More recently, advances in large language models (LLMs) have opened a concrete possibility for processing the textual content of work orders, which historically remained outside any systematic analysis [7]. Failure descriptions, technical observations, and intervention records can now be read automatically, making it possible to identify recurring semantic patterns and connect this qualitative information to classical quantitative indicators.

To broaden support for managers and promote effective use of the data already available in CMMS systems, this study proposes a multi-perspective approach that articulates different analyses to address real technology management problems. To this end, we explore three complementary dimensions from the same database: reliability and maintainability analysis by manufacturer, seasonal decomposition of maintenance demand, and the use of LLMs as an interpretive layer for the iden-

tified seasonal patterns. The objective is not to examine each method in isolation, but to demonstrate that the articulation among these perspectives reveals relationships and insights that independently conducted analyses would not be able to capture, offering a replicable framework for healthcare asset management guided by operational evidence.

II. Materials and Methods

A. Database and Equipment Selection

The analyzed database comes from the CMMS of a hospital network and includes maintenance records from 2020 to 2025, totaling 638,629 records in the global repository prior to category filtering, and 218,028 consolidated work orders (WOs) for the five studied technology categories after complete preprocessing (filtering of critical classes, removal of incoherent/unclassified records, duplicate consolidation, and elimination of non-positive intervention times).

To identify the equipment most relevant to the study, a multi-criteria selection was conducted considering three complementary dimensions. Initially, groups with significant participation in hospital capital expenditure (CAPEX) were selected, regardless of institutional complexity, considering both unit cost and aggregate investment resulting from installed quantities. From this initial group, equipment with higher volumes of preventive and corrective work orders was prioritized, ensuring greater data availability for analysis. Finally, clinical criticality was considered, prioritizing equipment whose failure could severely compromise healthcare delivery or pose a risk to patient life. The combined application of these criteria directed the selection to five groups: Electric Bed, Multiparameter Monitor, Anesthesia Machine, Pulmonary Ventilator, and Cardioverter. Table I presents the descriptive profile of each group, including the exact count of unique physical assets (Tags).

For all reliability analyses (MTBF calculation, Kaplan-Meier survival curves, and Cox regression), a failure event was exclusively defined by the closing of WOs structurally classified as "Corrective Maintenance" in the CMMS database. To model reliability accurately, continuous hours of operation were used as the standard time unit. The time between failures (TBF) was calculated by measuring the exact time elapsed, in continuous hours, between the closing of a corrective WO and the opening of the subsequent corrective WO for the same unique equipment identifier (tag). Repeated failures of the same equipment were treated longitudinally, allowing a single tag to contribute multiple operational intervals in the survival modeling. The last chronological observation recorded for each tag at the end of the collection period was treated statistically as right-censored, as the equipment might not have presented a new failure by the end of the observation window.

B. Reliability and Maintainability Analysis by Manufacturer

Mean Time Between Failures (MTBF) and Mean Time to Repair (MTTR) were calculated by manufacturer for each type of equipment, using continuous operating hours and technical intervention hours, respectively. Manufacturer groups were compared using the nonparametric Kruskal-Wallis test, with effect size estimated by the Eta^2 coefficient [8]. Interpretation followed the thresholds proposed by Cohen [9]: small effect ($\text{Eta}^2 \geq 0.01$), medium effect (≥ 0.06), and large effect (≥ 0.14).

Survival analysis was performed using Kaplan-Meier curves [10], with manufacturers compared by the log-rank test. To assess the simultaneous influence of multiple operational factors on the risk of failure, a multivariate Cox proportional hazards regression model was constructed [11]. Alongside the manufacturer dummy indicators, the model included the following fundamental operational control covariates:

- **Cumulative usage (Age Proxy):** The accumulated number of WOs for a specific equipment tag, acting as a surrogate variable to represent intensity of use and accumulated wear over time in the absence of exact manufacturing timestamps.
- **Preventive Maintenance Intensity (PM Intensity):** A continuous variable calculated through a rolling temporal window, accounting for the rate of preventive WOs the equipment (same tag) received in the exact 180 days prior to the analyzed failure event.
- **Annual and Semiannual Seasonality (Sine/Cosine):** To control for cyclical demand oscillations throughout the year, the WO opening month was converted into two-dimensional coordinates on the trigonometric circle (Sine and Cosine), capturing the continuous nature of calendar transitions.

Clustered robust standard errors were incorporated at the equipment tag level to account for intra-asset correlation and avoid risk distortion from repeat-failure units (the "lemon effect"). The model estimated Hazard Ratios (HRs) and 95% confidence intervals. All analyses were performed in Python using the *lifelines*, *scipy*, and *statsmodels* libraries.

C. Seasonal Decomposition of Demand

The STL (Seasonal-Trend decomposition using Loess) technique was selected to model monthly maintenance demand because of its ability to flexibly separate trend, seasonality, and residual components without imposing rigid parametric assumptions on the time series [12]. The Seasonal Index (SI) was calculated for each month, allowing the identification of peak and trough demand periods and the magnitude of seasonal fluctuations. Equipment with $SI > 150$ was classified as having high seasonal variability.

D. Proposed Interpretive Support Using Large Language Models

An intrinsic limitation of temporal decomposition methods is that they reveal when maintenance demand increases, but do not explain why the seasonal pattern is specific to each type of equipment or the qualitative nature of the failures concentrated at the peaks. To advance this dimension, the use of LLMs is proposed as an interpretive layer complementary to seasonal analysis.

Table I
CHARACTERIZATION OF THE SELECTED MEDICAL EQUIPMENT CATEGORIES.

Equipment	Total WOs	Corrective WOs (Failures)	Unique Assets (Tags)	Manufacturers	Period	Selection
Anesthesia Machine	11,378	2,139	736	15	2020–2025	Multi-Criteria
Cardioverter	69,120	2,057	1,342	12	2020–2025	Multi-Criteria
Electric Bed	9,536	5,709	2,671	33	2020–2025	Multi-Criteria
Multiparameter Monitor	70,601	22,462	7,898	52	2020–2025	Multi-Criteria
Pulmonary Ventilator	57,393	9,758	7,570	37	2020–2025	Multi-Criteria
Total	**218,028**	**42,125**	**20,201**	**124***	**2020–2025**	**–**

*Number of distinct manufacturer brands across all five analyzed critical equipment categories.

The methodology consists of selecting the work orders recorded during the peak months identified by STL decomposition ($SI > 150$) and submitting their descriptive fields to the LLM, requesting the identification and semantic grouping of the predominant failure patterns. Comparing the qualitative profiles between peak periods and normal periods makes it possible to reveal whether seasonal increases in demand are associated with specific types of failure, recurring components, or patterns of intensive clinical use. Table IV summarizes the analytical questions proposed for each equipment type, derived directly from the seasonal patterns identified in Section III-B.

III. RESULTS

A. Reliability and Maintainability by Manufacturer

For all five types of equipment analyzed, the Kruskal-Wallis test indicated significant differences in MTTR among manufacturers ($p < 0.001$). Although statistical significance was observed across categories, there was substantial variation in the magnitude of the effect measured by Eta^2. For Electric Beds ($\text{Eta}^2 = 0.3787$) and Multiparameter Monitors ($\text{Eta}^2 = 0.2660$), the MTTR effect size clearly exceeded the large-effect threshold (≥ 0.14) according to Cohen's criteria [9], demonstrating that manufacturer choice accounts for over a quarter to more than a third of the variance in repair times. In terms of reliability (MTBF), significant differences across manufacturers were confirmed for Multiparameter Monitors ($\text{Eta}^2 = 0.1341, p < 0.001$), Electric Beds ($\text{Eta}^2 = 0.1201, p < 0.001$), and Pulmonary Ventilators ($\text{Eta}^2 = 0.0332, p < 0.001$), whereas Cardioverters ($p = 0.067$) and Anesthesia Machines ($p = 0.115$) did not reach significance at $\alpha = 0.05$. Table II presents the complete results by equipment type.

The Kaplan-Meier survival curves revealed pronounced differences in reliability trajectories among manufacturers of the same equipment category. For Electric Beds, Manufacturer 04 demonstrated the highest survival probability, maintaining a stable operational curve with survival probability remaining above 0.40 throughout extended operational hours. In contrast, Manufacturer 43 exhibited the lowest reliability profile, characterized by severe early mortality with survival probability dropping sharply within the initial operational intervals ($t_{25} < 500$ hours). Intermediate survival trajectories were observed for Manufacturers 66, 12, and 52. The log-rank test confirmed that survival distributions across all evaluated manufacturers differ significantly ($p < 0.001$).

These results indicate that assets from lower-performing brands present elevated failure rates during initial operational phases, leading to premature downtime. From the perspective of hospital management, this disparity directly drives higher consumption of technical hours, accelerated turnover of mechanical components, and prolonged bed unavailability, emphasizing the necessity of integrating CMMS survival history into formal procurement criteria.

The multivariate Cox proportional hazards model quantified the relative contribution of manufacturer identity against operational control covariates, including cumulative usage (Age Proxy), preventive maintenance intensity, and cyclical seasonality. As illustrated in Fig. 2 for Pulmonary Ventilators, operational controls—Cumulative Usage (Age Proxy: HR ≈ 1.00, $p > 0.05$), Intensity of Preventive Maintenance (HR ≈ 1.00, $p > 0.05$), and Seasonality Cosine (HR ≈ 1.01, $p > 0.05$)—exhibited no statistically significant independent effect on failure hazard. The Seasonality Sine covariate captured a statistically significant cyclical demand oscillation ($p < 0.05$), consistent with mid-year respiratory surges.

Manufacturer identity emerged as the single dominant determinant of failure risk ($p < 0.05$). The model identified Manufacturers 33, 18, and 06 as the highest-risk brands (HR > 1.00), exhibiting substantially accelerated failure rates relative to the reference brand under identical operating regimes. Conversely, statistically significant protective effects were demonstrated by Manufacturers 14, 07, 11, 54, 34, and 92 (HR < 1.00), which exhibited significantly reduced hazards of corrective failure.

The pronounced spread in Hazard Ratios between protective and high-risk brands confirms that manufacturer selection is the primary structural factor governing medical technology reliability, substantially outweighing cumulative operational age and routine preventive maintenance frequency.

B. Seasonality of Maintenance Demand

STL decomposition showed that each type of equipment has its own maintenance demand calendar. This is not random variation: the identified seasonal patterns have sufficient regu-

Table II
RESULTS OF THE KRUSKAL-WALLIS TEST AND EFFECT SIZE (ETA^2) ACROSS MANUFACTURERS BY EQUIPMENT TYPE.

	Mean Time to Repair (MTTR)				Mean Time Between Failures (MTBF)			
Equipment	H	p-**value**	**Eta**^{2}	**Magnitude**	H	p-**value**	**Eta**^{2}	**Magnitude**
Anesthesia Machine	88.47	< 0.001	0.0389	Small	10.25	0.115	0.0128	Small†
Cardioverter	229.33	< 0.001	0.1078	Medium	14.63	0.067	0.0167	Small†

Multiparameter Monitor	5992.08	< 0.001	0.2660	Large	492.95	< 0.001	0.1341	Medium
Pulmonary Ventilator	812.01	< 0.001	0.0807	Medium	75.71	< 0.001	0.0332	Small

†Not statistically significant ($p \geq 0.05$). Effect size thresholds (Cohen [9]): Small ($\text{Eta}^2 \geq 0.01$), Medium (≥ 0.06), Large (≥ 0.14).

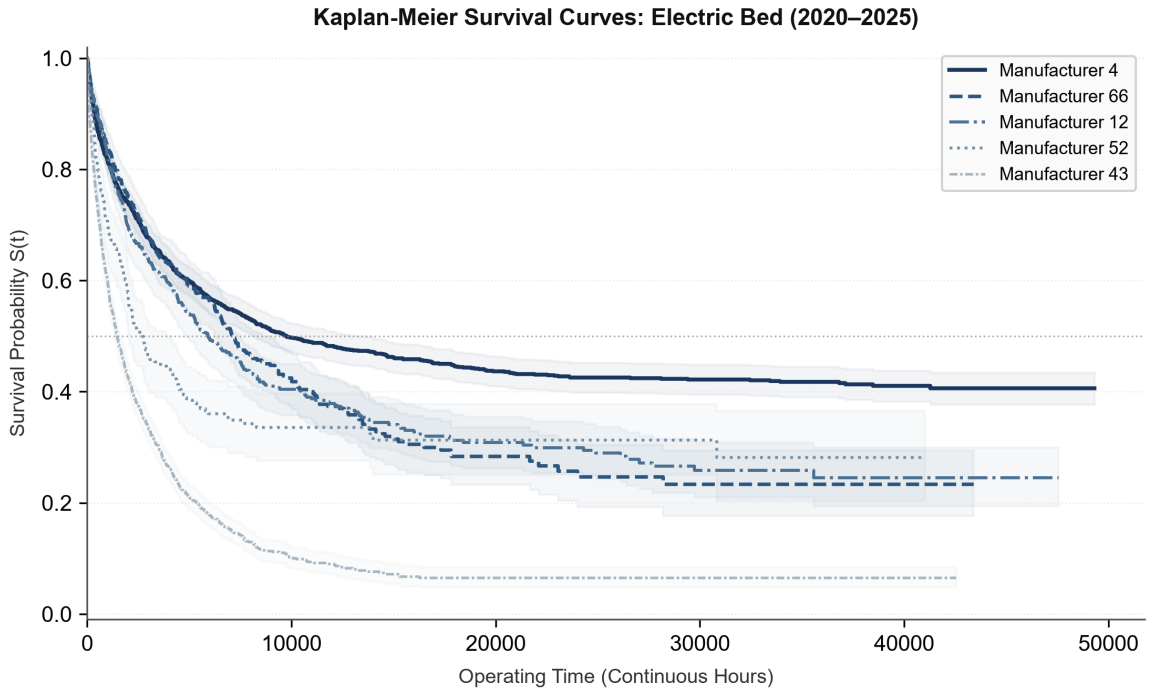

Figure 1. Kaplan-Meier survival curves stratified by manufacturer for Electric Bed (2020–2025). Manufacturer 04 (solid dark curve) represents the benchmark with superior operational longevity, stabilizing above 0.40 survival probability. Conversely, Manufacturer 43 (dashed light curve) exhibits rapid initial degradation and high early mortality ($p < 0.001$, log-rank test). 95% CI shaded.

larity and magnitude to inform operational planning. Table III presents the maximum and minimum Seasonal Indices by equipment type.

The STL decomposition revealed marked seasonal dynamics across all five medical technologies. For Pulmonary Ventilators, maintenance demand reached its annual maximum in June (SI $= 231.8$), coinciding with the winter surge in respiratory illnesses and elevated intensive care occupancy in the Southern Hemisphere. This concentration reflects operational stress during peak clinical utilization, followed by a demand trough in August (SI $= 67.8$).

Electric Beds exhibited their demand peak in September (SI $= 158.3$), driven by high hospital bed occupancy rates and accelerated patient turnaround in inpatient units during the third quarter, contrasting with a trough in August (SI $= 59.9$).

Anesthesia Machines displayed a peak in February (SI $= 128.4$), reflecting the resumption and rescheduling of elective surgical procedures following the year-end recess period. Multiparameter Monitors presented peak demand in August (SI $= 128.5$), associated with continuous ICU throughput, intensive sensor replacement cycles, and periodic transducer calibrations. In contrast, Cardioverters demonstrated limited seasonal variation throughout the year (SI between 77.9 in August and 114.5 in January), consistent with devices maintained in standby readiness where technical interventions are predominantly driven by routine inspection protocols rather than acute utilization fluctuations.

C. Emerging Perspective: LLM Support for the Qualitative Interpretation of Seasonality

Although identifying the period of increased demand is relevant, efficient management requires the qualitative characterization of recorded failures. This technical detail goes

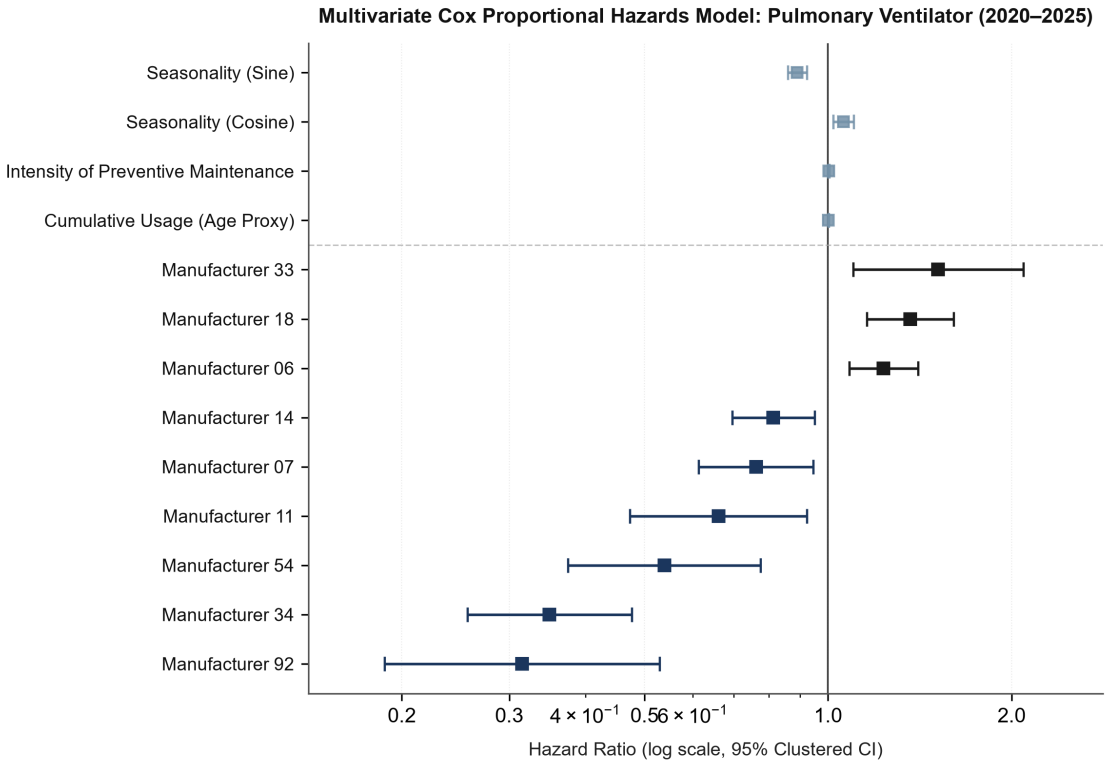

Figure 2. Hazard Ratios (log scale, 95% Clustered CI) from the multivariate Cox Proportional Hazards Model for Pulmonary Ventilator (2020–2025). Robust standard errors clustered at the asset tag level. High-risk brands (e.g., Manufacturers 33, 18, and 06) exhibit significantly elevated failure hazards (HR > 1.00), whereas protective benchmark brands (e.g., Manufacturers 14, 07, 11, 54, 34, and 92) demonstrate substantial hazard reductions (HR < 1.00). Operational controls (Age Proxy and PM Intensity) remain centered on the null line (HR ≈ 1.00, $p > 0.05$).

Table III
MAXIMUM AND MINIMUM SEASONAL INDICES (SI) BY EQUIPMENT TYPE.

Equipment	**Max. SI**	**Peak Month**	**Min. SI**	**Trough Month**	**Hypothesis**
Pulmonary Ventilator	231.8	June	67.8	August	Respiratory disease seasonality (winter ICU demand surge)
Electric Bed	158.3	September	59.9	August	Inpatient volume surge and post-winter bed turnover
Anesthesia Machine	128.4	February	61.5	August	Resumption of elective surgeries post-recess
Multiparameter Monitor	128.5	August	72.4	February	Intensive inpatient monitoring turnover and transducer maintenance
Cardioverter	114.5	January	77.9	August	Periodic emergency readiness tests and annual inspection routines

beyond the capabilities of traditional temporal decomposition methods, since the STL algorithm identifies volume peaks but does not distinguish the nature of the occurrences.

The descriptive fields of work orders record precisely this information in natural language. The proposal is to submit the WOs from the peak months identified by STL to a large language model (LLM), instructing it to classify and semantically group the failure descriptions. The result would be a qualitative profile of the peaks: which types of intervention predominate, whether there are recurring component or cause patterns, and whether the peak-period profile is structurally different from the profile of normal-demand months. Table IV organizes, for each equipment type, the concrete analytical question that this approach would make it possible to answer.

The methodological feasibility of the proposal is based on the use of routine historical records and the application of natural language processing procedures structured through systematic classification prompts. This approach does not require dedicated hardware and can be carried out by Clinical Engineering teams using standard computing resources. The resulting framework adds a semantic analysis layer capable of qualifying the temporal distribution obtained through statistical modeling.

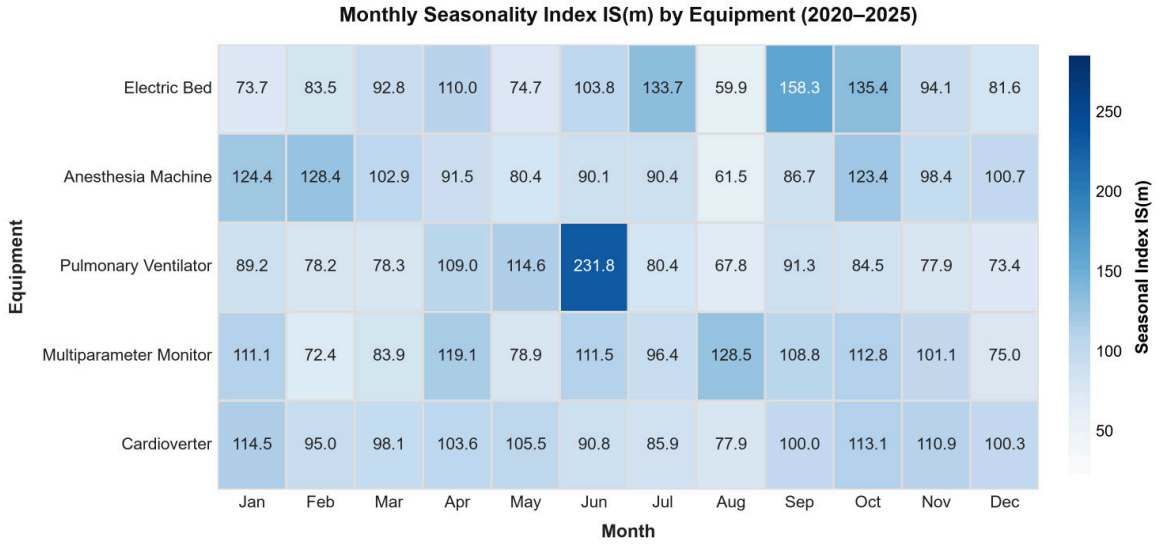

Figure 3. Monthly Seasonality Index (SI) by equipment type. SI = 100 represents the equipment's historical average demand. Values above 100 indicate a peak, whereas values below 100 indicate a trough. STL decomposition with annual periodicity (2020–2025).

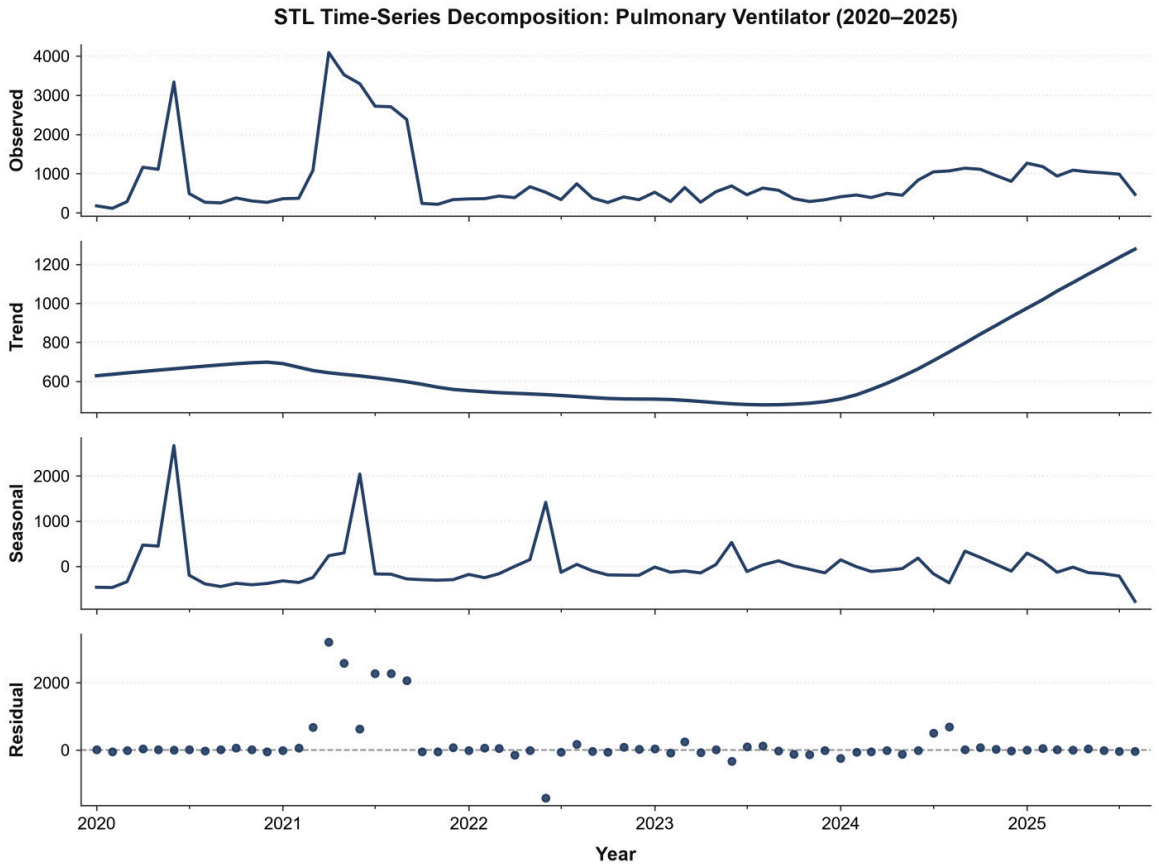

Figure 4. STL time-series decomposition for Pulmonary Ventilator (2020–2025): observed series, trend, seasonal component, and residual points. Recurring demand peak in June (SI = 231.8). Positive residual shocks in 2020–2021 capture acute pandemic demand surges.

IV. Discussion

A. Convergence between Perspectives: The Value of the Multi-Analytical Framework

Taken together, the findings from the two analytical perspectives implemented construct a more complete picture of

Table IV
FRAMEWORK OF ANALYTICAL QUESTIONS PROPOSED FOR APPLYING AN LLM TO WOS FROM SEASONAL PEAKS.

Equipment	Peak Month(s)	Max. SI	Analytical question proposed for the LLM
Pulmonary Ventilator	June	231.8	Which types of failure predominate in June WOs during the winter respiratory surge? Are they flow-sensor, valve, or pneumatic degradation failures?
Electric Bed	September	158.3	Is the September peak dominated by electromechanical failures (actuator, motor drive) or structural/control interface wear associated with inpatient turnover?
Anesthesia Machine	February	128.4	Does the February peak coincide with post-recess surgical resumption? Are occurrences concentrated in pneumatic circuits, vaporizers, or electronic calibration?
Multiparameter Monitor	August	128.5	Does the August peak reflect higher ICU monitoring turnover and accessory replacement (ECG leads, SpO_2 probes), or display/power board degradation?
Cardioverter	Not applicable	114.5	Does textual analysis of technical calls confirm that failures are predominantly detected during periodic testing and battery checks rather than acute emergency usage?

the operational behavior of the equipment than either would produce alone. Reliability analysis identifies the manufacturer as the main explanatory factor for differences in repair time, with a large effect for Electric Beds and substantial Hazard Ratios for Pulmonary Ventilators. This finding highlights the need to integrate historical reliability and technical performance indicators into the formal specification and evaluation criteria of medical-hospital equipment acquisition processes.

Practical experience in the hospital environment shows that, because of high technological complexity and multiple configuration possibilities, a significant proportion of technical calls for Pulmonary Ventilators and Anesthesia Machines is related to operational aspects and care adjustments, and therefore does not necessarily represent structural technical failures. Without a qualitative analysis layer, purely statistical indicators tend to treat all work orders homogeneously. The application of language models (LLMs) therefore appears to be a promising approach for refining these metrics, making it possible to distinguish intrinsic equipment failures from demands generated by operational support and configuration needs.

Seasonal analysis adds a second dimension that hospital maintenance planning commonly ignores: demand is not randomly distributed throughout the year. It rises and falls in regular patterns that reflect the rhythms of healthcare delivery itself. The SI of 231.8 in June for Ventilators and 158.3 in September for Electric Beds are not statistical noise. Rather, they are signals that could reduce the operational impact of peak periods if incorporated into resource and inventory planning.

Integrating LLMs into the descriptive analysis of technical calls complements traditional numerical approaches. While STL temporal analysis establishes the timing and intensity of demand variations, semantic processing can distinguish whether intervention peaks result from structural failures in critical components, such as flow sensors and seals, or from operational demands. This information may contribute to the transition from a predominantly reactive maintenance model to evidence-based planning of care contingencies grounded in qualitative historical evidence.

B. Implications for Clinical Engineering and Health Technology Assessment

One aspect worth emphasizing is that none of the results obtained contradicts what experienced Clinical Engineering teams already perceive empirically in their daily work. What the analysis does is make this perception quantifiable, comparable, and communicable beyond the technical team. This has specific value in the context of HTA: decisions on technology incorporation and replacement require evidence that can be justified and documented, not merely perceived.

The Cardioverter showed no relevant seasonal variation throughout the analyzed year. This statistical behavior is consistent with its clinical use characteristics: these devices have a low frequency of effective clinical activation and remain in a state of readiness for long periods. A substantial proportion of occurrences does not result from continuous use but is frequently identified during operational tests and routine inspections, which decouples maintenance demand from seasonal fluctuations in occupancy and hospitalization.

From the standpoint of replicability, the proposed framework does not depend on analytical infrastructure beyond the reach of hospital teams. The complete methodological sequence, ranging from multi-criteria equipment selection to the proposed qualitative interpretation by LLM, can be applied to any CMMS database with sufficient historical volume. Reliability analysis requires Python with the *lifelines* and *scipy* libraries. STL decomposition is equally accessible, while the LLM stage can be conducted using open-access tools. The barrier to dissemination is not technical complexity, but the absence of an analytical culture applied to healthcare asset management.

V. CONCLUSION

This study demonstrated that historical hospital maintenance records, routinely stored in CMMS systems, constitute a robust database for supporting managerial decisions in healthcare

asset management. The integration of multiple analytical approaches applied to the same dataset made it possible to extract performance indicators that enrich decision-making processes in Clinical Engineering and Health Technology Assessment (HTA).

Statistical reliability modeling demonstrated that the manufacturer acts as a predictive factor for repair time and operational survival with significantly greater weight than cumulative equipment usage (Age Proxy). For technologies such as Electric Beds, acquisition decisions based predominantly on initial cost, while disregarding operational performance history, may generate prolonged negative impacts on care availability because of increased mean repair time and the complexity of obtaining spare parts.

Additionally, time-series modeling revealed structured seasonal cycles consistent with the specific care dynamics of each technology. Equipment linked to elective surgical procedures, such as Anesthesia Machines, exhibits fluctuations in maintenance demand conditioned by the hospital calendar. In contrast, technologies maintained in a state of care readiness, such as cardioverters, have intervention demands that are less associated with occupancy rates, with some occurrences being identified during routine inspections and periodic operational tests.

To refine the interpretation of numerical indicators, the framework proposes incorporating large language models as a semantic layer for the textual classification of work orders. This natural language processing stage may help distinguish technical failures intrinsic to the equipment from calls resulting from operational support or configuration errors, qualifying the interpretation of reliability metrics.

In summary, the proposed methodological integration of reliability analysis, seasonality modeling, and textual processing by language models constitutes an analytical framework capable of transforming historical maintenance records into evidence to support Clinical Engineering and Health Technology Assessment. This approach may strengthen decisions related to technology incorporation, investment planning, equipment replacement, risk management, and technology governance. As future perspectives, empirical validation of the framework in different care profiles and CMMS platforms is recommended, as well as its integration into intelligent decision-support systems aimed at managing the life cycle of health technologies.

***Abstract*—Electricity costs represent a significant share of the operating budget of large Brazilian university hospitals, particularly those operating under the Free Contracting Environment (*Ambiente de Contratação Livre*, ACL) and the blue hourly tariff structure. This work proposes an optimization methodology for the contracted demand and energy volume of the University Hospital of Brasília (HUB-UnB), comparing three approaches: Sequential Quadratic Programming (SQP), Differential Evolution (DE), and a hybrid DE + SQP strategy. Monthly demand and energy consumption data were used to forecast the 2026 load profile through a Holt-Winters model, while the Settlement Price of Differences (PLD) was forecast with a Prophet model; both were validated against the first four months of 2026 with errors below 5 %. Applied to the forecasted profile, the SQP method alone reduced the estimated annual electricity cost by 3.76 %, the DE method achieved a 6.16 % reduction, and the hybrid DE + SQP approach achieved the largest reduction, 6.19 %, relative to the current contract. The results indicate that the hybrid approach consistently outperforms both individual methods and is particularly well-suited to problems in which the objective function exhibits derivative discontinuities arising from the demand-tolerance tariff rule.**

***Index Terms*—university hospital, free electricity market, contracted demand, optimization, differential evolution, sequential quadratic programming, hybrid optimization**

I. Introduction

The electricity bill of the University Hospital of Brasília, operated by HU Brasil (HUB-UnB/HU Brasil) ranks among the institution's largest fixed operating expenditures, a characteristic shared by large federal university hospitals throughout Brazil, where the continuous operation of critical equipment, HVAC systems, and lighting results in high and largely inflexible load profiles. As a Group A4 consumer enabled to operate under the Free Contracting Environment (ACL), the HUB-UnB/HU Brasil negotiates energy prices bilaterally with traders but still pays the local distribution utility, Neoenergia Brasília, for network access through the Distribution System Use Tariff (TUSD). Under this arrangement, setting the contracted demand levels for peak and off-peak periods, as well as the energy volume to be acquired in the ACL, carries direct financial consequences that go beyond the simple per-kWh cost.

The blue hourly tariff structure penalizes deviations from the contracted demand asymmetrically: exceedances above 5 % of the contracted value are billed at twice the demand tariff rate, whereas contracted values above actual consumption generate a guaranteed-minimum charge without offsetting compensation. On the energy side, the difference between the volume contracted in the ACL and the actual consumption is settled at the Settlement Price of Differences (PLD) at the Energy Trading Chamber (CCEE), a price that has changed during the year with hydropower reservoir levels. Forecasting future demand and consumption and, from those projections, determining the contractual parameters that minimize total cost therefore constitutes an optimization problem with concrete,

PPGEB – Postgraduate Program in Biomedical Engineering and HUB-UnB/HU Brasil

recurrent economic impact in the hospital.

The literature addresses this problem through distinct approaches. Linear and quadratic programming methods have been applied to energy contract optimization for industrial consumers [8], [9], yielding good results in settings where the cost function is convex and continuous. When nonlinearity or discrete variables complicate analytical approaches, metaheuristics such as genetic algorithms [10] and Particle Swarm Optimization (PSO) [11] have been used successfully in dispatch and energy procurement problems. These works, however, focus on industrial consumers or distribution networks with distributed generation: the Brazilian hospital context, with its ACL-specific regulatory constraints and a load profile driven by medical equipment, remains underexplored in the energy optimization literature.

The works most closely related to this paper address hospital energy efficiency from the perspective of energy audits and retrofit [12], [13], without addressing the contractual layer. The distinction is relevant: efficiency improvements reduce consumption but not necessarily cost, if the contractual parameters remain poorly sized. A hospital that reduces peak demand by 10 % but keeps the contracted demand at the previous level continues to pay for volume it does not use.

This paper implements and compares three optimization methods for the demand and energy procurement problem at the HUB-UnB/HU Brasil: SQP (Sequential Quadratic Programming) [1]; Differential Evolution (DE) [2], a global-search evolutionary algorithm; and a hybrid approach that uses DE to explore the solution space in the early stages and SQP to refine the best solution found. The motivation for this comparison lies in the fact that the cost function presents derivative discontinuities at the demand-tolerance thresholds, which may cause SQP to converge to local minima depending on the starting point, while DE navigates these regions without gradient bias, at the expense of a larger number of objective function evaluations. The hybrid strategy seeks to capture the advantages of both.

A distinguishing feature of this work relative to similar studies is the empirical data foundation: demand and consumption variables were collected from the hospital's electricity bills since the institution first became a free-market consumer. The historical dataset covers the period from March 2021 to December 2025, and the 2026 projections feeding the optimization module were obtained from time-series models validated against the already-available months of 2026 [3].

The paper is organized as follows. Section II presents the theoretical background on the tariff structure and the three optimization methods. Section III describes the hospital characterization, the forecasting procedure, and the method configurations. Section IV presents the results and comparison across approaches. Section V draws conclusions and outlines directions for future work.

II. Theoretical Background

A. Tariff Structure for Free-Market A4 Consumers — Blue Hourly Tariff

Under the blue hourly tariff, demand is billed separately for the peak period (18:00 – 21:00, business days) and the off-peak period, at distinct rates for each. The monthly demand charge follows a piecewise function: up to 5 % above the contracted demand D_c, billing equals the contracted value itself; beyond that threshold, the excess is charged at twice the tariff rate, as established by ANEEL Normative Resolution No. 1,000/2021 [4]:

$$f(\tilde{D}, D_c, \tau) = \begin{cases} D_c \cdot \tau, & \tilde{D} \leq 1{,}05\, D_c \\ D_c \cdot \tau + (\tilde{D} - D_c) \cdot 2\tau, & \tilde{D} > 1{,}05\, D_c \end{cases} \tag{1}$$

where $\tilde{D}$ is the maximum demand measured in the period, integrated over 15-minute intervals, and τ is the TUSD demand tariff for that period (R$/kW). The total monthly cost for a free-market consumer decomposes into three components:

$$C_m = C_{dem,m} + C_{tusd,m} + C_{acl,m} \tag{2}$$

The demand TUSD component applies function f from (1) to each period:

$$C_{dem,m} = f(\tilde{D}_p, D_p, \tau_{D_p}) + f(\tilde{D}_{fp}, D_{fp}, \tau_{D_{fp}}) \tag{3}$$

The consumption TUSD component remunerates network usage for the energy actually withdrawn from the distribution system:

$$C_{tusd,m} = \tilde{E}_p\, \tau_{E_p} + \tilde{E}_{fp}\, \tau_{E_{fp}} \tag{4}$$

The energy component combines the cost of the bilateral ACL contract with the settlement of the difference between actual consumption and contracted volume at the PLD:

$$C_{acl,m} = E_{acl}\, \rho_{acl} + (\tilde{E}_p + \tilde{E}_{fp} - E_{acl})\, \rho_{pld} \tag{5}$$

The third term in (5) may be negative when actual consumption falls short of the contracted volume, in which case the difference is settled as a credit at the PLD.

B. Optimization Problem Formulation

The objective is to find the decision vector $\mathbf{x} = (D_p,\, D_{fp},\, E_{acl})$ that minimizes the total annual cost:

$$\min_{\mathbf{x}}\ C_{annual}(\mathbf{x}) = \sum_{m=1}^{12} C_m(\mathbf{x}) \tag{6}$$

subject to the box constraints:

$$D_p \geq D_{min}, \quad D_{fp} \geq D_{min}, \quad E_{acl} \geq 0 \tag{7}$$

where D_{min} is the minimum contractable demand. The net demand effectively measured by the distribution utility in each

period corresponds to the larger of the minimum contractable demand and the forecasted demand:

$$\tilde{D}_{p,m} = \max\Big(D_{min},\ \hat{D}_{p,m}\Big) \tag{8}$$

$$\tilde{D}_{fp,m} = \max\Big(D_{min},\ \hat{D}_{fp,m}\Big) \tag{9}$$

where $\hat{D}_{p,m}$ and $\hat{D}_{fp,m}$ are the forecasted demands for month m. The function C_{annual} in (6) is piecewise continuous, with derivative discontinuities at the points $\tilde{D} = 1{,}05\, D_c$. This feature motivates the comparison between gradient-based and metaheuristic methods proposed in this work.

C. Sequential Quadratic Programming (SQP)

SQP is one of the most consolidated classical methods for nonlinear constrained optimization, with theoretical development dating back to the 1970s and extensive application to engineering problems in subsequent decades [1], [5]. Its central idea is to approximate the original problem by a sequence of quadratic subproblems, each solved analytically to produce a descent direction.

At each iteration k, SQP solves:

$$\min_{\mathbf{d}} \ \frac{1}{2}\mathbf{d}^\top W_k \mathbf{d} + \nabla C(\mathbf{x}^{(k)})^\top \mathbf{d} \tag{10}$$

where W_k is an approximation of the Lagrangian Hessian and $\mathbf{d}$ is the search direction. The solution $\mathbf{d}^*$ of (10) defines the step:

$$\mathbf{x}^{(k+1)} = \mathbf{x}^{(k)} + \alpha_k\, \mathbf{d}^* \tag{11}$$

where α_k is determined by a merit-function line search that penalizes constraint violations. The box constraints from (7) are incorporated directly into the quadratic subproblem, with no need for external projection. The implementation used here is SLSQP (Sequential Least Squares Programming), available in the SciPy library [6], which handles equality, inequality, and bound constraints in a unified framework.

SQP is a local search method: solution quality depends on the starting point. In functions with multiple local minima — such as the cost function in (6), which exhibits derivative discontinuities at the demand-tolerance thresholds — this dependence motivates the hybrid strategy with DE described in Section II-E.

D. Differential Evolution

Differential Evolution (DE) is an evolutionary algorithm for continuous optimization proposed by Storn and Price [2]. It maintains a population of N_p vectors $\{\mathbf{x}_i^g\}$ and evolves it through three operations. In the *mutation* step, a mutant vector is generated from the current best individual $\mathbf{x}_{best}^g$ and two randomly selected individuals:

$$\mathbf{v}_i^g = \mathbf{x}_{best}^g + F \cdot (\mathbf{x}_{r1}^g - \mathbf{x}_{r2}^g) \tag{12}$$

where $F \in [0, 2]$ is the scale factor and $r1 \neq r2 \neq i$. In the *binomial crossover*, each component of the trial vector $\mathbf{u}_i^g$ is selected from $\mathbf{v}_i^g$ with probability CR or from $\mathbf{x}_i^g$ otherwise, guaranteeing that at least one component comes from $\mathbf{v}_i^g$. In the *selection* step, the trial vector replaces the current one only if it reduces the cost: $\mathbf{x}_i^{g+1} = \mathbf{u}_i^g$ if $C(\mathbf{u}_i^g) \leq C(\mathbf{x}_i^g)$, and $\mathbf{x}_i^{g+1} = \mathbf{x}_i^g$ otherwise. The *best/1/bin* strategy adopted here balances global exploration and local convergence by directing mutations toward the current best solution.

E. Hybrid DE + SQP Approach

The complementarity between the two methods directly motivates the proposed hybrid strategy. DE performs global exploration without requiring continuity of the objective function, identifying the region of the solution space where the global optimum lies. SQP then exploits the local curvature of that region to converge rapidly to the optimal point.

In the adopted strategy, DE is run to convergence, and the resulting best individual $\mathbf{x}_{best}^{g_{trans}}$ is passed as the starting point to SQP, which carries out local refinement under the box constraints of (7). This transition reduces the total number of objective function evaluations relative to running DE alone to the same precision level, while preserving the ability to escape local minima that SQP alone does not possess.

III. Materials and Methods

A. HUB-UnB Characterization

The HUB-UnB is a large federal university hospital operated by HU Brasil (*Hospitais Universitários do Brasil*), located in Brasília (DF) and supplied at medium voltage under distribution utility Neoenergia Brasília's Group A4 tariff. Its load profile is dominated by HVAC systems and continuously operating medical equipment. The institution has been operating in the ACL since 2021.

The historical dataset covers 57 months of consolidated monthly electricity bills (March 2021 to December 2025), comprising four variables: peak maximum demand, off-peak maximum demand, represented on Fig. 1, and peak energy consumption, and off-peak energy consumption, represented on 2.

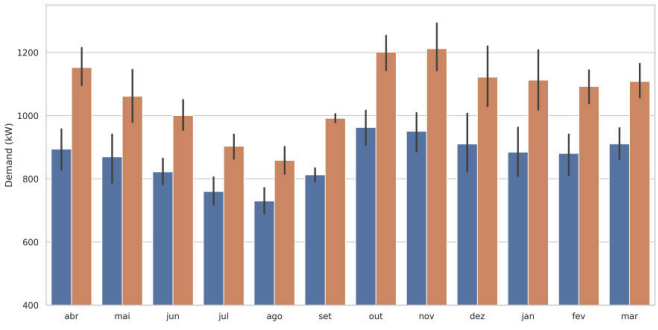

Fig. 1. Historical peak maximum demand (blue) and off-peak maximum demand (orange) colected from the electricity bills

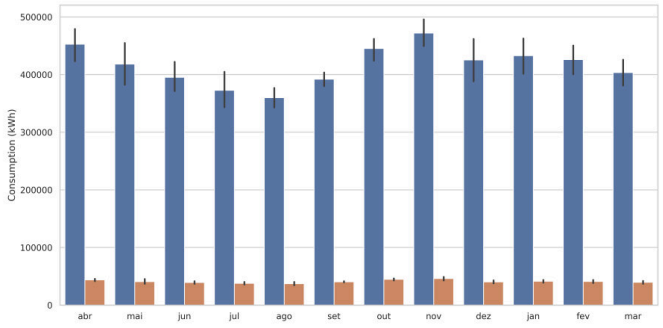

Fig. 2. Historical peak energy consumption (blue) and off-peak energy consumption (orange) colected from the electricity bills

B. Demand and Energy Forecasting for 2026

Three time-series models were fitted to each variable using data through December 2025, with validation on the four months of 2026 already available: Holt-Winters triple exponential smoothing (automatically testing additive and multiplicative combinations of trend and seasonality), SARIMA$(1,1,1)(1,1,1)_{12}$, and a Seasonal Naïve model as a baseline. The evaluation metric was the Mean Absolute Percentage Error (MAPE):

$$\text{MAPE} = \frac{1}{n}\sum_{t=1}^{n}\left|\frac{y_t - \hat{y}_t}{y_t}\right| \times 100 \tag{13}$$

where y_t is the observed value and $\hat{y}_t$ the forecasted value for month t. The model selected to feed the optimization module was the one with the lowest validation error over the first four months of 2026: Holt-Winters, with a MAPE of 3.2 % for peak demand and 4.42 % for off-peak demand [3].

C. PLD Forecasting for 2026

Estimating the CCEE settlement component described in (5) required projecting the PLD for all twelve months of 2026. The Prophet model, developed by Meta, was used; it natively handles multiple seasonalities and public holidays in the training process. The monthly PLD forecasts were validated against the four known months of 2026 using the historical PLD series published by the CCEE [7] from january 2002 until december 2025, achieving errors below 2 %.

D. Optimization Method Parameters

All three methods were implemented in Python 3.12 with the following configurations.

SQP (SLSQP): SciPy implementation [6], convergence tolerance *ftol* $= 10^{-12}$, *maxiter* $= 20\,000$. The starting point was set to the currently contracted values for peak demand, off-peak demand, and ACL energy volume.

DE: *best/1/bin* strategy, population size $N_p = 500$, scale factor $F = 0{,}8$, crossover probability $CR = 0{,}9$, maximum of *maxiter* $= 20\,000$ generations or relative variation tolerance $< 10^{-12}$ between consecutive generations. The search bounds are the same as those of SQP, as defined in (7).

Hybrid DE + SQP: DE is run to convergence with population size $N_p = 50$ and the remaining parameters as described above. The best resulting individual is then passed as the starting point to SQP with the same parameters.

The tariff parameters used in the objective function are listed in Table I.

TABLE I
TARIFF PARAMETERS USED IN THE OBJECTIVE FUNCTION

Parameter	Value	Unit
TUSD peak demand (τ_{D_p})	40.41	R$/kW
TUSD off-peak demand ($\tau_{D_{fp}}$)	16.92	R$/kW
TUSD peak consumption (τ_{E_p})	0.21	R$/kWh
TUSD off-peak consumption ($\tau_{E_{fp}}$)	0.21	R$/kWh
ACL price (ρ_{acl})	0.19937	R$/kWh
Demand tolerance	5	%
Exceedance penalty	2×	—

E. Comparison Criterion

The three methods were compared based on the lowest final cost found. Given that convergence, speed, and uncertainties are not relevant for this application, and since contractual adjustments can be made every two years but energy accounting is monthly, solution precision is more relevant for this problem than computational throughput.

IV. Results and Discussion

To assess consistency, mean, variance, and standard deviation were computed across 30 complete independent runs of each method. It is worth noting that SQP exhibits zero variance and zero standard deviation, since it is a deterministic algorithm: given the same starting point, it always returns the same solution, which, however, may not be the global optimum, as shown in Table II.

TABLE II
STATISTICAL RESULTS OF ANNUAL COST ACROSS 30 RUNS PER ALGORITHM

Method	Mean (R$)	Variance	Std. Dev. (R$)
SQP	3,050,917.23	0	0
DE	2,975,689.57	633,215.74	795.75
DE + SQP	2,975,548.29	1,330,317.05	1,153.39

Fig.3 summarizes the best results achieved by each method according to the criterion defined in Section III-E. The SQP method alone reduced the estimated annual electricity cost by 3.76 % (R$ 119,130.77). The DE method achieved a reduction of 6.16 % (R$ 195,383.48), and the hybrid DE + SQP approach yielded the best result among the three, with a 6.19 % reduction (R$ 196,166.66).

SQP reduces the cost rapidly in the first iterations but tends to stall at a local optimum that depends on the starting point. DE converges gradually and consistently, exploring the solution space more broadly in the early generations. The hybrid combines DE's initial exploration with SQP's accelerated convergence in the final phase, reaching the lowest

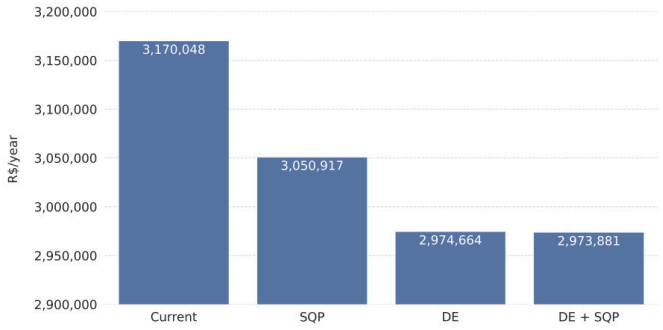

Fig. 3. Estimated annual electricity bill cost (best results)

cost with fewer total objective function evaluations than DE run to full convergence.

A. Optimal Proposal and Economic Analysis

The optimal parameter values obtained by the hybrid method are shown in Table III, alongside the current contract.

TABLE III
COMPARISON BETWEEN CURRENT CONTRACT AND OPTIMAL PROPOSAL

Parameter	Current	Proposal	Change
Peak Demand (kW)	1,090	840	−22.94 %
Off-Peak Demand (kW)	1,280	1,053	−17.73 %
ACL Energy (kWh/month)	494,503	727,870	+47.17 %
Annual Cost (R$)	3,170,048	2,973,881	−6.19 %

The estimated annual saving of R$ 196,166.66 arises primarily from the adjustment in the ACL contracted energy volume. Because the bilateral ACL price remained below the projected PLD for most of the year, contracting an energy volume above the average forecasted consumption proved advantageous: the surplus is settled in the short-term market (MCP) at the PLD, which remunerates that difference at a value above the ACL acquisition cost, as expressed by the second term of (5). Correctly sizing this contracted volume simultaneously avoids the extra cost of an undersized contract and the generation of surpluses that find no real counterpart in the market.

B. Discussion

The results show that the energy contract optimization problem for hospitals is not unimodal: SQP found distinct solutions depending on initialization. This behavior stems from the derivative discontinuity in the cost function at the demand-tolerance threshold, which can cause the gradient to point in misleading directions near those regions.

DE navigates this landscape without the bias of first-order methods, but does so at the expense of a larger number of evaluations. For a problem of this dimensionality, three decision variables, that computational cost is manageable, yet the hybrid approach showed that it is possible to obtain the best of both methods without incurring the full computational burden of either in isolation.

From a hospital management standpoint, the proposed methodology offers a direct practical contribution: executed on a biannual basis with up-to-date data, it produces a contract recommendation grounded in real measurements and calibrated forecasts, replacing the common practice of renewing contracts based solely on historical peak values or managerial experience.

Furthermore, the idea is to expand this methodology to other hospitals within the same network that share similar characteristics.

V. CONCLUSION

This paper compared three optimization methods (SQP, DE, and a hybrid DE + SQP strategy) applied to the demand and energy procurement problem of the HUB-UnB/HU Brasil in the Free Contracting Environment. Using real data extracted from electricity bills and 2026 forecasts of demand, energy, and PLD, the hybrid method achieved the largest estimated saving among the three approaches: 6.19 % (R$ 196,166.66) relative to the current contract. This result demonstrates that combining global search with local refinement is advantageous for this class of problems, whose cost function presents derivative discontinuities.

Key limitations of the study relate to the forecasting models for the variables used in the cost function. Both the demand-and-consumption forecasts and the PLD projections carry uncertainty inherent to the models employed, and that uncertainty propagates directly to the quality of the optimal solution found.

Future work will focus on validating the optimized parameters against the actual data as they become available, refining the peak and off-peak demand forecasting models, incorporating additional explanatory variables into the PLD forecasting model, and integrating a real-time SCADA monitoring system into the HUB-UnB/HU Brasil, enabling more granular consumption analysis and supporting contract sizing with direct measurement data.

Finally, operational considerations such as changes in hospital occupancy, installation of distributed generation, demand response strategies, or unexpected variations in electricity market prices are not incorporated into the optimization model since the primary objective is the correction of the electricity bill.

The contribution is a decision-support formulation tailored to a hospital in the free contracting environment, not proof of global superiority between those methods.

ACKNOWLEDGMENT

The authors thank the Graduate Program in Biomedical Engineering, the National Council for Scientific and Technological Development (CNPq) and the University Hospital of Brasília (HUB-UnB/HU Brasil) for their collaboration and institutional support, which made this study possible.

***Abstract*—This study presents tests performed on infusion pumps used in clinical practice at the University Hospital of the University of São Paulo. The evaluation was carried out through a partnership between the hospital and the Normative Testing Division of the Biomedical Engineering Laboratory at the Escola Politécnica of the University of São Paulo. To evaluate device performance, gravimetric tests were performed in accordance with IEC 60601-2-24. A representative sentinel case extracted from an ongoing surveillance initiative is presented, selected for significant flow rate deviations observed during performance testing. The evaluated infusion pump, manufactured in 2023, had recently been received by the hospital. Gravimetric tests were performed in accordance with IEC 60601-2-24 to assess flow-rate performance under predefined operating conditions. In the initial assessment, the device exhibited relevant deviations from the programmed flow rate, despite having previously been considered suitable for clinical use. Following the initial assessment, the device was segregated and sent to the manufacturer. The manufacturer did not provide information regarding any maintenance or calibration procedures performed before returning the device to the hospital. A second performance assessment was performed and showed improved flow-rate performance under the evaluated conditions. This case illustrates the importance of periodic testing as a complementary strategy for verifying the effectiveness of manufacturer intervention, to detect metrological issues before they present potential clinical risks, supporting the implementation of broader hospital sampling programs.**

***Index Terms*—infusion pump, flow-rate accuracy, performance testing, post-market surveillance, IEC 60601-2-24.**

I. Introduction

In a medical hospital setting, infusion pumps are routinely used in clinical care. These devices are widely employed to ensure the safe and accurate administration of medications, nutrients, and intravenous fluids, especially in critical care areas such as Intensive Care Units (ICUs) [1]. According to the International Electrotechnical Commission (IEC) 60601-2-24:2012 standard, an infusion pump is medical equipment intended for the controlled delivery of liquids to the patient through the pressure generated by its pump [2]. These devices are classified into several categories based on their operating mechanism, including peristaltic (rotary or linear), piston, diaphragm, and syringe [3].

Infusion pumps are designed to guarantee accurate dosing and optimal device performance; however, it is essential that healthcare professionals use these devices effectively [4] and that regular maintenance and calibration protocols are strictly followed to ensure patient safety [5].

The clinical impact of flow errors is particularly significant in critically ill patients, since small variations in infusion rate may alter the therapeutic concentration of highly sensitive drugs, compromising hemodynamic stability and patient safety [1].

In pediatric intensive care units (PICUs), infusion pumps are frequently used to continuously administer antimicrobials, vasoactive drugs, sedatives, and analgesics. According to the Surviving Sepsis Campaign guidelines, antimicrobial dosing strategies should be optimized based on pharmacokinetic and pharmacodynamic principles, since subtherapeutic dosing may lead to failure to clear infection, prolonged organ dysfunction, and the development of antimicrobial resistance. Furthermore, critically ill pediatric patients often present altered drug metabolism and clearance, making accurate drug delivery essential for achieving the intended therapeutic effect. Therefore, the performance and accuracy of infusion pumps play a crucial role in ensuring safe and effective treatment in pediatric critical care settings [6].

In this scenario, preventive maintenance, calibration, and post-market metrological evaluation play an important role in verifying whether the device continues to operate within the limits established by international standards. The importance of these activities is reinforced by evidence from the literature. A systematic review conducted by Atanda *et al.* (2023) reported that error rates in intravenous medication preparation and administration range from 13% to 84%, highlighting that device accuracy varies drastically based on both physiological and mechanical factors. The authors also highlighted a critical shortage of clinical tests directly correlating flow rate

accuracy with clinical patient outcomes [7]. In addition, other studies have reported that a significant proportion of infusion pumps used in hospitals present flow deviations associated with component wear, insufficient maintenance, or undetected functional failures [8].

Within this context, this study presents a representative sentinel case extracted from an ongoing investigation involving infusion pumps used in clinical practice. The selected device was chosen due to the magnitude of the deviations identified during performance testing carried out by the Normative Testing Division of the Biomedical Engineering Laboratory at the Escola Politécnica of the University of São Paulo (DENLEB/EPUSP).

The analyzed infusion pump belongs to the PICU at the University Hospital of the University of São Paulo (HU-USP). Before testing, it had been classified as operational and suitable for use, as stipulated by the contractual terms of the hospital's loan agreement.

By presenting test results and an analysis of medical device performance, this study aims to demonstrate that routine maintenance verification alone may be insufficient to ensure real-world flow accuracy. Ultimately, this work provides evidence to motivate structured, hospital-wide sampling strategies and refine evidence-based clinical engineering procedures.

II. Materials and Methods

The experimental tests were performed in the DENLEB. The laboratory is equipped with an analytical balance (BP221S, Sartorius, Germany); an 18G needle (Descarpack, Brazil); a $125\,\mathrm{mL}$ Erlenmeyer flask (Vidrolabor, Brazil); a vacuum gauge (63 mm, Wika, Germany); a pressure gauge (IDP-2000, Connect JCO, Brazil); an air compressor (Schulz S.A., Brazil); a vacuum pump (Schulz S.A., Brazil); and an environmental conditions meter (Davis Instruments, USA). All measuring instruments complied with the specifications established by IEC 60601-2-24:2012 and were duly calibrated with traceability to recognized metrological standards.

The tests were conducted at $(23 \pm 2)\,^{\circ}\mathrm{C}$; relative humidity was maintained at $(60 \pm 15)\,\%$, and water for medical use was utilized as the fluid throughout all experiments. Specifically, the procedures were carried out under items 201.12.1.101 and 201.12.1.102 of IEC 60601-2-24:2012, entitled Accuracy of Controls and Instruments, and followed the test configuration illustrated in Fig. 1.

The analytical balance was interfaced with a computer via RS-232 communication for real-time data acquisition. The system was operated by custom software developed in a graphical programming environment (LabVIEW 2012, National Instruments, USA), which guided the step-by-step execution of the tests and performed automated data processing.

The medical device, a volumetric infusion pump with a linear peristaltic mechanism manufactured in 2023 and its dedicated infusion sets, both newly acquired by HU-USP, were supplied by the PICU. To preserve institutional and commercial confidentiality, the exact manufacturer and model are kept undisclosed. According to the manufacturer's documentation, the nominal overall mean percentage flow error is $\pm 5\%$.

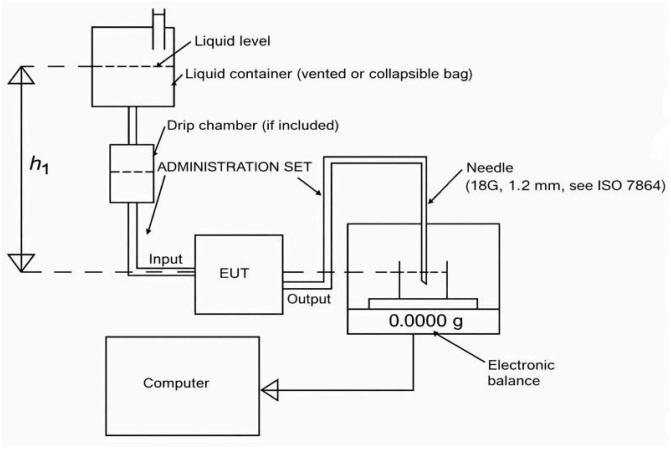

Fig. 1. Test apparatus for volumetric infusion pumps, adapted from IEC 60601-2-24:2012 [2]. EUT: equipment under test.

The tests at the nominal flow rate of $1\,\mathrm{mL/h}$ were conducted over a 24-hour period under ambient pressure conditions. In contrast, the tests at $25\,\mathrm{mL/h}$ were carried out for 2 hours under three distinct conditions: ambient pressure, positive pressure of $100\,\mathrm{mmHg}$, and negative pressure of $-100\,\mathrm{mmHg}$. For each condition, the global mean percentage errors were calculated for the second hour (T_1) and for the final hour (T_2).

Furthermore, all formulas and calculations employed in this research were based on IEC 60601-2-24:2012, which defines the technical criteria for evaluating infusion pump performance. The flow rate was calculated using

$$Q = \frac{60(W_j - W_k)}{Td}, \tag{1}$$

where W_j represents the final sample mass (g), W_k denotes the initial sample mass (g), T is the analysis period (min), and d represents the density of the fluid (g/mL).

For the 24-hour test, T_1 corresponds to the second hour of analysis, with the corresponding initial and final mass measurements taken at 120 and 240 min, respectively. For T_2, the corresponding measurements were taken at 1380 and 1440 min.

To calculate the overall mean percentage flow error, the following equation was used:

$$A = \frac{100(Q - r)}{r}, \tag{2}$$

where Q is the flow rate calculated using (1) and r is the flow rate programmed into the infusion pump. For tests lasting more than 2 hours, the overall mean percentage flow error was calculated for both T_1 and T_2.

For the construction of the start-up flow-rate graphs, the data acquisition procedure followed the prescriptions of IEC 60601-2-24:2012, with two measurements acquired per minute throughout the tests. For the start-up graphs, the flow rate was calculated as

$$Q_i = \frac{60(W_i - W_{i-1})}{Sd}, \tag{3}$$

where $i = 1, 2, \ldots, N$; W_i is the ith mass sample of the analysis period T_0 (g); T_0 is the analysis period (min); S is the interval between samples (min); and d represents the density of the fluid (g/mL).

The quantity Q_i represents the average flow rate over the interval between two consecutive mass measurements and should not be interpreted as an instantaneous flow rate.

A. Measurement Uncertainty

The evaluation of measurement uncertainty is essential for assessing the reliability of flow-rate determinations. In the experimental setup, the flow rate was measured gravimetrically based on the mass of the fluid collected over a defined time interval. The measurement model considered the initial and final mass readings, the time interval, and the fluid density.

Because the density is temperature-dependent, ambient room temperature was controlled throughout testing to minimize density fluctuations. Under these controlled environmental conditions, fluid density was treated as constant in the measurement model, and its uncertainty contribution was assumed negligible relative to the balance performance.

Similarly, time intervals were governed by automated data logging; hence, timing uncertainty was treated as negligible. Under these operational assumptions, the primary quantified uncertainty source originated from the mass measurements recorded by the analytical balance.

The flow rate (Q) was calculated using the gravimetric model:

$$Q = \frac{60(W_j - W_k)}{Td} \tag{4}$$

where W_k and W_j are the initial and final mass values (g), respectively, T is the analysis period (min), and d is the fluid density (g/mL).

Applying the law of propagation of uncertainty, the combined standard uncertainty of the flow rate, $u(Q)$:

$$u^2(Q) = \left(\frac{\partial Q}{\partial W_j} u(W_j)\right)^2 + \left(\frac{\partial Q}{\partial W_k} u(W_k)\right)^2 \tag{5}$$

The sensitivity coefficients are defined:

$$\frac{\partial Q}{\partial W_j} = \frac{60}{Td} \qquad \frac{\partial Q}{\partial W_k} = -\frac{60}{Td} \tag{6}$$

Assuming equal standard uncertainties for both initial and final mass readings, i.e., $u(W_k) = u(W_j) = u(W)$, the combined standard uncertainty simplifies to:

$$u(Q) = \frac{60\sqrt{2}}{Td} u(W) \tag{7}$$

The standard uncertainty $u(W)$ was derived from the calibration certificate of the analytical balance. The certificate reports an expanded uncertainty:

$$U(W) = 0.0002\,\mathrm{g} \tag{8}$$

with a coverage factor of $k = 2$. Therefore, the standard mass uncertainty was calculated:

$$u(W) = \frac{U(W)}{k} = \frac{0.0002\,\mathrm{g}}{2} = 0.0001\,\mathrm{g}. \tag{9}$$

The overall mean percentage flow error (E) was defined relative to the nominal flow rate r:

$$E_{=}\frac{Q - r}{r} \cdot 100(\%) \tag{10}$$

Since r is a flow rate adjusted by the operator on the infusion pump, its uncertainty contribution is zero. Consequently, the uncertainty associated with the error is obtained by propagating $u(Q)$:

$$u(E_p) = \left|\frac{\partial E_p}{\partial Q}\right| u(Q) = \frac{100}{r} u(Q) \tag{11}$$

The expanded uncertainty for the flow rate error is reported as $U(E_p) = k \cdot u(E_p)$, using a coverage factor of $k = 2$ (representing an approximate 95% confidence level) [10].

The uncertainty analysis was to T1 and T2. Consecutive flow-rate estimates Q_i (used for the start-up graph) are not statistically independent because each estimate is calculated from two consecutive mass measurements, and adjacent estimates share a common mass reading. Therefore, a complete uncertainty evaluation of the extrema of the trumpet curves would require consideration of covariance between successive estimates and statistical treatment of the extremum-selection process. Such an analysis is beyond the scope of the present study.

III. Results

To evaluate the pump's performance, the tests were carried out in two separate stages. Tables I and II show the results of the infusion pump before manufacturer intervention. Tables III and IV show the results after the device was returned by the manufacturer.

TABLE I
OVERALL MEAN PERCENTAGE FLOW ERROR AT 1 mL/h, TOTAL TIME OF 24 HOURS, AMBIENT PRESSURE, AND BEFORE MANUFACTURER INTERVENTION.

Medical Device	Error at T_1 (%)	Error at T_2 (%)
Infusion Pump	-9.89	-0.71

Figures 2, 3, 4, and 5 show the infusion pump's start-up graphs before manufacturer intervention. Figures 6, 7, 8, and 9 show the corresponding start-up graphs after manufacturer intervention.

Table V presents the measurement uncertainty results.

TABLE II
OVERALL MEAN PERCENTAGE FLOW ERROR AT 25 mL/h, TOTAL TIME OF 2 HOURS, UNDER THREE PRESSURE CONDITIONS, AND BEFORE MANUFACTURER INTERVENTION.

Pressure condition	Error (%)
No back pressure	-3.83
+100 mmHg back pressure	-11.13
−100 mmHg back pressure	-10.06

TABLE III
OVERALL MEAN PERCENTAGE FLOW ERROR AT 1 mL/h, TOTAL TIME OF 24 HOURS, AMBIENT PRESSURE, AND AFTER MANUFACTURER INTERVENTION.

Medical Device	Error at T_1 (%)	Error at T_2 (%)
Infusion Pump	-5.64	3.38

TABLE IV
OVERALL MEAN PERCENTAGE FLOW ERROR AT 25 mL/h, TOTAL TIME OF 2 HOURS, UNDER THREE PRESSURE CONDITIONS, AND AFTER MANUFACTURER INTERVENTION.

Pressure condition	Error (%)
No back pressure	-0.16
+100 mmHg back pressure	3.88
−100 mmHg back pressure	-0.29

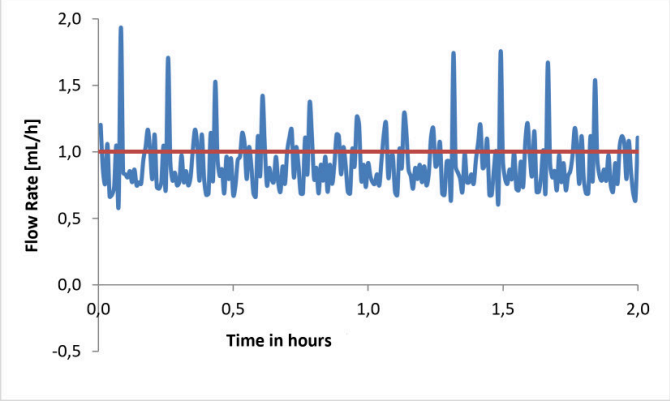

Fig. 2. Flow-rate behavior of the infusion pump operating at 1 mL/h, before manufacturer intervention, under ambient pressure conditions during the first two hours of testing.

IV. DISCUSSION

A. Performance Evaluation of the Infusion Pump

In the 1 mL/h test (T_1), the infusion pump presented an overall mean percentage flow error of -9.89%, indicating considerable underinfusion. Although the error was reduced in T_2 (-0.71%), the results demonstrated instability in the infusion pump performance over the 24-hour test period. At 25 mL/h, the medical device also showed negative overall mean percentage flow errors under all pressure conditions, especially with a back pressure of +100 mmHg, where the error reached -11.13%.

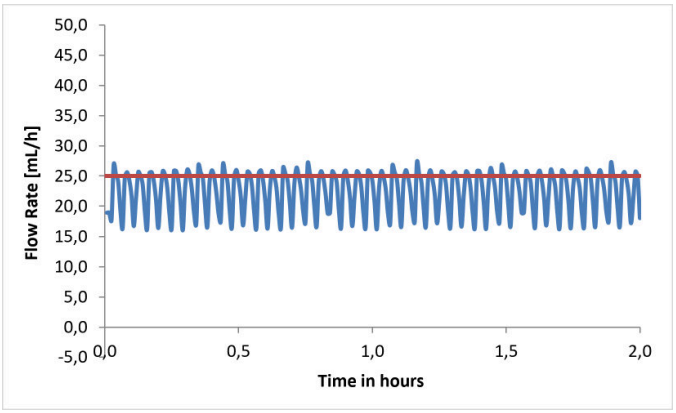

Fig. 3. Flow-rate behavior of the infusion pump operating at 25 mL/h, before manufacturer intervention, during two hours of testing, under +100 mmHg back pressure.

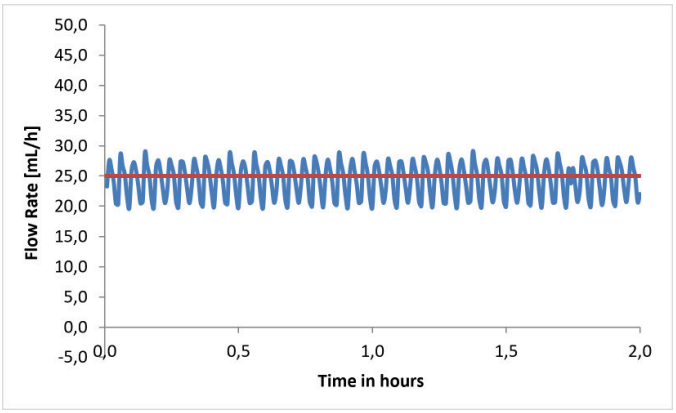

Fig. 4. Flow-rate behavior of the infusion pump operating at 25 mL/h, before manufacturer intervention, during two hours of testing, under ambient pressure.

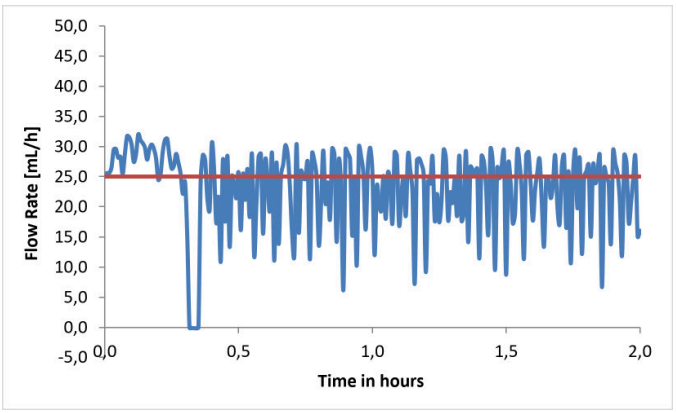

Fig. 5. Flow-rate behavior of the infusion pump operating at 25 mL/h, before manufacturer intervention, during two hours of testing, under −100 mmHg back pressure.

The start-up graphs before manufacturer intervention indicate transient behavior during the first thirty minutes of infusion. This is particularly true under the 1 mL/h condition and at 25 mL/h with a back pressure of −100 mmHg. At

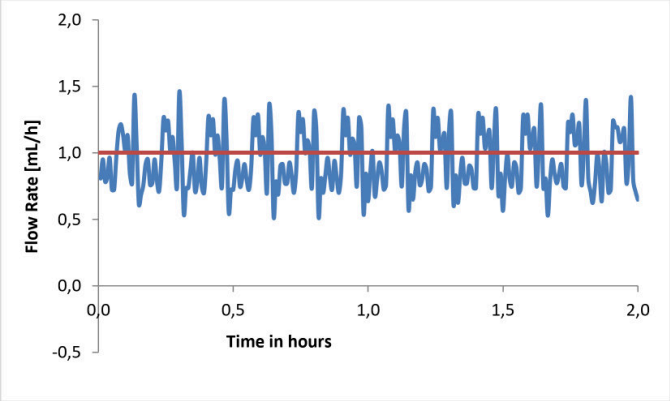

Fig. 6. Flow-rate behavior of the infusion pump operating at $1\,\mathrm{mL/h}$, after manufacturer intervention, during two hours of testing, under ambient pressure.

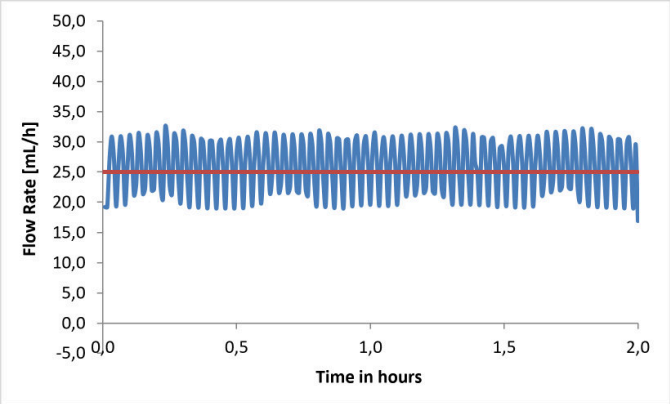

Fig. 7. Flow-rate behavior of the infusion pump operating at $25\,\mathrm{mL/h}$, after manufacturer intervention, during the first two hours of testing, under $+100\,\mathrm{mmHg}$ back pressure.

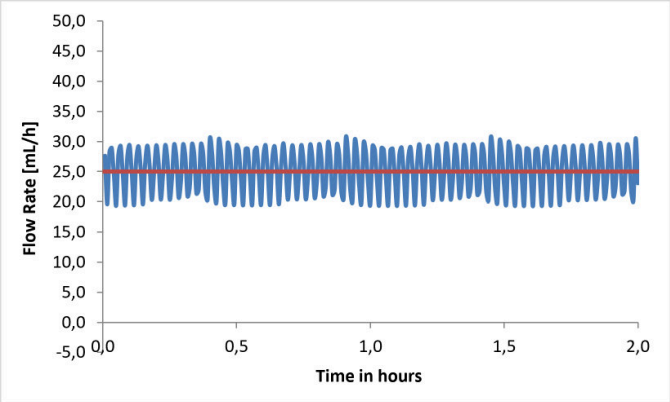

Fig. 8. Flow-rate behavior of the infusion pump operating at $25\,\mathrm{mL/h}$, after manufacturer intervention, during the first two hours of testing, under ambient pressure.

a programmed flow rate of $1\,\mathrm{mL/h}$ without back pressure, the flow fluctuated between $0.6\,\mathrm{mL/h}$ and $2.0\,\mathrm{mL/h}$. At a programmed flow rate of $25\,\mathrm{mL/h}$ with a back pressure of $-100\,\mathrm{mmHg}$, the flow exhibited considerably greater variability, ranging from $0\,\mathrm{mL/h}$ to $30\,\mathrm{mL/h}$.

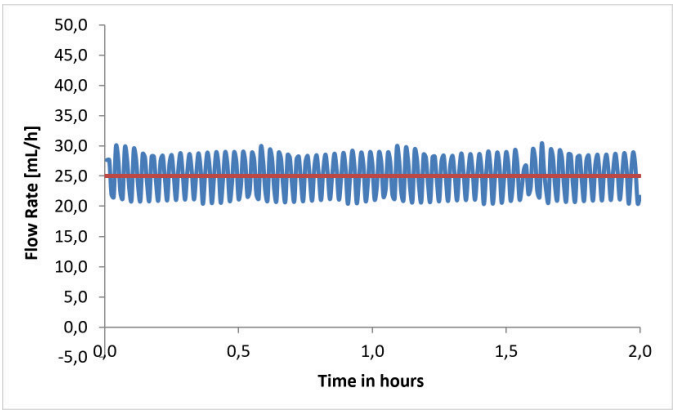

Fig. 9. Flow-rate behavior of the infusion pump operating at $25\,\mathrm{mL/h}$, after manufacturer intervention, during the first two hours of testing, under $-100\,\mathrm{mmHg}$ back pressure.

TABLE V
MEASUREMENT UNCERTAINTY

Parameter	**Flow: 1 mL/h**	**Flow: 25 mL/h**
Analysis interval (T)	60 min (1 h)	60 min (1 h)
Assumed density (d)	1 g/mL	1 g/mL
Balance uncertainty $u(W)$	0.0001 g	0.0001 g
Standard Uncertainty of Flow Rate, $u(Q)$		
Formula: $u(Q) = \frac{60}{T \cdot d}\sqrt{2} \cdot u(W)$		
Calculation	$\frac{60}{60 \cdot 1}\sqrt{2} \cdot 0.0001$	$\frac{60}{60 \cdot 1}\sqrt{2} \cdot 0.0001$
Calculated value	$\mathbf{0.0001}$ mL/h	$\mathbf{0.0001}$ mL/h
Standard Uncertainty of Error, $u(E_p)$		
Formula: $u(E_p) = \frac{100}{r} \cdot u(Q)$		
Calculation	$\frac{100}{1} \cdot 0.000141$	$\frac{100}{25} \cdot 0.000141$
Calculated value	$\mathbf{0.0141}\%$	$\mathbf{0.0006}\%$
Expanded Uncertainty of Error, $U(E_p)$		
Coverage factor (k)	2 (95% conf.)	2 (95% conf.)
Formula: $U(E_p) = k \cdot u(E_p)$		
Calculation	$2 \cdot 0.0141\%$	$2 \cdot 0.0006\%$
Final Result $U(E_p)$	$\pm\mathbf{0.0282}\%$	$\pm\mathbf{0.0012}\%$

As shown in Fig. 5, the infusion pump exhibited a temporary loss of infusion continuity when operated at $25\,\mathrm{mL/h}$ under a back pressure of $-100\,\mathrm{mmHg}$. This phenomenon was characterized by a complete cessation of fluid delivery lasting approximately 3.5 minutes, recorded between minutes 18 and 22 of testing.

These findings demonstrate that variations in pressure test conditions and low flow rates can severely compromise infusion pump accuracy despite up-to-date routine maintenance.

The classification "new and operational" does not necessarily ensure adequate metrological performance. In this case, the infusion pump was considered suitable for use, but the normative test showed that its flow delivery was still outside the expected tolerance range.

The results were presented to the clinical engineering team. The infusion pump was segregated and was immediately sent to the manufacturer for intervention. The manufacturer did not provide information regarding the procedures performed

during this intervention. Once the medical device was returned, all tests were repeated to evaluate its performance after the intervention.

At $1\,\mathrm{mL/h}$, the overall mean percentage flow error was reduced to -5.64% in T_1 and changed to 3.38% in T_2, demonstrating better accuracy and stability during long-term operation. Similarly, at $25\,\mathrm{mL/h}$, the errors decreased significantly under all test conditions, remaining close to the nominal flow rate. The best performance was observed without back pressure, with an error of only -0.16%, while the tests with $+100\,\mathrm{mmHg}$ and $-100\,\mathrm{mmHg}$ back pressure presented errors of 3.88% and -0.29%, respectively.

The start-up graphs obtained after manufacturer intervention also demonstrated smoother flow-rate stabilization and reduced oscillations during the first hours of operation.

B. Potential Clinical Impact of Flow Rate Deviations

The flow-rate deviations identified in the present study may have clinical relevance because infusion pumps are used to deliver medications and fluids at programmed rates, including in pediatric intensive care settings where relatively small absolute flow rates may be clinically important. However, the present study did not evaluate medication concentrations, administered doses, pharmacokinetic outcomes, clinical events, or patient outcomes.

The assessment demonstrated underinfusion, particularly at $1\,\mathrm{mL/h}$, as well as transient fluctuations under specific pressure conditions. From a clinical perspective, underinfusion is particularly concerning because it may not be immediately detected by the healthcare team, especially when the device does not trigger an alarm. In critical care, this delay can reduce the expected therapeutic effect of the medication and expose the patient to avoidable instability.

These discrepancies may be clinically relevant in intensive care settings, particularly when infusion pumps are used to administer medications for which accurate dosing and timely administration are important. The present study did not evaluate clinical outcomes, medication dosing errors, or treatment responses; therefore, no direct relationship between the measured flow-rate deviations and patient outcomes can be established. Nevertheless, clinical guidelines can help contextualize the potential relevance of accurate infusion delivery. In pediatric sepsis management, for example, the Surviving Sepsis Campaign guidelines emphasize timely and optimized antimicrobial therapy to reduce the risk of treatment failure and organ dysfunction.

C. Importance of Hospital-Based Performance Verification of Infusion Pumps

The results obtained in this study demonstrate that hospitals should not rely exclusively on the calibration reports provided by manufacturers or service/calibration providers. Healthcare institutions must also establish internal methods to periodically evaluate the performance and accuracy of infusion pumps used in clinical practice. Although it may not be feasible to test every medical device available in the hospital, a representative sampling strategy can be adopted to identify possible deviations and performance degradation over time.

Overall, this investigation illustrates how a documented sentinel case, identified through systematic testing, can support evidence-based clinical engineering decision-making, while underscoring that broader sampling programs are required to determine the true prevalence and underlying determinants of metrological deviations.

D. Considerations for Infusion Pump Manufacturers and Medical Device Calibration Providers

These findings indicate that quality assurance for infusion pumps must extend beyond routine calibration. Given their important role in intensive care and critical therapies, manufacturers and service/calibration providers must ensure flow-rate accuracy throughout the equipment's lifecycle.

While periodic preventive maintenance must follow manufacturer guidelines and standards like IEC 60601-2-24, our results show that standard calibration records cannot fully guarantee real-world functional performance. Consequently, post-maintenance protocols should incorporate functional testing under specific operational variables, such as low flow rates and varying backpressure conditions, before releasing the device back to clinical use.

Manufacturers and service/calibration providers also need to ensure metrological traceability and maintain history logs, including past failures and operational tests, to pinpoint recurring issues. Finally, continuous technician training and strict control over the compatibility of infusion sets are important, since third-party infusion sets may compromise flow accuracy.

E. Proposed Functional Verification Procedure

Considering the differences in financial resources and technical infrastructure among hospitals, some complementary approaches to verifying infusion pumps are proposed.

It is important to emphasize that neither of these verification procedures replaces the periodic calibration of the medical devices. Instead, they should be regarded as complementary post-market surveillance strategies intended to identify infusion pumps with potential performance degradation and verify the effectiveness of manufacturer intervention.

1) Hospitals Without Technical Instrumentation: The clinical engineering team could implement a simplified functional verification procedure as part of the post-market surveillance of infusion pumps. The procedure should begin with a visual inspection of the device and its accessories, including verification of the physical integrity, display, keypad, alarm system, power supply, and infusion set, and confirmation that preventive maintenance and calibration are up to date.

For the initial functional assessment, the infusion pump may be programmed to a predefined target flow rate to deliver a $0.9\,\%$ saline solution into a class A graduated cylinder over a specified time interval. The collected volume could be compared against the theoretical nominal volume.

Since this simplified verification relies on manual volume measurements, the uncertainty associated with graduated

cylinder readings should be considered. The measurements based on graduated cylinders or other low-resolution volumetric methods should be interpreted cautiously, particularly at low flow rates, because reading resolution, meniscus interpretation, evaporation, and the measurement interval can substantially influence the result.

Alternatively, automated drip counting can be employed to monitor flow rate accuracy. While subject to specific limitations, it also offers a practical solution for verifying infusion pump performance in the intervals between metrological calibrations [9].

2) Hospitals With Technical Instrumentation: Hospitals equipped with specialized testing facilities may perform a more comprehensive performance verification by following the prescriptions in IEC 60601-2-24. In this approach, the clinical engineering team may employ a calibrated analytical balance, automated data acquisition systems, and controlled environmental conditions to determine the actual flow rate delivered by the infusion pump over predefined time intervals using the gravimetric method.

Infusion pump analyzers may also be used. However, it should be recognized that the gravimetric method offers advantages over infusion pump analyzers for two main reasons: its lower acquisition cost and its versatility, as it allows the use of fluids with different densities and viscosities, a condition that is generally limited in infusion pump analyzers.

F. Study Limitations

The study did not include internal inspection or component-level failure analysis. Due to contractual restrictions, the infusion pump could not be internally inspected, and the manufacturer did not provide information regarding the procedures performed while the device was outside the hospital. Consequently, the root cause of the initial flow-rate deviations and the specific reason for the improvement observed during the second assessment could not be established.

Second, tests were performed under controlled laboratory conditions. The results, therefore, do not reproduce the full range of clinical conditions, including different medication viscosities, infusion solutions, infusion sets, or interactions with other medical equipment.

Finally, no direct clinical outcomes, medication dosing errors, adverse events, or patient safety incidents were evaluated. The clinical relevance discussed in this study is therefore based on the potential implications of the measured flow-rate deviations rather than on documented patient outcomes.

V. Conclusion

The results demonstrated that routine maintenance and calibration records alone may not fully reflect the actual performance of infusion pumps used in clinical practice. In the evaluated case, clinically relevant flow rate deviations were identified through independent testing, despite the device being considered operational.

The substantial performance improvement observed after manufacturer intervention reinforces the importance of post-market verification strategies capable of detecting flow rate deviations before they compromise infusion therapy.

Although this study presents a representative case from an ongoing broader investigation, the findings highlight the potential contribution of performance assessment programs to patient safety, quality assurance, and evidence-based clinical engineering practices.

Acknowledgment

This study was carried out within the framework of a partnership between the Escola Politécnica and the University Hospital of the University of São Paulo. ***Abstract*—Assessing the potential capacity of mammography equipment requires consideration of the number of units, their affiliation with the public health system, regional distribution, and the observed number of examinations performed. This study aimed to evaluate the potential capacity and territorial distribution of mammography equipment in the State of São Paulo, Brazil, using secondary data from the National Registry of Health Facilities, the Outpatient Information System of the Brazilian Unified Health System, and the National Supplementary Health Agency. Potential capacity was estimated using a reference parameter of 5,069 examinations per mammography unit per year. The historical series considered women aged 50 to 69 years from 2016 to 2024 and women aged 40 to 74 years in 2025 and 2026. For March 2026, three scenarios were analyzed: total capacity versus the female population aged 40 to 74 years, capacity available to the Brazilian Unified Health System versus the same population, and capacity available to the Brazilian Unified Health System versus the population without active private health insurance. At the state level, the capacity-to-demand ratio was 1.47 in the total-capacity scenario, 0.63 in the public-system scenario considering the total population, and 1.04 in the public-system scenario considering the population without private insurance. Although total capacity exceeded estimated demand in all 19 Regional Health Care Networks, 17 regions had ratios below 1.0 when only public-system capacity was considered, and eight remained below 1.0 after adjustment for private health insurance coverage. The results indicate that potential sufficiency depends on the population considered, availability within the public health system, and the regional distribution of mammography equipment, with findings that may support health managers in equipment planning, regional regulation, and the organization of access to mammography services.**

***Index Terms*—Mammography, mammography equipment, Brazilian Unified Health System, installed capacity.**

I. Introduction

Breast cancer remains a relevant public health issue in Brazil, both because of its epidemiological magnitude and because it requires organized health care networks capable of supporting early detection, timely diagnosis, and continuity of care. Mammography is the main imaging modality in this process, used for population-based screening of asymptomatic women and for the diagnostic investigation of suspicious signs and symptoms [1]. Within the Brazilian Unified Health System (Sistema Único de Saúde, SUS), Technical Note No. 626/2025 from the Ministry of Health recommends population-based mammography screening for women aged 50 to 74 years, with biennial periodicity, while clarifying that access to mammography is not restricted to this age group when there is clinical demand or indication [2].

Records of mammography equipment in official databases are relevant for health planning, but they do not, by themselves, ensure effective access to examinations. Equipment may be located in public, private, or contracted facilities, may or may not be available to SUS, and may be unevenly distributed across the territory. In addition, the observed number of examinations depends on operational factors such as scheduling, workforce availability, funding, regulatory flows, maintenance, image quality, and reporting capacity. Therefore, the assessment of mammography sufficiency should combine installed capacity, SUS availability, outpatient production, and regional distribution.

The aggregate number of mammography units may suggest sufficiency, whereas analyses based on distance, health regions, and equipment use can reveal locational inequalities and limitations that cannot be attributed only to a lack of machines [3], [4]. Inequalities between women with and without private health insurance should also be considered, since mammography use differs according to private health plan coverage and because diagnostic imaging services are not equally distributed between the public and private sectors [5], [6].

Public databases provide a useful basis for this type of evaluation, but they also have limitations. The National Registry of Health Facilities (Cadastro Nacional de Estabelecimentos de Saúde, CNES) makes it possible to identify facilities, equipment, and SUS affiliation, while the Outpatient Information

System of SUS (Sistema de Informações Ambulatoriais do SUS, SIA/SUS) allows monitoring of outpatient procedures recorded in the public system. The National Supplementary Health Agency (Agência Nacional de Saúde Suplementar, ANS), in turn, provides information on active private health plan beneficiaries, which can be used as a complementary proxy for interpreting potential demand on the public network. These databases have different purposes and structures and should not be interpreted as direct measures of individual access to mammography.

In the State of São Paulo, public databases allow the integration of information on equipment, outpatient production, reference population, private health plan coverage, and regionalization into Regional Health Care Networks (Redes Regionais de Atenção à Saúde, RRAS). This integration can help distinguish total potential capacity from potential capacity available to SUS and can identify regions in which the capacity-to-demand ratio remains low even after accounting for the population covered by active private health plans.

Thus, this study aimed to evaluate the potential capacity and territorial distribution of mammography equipment in the State of São Paulo, considering total availability and availability to SUS, the reference population for mammography, outpatient production recorded in SUS, and private health insurance coverage.

II. Materials and Methods

The study material consisted of secondary datasets related to mammography equipment, reference population, outpatient mammography procedures, and private health insurance coverage in the State of São Paulo. The analysis was designed as a scenario-based assessment of potential capacity and was not intended to measure actual access, waiting time, operational availability, or individual service utilization. Data processing, organization, and analysis were performed using R, version 4.5.0 (R Foundation for Statistical Computing, Vienna, Austria), with support from the RStudio Desktop integrated development environment, version 2024.12.1.563 (Posit Software, PBC, Boston, MA, USA). R packages were used for data import, cleaning, transformation, analysis, visualization, spatial processing, and export, including tidyverse, readr, readxl, janitor, lubridate, stringr, stringi, forcats, ggplot2, scales, sf, patchwork, and writexl [7].

A. Study Design and Data Sources

A retrospective, descriptive, quantitative ecological study was conducted using secondary data from official health information systems. Data on mammography equipment were obtained from CNES for the State of São Paulo between 2016 and March 2026, considering facility location, equipment type, operational status, and SUS affiliation [8]. For each year of the historical series, the March reporting period was used as the reference month. Equipment was classified according to whether it was registered as existing, in use, and available to SUS. For the historical series, the annual evolution of the mammography equipment inventory was represented by the March reporting period of each year, from 2016 to 2026, in order to maintain temporal comparability with the territorial snapshot from March 2026. The numbers of existing and in-use mammography units were consolidated, with identification of their availability to SUS.

The territorial analysis used data from March 2026, after geographic validation of facilities and exclusion of an extreme registry record that was incompatible with the expected distribution of the technology inventory. Mammography units in use were included, distinguishing equipment available and not available to SUS. This distinction was maintained throughout the analyses because the total availability of equipment in the territory does not necessarily correspond to availability for the population served by the public health system. Before aggregation, the territorial dataset underwent consistency checks involving municipal codes, geographic coordinates, duplicate facilities, compatibility with municipal boundaries, and coherence of state-level totals.

The observed number of examinations was obtained from SIA/SUS by place of care for the State of São Paulo, considering procedure codes 0204030188, bilateral screening mammography, and 0204030030, mammography [9]. Because these records include outpatient mammography procedures registered in SUS, observed production was interpreted as public-system production rather than as a direct measure of screening coverage. For 2026, the observed production was limited to the January to March period, according to data availability. Information on active private health plan beneficiaries was retrieved from the ANS TabNet platform, filtered by female sex, age group from 40 to 74 years, and municipality of residence in the State of São Paulo [10], [11].

B. Reference Population and Demand Estimation

The reference population was defined to preserve historical comparability while allowing evaluation of an expanded potential demand in the most recent years. From 2016 to 2024, women aged 50 to 69 years were considered. In 2025 and 2026, women aged 40 to 74 years were considered. This expanded age range was used as a planning and sensitivity denominator for potential demand, not as an indication that the 40 to 74 age group represents the single normative population for SUS population-based screening throughout the entire period. This distinction is relevant because current national guidance recommends population-based screening for women aged 50 to 74 years, while mammography may also be performed outside this age range when there is clinical indication or demand. Therefore, the 2016–2024 and 2025–2026 periods should not be interpreted as a single homogeneous historical trend, because the reference population denominator changed.

Estimated annual demand was calculated by dividing the reference population by two, considering biennial periodicity. For the territorial analysis of March 2026, the female population aged 40 to 74 years was used, followed by a complementary analysis of the population without active private health insurance. This population was estimated as the difference between the total female population aged 40 to 74 years and

the number of active private health plan beneficiaries reported by ANS. This adjustment was treated as a sensitivity scenario for potential public-system demand, not as a direct measure of individual dependence on SUS.

C. Potential Capacity and Observed Production

Annual potential capacity was estimated as the product of the number of mammography units in use and the parameter of 5,069 examinations per unit per year. This parameter was adopted from the INCA review of the production capacity of standard mammography equipment, which considers 3 examinations per hour, 8 hours per day, 22 days per month, 12 months per year, and an 80% utilization factor [12]. Thus, the parameter was used as a normative planning reference and should not be interpreted as the measured productivity of each facility. As a historical reference, the SUS health care criteria and parameters were also considered, since they present a previous benchmark of 6,758 examinations per unit per year and territorial planning criteria based on travel time or maximum distance [13].

Three main indicators were calculated: annual potential capacity, the capacity-to-demand ratio, and observed production in SUS. The capacity-to-demand ratio was defined as annual potential capacity divided by estimated annual demand. Observed production corresponded to the number of mammograms recorded in SIA/SUS during the analyzed period. Utilization of potential capacity was interpreted as a descriptive indicator, since the study did not measure effective operating time, staffing, scheduling, regulatory flows, examination quality, or reporting capacity.

D. Territorial Analysis and Analytical Scenarios

The territorial analysis was conducted by RRAS, according to the current regionalization of the State of São Paulo, composed of 19 RRAS and 62 Health Regions [14]. For March 2026, three analytical scenarios were defined. Scenario C1 compared total potential capacity, including SUS and non-SUS mammography units, with the estimated annual demand of the total female population aged 40 to 74 years. Scenario C2 compared SUS potential capacity with the same demand. Scenario C3 compared SUS potential capacity with the estimated demand of the female population aged 40 to 74 years without active private health insurance.

Results were presented as capacity-to-demand ratios. Values equal to or greater than 1.0 indicated potential capacity equal to or greater than estimated demand, whereas values below 1.0 indicated potential capacity below estimated demand. This classification was used only as an indicator of potential capacity and did not imply effective individual access to mammography. Ratios displayed in tables and figure labels were presented with two decimal places without rounding, while exact values were retained in the analytical datasets for classification.

III. Results and Discussion

A. Historical Series of Capacity and Observed Production

The CNES time series made it possible to monitor the ratio between estimated potential capacity and annual demand from 2016 to March 2026. Between 2016 and 2024, when the reference population was defined as women aged 50 to 69 years, the ratio associated with total mammography equipment remained above 2.7. The ratio associated with equipment available to SUS remained close to or above 1.0 during the same period. In 2025 and 2026, with adoption of the expanded reference population aged 40 to 74 years, the ratios decreased markedly, a pattern that should not be interpreted as a sudden loss of equipment. Rather, this decrease primarily reflects the change in the population denominator used to estimate annual demand; therefore, the two periods should be compared with caution and not interpreted as a continuous homogeneous trend.

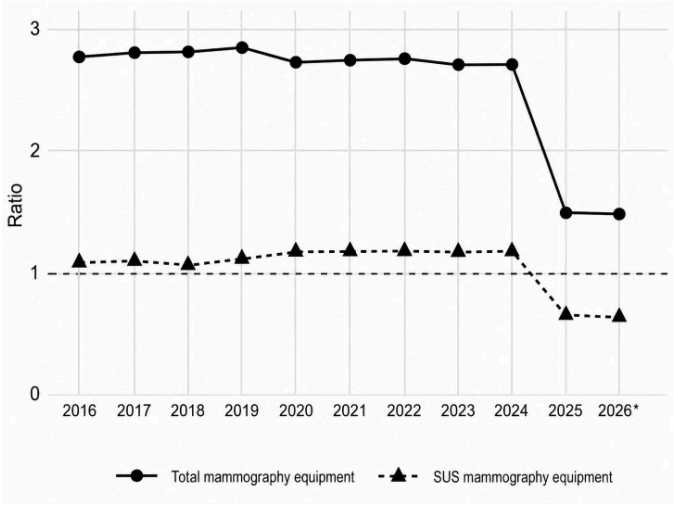

Fig. 1. Ratio of estimated potential capacity to annual mammography demand in the State of São Paulo, according to total mammography equipment and equipment available to SUS. The reference population was defined as women aged 50 to 69 years from 2016 to 2024 and women aged 40 to 74 years in 2025 and 2026; therefore, the most recent years should be interpreted considering the expanded denominator.

Fig. 1 shows that interpretation of potential sufficiency depends on the population considered and on the health care affiliation of the equipment. The total ratio remained above 1.0 throughout the period, but the SUS ratio fell below this threshold in the most recent years. This result introduces the difference observed in the 2026 territorial analysis, in which total capacity and capacity available to SUS provide distinct interpretations of the same technological network. For 2026, only the January to March period was considered.

Observed production in SUS followed a pattern that differed from potential capacity. In 2016, 1,411,157 mammograms were recorded in SIA/SUS, whereas 1,358,451 were recorded in 2019. In 2020, production decreased to 870,685 examinations, a result consistent with the interruption and reorganization of services during the COVID-19 pandemic.

In 2025, 1,423,569 examinations were recorded. In 2026, the value of 326,289 examinations corresponds only to the January to March period and should not be interpreted as annual production.

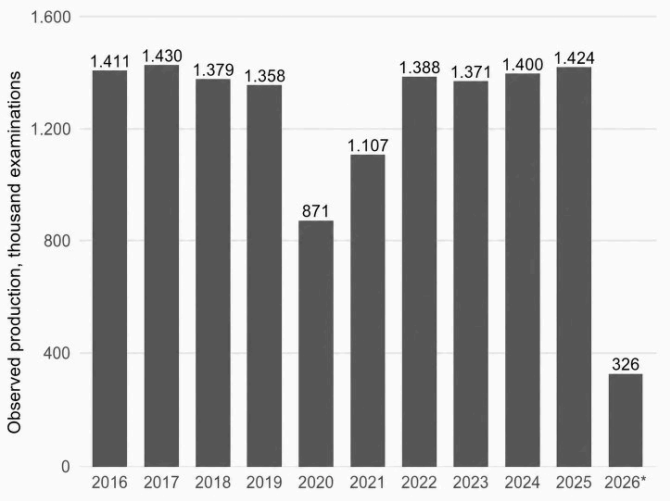

Fig. 2. Observed number of mammograms recorded in SIA/SUS in the State of São Paulo. The year 2026 corresponds to the January to March period.

Fig. 2 shows that observed production should be interpreted differently from potential capacity. The existence of mammography equipment in use does not imply a proportional number of examinations performed. Recorded production depends on operating conditions, appointment availability, referral flows, staffing, maintenance, supplies, and reporting capacity. This difference supports the need to evaluate the technology inventory using more than one indicator.

B. State-Level Potential Capacity Scenarios

In the March 2026 territorial analysis, after treatment of the registry outlier, 1,493 mammography units in use were considered, of which 638 were available to SUS and 855 were not affiliated with SUS. The female population aged 40 to 74 years was estimated at 10,253,362 women, resulting in an annual demand of 5,126,681 examinations. Total potential capacity was 7,568,017 examinations per year, while SUS potential capacity was 3,234,022 examinations per year.

TABLE I
ANALYTICAL SCENARIOS OF MAMMOGRAPHY POTENTIAL CAPACITY USING 5,069 EXAMINATIONS PER MAMMOGRAPHY UNIT PER YEAR.

Scenario	Population	Equipment	Annual demand	Capacity	Ratio	RRAS < 1
C1	Total	Total	5,126,681	7,568,017	1.47	0
C2	Total	SUS	5,126,681	3,234,022	0.63	17
C3	Without private insurance	SUS	3,099,553	3,234,022	1.04	8

Table I summarizes the three analytical scenarios. In scenario C1, the capacity-to-demand ratio was 1.47, suggesting potential sufficiency at the state aggregate level when all mammography units in use were considered. In scenario C2, restricted to equipment available to SUS in relation to the total reference population, the ratio was 0.63. This contrast indicates that an assessment based only on total capacity may mask limitations in public-sector availability.

In scenario C3, after excluding active private health plan beneficiaries, the reference population was reduced to 6,199,107 women and the estimated annual demand to 3,099,553.5 examinations. The state-level ratio increased to 1.04. This result suggests that SUS potential capacity approaches estimated demand when the population without active private health insurance is considered. However, the margin is narrow and should be interpreted with caution, particularly because regional distribution is not homogeneous.

C. Regional Distribution of the Three Scenarios

The RRAS analysis showed that state-level sufficiency in scenario C1 was not distributed equivalently in the scenarios restricted to SUS. All 19 RRAS had ratios equal to or greater than 1.0 in scenario C1. In scenario C2, 17 RRAS had ratios below 1.0. In scenario C3, eight RRAS remained below 1.0 even after adjustment for the population without active private health insurance.

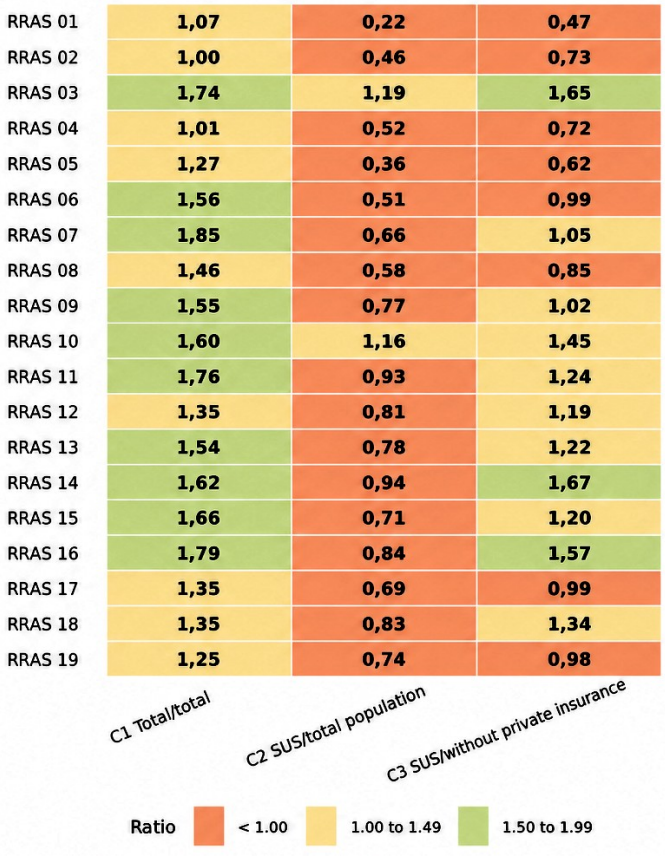

Fig. 3. Ratio between potential capacity and estimated annual demand by RRAS in three analytical scenarios, considering 5,069 examinations per mammography unit per year.

Fig. 3 summarizes the change in interpretation across the scenarios. Scenario C1 shows a predominance of ratios above 1.0, whereas scenario C2 indicates potential insufficiency in

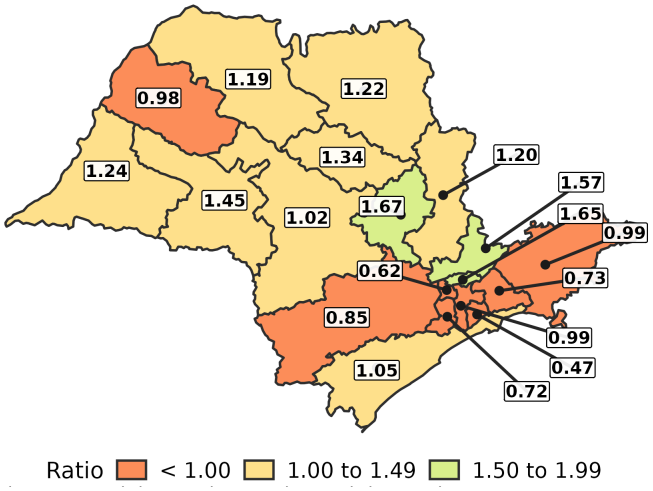

Fig. 4. Ratio between SUS potential capacity and estimated annual demand among women aged 40 to 74 years without active private health insurance, by RRAS.

almost all RRAS. Scenario C3 reduces the number of regions below 1.0 but does not eliminate regional inequality. This difference supports the need to distinguish total capacity from capacity available to SUS.

The observed pattern is consistent with previous reports in the literature, in which the overall availability of mammography equipment does not eliminate regional disparities in access and use. Amaral et al. observed that the total number of mammography units in Brazil could be sufficient when analyzed in aggregate, but that applying a 60 km distance criterion revealed areas without adequate provision [3]. Xavier et al. also reported that problems related to mammography coverage, allocation, and use across Health Regions cannot be explained only by a lack of equipment [4].

RRAS 03 and RRAS 10 were the only regions with a ratio of SUS capacity to total population equal to or greater than 1.0. The lowest ratios in scenario C2 occurred in RRAS 01, 05, 02, 06, and 04. This pattern indicates that SUS availability does not uniformly keep pace with demand estimated from the reference population. In highly populated regions, such as RRAS 06, the absolute number of SUS mammography units is high, but estimated demand is also greater, reducing the capacity-to-demand ratio.

D. Population Without Active Private Insurance and Regional Persistence

The map for scenario C3 shows the regional distribution of the ratio between SUS potential capacity and estimated demand among women aged 40 to 74 years without active private health insurance. This scenario improves the interpretation in relation to scenario C2 because it acknowledges that part of the population is covered by private health plans. Even so, the persistence of RRAS below 1.0 shows that the aggregate state-level analysis is insufficient to characterize the territorial distribution of capacity.

TABLE II
RRAS WITH SUS CAPACITY RATIOS BELOW 1.0 AFTER ADJUSTMENT FOR THE POPULATION WITHOUT ACTIVE PRIVATE HEALTH INSURANCE.

RRAS	SUS units	Pop. without insurance, thousands	SUS/total	SUS/without insurance
RRAS 01	14	297	0.22	0.47
RRAS 05	15	245	0.36	0.62
RRAS 04	13	181	0.52	0.72
RRAS 02	30	414	0.46	0.73
RRAS 08	31	366	0.58	0.85
RRAS 19	13	134	0.74	0.98
RRAS 17	39	399	0.69	0.99
RRAS 06	142	1,442	0.51	0.99

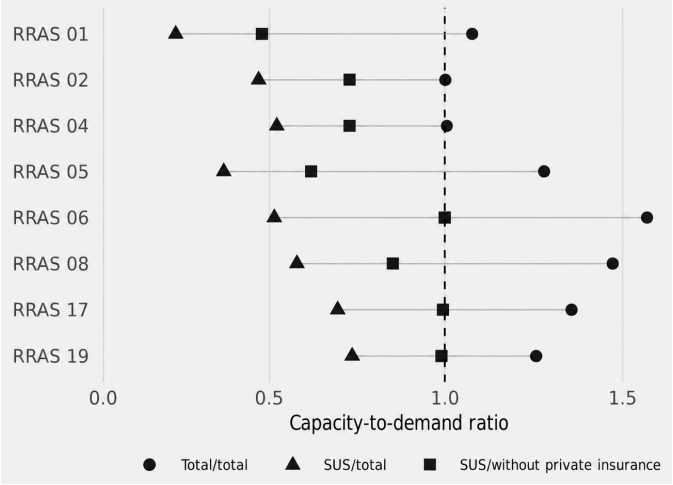

Fig. 5. RRAS with SUS capacity-to-demand ratios below 1.0 in the total-population scenario and in the complementary scenario excluding the population with active private health insurance.

Table II presents the eight RRAS that remained below 1.0 in scenario C3. The lowest ratios were observed in RRAS 01, 05, 04, 02, and 08. RRAS 19, 17, and 06 were close to 1.0, but remained below this threshold when exact values were used. This result shows that excluding the population with active private health insurance improves the ratio in all regions but does not eliminate the possibility of regional insufficiency in SUS capacity.

Fig. 5 reinforces that adjustment for the population without active private health insurance reduces the number of regions below the 1.0 threshold but does not eliminate regional inequality. The figure also shows that some RRAS remain close to the sufficiency threshold, a condition that should be interpreted with caution because it depends on the normative parameter and on the population denominator adopted.

The interpretation of scenario C3 should consider the nature of ANS data. The number of active private health plan beneficiaries was used as a proxy to reduce the population potentially dependent on the public network. However, this approach does not allow individual-level inference that all women without private insurance rely exclusively on SUS or that all beneficiaries undergo mammography outside SUS. For this reason, scenario C3 should be understood as a complementary sensitivity analysis.

Even so, the analysis using ANS data is useful for planning because it recognizes that the total female population does not exert the same pressure on the public health network. Population studies show differences in mammography use according to health insurance coverage, reinforcing the need to consider this dimension in capacity analyses [5]. In the present study, the improvement of scenario C3 in relation to C2 confirms that private coverage changes the estimated potential demand on SUS, but does not remove all regional inequalities.

E. Implications and Limitations

The results suggest that the discussion of mammography equipment in the State of São Paulo should not be limited to the acquisition of additional machines. Estimated total capacity indicates that the aggregate technology inventory is sufficient when all sectors are considered. However, SUS availability and territorial distribution change this interpretation. For Clinical Engineering, this result indicates that planning decisions should integrate inventory, health care affiliation, location, observed production, and regional demand.

The use of public data allows a reproducible and updatable assessment, but depends on the quality of the records. CNES reports the existence, operational status, and SUS affiliation of equipment, but it does not record the number of appointments effectively offered, number of shifts, workforce availability, operational quality of the equipment, or reporting capacity. SIA/SUS describes outpatient production recorded in the public system, but does not represent private-sector production. ANS data on beneficiaries indicate active private health plan coverage, but do not directly indicate where each woman undergoes mammography. These limitations do not invalidate the analysis, but they define the scope of the conclusions. The geographic restriction to the State of São Paulo should also be considered. The results reflect the organization, infrastructure, population distribution, and public-private composition of this state and should not be directly generalized to other Brazilian regions without additional analysis.

Another point concerns the age range adopted. The historical series used women aged 50 to 69 years until 2024 and women aged 40 to 74 years in 2025 and 2026. This decision makes it possible to assess expanded potential demand in recent years, but limits direct comparison between the entire historical period and the 2026 territorial snapshot. Therefore, the reduction in the capacity-to-demand ratio observed in 2025 and 2026 should be interpreted mainly as a consequence of the expanded reference population used in the denominator, rather than as evidence of a proportional reduction in installed or SUS-available capacity. For this reason, the results were interpreted as estimates of potential capacity in relation to the study reference population, rather than as a single normative measure for all mammography screening in SUS.

Taken together, the results suggest that the State of São Paulo presents aggregate potential sufficiency, but with relevant restrictions when public availability of equipment is considered. This type of result is useful for managers because it shifts the planning question from a simple count of mammography units to an analysis of where the equipment is located, to whom it is available, and how closely observed production approaches estimated capacity.

IV. Conclusion

The analysis indicated that the total potential capacity of mammography equipment in the State of São Paulo exceeded the estimated annual demand when all in-use units were considered. However, this potential sufficiency was not maintained when the analysis was restricted to equipment available to SUS in relation to the total reference population, a scenario in which 17 of the 19 RRAS had ratios below 1.0.

In the complementary scenario excluding women with active private health insurance, the state-level ratio between SUS capacity and estimated demand was slightly above 1.0. Nevertheless, eight RRAS remained below this threshold, indicating persistent regional inequalities even after adjustment for private health insurance coverage.

The assessment of mammography equipment sufficiency should not rely solely on the absolute number of units. To support technological and health care planning, it is necessary to consider SUS affiliation, observed production, reference population, territorial distribution, and the limitations of public information systems. Future studies may incorporate road travel time, waiting time, workforce distribution, equipment downtime, operating shifts, reporting capacity, utilization rates, and examination quality, thereby bringing potential-capacity estimates closer to actual access and service availability conditions.

***Abstract*—Quality control (QC) tests on diagnostic imaging equipment are mandatory in Brazil, in accordance with Anvisa's RDC No. 611/2022 and Normative Instructions (INs) 90 to 97, and are essential to guarantee adequate diagnostic images with the lowest possible radiation exposure. In health service practice, however, the recording of these tests lacks standardization, often being performed in spreadsheets, printed forms, or separate reports, which compromises the traceability required by legislation, leads to operational failures, and limits the consolidated analysis of results. Medical equipment management software available on the market does not incorporate, in its structure, the specific QC tests for imaging modalities, whose protocols involve their own technical parameters, tolerances, and frequency. To address this gap, this paper presents QUALIRAD, a progressive web application (PWA) that translates the QC requirements of RDC 611/2022 into typed checklists with automatic compliance calculation, operating entirely offline. The tool currently covers 4 of the 8 equipment modalities regulated by INs 90 to 97; the remaining four are planned (one under development and three on the roadmap). Its checklists were developed and reviewed in collaboration with a medical physics professional, ensuring theoretical adherence to the applicable regulations. As a proof of concept, QUALIRAD demonstrates the feasibility of standardizing test records, representing an improvement over manual documentation practices and enabling the temporal tracking of equipment performance, contributing to the strengthening of Quality Assurance Programs, the regulatory compliance of radiology services, and data-driven decision-making.**

***Index Terms*—Quality control, Imaging equipment, Diagnostic radiology, ANVISA, Progressive Web Application.**

I. Introduction

In Brazil, the Board Resolution (RDC) No. 611, of March 9, 2022, of the National Health Surveillance Agency (Anvisa), establishes that diagnostic or interventional radiology services must implement a Quality Assurance Program and perform acceptance and performance tests, maintaining records of the respective reports and technical opinions [1]. This resolution is complemented by Normative Instructions (INs) 90 to 97, which detail the technical parameters, acceptance criteria, and minimum test frequency for each equipment modality [2]–[9]. These tests allow the verification of technical parameter compliance, ensuring images with the required quality through the lowest radiation dose reasonably possible to the patient, and enabling the early identification of discrepancies that could compromise diagnostic accuracy or the safety of patients and workers. Despite the regulatory requirement and clinical relevance of these procedures, the recording of quality control (QC) tests still lacks standardization in the practice of diagnostic services. Results are frequently documented in electronic spreadsheets, printed forms, or loose reports without a uniform data structure, which hinders the traceability required by health surveillance legislation [1], leads to operational recording failures—such as the loss of reports, incomplete entries, and lack of frequency control and limits the capacity for consolidated analysis of results over time. The World Health Organization (WHO) highlights, in its global strategy on digital health, that

the adoption of digital technologies strengthens the integration of health information, improves decision-making, and enhances the quality of services provided [12]. Complementing this, Kruse et al. (2014) [13] conducted a literature review on health information technologies and concluded that their adoption is predominantly associated with error reduction, greater traceability of records, and increased efficiency in clinical processes. In the market, several software solutions aimed at medical equipment management are available, covering the registration of interventions such as preventive and corrective maintenance, electrical safety tests, and calibrations. However, these solutions do not include, within their structure, the recording and management of specific QC tests for diagnostic imaging equipment, whose protocols involve modality-specific parameters and require systematic tracking of tolerances and periodicities defined in official regulations. Given this gap, this paper presents **QUALIRAD**, a tool for managing QC tests of diagnostic imaging equipment. The main contributions are:

- A model that translates the QC requirements of RDC 611/2022 and INs 90 to 97 into typed checklists with **automatic compliance calculation**, reducing the subjectivity of result interpretation [1]–[9];
- An *offline-first* architecture based on PWA, inspired by Mozilla Developer Network recommendations on progressive web applications [14] and by studies demonstrating its application in healthcare systems and environments with limited connectivity [16], [18];
- A deployment case study in a diagnostic radiology service, covering 4 of the 8 regulated modalities, with theoretical content validity ensured by the collaboration of a medical physics professional. A practical validation phase is scheduled for the second half of 2026 in university hospitals, where medical physics professionals from accredited institutions will evaluate the tool in real-world scenarios.

Finally, this paper is organized as follows. Section II presents related works, contextualizing existing solutions for medical equipment management and the use of progressive web applications in healthcare. Section III describes the materials and methods employed, including the regulatory framework, requirements gathering, the compliance model, application architecture, and the report generation process. Section IV presents the results obtained from the tool's development. Section V discusses the contributions, limitations, and implications of the proposed solution. Lastly, Section VI presents the conclusions of the work and perspectives for future work.

II. Related Works

Medical equipment maintenance management systems are widely used to record maintenance, calibrations, and electrical safety tests; however, they do not cover specific quality control tests for diagnostic imaging equipment, whose parameters and frequency are defined by regulatory standards. In addition to regulatory requirements, the literature highlights the importance of standardizing quality control tests. Papp (2025) [25] presents a comprehensive approach to quality management in diagnostic imaging, describing QC protocols for modalities such as radiography, mammography, computed tomography, and magnetic resonance imaging. Complementing this perspective, Hasford et al. (2024) [27] implemented a harmonized International Atomic Energy Agency (IAEA) protocol in 108 diagnostic imaging devices distributed across five African countries, demonstrating that performance tests allow the identification of non-conformities that could otherwise go unnoticed during routine operation. In the context of digital health, the World Health Organization (WHO) presents, in its global strategy on digital health, guidelines for the adoption of digital technologies capable of strengthening healthcare systems through data integration, care quality improvement, and decision-making support [12]. Complementing this vision, Kruse et al. (2014) [13] conducted a systematic review on health information technologies and observed that most studies report benefits related to improving the quality of care, increasing operational efficiency, and reducing clinical errors resulting from process computerization. In the field of web applications, Aboarab et al. (2024) [16] present a *Progressive Web App* (PWA) aimed at the visualization and reconstruction of DICOM medical images, exploring features such as installability and offline operation. Meanwhile, Azhar and Mohan (2022) [17] propose in their work a PWA for efficient real-time communication between doctors and patients, demonstrating that this approach enables the development of platform-independent applications with usability similar to native applications. Furthermore, Setiawan et al. (2024) [18] explore the implementation of PWAs through a combination with microservices to improve application performance, scalability, and accessibility. Regarding PWA components, the Mozilla Developer Network (MDN) documentation [14] highlights the role of *service workers* in caching, intercepting network requests, and executing functionalities without a continuous Internet connection. Similarly, Parashuram et al. (2016) [15] present an approach to utilizing *service workers* beyond traditional caching, demonstrating strategies that increase the availability and reliability of web applications. Although these studies highlight the benefits of digitalizing healthcare processes and utilizing PWAs, none of them address the management of quality control tests in diagnostic imaging equipment considering the parameters, tolerances, and frequency defined by ANVISA regulations. Therefore, QUALIRAD distinguishes itself by integrating these regulatory requirements into a PWA application, offering structured support for the execution and recording of QC routines in diagnostic radiology. The importance of continuous monitoring of results is also highlighted by El Kafhali et al. (2025) [26], who conducted a four-year longitudinal study on PET/CT systems and observed that small variations in performance parameters allow the identification of gradual equipment degradation. Similarly, Wigati et al. (2025) [28] investigated the use of the Noise Power Spectrum (NPS) in digital mammography, demonstrating that quantitative metrics make it possible to detect changes in detector performance and support quality control tests.

III. Materials and Methods

The development of QUALIRAD followed an iterative and participatory process, organized in successive cycles of construction and evaluation, in which the regulatory foundation and collaboration with the healthcare service preceded and guided each increment of the tool. This approach aligns with the principles of Design Science Research [11], where an artifact is designed to solve a real-world problem and subjected to evaluations that feed back into its improvement. Fig. 1 synthesizes the adopted method, from the regulatory foundation to field application, with content validation by the medical physicist.

A. Development Method

The work began with the real needs of a diagnostic imaging service, identified through visits to the facility to understand the routine—specifically how QC reports were produced at that time (using electronic spreadsheets and printed forms), the main bottlenecks, and how the solution would integrate into daily practice. In parallel, the applicable regulations (RDC 611/2022 [1] and INs 90 to 97 [2]–[9]) were studied. Based on this understanding, versions of the functional artifact were iteratively built and submitted to evaluations by medical physics and clinical engineering professionals regarding the usability and adequacy of the implemented QC tests until the version presented in this study was reached, which is suitable as a proof of concept and will undergo practical testing in routine use.

B. Regulatory Foundation and Requirements Gathering

Requirements gathering was based on three complementary sources: (i) direct analysis of RDC 611/2022 [1] and associated INs, mapping the mandatory test types for each modality; (ii) interviews and meetings with the healthcare service, which revealed the actual routine and its bottlenecks; and (iii) analysis of the spreadsheets, forms, and reports effectively used to record the performed tests. The eight INs cover distinct modalities; Table I presents this mapping and indicates which modalities are currently covered by QUALIRAD. Of the eight regulated modalities, the application covers those associated with INs 90 to 93 and IN 97 (the latter under development); INs 94 to 96 (dental radiology and ultrasonography) remain as future scope.

Based on this mapping, the supported test types per modality were identified. The number of tests varies depending on the equipment, from three (bone densitometry) to nine (mammography). Table II lists the test types, organized by frequency, planned in the application.

Based on the regulation, the functional requirements were consolidated: (i) nominal identification of the user, without complex authentication in this first version; (ii) guided workflow Login → Equipment category → Equipment → Test type → Checklist → Report; (iii) support for three checklist item formats, detailed in Section III-C; (iv) mandatory equipment verdict upon completion; (v) PDF and CSV report generation without connection dependency; and (vi) local persistence with draft recovery. An entirely offline solution was chosen to ensure the practical viability of the tool even in areas with unstable connectivity, a common situation in diagnostic radiology services [16]–[18].

Table I
Modalities regulated by RDC 611/2022 and coverage in QUALIRAD

IN	Regulated modality	In the application	Coverage
90	Conventional medical radiography	Fixed X-ray; Mobile X-ray	Yes
91	Fluoroscopy and interventional radiology	Angiographic; C-arm	Yes
92	Mammography	Mammography system	Yes
93	Computed tomography	CT scanner	Yes
94	Extraoral dental radiology	—	Future
95	Intraoral dental radiology	—	Future
96	Diagnostic or therapeutic ultrasound	—	Future
97	Nuclear magnetic resonance	Magnetic resonance	Under dev.
—[a]	Bone densitometry (RDC 611, no dedicated IN)	Bone densitometry	Yes

Source: own elaboration based on RDC 611/2022 and INs 90-97 (ANVISA, 2021).
Note: [a]Bone densitometry is within the scope of RDC 611/2022, which mentions it explicitly, but does not have a dedicated IN among INs 90-97; its tests were structured based on manufacturer protocols and medical physics literature.

Table II
Supported quality control test types

Test Type	Description and Frequency
Acceptance	Performed upon initial installation of the equipment.
Daily	Quick check of critical parameters for each day of use (e.g., densitometer, mammography system).
Weekly	Weekly verification of complementary parameters (e.g., CT).
Monthly	Monthly performance evaluation (e.g., mammography system).
Semiannual	Periodic evaluation every six months.
Annual	Comprehensive annual review of all critical parameters.
Quadrennial	Long-term test required every four years.
After repairs	Mandatory verification after any technical intervention.
After modifications	Evaluation after configuration changes or system updates.

Source: own elaboration based on RDC 611/2022 and INs 90–97.

C. Compliance Model

The core of QUALIRAD is the structured representation of checklist items derived from the INs. Each item is typed into one of three categories, allowing compliance assessment to be standardized and, in quantitative cases, automated:

- *standard*: qualitative item, whose status is manually defined by the evaluator as Compliant or Non-compliant;
- *measured*: quantitative item with a target value and percentage tolerance, evaluated by relative deviation;
- *threshold*: quantitative item with a fixed threshold evaluated by a comparison operator.

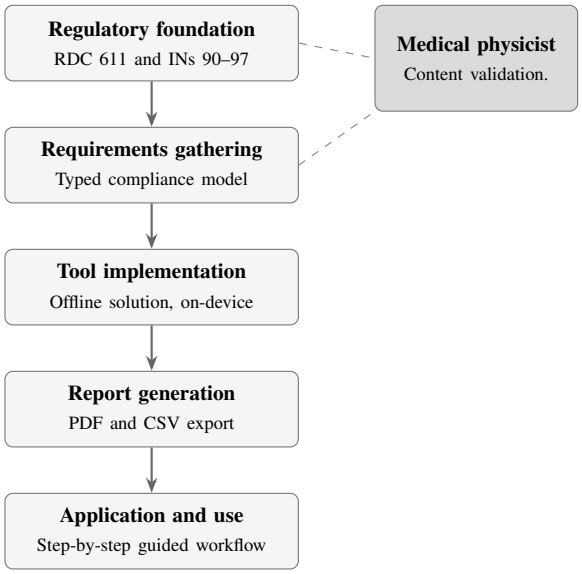

Figure 1. QUALIRAD development method, from regulatory foundation to field application, with content validation by the medical physicist.

As an example, the "tube voltage indicator accuracy" item (fixed X-ray, IN 90) is a *measured* item with a tolerance of 10% and a restriction of 20%. For a target of $v_t = 80$ kV and a reading of $v_m = 85$ kV, the relative deviation is $\delta = |85 - 80|/80 = 6.25\%$; since $\delta \leq \tau$, the item is classified as Compliant.

For a *measured* item with target value v_t, measured value v_m, tolerance τ and restriction ρ (percentages, with $\tau \leq \rho$), the relative deviation is defined as $\delta = |v_m - v_t|/v_t$ and the status as:

$$\text{status} = \begin{cases} \text{Compliant}, & \delta \leq \tau \\ \text{With restriction}, & \tau < \delta \leq \rho \\ \text{Non-compliant}, & \delta > \rho \end{cases} \tag{1}$$

For a *threshold* item with threshold L and operator $\oplus \in \{\leq, \geq, <, >, =\}$, the item is Compliant if the proposition $v_m \oplus L$ is true and Non-compliant otherwise; an optional intermediate threshold defines the With restriction range. As an example, the "compressed breast thickness indication" item (mammography, IN 92) is a *threshold* item with a tolerance limit of ≤ 5 mm and a restriction limit of > 10 mm: a reading of 2 mm falls within the tolerance limit and is therefore classified as Compliant, whereas a value above the restriction limit would be Non-compliant. Target values, tolerances, and thresholds were extracted directly from RDC 611/2022 and the respective INs [1]. Since the INs establish only the tolerance limits without prescribing the calculation method to be used, conventions established in reference protocols in medical physics were adopted [10], [22]–[24]: relative deviation for accuracy tests and, for reproducibility and linearity, the respective coefficients of variation and linearity. In cases where the regulation refers the baseline value to the equipment or manufacturer, the target value is provided by the evaluator at the time of the test; in other cases, it is pre-configured based on the IN. For instance, the tube voltage indicator accuracy limit ($\leq 10\%$) is taken directly from IN 90, whereas the water noise test in computed tomography is evaluated against a baseline standard deviation established at acceptance or provided by the manufacturer, which the evaluator enters manually, as the regulation refers this reference value to the equipment. The N/A button is enabled only for *standard* items in "after repairs" and "after modifications" test types, where some items may not apply depending on the intervention; *measured* and *threshold* items are always evaluated automatically. Finally, the equipment verdict is derived from the set of recorded statuses.

Since the classification of an item may depend on a comparison exactly at the tolerance limit, the evaluation incorporates controlled rounding prior to comparison, preventing floating-point representation errors—where a value mathematically equal to the limit is computed as slightly higher—from incorrectly failing a compliant item. This is a deliberate design decision, as incorrect compliance classification has direct consequences on equipment and patient safety.

The checklists implemented in QUALIRAD were structured based on the requirements of RDC 611/2022 and the respective Normative Instructions, also following quality management principles described by Papp [25], which organizes QC procedures according to the different diagnostic imaging modalities.

D. Content Validation by Specialist

The theoretical content validity of the tool, i.e., the adherence of the tests, tolerances, and frequencies to the applicable standards, was ensured at this stage through collaboration with medical physics and clinical engineering professionals experienced in radiology, diagnostic radiology, and quality control testing. The validation was conducted iteratively through five face-to-face and remote meetings, during which the specialists evaluated the checklists, compliance criteria, and tool behavior, indicating adjustments that were recorded and incorporated in subsequent development cycles. Furthermore, a practical validation phase will begin in the second half of 2026. This phase will take place in university hospitals and will be conducted by medical physics professionals from accredited hospitals, who will provide formal feedback reports to guide further tool adjustments and refinements.

E. Architecture and Technologies

The application was built as a client-side PWA, without a *backend* server in this version, which was implemented as a proof of concept. This decision reduces the required infrastructure, allows deployment via static servers, and keeps the architecture extensible for a future migration to a REST API. Offline operation is achieved using *service workers*, which, according to the Mozilla Developer Network (MDN), intercept network requests and cache resources to enable the application to run without a continuous connection [14]. Parashuram et al. (2016) [15] complement this approach by demonstrating that *service workers* offer advanced caching mechanisms that increase the availability and reliability of web applications. The checklist definitions are kept separate

from the state logic, so that adding new items or test types only requires editing the data, without modifying the business logic. The persistence of results and drafts in progress is local, and report generation occurs entirely in the browser. In this first version (MVP), no authentication mechanism was implemented, and user identification is merely nominal, so the application does not handle personal or sensitive data that would require encryption. All data produced during use, that is, drafts in progress and finalized reports, are stored entirely locally on the user's device, through the storage provided by the browser itself, without transmission to external servers. As a direct consequence of this decision, the records are restricted to the browser and to the device on which they were generated, so there is neither shared access among multiple users nor synchronization among different devices, and no data reconciliation occurs when connectivity is restored, since operation does not depend on a remote server at any point. Table III summarizes the main technologies and the reasons for their choice.

Table III
MAIN TECHNOLOGIES OF THE APPLICATION

Technology	**Layer**	**Justification**
React + TypeScript [19]	Framework / UI	Reusable components and static typing
Vite [20]	Build	Modern tooling with PWA support
Service Worker [14], [15]	Offline	Resource caching and offline functionality
Local persistence	Data	Zero infrastructure, sufficient for the MVP
jsPDF [21]	Report	Client-side PDF generation, works offline

Source: own elaboration.

F. Verification

The correctness of the compliance calculation was verified using two complementary strategies. First, through automated tests that exercise the limits of tolerance and restriction ranges for *measured* and *threshold* items, including boundary cases sensitive to rounding errors. Second, by comparing the reports generated by the tool with QC reports previously prepared by the service, verifying the equivalence of the verdicts and the fidelity of the recorded values. This verification ensures that the automated classification reproduces the expected judgment prior to evaluation in real-world use.

The automated boundary test suite covers 26 cases for the *measured* and *threshold* classification functions (15 for *measured*, including deviations below, at, and above τ and ρ, and floating-point boundary cases; 11 for *threshold*, covering both comparison directions and the intermediate restriction threshold), plus 15 additional cases for the controlled-rounding routine used before comparison. All 41 cases pass.

G. Report Generation and Export

Upon completing the checklist, the user is directed to the report screen, which displays the equipment data, the evaluator, date and time, test type, item-by-item results with their respective compliance status, recorded observations, and the final equipment verdict. The report can be exported in PDF or CSV format; generation is performed programmatically in the browser [21], without any server calls, thereby preserving offline operation.

IV. RESULTS

QUALIRAD is functional for 4 of the 8 regulated equipment modalities (Table I), with the solution for magnetic resonance currently under development. Within each modality, it is possible to select the equipment present in the institution, and all planned test types (Table II) have been adapted to each device. The complete implemented and operational workflow consists of: Login $\rightarrow$ Category $\rightarrow$ Equipment $\rightarrow$ Test Type $\rightarrow$ Checklist $\rightarrow$ Report. The application is installable as a PWA on mobile devices and desktops and operates offline after the first access.

The checklists and respective compliance criteria were developed and reviewed in collaboration with a qualified professional, which ensures the tool's theoretical content validity, i.e., the adherence of the tests, tolerances, and frequency to applicable standards. Continuous improvements will rely on the upcoming practical validation in the second half of 2026, which will yield formal reports from field specialists. Figures 2, 3, and 4 illustrate, respectively, the home screen, the equipment and test selection environment, and the generated report with export options.

Figure 2. Home screen of the tool.

Table IV summarizes the comparison between the usual process in most institutions and the developed solution. It should be noted that this version constitutes a proof of concept: no quantitative data on operational use (filling time, error rate, or inter-observer agreement) have been collected so far, which is discussed in Section VI as a limitation and future work.

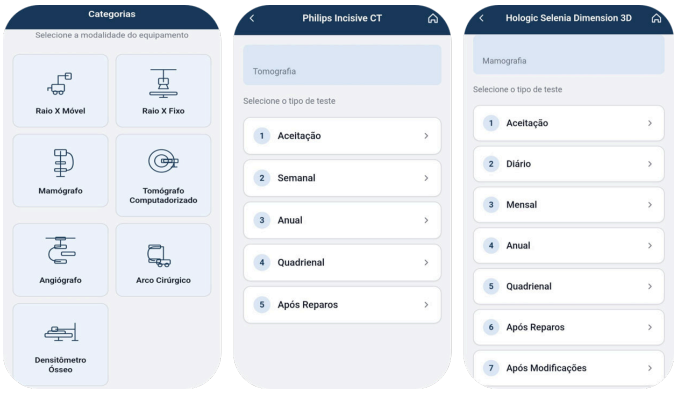

Figure 3. Environment for selecting the equipment to be tested and the test to be performed.

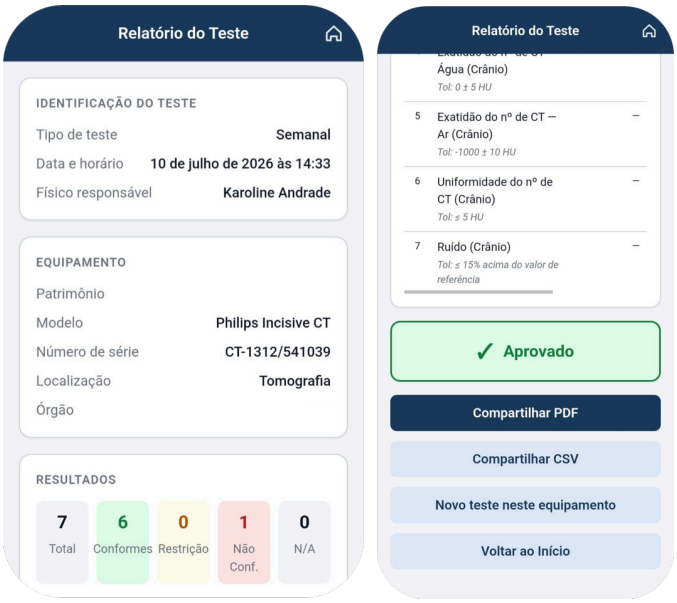

Figure 4. Test report and export options.

Table IV
COMPARISON BETWEEN MANUAL PROCESS AND QUALIRAD

Usual situation	**With QUALIRAD**
Paper forms, susceptible to loss	Persistent digital record
Spreadsheets disconnected from the workflow	Step-by-step guided workflow in the application
No standardization across tests and equipment	Checklists structured by modality and test type
Dependence on connectivity for access	Works offline as an installed PWA
Report manually compiled after testing	Automatic PDF generation upon checklist completion

Source: own elaboration.

V. DISCUSSION

The development of QUALIRAD demonstrated that it is possible to fully digitalize the QC process for imaging equipment using exclusively client-side technologies, with zero server infrastructure in the MVP. The main gain lies not in the technology itself, but in the direct translation of regulatory requirements into an operational instrument: the standardization of checklists by modality and frequency and the persistent digital record directly target the weaknesses of paper- and spreadsheet-based processes—loss of reports, incomplete entries, and lack of frequency control—strengthening the traceability required by RDC 611/2022 [1]. The automatic compliance calculation for *measured* and *threshold* items reduces the subjectivity of interpretation and makes results more objective and reproducible.

The PWA approach proved suitable for the context of use: offline support eliminates dependency on connectivity during field inspections [16], [18], and in-browser installability bypasses the need for app store publication [17]. Separating checklist definitions from state logic enhances extensibility, which is crucial for adapting to future regulatory updates.

Maintaining the test history facilitates the identification of trends and gradual changes in equipment performance, an aspect observed by El Kafhali et al. (2025) [26] in PET/CT systems. Furthermore, the structured storage of results benefits the analysis of quantitative parameters used in modern QC tests, such as those discussed by Wigati et al. (2025) [28].

VI. CONCLUSION

We presented QUALIRAD, a PWA that structures the QC of diagnostic imaging equipment in accordance with RDC 611/2022 and INs 90 to 97, using typed checklists and automatic compliance calculations. As a proof of concept with theoretical content validity ensured by a qualified professional, the tool highlights the feasibility of standardizing test records and represents an improvement over manual documentation practices.

This work presents limitations that guide its future development. First, the evaluation conducted consists of content validation by an expert; empirical studies of usability, execution time, inter-observer agreement, or error reduction quantifying the benefits under real-world conditions have not yet been carried out. Second, persistence is local, occurring exclusively in the browser storage of the device used, without any server component, which restricts the records to that device, prevents multi-user centralization, and limits institutional audits. Third, there is no robust authentication mechanism, since the login is nominal and simple by design decision, as described in Section III-B, which is adequate for a proof of concept but insufficient for environments requiring individual accountability and access control. Fourth, the magnetic resonance modality and those regulated by INs 94 to 96 (dental radiology and ultrasonography) have not yet been implemented.

Priority future works include: (i) an empirical evaluation of usability and performance in real-world use, with practical

validation planned for the second semester of 2026 in university hospitals. This evaluation will consider not only objective functional criteria, such as the coverage of all prescribed tests and the adequacy of field completion and ordering, but also qualitative feedback from healthcare professionals regarding the clarity, usability, and suitability of the tool in their routine practices; (ii) storage of test history with visualization and filters; (iii) photographic recording of observed conditions per item; (iv) migration from local persistence to a REST API with a database, enabling centralization and audits; (v) report customization with logos and digital signatures; and (vi) expansion of covered modalities, including magnetic resonance [24] and, subsequently, ultrasonography and dental radiology. Beyond being a management tool, QUALIRAD serves educational and continuous training purposes, so a future improvement involves incorporating step-by-step execution guides for each test, promoting practices that meet the standards expected by institutions and regulatory bodies.

***Abstract*—Equipment failure in Brazilian public hospitals affects patient safety, and the problem is sharpest in facilities operating under the Unified Health System (SUS), where maintenance budgets are tight and downtime translates quickly into cancelled procedures. We propose a Risk-Based Maintenance Priority Index (RBMPI) built from four criteria: failure frequency, clinical severity of failure, substitute device availability, and a regulatory weight derived from the Brazilian Health Regulatory Agency (ANVISA) device risk class. Frequency and severity are expert-elicited ordinal scores informed by the aggregate composition of ANVISA post-market surveillance notifications and by clinical engineering references. They are not measured device-specific rates, which Brazilian public reporting does not disaggregate. Across ten equipment categories common in SUS hospitals the index yields three tiers: Critical, Essential, and Elective. Infusion pumps, mechanical ventilators, syringe pumps, and defibrillators fall in the Critical tier. A Monte Carlo analysis perturbing every scored parameter at once keeps those four in tier in 88% to 100% of runs, while five devices sitting near a boundary change tier often enough to be treated as provisional. Three further tests probe the model's own construction: natural-breaks clustering supports the Critical boundary but finds no data support for the lower one; varying the redundancy multiplier leaves rank order untouched; and an equal-weight additive analogue reproduces the multiplicative ranking at $\rho = 0.964$, which shows the aggregation rule contributes far less than the criterion set. Against the Fennigkoh–Smith index the RBMPI agrees at the extremes ($\rho = 0.835$) and reprioritizes devices that have a functional substitute, a dimension the additive model cannot express. The RBMPI is offered as a preliminary framework for resource-constrained settings. It has not been validated prospectively in hospitals.**

***Index Terms*—Medical equipment maintenance, clinical engineering, patient safety, ANVISA, Brazilian public hospitals, risk-based maintenance, technovigilance, SUS.**

I. Introduction

Maintenance of medical equipment in Brazilian public hospitals is a persistent problem, and it bears directly on whether diagnostic and therapeutic procedures can be delivered at all. An operational audit of nine federal hospitals by the Federal Court of Accounts (TCU) found equipment purchased in earlier years still uninstalled while the same units proceeded with fresh acquisitions, together with absent acquisition planning and deficient technical specification [1]. Field studies of clinical engineering practice in Brazilian public facilities report a substantial share of the installed base underutilized or inoperative, with missing spare parts and consumables among the recurring causes [2].

Clinical engineers in these settings face a narrow, recurring question: with limited resources, which equipment gets attention first? Lacking an objective rule, the answer tends to follow individual judgment or whichever failure is loudest that week, rather than a structured reading of risk and clinical impact [3].

Brazilian regulation offers a starting point. ANVISA operates a national post-market surveillance system in which hospitals, manufacturers, and health professionals report adverse events and technical complaints for medical devices [4]. Between 2014 and 2024 the system received 149,099 device-related notifications; of the 23,716 classified as adverse events, 57.2% involved Class III (high-risk) devices [5]. We are not aware of prior work using this source to inform maintenance prioritization in SUS facilities.

Established models were built elsewhere. The Equipment Management Index of Fennigkoh and Smith [3] assumes a well-resourced department and has no way to express redundancy in the installed base, which is precisely the constraint that binds in public health facilities. Sensor-driven predictive maintenance [6], [7] assumes instrumentation that most SUS hospitals do not have.

This paper proposes an index combining failure frequency, clinical severity, substitute availability, and regulatory risk class into a single score, yielding a three-tier prioritization scheme. The inputs are drawn from sources a facility already holds or can consult without new instrumentation. We treat the published scores as a starting profile to be recalibrated locally, not as a ready-to-deploy ranking.

II. Related Work and Regulatory Context

A. Medical Equipment Management in Brazil

RDC 509/2021 governs health technology management in Brazilian health services, setting requirements for preventive and corrective maintenance planning, equipment registration, and lifecycle documentation [9]. Compliance is uneven. It is weakest in smaller municipalities, where clinical engineering capacity is thin or absent [2]. The Ministry of Health has issued guidance on maintenance management for public facilities [11], and the Brazilian literature reports preventive

programmes routinely interrupted by budget, spare part availability, and the lack of a clinical engineer on staff [12], [2].

B. ANVISA Post-Market Surveillance System

The surveillance system coordinated by ANVISA monitors adverse events and technical complaints for devices in clinical use. Of the 149,099 notifications recorded between 2014 and 2024, 23,716 (15.9%) were adverse events and 125,383 (84.1%) technical complaints [5]. Class III devices account for 57.2% of the adverse events, so a large share of reported incidents involve devices capable of causing direct harm. These are aggregate figures. Public reporting does not break counts down by equipment category at the resolution a maintenance index would need, and that constraint shapes the scoring procedure described in Section III-C.

ANVISA sorts devices into four risk classes by intended use, invasiveness, and the consequences of failure: Class I (low), Class II (moderate), Class III (high), and Class IV (maximum). The class determines pre-market and post-market regulatory obligations [9].

C. Existing Prioritization Models

The Equipment Management Index (EM) of Fennigkoh and Smith [3] sums scores for function, physical risk, and maintenance requirements, admitting to the maintenance programme any device above a threshold. It has been widely adopted. It also carries no surveillance input and no representation of substitute availability, and both its additive structure and its inclusion threshold have been revisited since, notably by Wang and Levenson, who recast the function criterion as mission criticality and add a utilization term [13].

D. Multi-Criteria and Predictive Approaches

Prioritization has also been posed as a multi-criteria decision problem. Taghipour et al. [8] rank 26 devices from a hospital maintenance database using weighted criteria spanning function, mission criticality, age, risk, recall history, and maintenance requirements, then assign maintenance strategies by class. Sezdi [7] argues for differentiating strategy by device technology level. Radzi et al. [6] review 40 studies from 2016 to 2024 and find sensor-based monitoring dominant, which confirms how heavily this line of work depends on instrumentation.

Two things separate the RBMPI from these. It makes substitute availability an explicit criterion, so redundancy lowers priority. And it is computable without a maintenance database, sensors, or an expert panel performing pairwise weighting. The price is coarser inputs, which is why Sections IV-B and V-B test the classification rather than assert it.

III. Proposed Maintenance Priority Index

A. Index Structure

The Risk-Based Maintenance Priority Index combines four criteria:

$$\text{RBMPI} = F \times S \times (2 - A) \times W_r \tag{1}$$

where F is the failure frequency score (0–5), S the clinical severity score (1–5), A the substitute availability (0 = unavailable, 1 = available), and W_r the regulatory weight. The term $(2 - A)$ doubles the index for equipment with no functional substitute. A factor of two is a modeling decision, not a calibration against data; Section V-B reports what happens when it moves.

The product form follows the risk-priority-number logic of failure mode and effects analysis, where criticality is a product of severity and occurrence terms [14], and the multi-criteria scoring used in the equipment prioritization literature [8]. The choice carries an assumption worth naming. A product is non-compensatory in the limit: a device scoring zero on any criterion scores zero overall, whereas a weighted sum lets strength on one criterion offset weakness on another. It is also symmetric in F and S, so a rare but lethal failure and a frequent but harmless one receive the same index. Whatever asymmetry the model expresses comes from the tier thresholds, not from the functional form. Section V-B tests how much the choice of form actually changes the outcome here, and the answer is less than one might expect.

B. Regulatory Weight

W_r follows the ANVISA risk class: Class I ($W_r = 1.0$), Class II ($W_r = 1.1$), Class III ($W_r = 1.3$), Class IV ($W_r = 1.5$), raising priority for devices under stricter oversight. No device in this sample is Class IV, so the effective range here is 1.0 to 1.3. The Class IV level is retained for wider inventories. Section V-B tests three alternative schemes and quantifies how little of the classification any of them drive.

C. Failure Frequency Score

F is an expert-elicited ordinal score on a 0–5 scale. Two sources informed it: the aggregate composition of the Brazilian post-market surveillance notification base [5], which gives the overall volume and risk-class distribution of device notifications, and the failure-behaviour and maintenance-intensity patterns described in the clinical engineering literature [18], [11], [7]. Categories most often associated with reported incidents anchor the upper end of the scale. Both authors scored the ten categories independently against these sources and reconciled the six categories where their initial scores differed by discussion, without a formal consensus protocol such as Delphi. Inter-rater agreement was therefore not quantified, a limitation revisited in Section V-E.

The scores are not measured failure rates. Device-specific notification counts are not published at the resolution the index requires, so F ranks relative failure propensity across these ten categories and nothing finer. This is the weakest input in the model. Section IV-B quantifies what it costs the classification.

D. Clinical Severity Score

S scores the consequence of an unplanned failure during active use:

- 5: immediate risk to life (ventilator, infusion pump, defibrillator)

- 4: serious but not immediately life-threatening harm (monitor, syringe pump)
- 3: moderate impact with manageable consequences (pulse oximeter, electrosurgical unit)
- 2: limited clinical impact (electrocardiograph, ultrasound, patient bed)
- 1: no direct patient safety consequence

Assignments follow established clinical engineering references [3], [18] and the same two-rater procedure described above. No device here scores 1; the level is kept for generality. Like F, S is an ordinal judgment and is perturbed in the robustness analysis.

E. Substitute Availability

A records whether a functional replacement is typically reachable in a SUS hospital when the primary unit fails, coded from Ministry of Health equipment census data [10] and clinical engineering management literature [11], [2].

Binary coding is a real simplification. Actual substitutability depends on how many units exist, occupancy at the moment of failure, physical distance between the failed unit and its replacement, transfer time for the patient or the device, and the local operational criticality of the service involved. A single spare ventilator three floors away in a full ICU is not the same resource as a spare beside the bed. Section V-D sets out a graded alternative built from census counts, and the Monte Carlo analysis identifies this coding as the largest single source of tier instability.

F. Priority Classification

Three tiers were defined:

- **Critical** (RBMPI $\geq$ 20): maximum-frequency preventive maintenance, immediate corrective response, formal downtime reporting.
- **Essential** ($10 \leq$ RBMPI < 20): regular preventive maintenance, corrective response within 24 hours.
- **Elective** (RBMPI < 10): standard institutional schedule, corrective response within working hours.

G. Deriving the Thresholds

Thresholds placed by eye invite the objection that they were chosen to produce a desired answer. We therefore tested them against the score distribution using Jenks natural-breaks optimization [15], which partitions a univariate distribution to minimize within-class variance. With $n = 10$ the search is exhaustive, so the reported partitions are optimal rather than heuristic.

The evidence splits. The distribution contains one dominant gap of 18.2 index points, between the lowest Critical device (36.4) and the highest Essential device (18.2); every other gap is 12.0 points or smaller. The two-class solution (goodness of variance fit, GVF $= 0.870$) cuts exactly there, reproducing the Critical / non-Critical split. Any threshold in the interval $(18.2, 36.4]$ produces the same Critical tier, and the value 20 sits inside it.

The lower boundary has no such support. Gaps in the region below 18.2 run from 0.8 to 3.6 points, and the three-class solution (GVF $= 0.960$) prefers to subdivide the Critical cluster into $\{62.4, 54.6\}$ and $\{42.6, 36.4\}$ rather than split the lower six devices at all. On this distribution the Essential / Elective boundary at 10 is a maintenance-policy decision about response times, not a feature of the data. We state it as such. The Monte Carlo analysis points the same way: every device whose tier is unstable sits in that lower region.

All computations used Python 3.12 with Pandas [19], Matplotlib [20], and SciPy [21]. Table I lists every input, and Sections III-A through III-G specify the scoring rules, the perturbation distributions, and the iteration counts, so the analysis can be reproduced from the paper alone.

IV. Results

A. RBMPI Scores and Classification

Table I gives scores, ranks, and tiers for all ten categories. Four devices are Critical: infusion pumps (62.4), mechanical ventilators (54.6), syringe pumps (42.6), and defibrillators (36.4). All four carry severity 4 or 5, ANVISA Class III, and no coded substitute. That coding comes from national census data [10] and the clinical engineering literature [11], [2]; it describes a general SUS profile and was not verified facility by facility.

A word on precision. Index values are reported to one decimal so the arithmetic can be checked against Table I, not because the inputs support that resolution. The Monte Carlo analysis in Section IV-B gives a per-device interquartile width with a median of 5.2 index points and a median standard deviation of 6.6. Differences below roughly five points therefore fall inside the uncertainty of a single device and should not be read as a meaningful ranking gap. The pulse oximeter at 12.9 and the electrosurgical unit at 12.1 are tied for practical purposes. The infusion pump at 62.4 and the electrocardiograph at 4.8 are not.

TABLE I
Risk-Based Maintenance Priority Index by Equipment Category

Equipment	Components				Rank	RBMPI	P(tier)	Level
	F	S	A	W_r			%	
Infusion Pump	4.8	5	No	1.3	1	62.4	100	Critical
Mech. Ventilator	4.2	5	No	1.3	2	54.6	100	Critical
Syringe Pump	4.1	4	No	1.3	3	42.6	95	Critical
Defibrillator	2.8	5	No	1.3	4	36.4	88	Critical
Multipar. Monitor	3.5	4	Yes	1.3	5	18.2	62	Essential
Pulse Oximeter	3.9	3	Yes	1.1	6	12.9	76	Essential
Electrosurg. Unit	3.1	3	Yes	1.3	7	12.1	71	Essential
Ultrasound System	2.5	2	No	1.1	8	11.0	55	Essential
Bed/Stretcher	3.7	2	Yes	1.0	9	7.4	78	Elective
Electrocardiograph	2.2	2	Yes	1.1	10	4.8	93	Elective

[a] F: failure frequency (0–5); S: clinical severity (1–5). Both are expert-elicited ordinal estimates (Section III-C).
[b] A: substitute available; W_r: regulatory weight.
[c] Values are relative priority scores, not absolute risk. Differences below ˜5 points are within simulated uncertainty.
[d] P(tier): Monte Carlo probability of retaining the tabulated tier under joint perturbation of F, S, and A (Section IV-B).

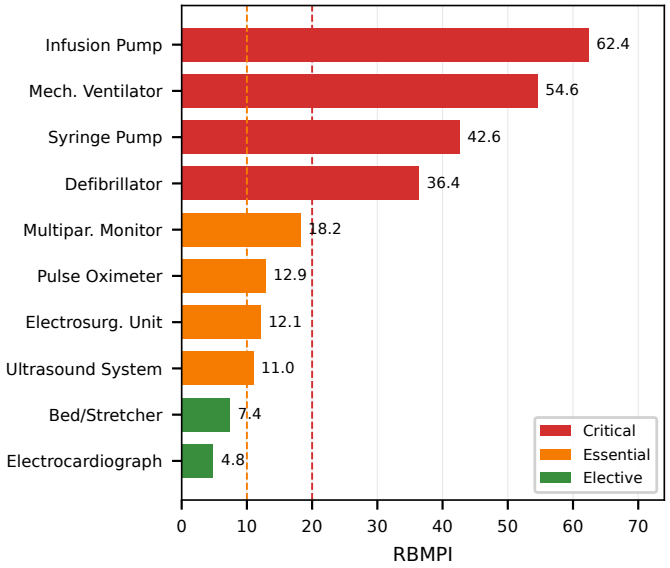

Fig. 1. Equipment ranking by RBMPI. Red: Critical; orange: Essential; green: Elective. Dashed vertical lines mark the Critical (20) and Essential (10) thresholds. The gap between the lowest Critical device (36.4) and the highest Essential device (18.2) is the dominant break in the distribution (Section III-G).

B. Robustness of the Classification

Because F and S are ordinal estimates and A is binary, we tested classification stability over 10,000 Monte Carlo iterations. Each iteration perturbed F and S by up to one level using a triangular distribution centred on the assigned score, and drew A as a Bernoulli variable reflecting 85% confidence in the coded value. Draws falling outside the scale were clipped to the bounds rather than resampled, which places a point mass at the extremes; S was additionally rounded to integers, since it is defined on an integer scale, while F remained continuous. For devices already at the scale maximum this concentrates a substantial share of draws at that bound, and it is the mechanism behind the one-sided behaviour described below. Regulatory class is a legal attribute of the device, so it was held fixed here and varied separately in Section V-B. Fig. 2 reports tier assignment probabilities.

The four Critical devices hold tier in 88.1% to 100% of iterations (infusion pump 100%, mechanical ventilator 99.5%, syringe pump 94.8%, defibrillator 88.1%), and the electrocardiograph holds Elective in 93.2%. The other five are less stable, and all five sit within one tier width of a boundary. The ultrasound system stays Essential in 54.6% of runs and drops to Elective in 44.1%. The multiparameter monitor stays Essential in 62.1% and crosses into Critical in 37.9%. The electrosurgical unit (71.1%), pulse oximeter (76.1%), and patient bed (78.0%) hold tier in roughly three quarters of runs. Read the classification as firm for the four Critical devices and the electrocardiograph, provisional for the rest.

Two features of the simulated distributions run in opposite directions and are worth noting. The mean simulated index for the multiparameter monitor (21.0) exceeds its baseline of 18.2, because treating substitute availability probabilistically means the assumed substitute is sometimes absent and the score doubles. Devices at the top of the F and S scales move the other way: clipping makes perturbation one-sided there, so their simulated means fall below baseline (infusion pump 55.3 against 62.4). Neither effect changes the tier probabilities, but together they show the index carries asymmetric uncertainty and should not be read as a point estimate.

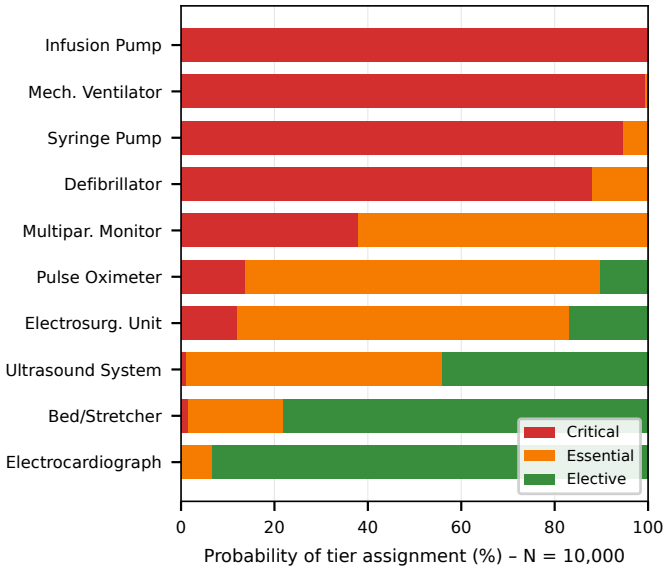

Fig. 2. Monte Carlo tier stability over 10,000 iterations with F, S, and A perturbed simultaneously. Each bar gives one device's probability of assignment to each tier. Single-colour bars are stable; mixed bars mark boundary devices sensitive to score uncertainty.

C. Comparison with the Fennigkoh–Smith Model

To position the index against an established baseline we computed the Fennigkoh–Smith equipment management number (EM = Function + Physical Risk + Maintenance) for the same ten categories. To avoid ad hoc scoring, each device was mapped to the published Fennigkoh–Smith functional categories, to a failure-consequence category, and to standard maintenance-intensity levels, so every score follows a documented rule. Rank agreement is strong (Spearman's $\rho = 0.835$, $p = 0.003$), and the two models converge at the extremes, both placing the mechanical ventilator highest and the patient bed lowest. That convergence is evidence of convergent validity, not of correctness: it shows the RBMPI agrees with an accepted model where that model is most confident.

Divergences track the RBMPI's extra criteria (Fig. 3). Under the original inclusion rule (EM $\geq$ 12), seven of ten categories would enter the maintenance programme. The sharpest disagreement is the electrosurgical unit: Fennigkoh–Smith ranks it fifth (EM = 15, comfortably above threshold) while the RBMPI ranks it seventh and calls it Essential, because the census-derived profile codes it as having a functional substitute. The additive model has no way to represent that.

Running the other way, the RBMPI lifts the infusion pump to first, whereas the additive EM compresses the high-severity devices into a band from 18 to 20.

Perturbing every Fennigkoh–Smith component score by up to one level over 10,000 iterations (Fig. 4) keeps rank correlation strong (mean $\rho = 0.828$, 95% CI [0.687, 0.936]), and the electrosurgical-unit divergence holds direction in 96% of runs. The redundancy-driven reclassification is structural, not an artifact of which scores we picked.

Two further divergences move a device by two or more positions and are equally robust. The pulse oximeter rises 2.5 positions under the RBMPI (direction preserved in 97% of runs), because a comparatively high failure frequency ($F = 3.9$) counts for more in a product than in a sum dominated by the function score. The defibrillator falls two positions (89%), penalized by moderate failure frequency, though it stays firmly Critical. Divergences among near-tied devices in the Critical cluster, such as the syringe pump against the mechanical ventilator, hold direction in only 48% to 60% of runs and should be read as ties.

V. Discussion

A. Applicability in the SUS Context

The index was built for facilities with no sensor infrastructure, no analytics platform, and often no biomedical engineering department. Its four inputs come from publicly available ANVISA and CNES data, standard clinical engineering references, and direct inventory knowledge. Computing it requires a spreadsheet and an accurate equipment list, which puts it within reach of clinical engineers across facilities of varying size, unlike the sensor-based approaches that dominate the recent literature [6]. That is a claim about data requirements, not about validated benefit.

B. What the Model's Free Parameters Actually Drive

Three components of the index were chosen rather than measured: the redundancy multiplier, the regulatory weight vector, and the aggregation rule. We tested each.

Redundancy multiplier. Replacing $(2 - A)$ with $(k - A)$ leaves rank order untouched for $k \geq 2$ ($\rho = 1.000$ at $k = 2.5$ and $k = 3.0$) and nearly untouched below ($\rho = 0.988$ at $k = 1.75$; $\rho = 0.964$ at $k = 1.5$). Tier assignment responds more: $k = 1.5$ moves four devices, $k = 2.5$ moves two. Every device that moves under any k belongs to the boundary group already flagged in Section IV-B. The four Critical devices and the electrocardiograph never change tier at any k tested.

Regulatory weight. A linear scheme (1.0/1.2/1.4/1.6) and an aggressive one (1.0/1.3/1.6/2.0) both leave rank order unchanged ($\rho = 1.00$); dropping the weight entirely still gives $\rho = 0.99$, with one adjacent swap between the electrosurgical unit and the ultrasound system. Tier assignment shifts slightly: the unweighted scheme moves the electrosurgical unit to Elective, the aggressive scheme moves the multiparameter monitor to Critical. Both devices were already flagged as unstable. We state the conclusion plainly: in this sample W_r contributes almost nothing. With no Class IV device present its range is 1.0 to 1.3, and rank order is effectively invariant to it. Its role here is interpretive, tying maintenance priority to ANVISA's own risk assessment in keeping with RDC 509/2021 [9], rather than discriminative. Whether it earns a place as a fourth criterion is a question a larger inventory containing Class IV devices would settle.

Aggregation rule. We also tested the product form itself against an equal-weight additive analogue computed on min-max normalized criteria. The two agree at $\rho = 0.964$. Only three devices shift position, none by more than two, and all three belong to the same boundary group. Ranks one through five and nine through ten are identical under both rules. This is a negative result and we report it as such: on this data the choice between multiplying and adding changes very little. What distinguishes the RBMPI from Fennigkoh–Smith is the substitute availability criterion, not the functional form. Readers should weigh the contribution accordingly.

Across all three tests the pattern is consistent. The parameter values are not what drives the classification; the ordinal structure of F, S, and A is. And the same small set of boundary devices proves fragile under every perturbation applied, which makes calibration effort targetable rather than open-ended.

C. Interpretation of Key Results

Placing infusion and syringe pumps in the Critical tier is consistent with the documented contribution of infusion devices to medication administration errors. A systematic review of smart infusion pump interoperability reports reductions of 21.2% to 90.5% in overall medication administration errors after implementation [16], which indicates the scale of the error burden these devices carry beforehand. The defibrillator is the instructive case: moderate failure frequency, maximal severity, no substitute. Any frequency-only or severity-only rule would rank it lower than the combined criteria do.

The tier definitions aim at the hazard-driven maintenance attention that device safety bodies recommend, where preventive intensity tracks the consequence of failure rather than acquisition cost [17].

D. Calibration for Different Hospital Profiles

The index is meant to be recalibrated, not adopted as printed. Three steps use data an institution already holds.

Failure frequency. Replace the literature-informed F with corrective work orders per device category over twelve months, normalized by installed units and rescaled to 0–5 across the local inventory. Without a computerized maintenance management system, the corrective service records required by RDC 509/2021 [9] carry the same information. This step swaps the model's weakest input for a measured one and should be treated as a precondition for using the index to allocate resources.

Clinical severity. Re-score S against services the facility actually operates. A unit with no intensive care bed or operating theatre has nothing in the immediate-risk-to-life band during routine operation and leaves the top of the scale unused. A tertiary referral centre applies the scale as published.

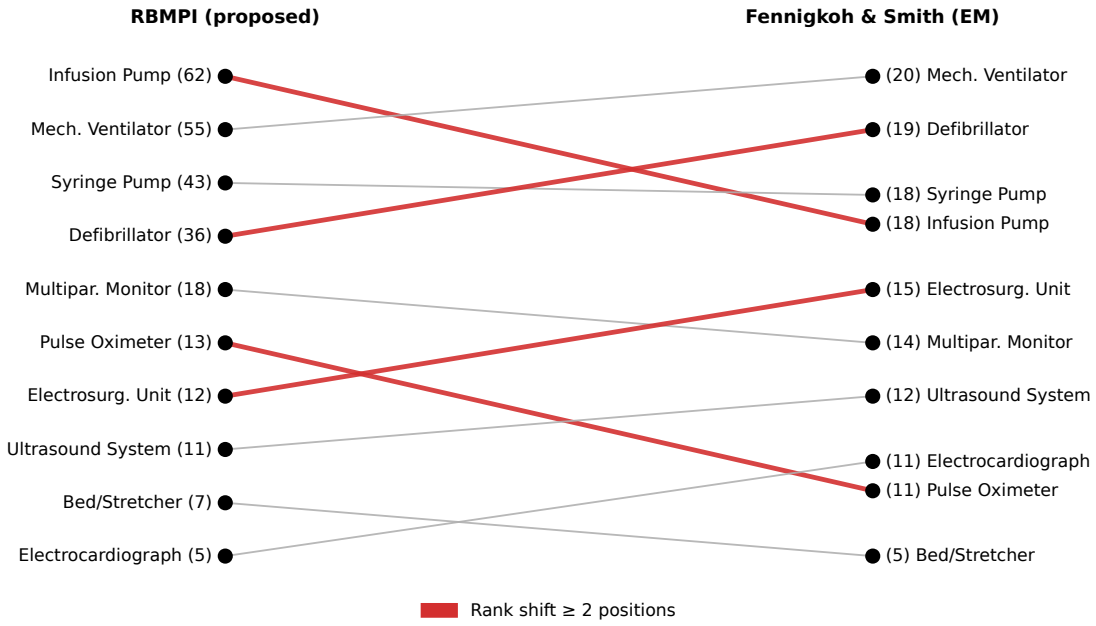

Fig. 3. Rank comparison between the RBMPI (left) and the Fennigkoh–Smith EM number (right). Marker colour is the device's RBMPI tier on both sides. Red connectors mark rank shifts of two or more positions.

Substitute availability. Replace binary A with the facility's unit count from its CNES record [10]: $A = 0$ for a single installed unit, $A = 1$ when units exceed peak simultaneous demand, an intermediate value otherwise. Where transfer time or physical distance materially limits access, those units should not count toward redundancy.

Thresholds must be re-derived, not carried over. Section III-G shows the Critical boundary rests on a gap specific to this distribution and the Essential boundary rests on policy; both need re-examination against the recalibrated scores. Expected direction of change differs by profile. In a small municipal unit, low unit counts push most categories to $A = 0$ while a compressed severity scale lowers top scores, flattening the ranking and enlarging the Critical tier. In a medium general hospital, redundancy among monitoring devices dominates and the Essential tier expands. In a tertiary centre with its own clinical engineering department, local failure counts replace the ordinal F entirely and the index converges on a conventional risk priority number. These are expectations to be tested, not results.

E. Limitations

The index rests on expert-elicited ordinal scores rather than measured data, and that is its principal limitation. Failure frequency was informed by aggregate surveillance composition rather than device-specific ANVISA counts, which are not published at the required resolution. Severity and substitute availability reflect general SUS conditions assigned from literature rather than observation. Two raters produced the scores without a formal consensus protocol, so inter-rater agreement is unquantified. The Monte Carlo analysis bounds how far the classification survives perturbation of these estimates, but perturbing one's own assumptions measures internal fragility, not external accuracy.

Several further limitations follow. The sample is ten categories, which makes the rank correlation with Fennigkoh–Smith a weak statistic, as its 95% interval [0.687, 0.936] shows. Substitute availability remains binary. Equipment age is absent and is a priority for model development. The product form treats F and S symmetrically, which is arguably wrong for a patient-safety application where a rare catastrophic failure and a frequent trivial one should not score alike; an asymmetric weighting deserves testing.

The most consequential gap is that we cannot say whether using this index improves anything. Establishing that the RBMPI raises equipment availability, reduces safety incidents, or improves maintenance performance requires a prospective comparison against decisions made without it, with outcomes measured over at least a maintenance cycle. No such study was possible here: corrective service records are not standardized across SUS facilities and are not publicly accessible. The Fennigkoh–Smith comparison establishes convergent validity with an existing model and nothing more. Until outcome data exist, the RBMPI should be treated as a way to make prioritization assumptions explicit and testable, not as a validated decision rule, and the prospective study is the single most valuable next step.

VI. Conclusion

We proposed a Risk-Based Maintenance Priority Index for medical equipment in Brazilian public hospitals, combining failure frequency, clinical severity, substitute availability, and

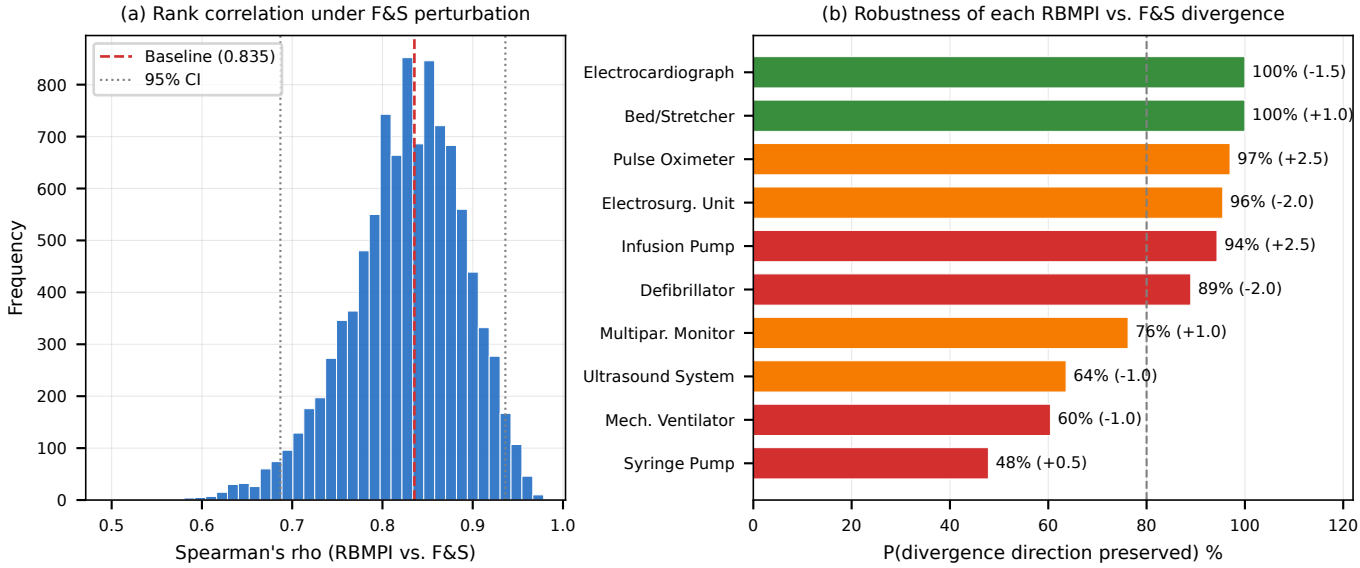

Fig. 4. Robustness of the RBMPI versus Fennigkoh–Smith comparison under ± 1-level perturbation of the Fennigkoh–Smith scores (10,000 iterations). (a) Distribution of Spearman's ρ with baseline and 95% interval marked. (b) Probability that each device preserves the direction of its divergence.

regulatory risk class. Across ten categories it produced a three-tier classification with four devices Critical. Monte Carlo analysis showed those four and the electrocardiograph hold tier under simultaneous variation of all scored parameters, while five boundary devices change tier often enough to be treated as provisional. Comparison with Fennigkoh–Smith showed broad agreement and one robust divergence: the RBMPI lowers priority for devices with a functional substitute, which the additive model cannot express.

Three lessons emerge. Substitute availability changes maintenance priorities in ways function-and-risk models miss, but only for a subset of devices; where equipment is clearly critical, the models agree. Fragility is concentrated rather than diffuse, since the same small group of devices moves under every perturbation applied, whether score noise, redundancy multiplier, regulatory weighting, or aggregation rule. And the aggregation rule itself matters less than its prominence in the formula suggests: an additive analogue reproduces the ranking at $\rho = 0.964$, which locates the contribution in the criterion set rather than the arithmetic.

The open gaps are a prospective hospital study measuring whether the index improves availability or safety outcomes, device-specific notification rates from NOTIVISA, a graded availability measure, and inclusion of equipment age. We offer the RBMPI as a preliminary and transparent framework whose value depends on local calibration and prospective validation before broader adoption.

Acknowledgment

The authors thank the Brazilian Health Regulatory Agency (ANVISA) for maintaining public access to post-market device surveillance data, which informed the scoring in this work.

***Abstract*—Humanization in diagnostic imaging environments represents a growing challenge due to the need to reduce anxiety, promote well-being, and enhance the patient experience during imaging procedures. Although different strategies have been investigated in the literature, scientific production remains dispersed across distinct fields of knowledge, hindering an integrated understanding of the topic. Considering this scenario, this study aims to map and analyze the scientific literature addressing humanization strategies in diagnostic imaging environments, with special attention to the potential of immersive technologies. To this end, a scientometric analysis of the national and international scientific literature was conducted based on structured searches in the Web of Science Core Collection, complemented by exploratory searches in SciELO and Google Scholar Labs. Keyword co-occurrence analysis was performed using VOSviewer. The results highlight the convergence of four key dimensions: patient experience, humanization of care, evidence-based design, and immersive technologies. Based on this synthesis, the concept of Immersive Humanization is proposed as a conceptual framework integrating these dimensions to inform future research and the development and evaluation of solutions aimed at enhancing the patient experience in diagnostic imaging environments.**

***Index Terms*—diagnostic imaging, healthcare humanization, patient experience, immersive technologies.**

I. Introduction

Medical examinations can represent potentially stressful experiences for many patients, involving factors that go beyond expectations regarding the diagnosis. This scenario highlights the importance of adopting strategies capable of minimizing discomfort and promoting a more positive experience during imaging procedures.

In the context of diagnostic imaging, an important tool for the early detection, monitoring, and treatment planning of multiple diseases [1], imaging modalities such as magnetic resonance imaging (MRI) and computed tomography (CT) present characteristics that pose challenges to patients. Enclosed spaces, intense noise, the need to remain still, and prolonged examination times are factors that may trigger anxiety, discomfort, and claustrophobia [1], [2].

From this perspective, the environment in which imaging examinations are performed can influence patients' emotional responses [3], making the design of diagnostic imaging rooms and the adoption of appropriate care protocols strategic elements for promoting the humanization of care.

In this regard, different approaches have been investigated to reduce the emotional impacts associated with imaging procedures and enhance the patient experience. The literature includes non-pharmacological interventions based on design [3], art [4], music therapy, hypnosis, and health psychology [5], as well as studies focused on the development of communication strategies to facilitate magnetic resonance imaging without anesthesia in children [6] and the application of graphic design in computed tomography environments to promote children's well-being [7].

More recently, advances in digital technologies have expanded this range of approaches by incorporating multimedia resources [8] and immersive applications, such as virtual reality [9] and moving image projection systems [10]. In this context, studies indicate that these solutions offer new possibilities for supporting diagnostic imaging procedures and improving the patient experience, establishing themselves as a promising area of innovation in healthcare [11].

Although these initiatives have been investigated in different healthcare contexts, their scientific foundations remain dispersed across fields such as healthcare, design, architecture, computer science, and engineering, hindering an integrated understanding of the field and the consolidation of a conceptual framework for humanization in diagnostic imaging environments.

In view of this gap, this study presents a scientometric analysis of the national and international scientific literature with the aim of mapping, systematizing, and understanding how the literature has supported humanization strategies in diagnostic imaging environments. Based on the identified convergences, the conceptual model of *Immersive Humanization* is proposed, integrating principles of humanization of care, environmental design, patient experience, and the use of immersive technologies.

II. Materials and Methods

A. Research Design

This study is characterized as exploratory research based on scientometric analysis using bibliometric indicators derived from keyword co-occurrence networks. Its objective was to map, systematize, and interpret the scientific literature related to humanization strategies in diagnostic imaging environments, seeking to identify convergences capable of supporting the proposal of the conceptual model of *Immersive Humanization*.

The methodological design was organized around four analytical axes: (i) healthcare humanization; (ii) patient experience in diagnostic imaging examinations; (iii) immersive technologies applied to healthcare; and (iv) healthcare environment and hospital design. These categories guided both the definition of the search strategies and the organization and interpretation of the results.

B. International Literature Survey

The international literature search was conducted in the Web of Science Core Collection on June 26, 2026, covering publications indexed between 2015 and 2026, a period selected because it corresponds to the consolidation of immersive technologies in healthcare. For each analytical axis, specific search strategies were developed, resulting in the establishment of seven independent thematic corpora, as presented in Table I. The searches were refined to include records classified as Articles or Review Articles and indexed as Open Access. No language restriction was applied.

TABLE I. SEARCH STRATEGIES USED IN THE WEB OF SCIENCE CORE COLLECTION

Analytical axis	*Search strategy*	*Records*
Patient experience	patient experience AND MRI	112
	patient experience AND "computed tomography"	55
Healthcare humanization	healing environment AND hospital	75
	positive distraction AND hospital	19
Immersive technologies	virtual reality AND MRI	209
	virtual reality AND "diagnostic imaging"	23
Healthcare environment and hospital design	visual environment AND (hospital OR healthcare)	9

It should be emphasized that the record counts reported in Table I correspond to the searches conducted on June 26, 2026. Because Web of Science is continuously updated, rerunning the same searches at a later date may yield different numbers of records.

C. National Literature Survey

To contextualize the Brazilian scientific production, a complementary literature search was conducted in the SciELO Brazil collection on June 30, 2026, considering publications from 2015 to 2026. Initially, search strategies directly related to the research topic were employed, using search expressions such as *humanização AND diagnóstico por imagem*, *Política Nacional de Humanização AND ressonância magnética*, *humanização imersiva*, and *humanização AND projeção*. However, these searches retrieved few or no studies, highlighting the scarcity of Brazilian publications directly addressing the relationship between humanization, diagnostic imaging, and immersive technologies.

Given this scenario, the search strategy was expanded to include broader search terms, namely *humanização hospitalar* (35 records), *Política Nacional de Humanização* (42 records), *ambiência hospitalar* (7 records), and *humanização AND projeção* (1 record). The retrieved studies were subjected to an exploratory reading of titles and abstracts, allowing the identification of contributions related to the foundations of humanization of care and the organization of healthcare environments. These records were used for contextual and thematic interpretation rather than for keyword co-occurrence analysis.

TABLE II. SEARCH STRATEGIES USED IN SCIELO

Search term	*Records*
Humanização hospitalar	35
Política Nacional de Humanização	42
Ambiência hospitalar	7
Humanização AND diagnóstico por imagem	0
Política Nacional de Humanização AND ressonância magnética	0
Humanização imersiva	0
Humanização AND projeção	1

D. Exploratory Survey Using Google Scholar

In addition to the indexed scientific databases, an exploratory survey was conducted using Google Scholar on June 26, 2026, through the experimental Google Scholar Labs feature, which enables the retrieval of scientific literature using natural language queries. The search was performed using the following prompt: *"I need to find studies addressing healthcare humanization supported by audiovisual projections in examination rooms, with a focus on magnetic resonance imaging and computed tomography environments."*

This procedure resulted in the identification and selection of 17 relevant publications, including scientific articles, master's dissertations, undergraduate theses, books, and literature reviews. This stage had a complementary purpose and was intended to enrich the contextualization of the scientific literature, particularly with regard to practical experiences and applications developed in Portuguese. In this case, no time restriction was adopted. These materials were used to provide additional contextual and thematic insights and were not included in the VOSviewer co-occurrence analysis.

E. Data Processing and Analysis

Across the three complementary sources, 604 records and publications were identified: 502 records from the Web of Science Core Collection, 85 records from SciELO, and 17 publications identified through Google Scholar Labs. The 502 records retrieved from the Web of Science Core Collection were organized into seven independent thematic corpora and exported in a compatible format for bibliometric analysis using VOSviewer software (version 1.6.20).

Keyword co-occurrence analysis was performed using full counting. For corpus A1, author keywords were used as the unit of analysis, with a minimum occurrence threshold of two. For corpora A2, B, C, D1, and D2, all keywords were considered, with a minimum occurrence threshold of five. For corpus E, all keywords were considered, with a minimum occurrence threshold of two. The resulting networks were described using the number of keywords meeting the occurrence threshold, number of clusters, number of links, total link strength, and keyword occurrence frequency. Because keyword occurrence thresholds differed among the corpora, network indicators such as the number of selected keywords, links, and total link strength were interpreted descriptively and in relation to the specific search strategy and corpus structure, rather than as direct measures of scientific maturity or clinical effectiveness.

The seven Web of Science corpora were treated as independent thematic datasets rather than merged into a single corpus because each corpus resulted from a distinct search strategy designed to address a specific analytical dimension. Therefore, a publication could appear in more than one corpus when it met the respective search criteria, as such overlap represented thematic convergence rather than duplication within a single analytical dataset.

The 85 records retrieved from SciELO and the 17 publications identified through Google Scholar Labs were subjected to exploratory screening and thematic interpretation by the first author through examination of titles and abstracts. The resulting interpretations were subsequently discussed with the co-author. No independent duplicate screening or coding procedure was performed. These complementary sources were used for contextual and thematic interpretation.

Subsequently, an interpretative synthesis of the different document sets was carried out to identify convergences among the four analytical axes of the study. This stage made it possible to systematize the main scientific foundations related to humanization in diagnostic imaging environments and to formulate the conceptual model of *Immersive Humanization*.

III. Results

A. International Scientific Production

The search strategies adopted enabled the identification of different theoretical perspectives and applications related to humanization in diagnostic imaging environments. The integrated analysis of the corpora revealed convergences among the four investigated axes – patient experience, healthcare humanization, immersive technologies, and healthcare environment and hospital design – highlighting recurring elements that informed the formulation of the conceptual model of *Immersive Humanization*.

1) Patient experience: The analysis of the corpora dedicated to patient experience in magnetic resonance imaging (112 records) and computed tomography (55 records) highlights a substantial body of research addressing the patient experience in diagnostic imaging. Although both imaging modalities share a common interest in the patient experience, the literature reveals distinct thematic emphases.

In the MRI corpus, a predominance of studies addressing emotional aspects associated with the examination was observed, with emphasis on anxiety, claustrophobia, and strategies aimed at enhancing the patient experience during the procedure. In contrast, the literature related to CT is more closely associated with oncological contexts, in which patient experience is investigated as part of the diagnostic and therapeutic journey.

The keyword co-occurrence analysis generated a network with 16 selected keywords, organized into four clusters and 47 links, with a total link strength (TLS) of 96 for the MRI corpus. The CT corpus comprised seven selected keywords distributed across three clusters and connected by 13 links, with a TLS of 19. Although the occurrence thresholds differed between the two corpora, the results indicate a broader range of thematic connections in the MRI network.

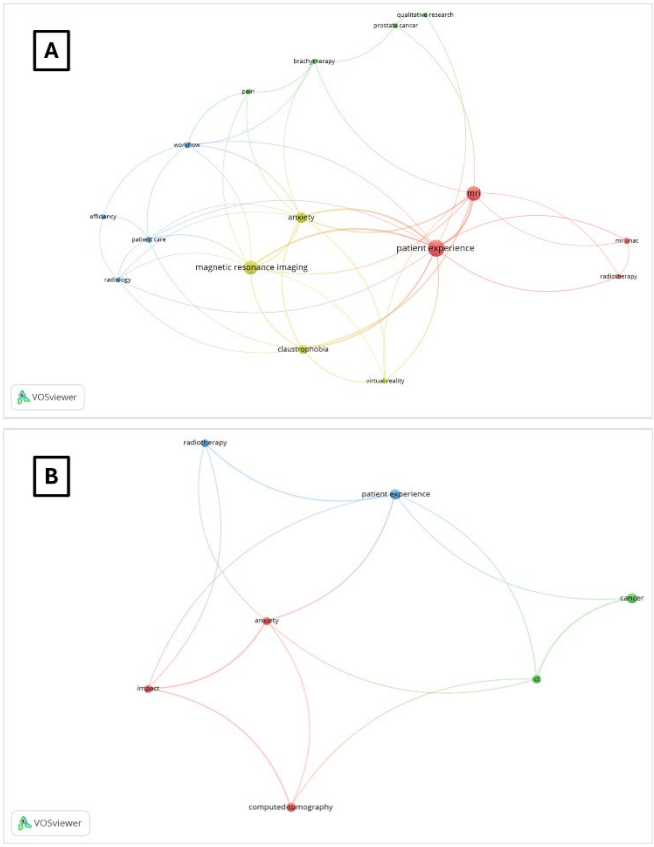

Fig. 1. Keyword co-occurrence networks of the corpora related to patient experience in magnetic resonance imaging (A) and computed tomography (B).

Figure 1 illustrates that, in both corpora, the term *patient experience* occupies a central position in the network, establishing connections with different dimensions of diagnostic imaging care. While the magnetic resonance imaging literature presents a more diverse thematic structure, encompassing emotional, organizational, and technological aspects, the computed tomography corpus shows a closer association with oncological and radiotherapy contexts, relating the patient experience to the impacts of treatment and the care pathway.

In summary, both corpora demonstrate that patient experience represents an important dimension of research on diagnostic imaging. Across the two imaging modalities, anxiety, perception of the examination, communication, and the healthcare context recur as relevant themes, indicating the importance attributed by the literature to the conditions surrounding the imaging experience.

2) Healthcare humanization: The analysis of the corpora related to healthcare humanization comprises 94 publications distributed across the concepts of Healing Environment (75 records) and Positive Distraction (19 records). Overall, these studies indicate that the international literature approaches the humanization of healthcare environments beyond interpersonal relationships, also considering the physical environment as a relevant dimension of well-being, quality of care, and patient experience.

The *Healing Environment* corpus is characterized by a broad and interdisciplinary approach, primarily grounded in the principles of *Evidence-Based Design*. The studies focus on

architectural planning, environmental design, and the organization of healthcare spaces in relation to comfort, quality of care, and health promotion.

The *Healing Environment* keyword network comprised 11 selected keywords distributed across three clusters, with 39 links and a total link strength of 117. In comparison, the *Positive Distraction* network comprised six keywords concentrated in a single cluster, with 15 links and a TLS of 27. These indicators are consistent with the broader thematic scope of the Healing Environment corpus and the more focused thematic structure of *Positive Distraction*.

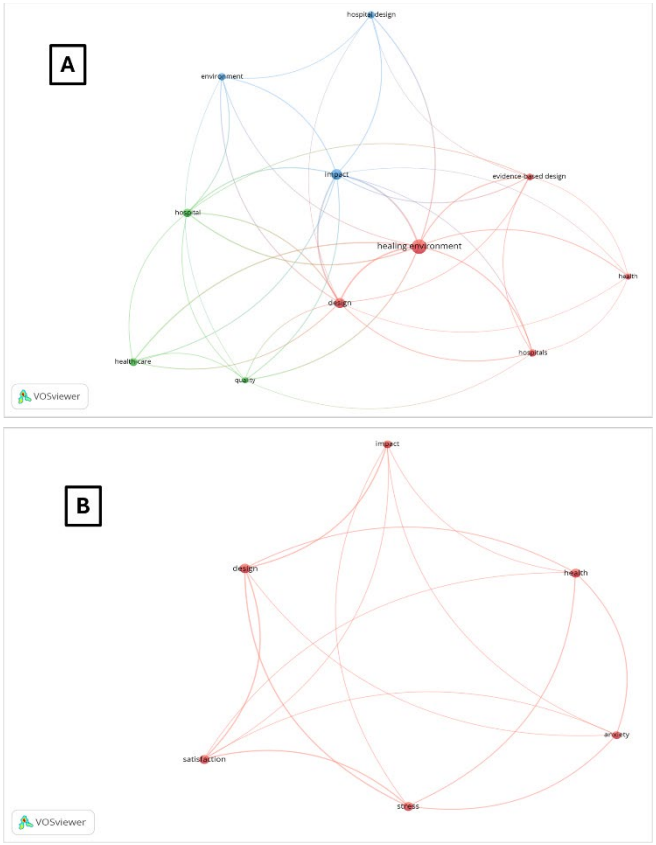

Fig. 2. Keyword co-occurrence networks of the *Healing Environment* (A) and *Positive Distraction* (B) corpora.

Figure 2 shows the complementarity between the two corpora. While the *Healing Environment* map is organized around concepts associated with the planning of healthcare environments, such as *evidence-based design*, *hospital design*, *environment*, and *quality*, the *Positive Distraction* corpus focuses on themes associated with *design*, *stress*, *anxiety*, *satisfaction*, and *health*. This difference indicates that the two fields investigate distinct, yet complementary, dimensions of the humanization of healthcare environments.

Thus, the results suggest that humanization extends beyond the exclusively relational dimension of care and incorporates the physical environment as an important component of the healthcare experience. From this perspective, *Healing Environment* provides conceptual foundations for evidence-based planning of healthcare environments, whereas *Positive Distraction* is discussed in the literature as an environmental intervention approach intended to address stress and anxiety and to support more welcoming and patient-centered experiences.

3) Immersive technologies: Upon examining the corpora related to immersive technologies, a substantial body of scientific production concerning the application of virtual reality in diagnostic imaging examinations can be observed. The corpus related to magnetic resonance imaging comprises 209 publications, whereas the broader corpus focused on diagnostic imaging comprises 23 publications, revealing different thematic scopes within the literature.

The MRI corpus generated a network of nine selected keywords distributed across four clusters, with 28 links and a TLS of 110. The diagnostic imaging corpus comprised four keywords concentrated in a single cluster, with six links and a TLS of 23. The larger number of records and the greater network structure observed in the MRI corpus reflect its more specific research focus on virtual reality in magnetic resonance imaging.

In the MRI corpus, virtual reality emerges as the central focus of the investigations, establishing connections with terms such as *anxiety*, *claustrophobia*, *sedation*, and *pediatric population*. As illustrated in Fig. 3(A), these co-occurrences show that publications in this corpus frequently associate immersive technologies with emotional responses and examination-related challenges.

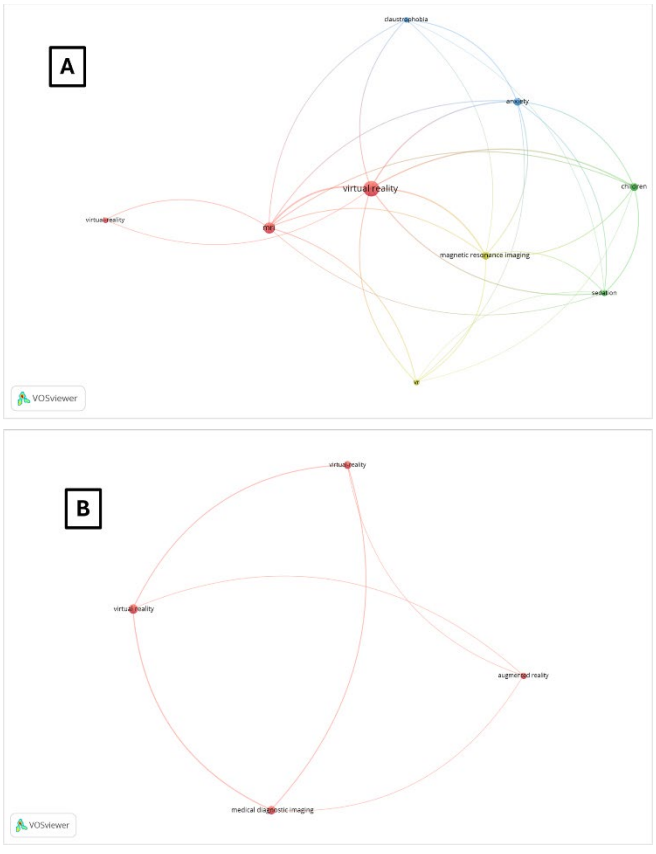

Fig. 3. Keyword co-occurrence networks of the *Immersive Technologies* corpora. (A) *virtual reality* AND *MRI*. (B) *virtual reality* AND *diagnostic imaging*.

The corpus dedicated to diagnostic imaging, in turn, presents a more concise thematic structure (Fig. 3(B)), organized around the concepts of *virtual reality*, *augmented reality*, and *medical diagnostic imaging*. Unlike the first corpus, which focuses on the patient experience during magnetic resonance imaging, this set of studies broadens the scope of investigation by addressing the incorporation of

different immersive technologies into diagnostic processes, including applications related to visualization, planning, and technological innovation.

Thus, the two corpora demonstrate complementary research orientations. The first is more closely associated with the patient experience during MRI examinations, particularly in relation to anxiety, claustrophobia, and sedation-related outcomes. The second broadens the technological scope to include virtual and augmented reality in diagnostic imaging, indicating a wider research agenda concerning the incorporation of immersive technologies into healthcare.

4) Healthcare Environment and Hospital Design: The corpus related to healthcare environment and hospital design comprises nine publications, representing the smallest document set identified in the international literature. Despite the limited number of studies, a recent and interdisciplinary research agenda can be observed, focusing on the investigation of the visual components of the built environment and their relationship with the patient experience. The retrieved studies address aspects related to sensory design, restorative environments, Evidence-Based Design, environmental quality, and the application of visual technologies in healthcare settings.

The keyword co-occurrence analysis (Fig. 4) reveals a sparse thematic network, composed of a limited number of terms and a low density of connections. The network comprises three selected keywords distributed across two clusters and connected by a single link. Unlike the other corpora, the network does not present consolidated thematic groupings, suggesting that research on visual healthcare environments remains comparatively underexplored. The few identified terms are distributed between the concepts of *information* and *stress*, suggesting that the visual environment has been investigated both as a communication and wayfinding resource and in relation to stress.

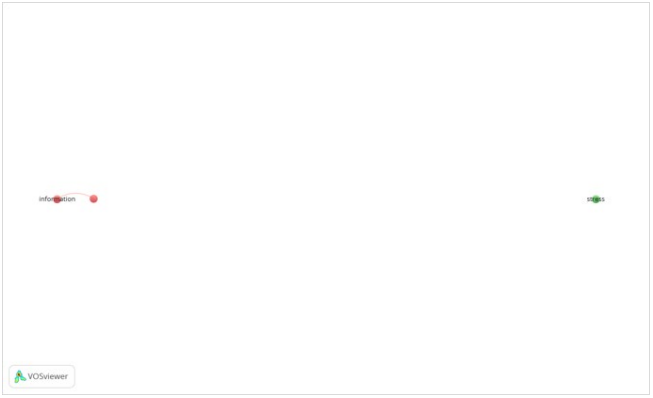

Fig. 4. Keyword co-occurrence network of the *Visual Environment* corpus.

Taken together, the findings indicate that the visual environment constitutes a relatively underexplored area of research in healthcare humanization. Although still underexplored, this field brings together knowledge from architecture, engineering, computer science, and health sciences, pointing to the potential of environmental design as a component of the patient experience and the improvement of spaces dedicated to diagnostic imaging.

B. National Scientific Production (SciELO)

The literature survey conducted in SciELO demonstrates that the Brazilian scientific production on healthcare humanization presents a different scenario from that observed in the international literature. The search strategies initially directed toward the interface between humanization, diagnostic imaging, and immersive technologies did not retrieve studies directly related to the specific research focus. The search terms *humanização* and *diagnóstico por imagem*, *Política Nacional de Humanização* and *ressonância magnética*, and *humanização imersiva* returned no results, whereas the search for *humanização* and *projeção* retrieved only one record that was not directly related to the healthcare context. Within the SciELO Brazil literature retrieved by the present search strategy, these findings suggest that the integration of humanization, immersive technologies, and diagnostic imaging has not yet been consolidated.

Given this scenario, the search strategy was expanded by using broader search terms related to *humanização hospitalar* (35 records), *Política Nacional de Humanização* (42 records), and *ambiência hospitalar* (7 records). The integrated analysis of these data made it possible to characterize the main axes of Brazilian scientific production on healthcare humanization.

The studies related to *Política Nacional de Humanização* are predominantly focused on organizational and institutional aspects, addressing topics such as *HumanizaSUS*, co-management, institutional support, professional training, and the implementation of public policies. In contrast, the corpus related to *humanização hospitalar* emphasizes care practices, bringing together studies on patient welcoming, nursing, occupational therapy, hospital psychology, patient-centered care, and healthcare environments. In turn, the corpus dedicated to *ambiência hospitalar* highlights the recognition of the physical environment as a component of care, encompassing studies on professionals' perceptions, environmental comfort, Florence Nightingale's environmental theory, and the organization of healthcare spaces.

Although these three corpora reveal a consistent body of research on humanization policies, care practices, and healthcare environments, these topics remain addressed relatively independently. No studies were identified within the retrieved SciELO records that directly articulate the principles of humanization of care, the planning of healthcare environments, and the use of immersive technologies in diagnostic imaging contexts. This gap in the retrieved literature informed the formulation of the *Immersive Humanization* model.

C. Exploratory Survey Using Google Scholar

In addition to the indexed scientific production, an exploratory survey was conducted using Google Scholar and the experimental Google Scholar Labs feature to identify studies related to humanization in diagnostic imaging environments supported by audiovisual and immersive technologies.

TABLE III. CLASSIFICATION OF STUDIES IDENTIFIED USING GOOGLE SCHOLAR LABS

Document type	*Count*	*Examples*
Scientific articles	5	Anxiety in PET/CT; humanized care in radiotherapy; multimedia resources in hospitals
Master's dissertations	3	Humanization in MRI rooms; communication in MRI; anxiety in MRI
Undergraduate theses	4	Hypnosis in MRI; graphic design in computed tomography; pediatric radiology
Books	3	Virtual reality in healthcare; humanization of technologies
Other	2	Meta-analysis; human–computer interaction study

The distribution of document types shows that the literature identified on the topic is dispersed across different publication formats, including scientific articles, master's dissertations, undergraduate theses, and books. This diversity indicates that contributions to the topic have emerged across different levels of investigation and publication formats.

The retrieved studies can be grouped into four main perspectives. The first comprises studies addressing anxiety, claustrophobia, and discomfort during diagnostic imaging examinations through non-pharmacological approaches such as hypnosis, music therapy, health psychology, and patient communication. The second encompasses research related to the design and physical environment of magnetic resonance imaging and computed tomography rooms, emphasizing architectural aspects, environmental comfort, and patient experience. A third group addresses applications of virtual reality in different healthcare contexts, including rehabilitation, mental health, and pain management. Finally, studies focusing on the humanization of care in diagnostic imaging examinations and the use of multimedia resources in healthcare environments were identified.

Overall, the results obtained through Google Scholar Labs complement the panorama observed in SciELO. While the indexed literature retrieved in SciELO showed limited integration among humanization, immersive technologies, and diagnostic imaging, the exploratory survey identified contributions distributed across different types of academic and applied literature. These findings suggest that relevant evidence on the topic remains dispersed across different areas of knowledge and publication formats rather than concentrated within a consolidated research field.

This scenario reinforces the relevance of an integrative framework capable of articulating the principles of humanization of care, patient experience, healthcare environment, and immersive technologies applied to diagnostic imaging environments.

IV. Discussion

Based on the scientometric analysis conducted, humanization in diagnostic imaging environments can be understood as a complex and multidimensional field. While the international literature reveals a greater concentration of research on themes related to patient experience, immersive technologies, and healthcare environments, the Brazilian scientific production primarily highlights the foundations of humanization of care and the organization of healthcare services. The comparison between these bodies of literature suggests that the articulation among these dimensions remains limited, particularly in relation to diagnostic imaging environments.

Drawing on the collected and interpreted data, and from the perspective of *Evidence-Based Design*, the hospital environment can be understood not merely as a passive setting, but as an integral component of the care experience. In this context, elements such as the *visual environment*, *audio environment*, and spatial organization have been investigated as strategies for improving care [12].

It is within this line of thought that the concept of *Positive Distraction* is situated. In stressful situations, positive distractions have been discussed as a coping strategy [13]. In this regard, the use of resources that promote relaxation – such as natural landscapes, soft colors, and calming sounds – may contribute to the creation of more supportive environments for patients and healthcare professionals [14].

This framework is further expanded when positive distraction mechanisms incorporate immersive technologies. The literature identified in the MRI corpus frequently associates virtual reality with patient preparation, familiarization, and examination-related challenges, including anxiety and claustrophobia. Individual studies have also reported outcomes related to anxiety, adherence, and acceptability [15]. These findings are derived from individual investigations and should not be interpreted as a direct result of the scientometric analysis, which identifies thematic associations and co-occurrence patterns rather than clinical effectiveness.

Thus, one of the central challenges in healthcare is to implement more “hospitable” hospitals, capable of adopting strategies that reduce rumination and enhance the patient experience [16]. Furthermore, according to researchers, institutions that invest in the integration of technology and care tend to receive more favorable evaluations from patients [17].

None of these perspectives, however, is sufficient when considered in isolation. Based on the results of the analysis of the national and international academic debate – plural and fragmented – the proposal of *Immersive Humanization* was developed, grounded in the convergence of four complementary dimensions: patient experience, understood as the guiding axis of the interventions; humanization of care, responsible for guiding ethical and care principles; evidence-based healthcare environments, focused on the physical planning of healthcare spaces; and immersive technological solutions, understood as resources capable of supporting patient welcoming, preparation, familiarization, and positive distraction during diagnostic procedures.

The proposed framework does not replace these perspectives, but seeks to articulate dimensions that are commonly addressed separately. In this sense, *Immersive Humanization* brings together the experiential perspective of patient-centered approaches, the environmental principles of *Evidence-Based Design*, the coping strategies associated with *Positive Distraction*, and the possibilities offered by immersive technologies within a framework specifically oriented toward diagnostic imaging environments. Its

contribution lies in this integrative articulation, which provides a conceptual basis for examining how environmental, experiential, care-related, and technological dimensions may be considered together.

The concept of immersion can also be understood as multidimensional rather than restricted to the use of a specific technological device. Drawing on Marín's typology of immersion in audiovisual nonfiction, three complementary modalities can be distinguished: perceptual immersion, associated with the sensory and technical characteristics of the medium; narrative-level immersion, related to the user's involvement in the story; and immersion as a response, which emphasizes active participation and the user's responses to the experience [18]. Although originally developed in the context of immersive audiovisual narratives, this typology provides a useful analytical lens for examining different configurations of immersive experiences in healthcare contexts.

From this perspective, immersive humanization may encompass different modes of engagement according to the technological and experiential configuration adopted. Immersive audiovisual projection in diagnostic imaging environments can be understood as approaching perceptual immersion, insofar as it modifies the patient's sensory relationship with the examination space [19], [20]. Virtual reality experiences incorporating narrative or playful elements in pediatric healthcare contexts may approximate narrative-level immersion by engaging patients through contextualized experiences [21]. In turn, VR-based therapeutic interventions for fears and phobias may approach immersion as a response, as the patient actively engages with virtual environments and is repeatedly exposed to stimuli associated with the feared situation as part of the intervention [22]. These examples are presented to illustrate different configurations of immersive experience and do not constitute evidence of the clinical effectiveness of the *Immersive Humanization* framework.

In this context, an immersive audiovisual projection system used in diagnostic imaging environments provides a concrete illustration of how some of these principles can be configured technologically. The proposal uses synchronized audiovisual projections on the walls, ceiling, and the magnetic resonance imaging and/or computed tomography equipment itself, creating an immersive environment to be experienced by the patient. From a technological perspective, this solution is conceptually related to CAVE (Cave Automatic Virtual Environment) immersive systems, developed to promote the sense of presence through audiovisual immersion [23]. Publicly available 360-degree audiovisual materials documenting the MRI and CT applications of the system are used here to illustrate its configuration and operation (Fig. 5A-B).

Beyond illustrating how the solution operates, 360-degree images may constitute a healthcare communication strategy, in line with recent studies [24]. By enabling prior familiarization with the environment and the diagnostic procedure through immersive experiences, these resources may contribute to reducing uncertainty and supporting patient preparation before the examination [25]. These potential contributions, however, require empirical evaluation and should not be inferred solely from the technological characteristics of the system or from the illustrative materials.

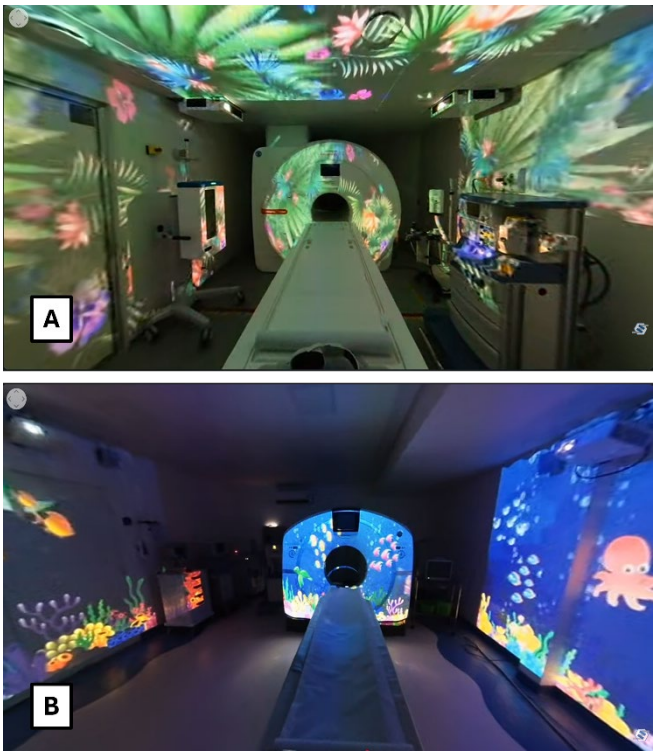

Fig. 5. Application of an immersive audiovisual projection system in diagnostic imaging environments: (A) magnetic resonance imaging room [19]; (B) computed tomography room [20].

Although initiatives of this nature remain limited and involve challenges related to implementation costs, infrastructure, and the evaluation of their clinical impacts, they point to the possibility of integrating environmental design, audiovisual resources, and immersive technologies into diagnostic imaging environments. In light of these findings, *Immersive Humanization* is proposed as a conceptual framework capable of guiding future research and supporting the development of solutions aimed at enhancing the patient experience.

V. Conclusion

This study conducted a scientometric analysis of the national and international scientific production on humanization strategies in diagnostic imaging environments to understand how the literature has addressed patient experience, healthcare environment, humanization of care, and the use of immersive technologies.

The search strategies retrieved 604 records across the different sources consulted, revealing a broad field of research distributed across different areas of knowledge and theoretical approaches. The analysis of the corpora made it possible to identify convergences among these perspectives, indicating that patient experience, evidence-based healthcare environments, humanization of care, and immersive technologies can be understood as complementary dimensions in the consideration of diagnostic imaging environments.

As its main contribution, this study proposes the concept of *Immersive Humanization*, understood as a conceptual framework that integrates established principles of humanization of care, *Evidence-Based Design*, *Positive Distraction*, and immersive technologies, without intending to replace them, but rather articulating them within a perspective directed toward diagnostic imaging environments.

As this is an exploratory study, supported by specific literature search strategies, the results should be interpreted in light of the methodological scope adopted, including the databases, search terms, and publication types considered. In this regard, future studies may expand the databases consulted, empirically validate the proposed framework, and investigate the effects of immersive solutions on objective indicators related to patient experience, anxiety, and the quality of diagnostic procedures.

It is expected that the findings presented herein will contribute to strengthening the dialogue among healthcare, design, communication, and immersive technologies, stimulating further research while supporting the development of more welcoming, humanized, and patient-centered diagnostic imaging environments.

***Resumo*—A ressonância magnética (RM) é uma modalidade fundamental de diagnóstico por imagem na medicina moderna, destacando-se por não utilizar radiação ionizante. No entanto, a presença de um campo magnético estático de alta intensidade torna o ambiente de RM suscetível a acidentes decorrentes da introdução de objetos ferromagnéticos, entre os quais se incluem incidentes classificados como "*projectile event*". Tais ocorrências podem resultar em lesões graves, óbitos, danos ao equipamento e impactos operacionais e financeiros. Nesse contexto, os Sistemas de Detecção de Materiais Ferromagnéticos (FMDS) constituem um recurso complementar de mitigação de riscos, permitindo a identificação de objetos potencialmente perigosos antes da entrada em áreas controladas de RM. Este estudo apresenta uma análise técnico-narrativa dos principais riscos associados ao ambiente de RM, das normas e diretrizes nacionais e internacionais aplicáveis e das tecnologias e configurações de sistemas de detecção. São discutidas as características, os princípios de funcionamento, as limitações e as aplicações de detectores portáteis (manuais), do tipo barra e do tipo portal, considerando sua integração aos procedimentos de segurança em RM.**

***Palavras-chave*—Ressonância Magnética (RM), Segurança em Ressonância Magnética, Sistemas de Detecção de Materiais Ferromagnéticos (FMDS), Segurança do Paciente.**

I. Introdução

A ressonância magnética (RM) é amplamente utilizada no diagnóstico por imagem e é considerada uma modalidade relativamente segura, além de não utilizar radiação ionizante [1]. No entanto, a presença de um campo magnético estático de alta intensidade, que permanece ativo continuamente, introduz riscos específicos que exigem medidas de controle adequadas.

Entre esses riscos, os incidentes com projéteis – causados pela introdução inadvertida de objetos ferromagnéticos no ambiente de RM – representam um importante perigo à segurança. Objetos aparentemente inofensivos, como tesouras, cilindros de oxigênio, cadeiras de rodas, injetores de contraste e ferramentas de manutenção, podem ser atraídos em direção ao ímã, resultando em danos ao equipamento, interrupções operacionais e, em casos graves, lesões ou óbitos.

Para fins de comparação, o campo magnético da Terra varia de aproximadamente 25 a 65 μT [2], enquanto um sistema de RM de 1,5 T produz aproximadamente 1.500.000 μT, quase 30.000 vezes mais que o valor terrestre. Essa diferença evidencia a elevada intensidade presente nos sistemas de RM e a necessidade de medidas adequadas de controle e segurança.

Segundo dados do Cadastro Nacional de Estabelecimentos de Saúde (CNES), o Brasil contava com 3.181 sistemas de ressonância magnética em operação em maio de 2026 [3]. A presença de um número expressivo de equipamentos de RM em funcionamento reforça a importância de procedimentos adequados de segurança, especialmente diante dos riscos associados à introdução inadvertida de materiais ferromagnéticos nesses ambientes.

Nesse contexto, a segurança em RM envolve diferentes medidas de controle, incluindo procedimentos de triagem, treinamento de pessoal, controle de acesso e identificação de objetos e equipamentos potencialmente perigosos. Os Sistemas de Detecção de Materiais Ferromagnéticos (FMDS) podem constituir uma camada adicional de proteção, contribuindo para a identificação de materiais ferromagnéticos antes de seu ingresso em áreas controladas de RM.

Assim, este artigo analisa as principais tecnologias de detecção de materiais ferromagnéticos utilizadas em ambientes de RM, discutindo seus princípios de funcionamento, características, limitações e aplicações práticas. Além disso, são apresentadas as principais normas e diretrizes nacionais e internacionais relacionadas à segurança em RM, considerando o papel dos FMDS como uma camada adicional de mitigação de riscos em programas abrangentes de segurança em RM.

II. Materiais e Métodos

Este estudo caracteriza-se como uma análise técnico-narrativa sobre sistemas de detecção de materiais ferromagnéticos aplicados à segurança em ambientes de ressonância magnética. A investigação foi desenvolvida por meio de pesquisa bibliográfica não sistemática, pesquisa documental e análise reflexiva da experiência profissional do autor.

A pesquisa bibliográfica foi realizada por meio de buscas gerais na web, com o objetivo de identificar publicações relacionadas à segurança em ressonância magnética, incidentes envolvendo materiais ferromagnéticos e tecnologias de detecção. Já a pesquisa documental contemplou normas, diretrizes, documentos regulatórios e materiais técnicos relacionados aos sistemas de detecção. Esses materiais foram utilizados para caracterizar funcionalidades e aspectos operacionais, não sendo considerados evidências

independentes de desempenho. Complementarmente, a experiência profissional do autor no contexto de tecnologias aplicadas à segurança em ressonância magnética foi considerada na análise dos aspectos técnicos e operacionais discutidos no estudo.

As informações identificadas foram organizadas e examinadas considerando os princípios de funcionamento, características, aplicações, limitações e aspectos operacionais das diferentes tecnologias de detecção, bem como as recomendações normativas relacionadas à segurança em ambientes de ressonância magnética.

III. O CASO MICHAEL COLOMBINI: UM MARCO NA SEGURANÇA EM RM

Apesar dos avanços na Ressonância Magnética (RM), o histórico de segurança dessa modalidade abrange incidentes que evidenciaram os riscos associados aos campos magnéticos estáticos de alta intensidade. Entre esses eventos, o caso de Michael Colombini tornou-se um marco nessa discussão [4].

Em 27 de julho de 2001, Michael Colombini, uma criança de seis anos, submetia-se a um exame de rotina de RM no *Westchester Medical Center*, em Nova York (EUA). Durante o procedimento, um cilindro de oxigênio de aço, classificado como inseguro para RM (*MR Unsafe*), foi inadvertidamente levado para a sala de exames. O cilindro foi fortemente atraído pelo campo magnético e atingiu a cabeça de Michael, provocando lesões que resultaram em sua morte [4], [5].

O acidente revelou falhas em diferentes aspectos das práticas de segurança em ressonância magnética (RM), incluindo questões relacionadas ao treinamento, à triagem de materiais e ao controle de acesso. O episódio também demonstrou que, embora a RM não utilize radiação ionizante, seu campo magnético estático pode representar riscos graves quando as medidas de segurança e controle não são adequadamente aplicadas [6].

Após o ocorrido, o *American College of Radiology* (ACR) publicou, em 2002, um documento de consenso sobre segurança em RM, posteriormente revisado e atualizado [7]. Essas recomendações contribuíram para a consolidação de práticas estruturadas de segurança, incluindo o zoneamento dos serviços de RM em quatro áreas (Zonas I a IV), o controle de acesso e o treinamento dos profissionais envolvidos no ambiente de RM [7].

O período posterior ao caso também coincide com o desenvolvimento de Sistemas de Detecção de Materiais Ferromagnéticos (FMDS) específicos para ambientes de RM. Segundo Keene [8], os primeiros sistemas desse tipo surgiram em 2002, pouco depois do acidente, oferecendo uma camada adicional de proteção contra incidentes do tipo “projétil”.

Mais de duas décadas depois, o caso Michael Colombini permanece como uma referência para o debate sobre segurança em RM, evidenciando que esta depende não apenas de recursos tecnológicos, mas também de treinamento, procedimentos adequados, controle de acesso e múltiplas camadas de proteção [6], [7].

IV. O CASO LEANDRO MATHIAS E OS RISCOS EM AMBIENTES DE RM

Embora acidentes relacionados à ressonância magnética (RM) sejam relativamente raros, alguns podem apresentar consequências graves, especialmente aqueles envolvendo objetos ferromagnéticos introduzidos inadvertidamente no ambiente de exame [9]. Em janeiro de 2023, um novo incidente voltou a evidenciar que esses riscos permanecem presentes nos ambientes de RM [10], [11].

Leandro Mathias de Novaes, advogado de 40 anos, acompanhava sua mãe durante um exame de ressonância magnética em São Paulo, Brasil, quando a arma de fogo que portava foi atraída pelo campo magnético do equipamento e disparou, atingindo seu abdômen. O incidente provocou graves lesões, e Leandro faleceu em 6 de fevereiro de 2023, cerca de três semanas após o ocorrido [10].

O episódio ilustra que os riscos associados à introdução de materiais ferromagnéticos em ambientes de RM não se restringem a equipamentos médicos, cilindros ou ferramentas, podendo também envolver objetos pessoais introduzidos inadvertidamente nas áreas controladas. A presença de uma arma de fogo no ambiente de RM resultou em um evento grave e reforça a importância de procedimentos adequados de triagem, da comunicação eficaz com pacientes e acompanhantes, bem como do controle de acesso às áreas restritas. Nesse contexto, diferentes camadas de proteção podem ser adotadas de forma complementar, incluindo Sistemas de Detecção de Materiais Ferromagnéticos (FMDS), conforme as características do serviço e do programa de segurança. O exemplo também mostra que os recursos tecnológicos devem estar integrados a procedimentos e treinamento, uma vez que nenhuma medida isolada elimina completamente os riscos associados ao ambiente de RM.

V. CONTEXTO E RELEVÂNCIA DOS SISTEMAS DE DETECÇÃO FERROMAGNÉTICA

Estudos sobre segurança em ressonância magnética (RM) indicam que muitos incidentes estão ligados a fatores humanos e a falhas nos processos de segurança, incluindo deficiências na triagem, treinamento inadequado, descumprimento de procedimentos e lacunas no controle de acesso [6], [7]. Embora acidentes relacionados à RM sejam relativamente raros, alguns podem apresentar consequências graves quando ocorrem [9].

A gravidade desses incidentes está relacionada, entre outros aspectos, à intensidade do campo magnético presente nos sistemas de RM. Objetos ferromagnéticos podem ser fortemente atraídos pelo magneto e adquirir velocidade suficiente para causar lesões ou danos ao equipamento. Um exemplo frequentemente utilizado na literatura é o de objetos ferromagnéticos que podem atingir velocidades superiores a 60 km/h em determinadas condições [8].

Além do risco de lesões, eventos de efeito projétil podem resultar em danos aos equipamentos, cancelamento de exames, interrupções não planejadas das atividades, necessidade de intervenções técnicas e prejuízos financeiros substanciais [8], [12]. Estimativas apresentadas em material técnico sobre

segurança em RM indicam que os custos de acidentes envolvendo efeito projétil, sem lesão humana, podem variar de aproximadamente US$ 20.000 a mais de US$ 200.000, dependendo da natureza do incidente e de suas consequências [8].

No contexto brasileiro, um levantamento realizado em 29 instituições de saúde de Porto Alegre, abrangendo 49 equipamentos de RM, identificou diferentes estratégias de detecção de metais nos serviços avaliados [13]. A maioria das instituições utilizava entrevista de triagem associada a detector portátil, enquanto alguns serviços combinavam detectores portais e portáteis. O estudo também identificou instituições que utilizavam exclusivamente a entrevista e serviços que não informaram, em seus Programas de Segurança em RM, como era realizada a detecção de metais [13]. Esses resultados evidenciam a diversidade das estratégias adotadas na prática e reforçam a importância da definição e padronização dos procedimentos de triagem nos serviços de RM.

O levantamento também identificou lacunas na documentação relacionada à segurança. Apenas 55,17% das instituições avaliadas apresentavam descrição dos riscos inerentes à RM e 58,62% apresentavam descrição da compatibilidade dos materiais com o ambiente de RM [13]. Esses achados reforçam que a utilização de sistemas de detecção deve estar inserida em um programa de segurança mais amplo, que envolva procedimentos de triagem, treinamento, avaliação de riscos e controle de acesso.

Nesse contexto, os Sistemas de Detecção de Materiais Ferromagnéticos (FMDS) constituem um recurso complementar para a mitigação de riscos em ambientes de RM. Diferentemente dos detectores de metais convencionais, os FMDS são projetados para detectar perturbações no campo magnético associadas à presença de materiais ferromagnéticos, permitindo maior seletividade quanto às propriedades magnéticas dos objetos avaliados [8].

As recomendações do *American College of Radiology* (ACR) incluem os sistemas de detecção ferromagnética como recurso adicional aos procedimentos de triagem, especialmente antes do acesso às áreas controladas da RM [14]. Dessa forma, os FMDS devem ser compreendidos como uma camada complementar de proteção, integrada aos procedimentos de triagem, controle de acesso, treinamento e protocolos operacionais padronizados.

VI. Normas e diretrizes aplicadas à detecção de materiais ferromagnéticos em ambientes de ressonância magnética

No Brasil, as principais referências regulatórias relacionadas à segurança em ambientes de ressonância magnética (RM) incluem a Instrução Normativa nº 97/2021 da ANVISA e a RDC nº 611/2022. Esses documentos estabelecem requisitos relacionados à segurança dos ambientes de RM, incluindo medidas de detecção de metais e controle do acesso às áreas restritas [15], [16]. As normas não especificam uma tecnologia única para a detecção, permitindo diferentes abordagens de acordo com as características e os procedimentos de segurança adotados pelos serviços [15], [16].

Internacionalmente, o *American College of Radiology* (ACR) recomenda uma abordagem baseada em múltiplas camadas de proteção para a segurança em RM, incluindo procedimentos de triagem, inspeção de pessoas e objetos, treinamento da equipe, sinalização adequada e controle de acesso. O ACR recomenda a triagem de pessoas antes do acesso às Zonas III e IV e considera os Sistemas de Detecção de Materiais Ferromagnéticos (FMDS) um recurso complementar às medidas de segurança estabelecidas para o ambiente de RM [14].

Na Europa, a Diretiva 2013/35/UE estabelece requisitos para a proteção dos trabalhadores contra riscos associados à exposição a campos eletromagnéticos, incluindo efeitos indiretos relacionados à presença de materiais ferromagnéticos [17]. A diretiva, entretanto, não estabelece uma exigência específica para a utilização de FMDS em instalações de RM. Orientações da *Medicines and Healthcare products Regulatory Agency* (MHRA) também abordam os riscos associados à introdução de objetos metálicos em ambientes de RM e apresentam recomendações relacionadas aos procedimentos de segurança e triagem [18].

De modo geral, os documentos regulatórios e as diretrizes analisados indicam que a segurança em ambientes de RM deve ser estruturada por meio de medidas complementares de controle e triagem. No Brasil, os requisitos regulatórios estabelecem medidas de segurança e detecção, sem determinar uma tecnologia específica. Internacionalmente, o ACR recomenda a utilização de FMDS como recurso complementar às medidas de triagem e segurança antes do acesso às áreas controladas da RM [14]. Dessa forma, a adoção de sistemas de detecção deve ser considerada em conjunto com os procedimentos de triagem, treinamento, controle de acesso e demais medidas estabelecidas no programa de segurança da instituição.

VII. Tecnologias de detecção aplicadas em ambientes de ressonância magnética

A prevenção de acidentes em ambientes de Ressonância Magnética (RM) baseia-se na implementação de sistemas capazes de identificar objetos potencialmente perigosos antes que estes ingressem nas Zonas III e IV [14]. Na prática, podem ser encontrados três tipos de tecnologia de detecção em aplicações de segurança em RM: detectores de metais convencionais, detectores ferromagnéticos e sistemas de detecção híbridos. Cada tecnologia apresenta características, vantagens e limitações distintas, que devem ser consideradas no planejamento e na implementação de programas de segurança em RM.

A. Detectores de metais convencionais

Detectores de metais convencionais (Figura 1) funcionam gerando campos eletromagnéticos alternados e analisando perturbações causadas pela presença de objetos metálicos.

Esses sistemas são amplamente utilizados em aeroportos e aplicações de segurança, pois conseguem detectar diferentes tipos de materiais metálicos, incluindo materiais ferromagnéticos e não ferromagnéticos.

No entanto, em ambientes de ressonância magnética (RM), essa característica pode representar uma limitação, uma vez que nem todos os metais apresentam risco de efeito projétil. Ao não diferenciarem materiais ferromagnéticos de materiais não ferromagnéticos, esses detectores podem gerar alarmes para objetos que não representam necessariamente risco de interação com o campo magnético, exigindo avaliação adicional durante a triagem. Essa limitação é particularmente relevante nas áreas de acesso às Zonas III e IV, nas quais o controle de objetos e equipamentos metálicos constitui parte importante das práticas de segurança em RM [14].

Outra limitação importante está relacionada à utilização desses equipamentos nas proximidades de campos magnéticos estáticos intensos. Quando instalados nas proximidades das Zonas III e IV da RM, sua utilização deve considerar as características do equipamento, sua compatibilidade com o ambiente de RM e sua localização em relação ao magneto. Estudos que avaliaram diferentes dispositivos de detecção também indicam que o desempenho pode variar de acordo com o tipo e o tamanho do objeto, sua posição e a distância em relação ao detector [19].

Por essas razões, os detectores de metais convencionais não devem ser considerados substitutos dos procedimentos específicos de triagem e controle de acesso aplicáveis à segurança em RM. As recomendações do *American College of Radiology* (ACR) indicam a utilização de procedimentos complementares de detecção e avaliação de objetos potencialmente perigosos, incluindo sistemas de detecção ferromagnética, no contexto do programa de segurança em RM [14].

Fig. 1. Detectores de metais convencionais. Fonte: O autor (2026).

B. Detectores ferromagnéticos

Os Sistemas de Detecção de Materiais Ferromagnéticos (FMDS) foram desenvolvidos especificamente para aplicações em ressonância magnética (RM). Seu princípio de funcionamento baseia-se na detecção de perturbações no campo magnético ambiente causadas pela presença de materiais ferromagnéticos. Como resultado, materiais não ferromagnéticos – como alumínio, cobre, titânio e alguns materiais não ferromagnéticos utilizados em dispositivos médicos – geralmente não acionam alarmes.

Uma das principais características dos FMDS (Figura 2) é a seletividade para materiais ferromagnéticos, o que os diferencia dos detectores de metais convencionais. Essa característica permite direcionar a detecção para objetos que apresentam potencial de interação com o campo magnético e risco de efeito projétil, reduzindo a necessidade de investigação de objetos metálicos que não apresentam esse tipo de propriedade.

Evidências experimentais e clínicas demonstram que o desempenho dos FMDS pode variar de acordo com o sistema utilizado e as condições de avaliação. Em um estudo clínico de implementação, foram realizados 1.032 eventos de triagem em 977 pacientes, com 55 resultados verdadeiramente positivos, 21 falsos positivos e nenhum falso negativo. Nesse estudo, a sensibilidade foi de 100% e a especificidade de 98%, e o tempo adicional associado à etapa de detecção foi considerado pequeno [20]. Em outro estudo, que avaliou 67 implantes e outros objetos em condições experimentais, foram observados 58 verdadeiros positivos, quatro verdadeiros negativos, nenhum falso positivo e cinco falsos negativos, correspondendo a uma sensibilidade de 92% e especificidade de 100% [21]. Esses resultados indicam que o desempenho dos FMDS deve ser interpretado considerando o equipamento, o objeto avaliado e as condições de triagem.

A relação entre sensibilidade, especificidade e ocorrência de falsos alarmes também deve ser considerada na análise dos sistemas, uma vez que esses parâmetros influenciam a necessidade de avaliação adicional durante o processo de triagem [20], [21].

Diretrizes do *American College of Radiology* (ACR) reconhecem os FMDS como recurso complementar aos procedimentos de triagem de segurança em RM, e não como substitutos desses procedimentos. Dessa forma, sua utilização deve ser integrada às medidas de controle de acesso, triagem clínica e administrativa e avaliação da compatibilidade de dispositivos e implantes com a RM [14].

Embora os FMDS sejam direcionados à detecção de materiais ferromagnéticos, determinados objetos, implantes e dispositivos médicos podem não ser detectados ou podem exigir avaliação complementar. Assim, o resultado do sistema deve ser interpretado em conjunto com os demais procedimentos estabelecidos no programa de segurança em RM.

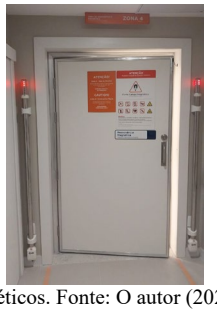

Fig. 2. Detectores ferromagnéticos. Fonte: O autor (2026).

C. Detectores Híbridos

Sistemas de detecção híbridos (Figura 3) combinam as funcionalidades de detectores de metais convencionais e detectores ferromagnéticos em um único dispositivo. Esses

equipamentos podem detectar objetos metálicos em geral e, adicionalmente, identificar materiais ferromagnéticos, permitindo diferenciar, durante a triagem, os objetos que apresentam propriedades ferromagnéticas daqueles que não apresentam.

Alguns dispositivos fornecem indicações separadas para materiais metálicos e ferromagnéticos, o que pode auxiliar na interpretação dos alarmes e ampliar a flexibilidade operacional. No entanto, os sistemas híbridos podem apresentar maior complexidade de operação e exigir treinamento específico dos operadores, dependendo da configuração e das características do equipamento. Aspectos como custo de aquisição, manutenção e requisitos de treinamento devem ser avaliados de acordo com a aplicação e o modelo considerado.

Fig. 3. Detectores híbridos. Fonte: O autor (2026).

D. Comparação de tecnologias

De modo geral, os detectores de metais convencionais apresentam capacidade de detectar diferentes materiais metálicos, incluindo materiais ferromagnéticos e não ferromagnéticos. Essa característica amplia o conjunto de objetos identificados, mas limita a diferenciação entre materiais que apresentam ou não propriedades ferromagnéticas, o que pode exigir avaliação adicional durante a triagem.

Em contrapartida, os sistemas de detecção de materiais ferromagnéticos (FMDS) são direcionados à identificação de objetos com propriedades ferromagnéticas, característica diretamente relacionada à prevenção de eventos de efeito projétil em ambientes de RM. Estudos experimentais e clínicos demonstram que o desempenho pode variar conforme o sistema, o objeto investigado e as condições de utilização [20], [21].

Os sistemas híbridos buscam combinar diferentes princípios de detecção em um mesmo equipamento, podendo ampliar as possibilidades de triagem conforme sua configuração. A escolha da tecnologia deve considerar o objetivo da detecção, o perfil operacional da instituição, o fluxo de pacientes, as características físicas do ambiente, a compatibilidade do equipamento com o campo magnético, os protocolos de segurança, os requisitos de treinamento e manutenção e as regulamentações aplicáveis [14].

VIII. Tipos de detectores utilizados em ambientes de RM

Os sistemas de detecção para RM podem ser encontrados, de acordo com sua configuração física, em formatos portáteis (manuais), do tipo barra e do tipo portal. A escolha da solução mais adequada depende de fatores como o nível de segurança requerido, o fluxo de pacientes, o layout das instalações e a estratégia de gestão de riscos da instituição.

A. Detector portátil

Detectores manuais são dispositivos portáteis alimentados por bateria, destinados à inspeção de pacientes, funcionários, visitantes e objetos. Essa categoria abrange detectores de metais convencionais, ferromagnéticos e híbridos. Sua principal vantagem é a flexibilidade operacional, permitindo a inspeção de pacientes acamados, cadeiras de rodas, macas, incubadoras, cilindros de gases medicinais e equipamentos médicos móveis [22].

O desempenho dos detectores portáteis depende do princípio de detecção, da configuração do equipamento e das características do objeto avaliado. A documentação técnica consultada estabelece procedimentos específicos de varredura e indica a influência das condições de utilização sobre o processo de detecção [22].

Embora possam complementar sistemas fixos, os detectores manuais envolvem inspeção realizada diretamente pelo operador, tornando treinamento, padronização da técnica e verificações periódicas fatores relevantes para sua utilização [22]. Seu uso não substitui os demais procedimentos de segurança estabelecidos para a triagem antes do acesso às áreas controladas da RM [14].

B. Detectores do tipo barra

Detectores do tipo barra consistem em um ou mais sensores fixos instalados próximos a portas, corredores ou pontos de acesso às Zonas III e IV de RM. Os sistemas disponíveis para aplicações em RM utilizam predominantemente tecnologia de detecção de materiais ferromagnéticos e são projetados para operar em ambientes com campos magnéticos estáticos intensos.

Esses sistemas monitoram a passagem de pessoas e objetos, emitindo alarmes visuais e sonoros quando materiais ferromagnéticos são detectados. Em comparação com os detectores portáteis, podem proporcionar maior padronização do processo de triagem e menor dependência da atuação do operador. A configuração e o espaçamento entre sensores devem considerar as características do sistema e as condições específicas de instalação [19].

C. Detectores do tipo portal

Detectores do tipo portal consistem em duas colunas de sensores posicionadas em lados opostos de uma passagem, permitindo o monitoramento de pessoas e objetos que atravessam a área de detecção. Podem utilizar tecnologias convencionais de detecção de metais ou de detecção de materiais ferromagnéticos.

Os portais convencionais identificam diferentes tipos de materiais metálicos, mas não distinguem materiais ferromagnéticos de não ferromagnéticos, constituindo uma limitação para aplicações específicas em RM [14]. Já os portais

ferromagnéticos são projetados para identificar materiais com potencial de interação com o campo magnético e podem proporcionar triagem contínua nos pontos de passagem, inclusive como parte das medidas de controle de acesso às áreas controladas [14].

Características como distância entre sensores, largura da passagem e proximidade de estruturas metálicas devem ser consideradas na configuração e avaliação do sistema [19], [22].

D. Comparação entre os tipos de detectores

Os detectores portáteis oferecem maior flexibilidade operacional, enquanto os sistemas do tipo barra e do tipo portal permitem a detecção em pontos fixos de passagem, podendo proporcionar maior padronização do processo de triagem, conforme sua configuração e as condições de instalação [22].

Entre as tecnologias disponíveis, os sistemas de detecção ferromagnética apresentam como característica a seletividade para materiais ferromagnéticos, aspecto particularmente relevante em ambientes de ressonância magnética (RM), nos quais o potencial de interação com o campo magnético constitui um dos principais critérios de segurança [8]. Estudos de desempenho demonstram, entretanto, que a capacidade de detecção pode variar conforme o sistema utilizado, o tipo e o tamanho do objeto e as condições de avaliação [19], [20], [21]. O Quadro 1 sintetiza as principais características, aplicações, vantagens e limitações dos diferentes tipos de detectores discutidos.

Nenhuma tecnologia de detecção, isoladamente, elimina os riscos associados à RM. A utilização desses sistemas deve estar integrada a um programa de segurança abrangente, que inclua procedimentos de triagem, treinamento da equipe, controle de acesso e identificação da compatibilidade de pacientes, equipamentos e objetos com o ambiente de RM [14]. Nesse contexto, os sistemas de detecção ferromagnética devem ser compreendidos como recursos complementares às demais medidas de segurança.

QUADRO 1. COMPARAÇÃO ENTRE TIPOS DE DETECTORES

Característica	**Detector de metais convencional**	**Detector ferromagnético (FMDS)**	**Detector híbrido**
Princípio de detecção	Detecta diferentes materiais metálicos por meio de campos eletromagnéticos	Detecta perturbações associadas à presença de materiais ferromagnéticos	Combina modos de detecção de materiais ferromagnéticos e, conforme o equipamento, outros metais
Seletividade	Baixa para aplicações em RM, pois não diferencia materiais ferromagnéticos de não ferromagnéticos	Direcionada a materiais ferromagnéticos	Pode combinar diferentes modos de detecção
Aplicação em RM	Uso complementar; não substitui os procedimentos específicos de triagem em RM [14]	Desenvolvido especificamente para aplicações de segurança em RM [8]	Depende das características e da configuração do equipamento
Dependência do operador	Varia conforme a configuração	Tende a ser menor em sistemas fixos; presente em sistemas portáteis	Varia conforme a configuração
Sensibilidade	Depende do equipamento e do objeto avaliado	Depende do sistema, do objeto e das condições de avaliação [19], [20], [21]	Depende do modo de operação e do equipamento
Falsos alarmes	Pode detectar objetos metálicos que não apresentam risco ferromagnético	Pode apresentar alarmes associados às condições de detecção e ao objeto avaliado	Depende do modo de detecção e da configuração
Identificação do risco de efeito projétil	Limitada, pois não diferencia propriedades magnéticas	Maior direcionamento para materiais ferromagnéticos	Depende do modo de detecção
Aplicações típicas	Aplicações gerais de segurança e detecção de metais	Triagem e controle de acesso em ambientes de RM	Triagem em RM, quando o equipamento oferece modos combinados
Principais vantagens	Ampla capacidade de detecção de materiais metálicos	Seletividade para materiais ferromagnéticos e aplicação específica em RM	Flexibilidade de modos de detecção
Principais limitações	Não diferencia materiais ferromagnéticos de não ferromagnéticos	Não substitui os demais procedimentos de segurança e não detecta necessariamente todos os objetos relevantes	Desempenho e aplicação dependem do modelo e do modo de operação

IX. IMPACTOS ECONÔMICOS DE ACIDENTES ENVOLVENDO O EFEITO PROJÉTIL EM AMBIENTES DE RESSONÂNCIA MAGNÉTICA

Embora os acidentes envolvendo materiais ferromagnéticos em ambientes de ressonância magnética (RM) sejam discutidos principalmente sob a ótica da segurança do paciente, suas consequências econômicas também podem ser significativas. Um incidente do tipo "projétil" pode resultar em danos ao equipamento, interrupções operacionais, cancelamentos de exames, necessidade de manutenção corretiva e outros impactos associados à continuidade dos serviços [8], [12].

Em alguns casos, a ocorrência de um incidente pode exigir a interrupção das atividades na sala de RM para avaliação técnica e adoção das medidas necessárias para restabelecer as condições de operação. A duração dessa interrupção e seus custos associados dependem da natureza do incidente, dos danos provocados e das condições específicas do equipamento e da instituição. Estimativas para o custo de acidentes relacionados ao efeito projétil, sem lesão humana, variam de US$ 20.000 a mais de US$ 200.000 [8].

Um *quench* não planejado, caracterizado pela perda da supercondutividade e pela extinção do campo magnético, pode representar uma consequência de elevado impacto operacional em sistemas de RM supercondutores. Além da perda de hélio criogênico, o evento pode envolver custos relacionados ao reabastecimento, transporte e consultoria técnica, bem como período de indisponibilidade do equipamento para realização de exames [7], [23].

O impacto financeiro do tempo de inatividade também pode ser estimado a partir da capacidade operacional do equipamento. Como exemplo hipotético, considerando um sistema de RM que realize 25 exames por dia e um valor médio de R$ 500 por exame, uma interrupção de 20 dias poderia representar uma receita potencial não realizada de R$ 250.000, conforme apresentado no Quadro 2.

Esse cálculo representa uma estimativa ilustrativa de receita não realizada, e não uma estimativa do custo efetivo de um acidente. O impacto econômico real depende de fatores como o volume de exames, o modelo de remuneração, os custos fixos, os custos de manutenção, a duração da indisponibilidade e a possibilidade de transferência dos exames para outros equipamentos.

QUADRO 2. EXEMPLO ILUSTRATIVO DO IMPACTO ECONÔMICO DA INDISPONIBILIDADE DE UM EQUIPAMENTO DE RM

Item	Premissa/estimativa
Exames realizados por dia	25
Valor médio considerado por exame	R$ 500
Receita potencial diária	R$ 12.500
Período hipotético de inatividade	20 dias
Receita potencial não realizada	R$ 250.000

Nota: Os valores apresentados constituem uma simulação hipotética destinada a ilustrar o impacto econômico da indisponibilidade de um equipamento de RM. Não representam custos médios de acidentes nem estimativas de retorno sobre investimento.

Sob a ótica da Engenharia Clínica, a análise econômica dos incidentes deve considerar não apenas os custos diretos de reparo, mas também os efeitos associados à indisponibilidade do equipamento e à continuidade dos serviços. Nesse contexto, medidas de segurança, incluindo procedimentos de triagem, treinamento da equipe, controle de acesso e sistemas de detecção ferromagnética, podem ser analisadas como componentes de uma estratégia integrada de gerenciamento de riscos operacionais.

A análise evidencia que a indisponibilidade de equipamentos de RM pode representar impacto econômico relevante para os serviços de diagnóstico por imagem. A avaliação do custo-benefício da implementação de sistemas de detecção ferromagnética, entretanto, requer dados específicos sobre custos de aquisição e manutenção, frequência de incidentes, desempenho dos sistemas e perdas potencialmente evitadas.

X. PERSPECTIVAS FUTURAS

A evolução dos Sistemas de Detecção de Materiais Ferromagnéticos (FMDS) está associada às demandas por maior segurança em ambientes de ressonância magnética (RM), padronização dos processos de triagem, rastreabilidade e continuidade operacional. Nesse contexto, observa-se uma tendência de integração dos sistemas de detecção com outros recursos de segurança e gerenciamento das instalações de RM.

Os sistemas FMDS disponíveis atualmente podem incorporar recursos como monitoramento remoto, armazenamento de eventos, gerenciamento de alarmes e integração com sistemas de controle de acesso, de acordo com as características de cada equipamento [22]. Recursos de inteligência artificial (IA) e análise de dados também apresentam possibilidades de aplicação na identificação de padrões de eventos, apoio à gestão de alarmes e análise de informações operacionais. Essas aplicações, entretanto, ainda devem ser avaliadas quanto à sua efetividade e confiabilidade em contextos específicos de segurança em RM.

Outra possibilidade é a integração dos sistemas de detecção com mecanismos de controle de acesso, dispositivos de sinalização e outros elementos da infraestrutura das salas de RM. Nessas configurações, informações provenientes da triagem podem ser utilizadas em conjunto com mecanismos de controle de acesso às áreas restritas e sistemas de comunicação de eventos. A adoção de mecanismos de intertravamento deve considerar os requisitos de segurança, o fluxo operacional e a necessidade de preservar procedimentos de intervenção e controle manual.

Esses desenvolvimentos apontam para uma possível evolução das instalações de RM em direção a ambientes mais integrados, nos quais sistemas de detecção, controle de acesso, sinalização e gerenciamento de informações possam atuar de forma coordenada. A convergência entre detecção de materiais ferromagnéticos, automação, análise de dados e recursos de Saúde Digital constitui uma perspectiva para o desenvolvimento de sistemas de segurança mais integrados e rastreáveis.

XI. CONCLUSÃO

A ressonância magnética (RM) consolidou-se como uma das principais modalidades de diagnóstico por imagem na medicina moderna. Entretanto, a presença de um campo magnético estático de alta intensidade envolve riscos específicos, demandando medidas de segurança adequadas e continuamente aprimoradas.

Acidentes envolvendo a introdução de objetos ferromagnéticos em ambientes de RM demonstram que falhas nos processos de triagem e controle de acesso podem resultar em lesões graves, óbitos, danos ao equipamento, interrupções operacionais e impactos financeiros. Consequentemente, a segurança em RM deve ser compreendida como um processo multidisciplinar baseado em múltiplas camadas de proteção.

Nesse contexto, os Sistemas de Detecção de Materiais Ferromagnéticos (FMDS) constituem um recurso complementar aos procedimentos de segurança em RM. Diferentemente dos detectores de metais convencionais, esses sistemas são direcionados à identificação de materiais ferromagnéticos, característica relevante para a avaliação de objetos com potencial de interação com o campo magnético. As diferentes configurações de FMDS, incluindo sistemas portáteis, do tipo barra e do tipo portal, apresentam características operacionais distintas e devem ser selecionadas de acordo com as necessidades da instituição e as condições específicas de instalação.

No entanto, nenhuma tecnologia isolada pode eliminar completamente os riscos associados à RM. A utilização dos FMDS deve estar integrada a programas de segurança abrangentes que incluam zoneamento, procedimentos de triagem, treinamento de pessoal, identificação da compatibilidade de objetos e dispositivos e controle de acesso

às áreas restritas. Considerando esses aspectos, sua adoção deve levar em conta as características da instituição, o fluxo de pacientes e equipamentos, os procedimentos de segurança existentes e as condições específicas de instalação [14].

Este estudo apresenta como limitação seu delineamento de análise técnico-narrativa, baseado em pesquisa bibliográfica não sistemática, pesquisa documental e análise reflexiva da experiência profissional do autor, não contemplando comparações experimentais próprias ou análises estatísticas de desempenho entre diferentes sistemas de detecção. Estudos futuros podem investigar comparativamente o desempenho, a efetividade operacional e o custo-benefício de diferentes configurações de FMDS, utilizando avaliações multicêntricas e dados operacionais de diferentes instituições.

***Abstract*—The sterile barrier system is a critical component in the medical device processing chain, responsible for ensuring the sterility of surgical instruments until their time of use. This study analyzes the consequences of the variability of operational parameters, such as specifically temperature, pressure, and dwell time/speed, within the heat-sealing process of medical grade paper and laminated film packaging, within the framework of ABNT NBR ISO standards and local perioperative guidelines (SOBECC). Through a structured review of the technical literature and materials engineering principles, we investigated how deviations in these three fundamental axes compromise seal integrity, focusing on the delamination phenomenon. The results indicate that underheating and insufficient thermal dwell time lead to incomplete polymer fusion and premature delamination. In contrast, overheating and overpressure trigger thermal degradation of the materials and polymer extrusion, causing cohesive tearing of the paper matrix and the subsequent release of cellulose microfibers during aseptic opening (peel-off). We conclude that mitigating heat-sealing failures and reducing operator-dependent variability are strongly associated with the integration of hardware and software technological solutions into modern heat sealers, in conjunction with automatic interlocking systems, based on the technical and normative literature reviewed, rather than on experimental or clinical data. Ultimately, this study is intended as a practical framework to support Clinical Engineering departments in conducting procurement, qualification, and routine analysis in compliance with current standards and guidelines, contributing to patient safety and to mitigation of healthcare-associated infections.**

***Index Terms*—Heat sealing, sterile barrier system, delamination, process validation, clinical engineering.**

I. Introduction

Central Sterile Supply Departments (CSSDs), or medical device processing units, are essential sectors within healthcare facilities responsible for processing medical devices, including critical stages such as cleaning, preparation, sterilization, storage, and distribution. Within this workflow, the packaging and sealing stage plays a determining role in maintaining the sterility of the device until the exact moment of clinical use.

The integrity of the Sterile Barrier System (SBS) is the primary factor in ensuring that a sterilized product remains free of microbiological contamination. This system is defined as the minimum packaging capable of preventing the ingress of microorganisms while simultaneously allowing aseptic presentation of the product at the point of use. In this context, sealing is not merely an operational step, but a critical process that directly impacts patient safety.

Brazilian regulation, through the normative resolution RDC No. 15/2012 [1], reinforces that the packaging architecture must allow the penetration of the sterilizing agent while concurrently preventing the entry of contaminants. Furthermore, the standard establishes that seal integrity is one of the key factors considered when defining the shelf life of the sterilized device, highlighting the relevance of this engineering process within the healthcare assistance context.

In the CSSD environment, the execution of the sealing process must strictly follow the guidelines provided by both the packaging material manufacturers and the equipment developers. To achieve this, Clinical Engineering departments must technically support CSSD management during equipment procurement, ensuring that selected automated heat-sealing technologies feature the mandatory metrological controls required to ensure process standardization, repeatability, and reliability. Accordingly, this study does not propose new universal design requirements; it offers an applied technical synthesis intended to support equipment specification, procurement, qualification, and routine monitoring by Clinical Engineering teams, grounded in currently available standards, professional guidelines, and technical literature.

II. Literature Review

A. Review Methodology

This study is based on a narrative, non-systematic review of Brazilian and international normative documents (ABNT NBR ISO 11607-1/2 [2], [3] , ABNT ISO/TS 16775 [4], ABNT NBR ISO 17665-1/2 [5], [6], ABNT NBR 14990 [6], ASTM F88 [7], EN 868-5 [8] the SOBECC perioperative guidelines [9], and complementary technical and manufacturer literature on heat-sealing equipment used in CSSD environments. Sources published up to 2023 and available in Portuguese or English were considered; documents were included when they directly addressed sterile barrier system sealing requirements,

validation, or process parameters, and excluded when addressing sterilization modalities or packaging materials outside this scope. Recommendations were extracted by cross-referencing normative requirements with the technical and engineering literature and are identified throughout the manuscript as originating from standards, professional guidelines, manufacturer specifications, or the authors' own engineering interpretation.

B. Normative and Technical References

The primary normative reference for medical device packaging sealing processes is the ABNT NBR ISO 11607 standard, particularly Part 2 [3], which specifies the validation requirements for forming, sealing, and assembly processes of packaging systems.

This standard establishes that every sealing process must be duly validated, ensuring that the sterile barrier system fulfills its essential functions: enabling sterilization, maintaining sterility, and allowing aseptic presentation. Consequently, it requires the definition, monitoring, and control of critical process parameters (CPPs), notably temperature, contact pressure, and dwell time (or sealing speed in rotary continuous sealers).

Furthermore, the standard emphasizes that seal quality must be demonstrated through measurable and verifiable characteristics. Key among these characteristics are adequate mechanical seal strength, seal continuity, the absence of structural defects (such as channels, pinholes, or tears), and the absence of material delamination, especially in systems designed for peel-open aseptic presentation.

The ABNT ISO/TS 16775 technical specification [4] provides practical guidance for applying these requirements, highlighting relevant operational aspects for healthcare institutions, such as correct packaging dimensioning, material compatibility, and the critical importance of controlling sealing parameters.

The ABNT NBR 14990-7 standard [6] describes the strength and integrity testing protocols for seals, ensuring the safety and reliability of the packaging system when subjected to the sterilization process.

The ABNT NBR ISO 17665 standard [5] focuses strictly on the requirements for the development, validation, and routine control of moist heat (steam) sterilization processes for medical devices. Although it does not dictate isolated rules for heat sealers, it determines that the SBS, which encompasses the sealing of packages within CSSD environments, must be fully integrated and validated to guarantee that steam penetrates the material and maintains its sterile state until point of use.

Finally, the ASTM F88 standard [7] defines the standard test methods for seal strength testing via tensile and peel testing to measure the mechanical force of flexible barrier material seals, such as medical grade paper, within the CSSD environment. It establishes testing techniques and acceptance criteria to ensure that the seal is neither too weak, which would compromise sterility, nor excessively strong, which would cause material tearing and subsequent particulate contamination during opening.

III. Technical Aspects of Heat Sealing

Heat-sealing equipment, particularly the thermal sealers deployed in CSSDs, must exhibit technical characteristics that guarantee strict process control. A fundamental requirement is the ability to continuously monitor and control the Critical Process Parameters (CPPs), namely temperature, pressure, and dwell time.

Furthermore, these devices must be equipped with alarm systems or hardware/software safety mechanisms designed to interrupt the cycle or alert the operator in the event of any deviation from the established operating parameters. This functionality is essential to prevent the production of inadequate seals that could compromise the integrity of the sterile barrier system.

The Brazilian regulatory standard RDC No. 15/2012 [1] establishes periodic calibration of heat sealers with a minimum annual frequency, Under a clinical engineering asset management framework, this calibration must not be treated as a mere administrative milestone, but as a continuous metrological safety program where Clinical Engineering monitors sensor drift tolerances to safeguard the reliability of measurement and the long-term performance of the equipment.

Another relevant aspect is the requirement for comprehensive equipment documentation, including operation manuals, preventive maintenance logs, calibration certificates, and standard operating procedures (SOPs). In addition, operators must undergo structured training and qualification, as the human factor is an integral component of the overall process validation.

Seal quality evaluation must be performed using well-defined criteria to ensure the integrity and functionality of the sterile barrier system. Sealing tracks must present a uniform aesthetic aspect, featuring adequate width and a smooth, continuous surface free of wrinkles, bubbles, fractures, or delamination.

Seal strength is a fundamental parameter; it must be sufficient to maintain integrity of the packaging during transportation, storage, and handling, without hindering the subsequent aseptic presentation. To evaluate this mechanical property, specific destructive protocols are utilized, such as the tensile seal strength test described in ASTM F88 [7].

Additionally, two integrity testing methods are widely employed to detect sealing failure pathways, such as channels or micro-leaks: the dye penetration test and the bubble leak test.

The Dye Penetration Test (Ink Test) is specifically engineered to detect channels and discontinuities along the sealing line caused by insufficient pressure or underheating. It relies on capillary action; if a micro-channel is present, the liquid solution will migrate through it. The standards ABNT NBR ISO 11607-2 [3] and ABNT ISO/TS 16775 [4] recommend the dye test as physical and documentable evidence during Operational Qualification (OQ) and Performance Qualification (PQ), as well as routine daily monitoring in CSSD workflows, in accordance with local perioperative guidelines (SOBECC) [9].

The Bubble Leak Test is an integrity assay based on internal pressurization. While the dye test targets chemical capillarity, the bubble test utilizes differential air pressure to indicate pinholes, tears, or macroscopic seal failures. Following SOBECC guidelines [9], this method serves as an alternative for evaluating the global resistance of the sterile barrier against macroscopic defects.

Visual inspection also plays an important role as a tool for continuous monitoring, although it is insufficient as a standalone evaluation method.

The validation of these testing methodologies is equally mandated by current standards, which state that the assays must demonstrate adequate repeatability, reproducibility, and sensitivity for defect detection.

Finally, packaging sealing is directly correlated with the efficacy of the sterilization process. The ABNT NBR ISO 17665-1 standard [5] establishes that packaging systems must withstand processing conditions, including acute variations in temperature, pressure, and humidity, without compromising their physical integrity. Ultimately, the standard demands that the packaging system's integrity be verified during sterilization process qualification and throughout routine activities. This includes physical inspection of processed loads and verification that the sterile barrier system remains structurally intact after the cycle.

IV. Primary Sealing Failures

The literature on sterile barrier systems highlights that seal strength depends directly on proper stabilization and combination of three critical variables: temperature, contact pressure, and dwell time. Figures 1–6 illustrate representative seal defects associated with the corresponding process deviation for didactic purposes; they do not constitute a controlled experimental dataset with fully disclosed packaging materials or process parameters, and are used here to support qualitative, not quantitative, discussion of each failure mode.

According to the guidelines of the Brazilian Association of Operating Room Nurses, Anesthesia Recovery and Central Sterile Supply Center (SOBECC) [9] and the requirements of the ABNT NBR ISO 11607-2 standard [3], deviations in sealing temperature due to underheating or overheating compromise the integrity of the sterile barrier system, resulting in incomplete fusion or material embrittlement.

When the sealer temperature falls below the lower threshold recommended by the manufacturer and technical standards (underheating - Fig.1), the thermal energy is insufficient to properly melt the plastic layer (polymer) and bond to medical grade paper.

- **Weak or Partial Sealing**: Incomplete fusion results in inadequate adhesion. Visually, the sealing track may appear continuous, but it lacks the necessary mechanical peeling strength.
- **Premature Opening (Delamination)**: Packaging may open spontaneously during handling, transport, or inside the autoclave itself due to pressure fluctuations during the sterilization cycle.

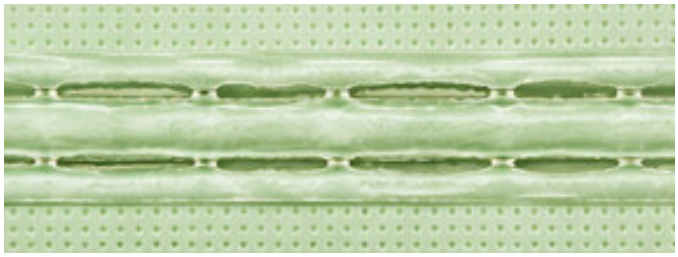

Fig. 1. Low Temperature Seal

Fig. 2. High Temperature Seal

- **Loss of Sterile Barrier**: Any micro-gap resulting from poor polymer fusion negates the packaging's barrier properties, allowing the ingress of microorganisms and contaminating the device.

In contrast, a temperature exceeding the upper threshold (overheating - Fig. 2) burns or degrades the packaging materials.

- **Plastic Crystallization and Embrittlement**: Excessive heat alters the molecular structure of the plastic film, making it rigid and brittle.
- **Micro-perforations and Scorching**: Medical grade paper or the film may develop micro-holes or tears along the sealing line that are imperceptible to the naked eye.
- **Incorrect Opening (Tearing/Fiber Shedding)**: When the package is opened within the sterile field, the thermally degraded paper will tear or peel irregularly (erratic delamination), releasing cellulose fibers and particulate matter that can fall into the surgical site or contaminate the instruments.
- **"Permanent Bonding" Effect**: The film undergoes excessive fusion, hindering proper aseptic peel-open presentation. This forces healthcare personnel to use scissors, increasing the risk of breakthrough contamination.

Furthermore, in accordance with the ABNT NBR ISO 11607-2 standard [3], the sealing pressure is another critical process parameter that directly affects the uniformity of the fusion. Failure to control this compressive force, whether through underpressure or overpressure, compromises the structural integrity of the sterile barrier system, as established by SOBECC safety guidelines [9].

When the compressive force exerted by the heat sealer is less than the validated parameters (underpressure), the two packaging layers are not pressed together with the necessary

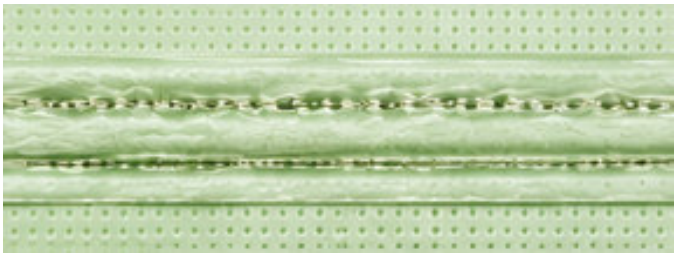

Fig. 3. Low pressure seal

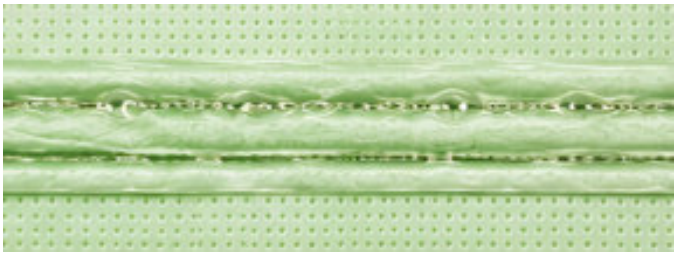

Fig. 4. High pressure seal

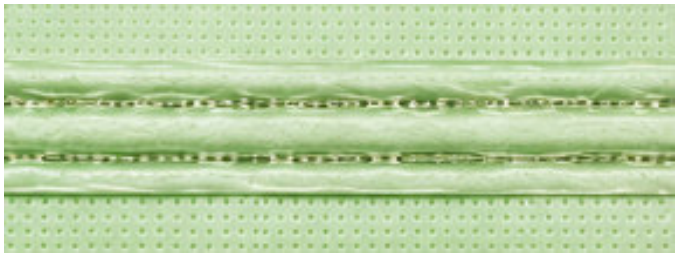

Fig. 5. High speed seal

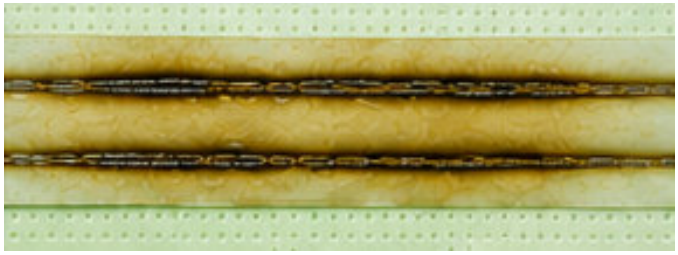

Fig. 6. Low speed seal

intensity. Fig. 3 illustrates the outcome of a low sealing pressure.

- **Incomplete or Intermittent Sealing**: Even if the temperature is correct, insufficient pressure prevents the molten plastic from properly penetrating the microfibers of the medical grade paper. This generates falsely sealed areas known as "blind spots" or "air islands."
- **Micro-leakage Channels (Canaliculus)**: Underpressure creates micro-channels along the sealing track. These channels, invisible to the naked eye, act as pathways for microbial ingress, breaking the sterile barrier before clinical use.
- **Low Mechanical Strength**: The package will exhibit low seal strength, rupturing easily under the weight of the surgical instrumentation or due to physical pressure differences inside the autoclave during the vacuum phase.

In contrast, excessive mechanical force crushes the packaging materials beyond the structural tolerance of the components. This effect is shown in Fig. 4.

- **Polymer extrusion ("Squeezed" Plastic)**: Excessive pressure pushes the molten plastic out of the original sealing line. This leaves the central zone of the seal extremely thin, weakened, and susceptible to bursting.
- **Paper Piercing and Shearing**: The excessive force of the sealing bars can cut, crush, or weaken the fibers of the medical grade paper at the edge of the seal, creating points of immediate tearing or micro-perforations.
- **Incorrect Polymer Transfer Upon Opening**: When the healthcare professional opens the pouch utilizing the aseptic peel-open technique, the effects of overpressure cause the paper matrix to tear rather than detach smoothly from the plastic film. This removes particulate matter and destabilizes the safety of the aseptic presentation.

The thermal dwell time, or the packaging traction speed through the sealer, is the critical process parameter that governs the efficiency of heat transfer. If the substrate travels too quickly or too slowly across the sealing bars, the thermal-mechanical equilibrium of the process is disrupted, directly compromising the security of the sterile device.

When the heat sealer operates at a linear velocity higher than the validated baseline (sub-exposure), the pouch travels too quickly across the heated elements, reducing the physical contact time, as illustrated in Fig. 5.

- **Insufficient Thermal Input (Under-dwelling)**: Even if the bar temperature is accurately regulated, the polymer does not remain in contact with the heat source long enough to reach its melting point.
- **"False" or Superficial Sealing**: The plastic film undergoes merely a visual, aesthetic alteration, appearing bonded without achieving an intimate, intermolecular fusion within the porous matrix of the medical grade paper. Under minimal physical stress (such as the weight of a surgical instrument tray), the layers immediately separate.
- **Discontinuity Genesis**: Excessive linear velocity prevents the stabilization of pressure and heat distribution along the sealing track, generating intermittent bonding points interspersed with completely unsealed pathway.

In contrast, when the packaging advances too slowly or remains stationary between the heating bars beyond the specified threshold, it induces an over-exposed state that causes severe structural degradation, as depicted in Fig. 6.

- **Total Thermal-Mechanical Degradation**: Excessive exposure to heat melts the plastic and dries out the cellulose fibers of medical grade paper.
- **Melting-induced Punctures**: The plastic film can liquefy to the point of shrinking, piercing, or rupturing entirely

within the sealing track, rendering the packaging immediately defective.
- **Adhesion to Sealing Bars**: Over-fused plastic may adhere to the internal components of the machine (such as Teflon belts or heating bars), jamming the equipment, tearing the pouch, and contaminating the sealing path with burned residues.

V. Root Cause Analysis of Delamination

One of the most prevalent failure modes within the medical sterilization cycle is package delamination. In heat-sealing processes, delamination is defined as the undesirable separation of the constituent layers of a multilayer material during or after thermal sealing, resulting in a total loss of the laminate's structural cohesion. Within sterile barrier systems for medical devices, this is classified as a critical failure. It severely compromises sterile barrier integrity, hinders aseptic presentation at the point of use, and breaches the strict compliance criteria of the ABNT NBR ISO 11607 standard [2], [3] for terminally sterilized medical device packaging. Although sealing-parameter deviations are a major and well-documented trigger, delamination may also result from interactions among substrate composition, adhesive properties, material aging, environmental humidity, sterilization conditions, storage, and packaging manufacturing quality. This study focuses specifically on the sealing-process contribution to delamination, without excluding these other contributing factors.

In a multilayer packaging structure (e.g., PET film + adhesive + PE, or Tyvek® + plastic film), distinct bonding interfaces exist. When the package is opened correctly, material separation must occur exclusively at the interface specifically engineered for peeling. Conversely, when delamination occurs, the applied mechanical force overcomes the internal adhesion between the laminate layers, producing partial peeling, loose fibers, material residues, irregular tearing, and potential particulate generation. In sterile medical devices, this phenomenon is particularly critical as it invalidates aseptic presentation.

A. Failures Induced by Underheating or Sub-exposure (Incomplete Bonding)

In this scenario, delamination occurs prematurely and spontaneously prior to clinical use (during autoclaving, transport, or storage) because the interface materials never achieved true intermolecular fusion.

- **Temperature Below Specification**: Without the required thermal energy input, the plastic polymer does not reach its softening or melting point, merely contacting the paper matrix without penetrating its microfibers. Consequently, any physical vibration or internal pressure differential inside the autoclave causes the plastic film to completely detach from the paper (fusionless delamination).
- **Insufficient Dwell Time / High Sealing Speed**: Even if the temperature is accurate, if the packaging travels too quickly across the heating bars, thermal transfer cannot be successfully completed. This yields a superficial seal that undergoes immediate delamination under minimal mechanical stress.

B. Failures Induced by Overheating (Thermal Degradation)

Delamination caused by overheating manifests during aseptic opening within the surgical field, occurring in an irregular, defective manner that introduces biological risks. Excess heat degrades the chemical bonding properties of the plastic film and severely desiccates the cellulose fibers of medical grade paper. Upon attempting to open the package using the proper peel-open technique, instead of a smooth film detachment, the layers fracture into splinters or scale off. The paper matrix splits internally (delaminates), shedding cellulose microfibers that contaminate the surgical field.

C. Failures Induced by Overpressure (Mechanical Crushing)

Under excessive mechanical compression, delamination also manifests itself erratically during opening within the operating room. Excessive force crushes and extrudes the molten polymer from the original sealing line. The remaining plastic within the joint becomes extremely thin and brittle. During aseptic opening, this weakened track does not withstand tensile stress, scaling irregularly, and tearing the paper fibers instead of achieving a flawless, clean peel.

VI. Qualification Process

According to the mandates of the ABNT ISO/TS 16775 technical specification [4], which provides guidance on the application of the ABNT NBR ISO 11607-1 [2] and ABNT NBR ISO 11607-2 [3] standards, the heat-sealing equipment must undergo Installation Qualification (IQ), Operational Qualification (OQ) and Performance Qualification (PQ). Unless explicitly attributed to a cited standard, the specific numerical values, examples, and workflows described in this section (e.g., temperature boundaries, seal-strength reference values, and setpoint-definition criteria) illustrate common clinical-engineering and industry practice rather than requirements mandated verbatim by the referenced documents. These sequential validation stages, co-executed and formally approved by Clinical Engineering and CSSD specialists, stages enable the characterization and definition of the safe operating window of the process.

During Installation Qualification (IQ), it is recommended to employ a structured checklist to evaluate physical installation status, verifying previous calibration procedures backed by official certificates, as well as the implementation of a continuous calibration program. This ensures that the sealing parameters remain accurate throughout the use of the equipment. Furthermore, environmental conditions (such as cleanliness, ambient temperature and relative humidity) must be observed, along with documented operator training and the availability of operating manuals or standard operating procedures (SOPs).

Critical Process Parameters (CPPs) must be clearly established, encompassing at least contact pressure, temperature, and sealing dwell time or speed. For rotary continuous sealers, the dwell time is expressed as the sealing speed (e.g. meters

per minute). For bar sealers, the dwell time represents the exact duration for which the heated bars remain in direct contact with the packaging substrates. The sealing temperature must comply with the sterile barrier system manufacturer's technical specifications. Additionally, the heat sealer must feature integrated control and monitoring hardware for these CPPs, incorporating alarm/warning systems or automatic cycle interruption mechanisms if parameters drift beyond acceptable limits.

During Operational Qualification (OQ), usability aspects are assessed, including the identification of the target sealing temperature, which varies depending on the polymeric formulation of the sterile barrier system. The upper and lower boundaries for temperature, pressure, and dwell time must be rigorously mapped. The equipment manufacturer must demonstrate the monitoring mechanism for these variables. The sealer must be technically capable of operating within the boundaries recommended by the preformed sterile barrier system manufacturer. Higher flexibility in boundary configuration translates to enhanced equipment performance across the wide range of commercially available sterile barrier systems.

Testing during OQ must be performed at the established lower and upper temperature boundaries after the equipment calibration has been finalized. The primary acceptance criteria for process approval include seal integrity, which must remain intact without gaps, channels, punctures, wrinkles, folds, or material delamination.

For seal and temperature characterization, a minimum mechanical seal strength threshold is required. Following European reference standards (EN 868-5 [8]), which are widely adopted in the absence of local regulatory values, a minimum reference value of 1.5 N per 15 mm is established for moist heat sterilization processes and 1.2 N per 15 mm for alternative sterilization methods.

Commercially available dye penetration test kits or other seal integrity indicators can also be deployed, provided that all test results are formally documented.

To complement the validation matrix, the Seal Test is deployed as a critical indicator for routine monitoring and quality control across both Operational Qualification (OQ) and Performance Qualification (PQ) stages, in accordance with the ABNT ISO/TS 16775 technical specification [4]. During the OQ phase, the chemical indicator sheets are processed at the established upper and lower temperature boundaries to physically challenge and verify seal continuity, ensuring the absence of unsealed channels or structural gaps even under extreme operational limits. In contrast, within the PQ workflow and routine monitoring, the Seal Test is recommended by SOBECC [9] and widely adopted in clinical practice as a pre-production verification tool under nominal parameters, providing documented, reproducible evidence that the heat sealer successfully transfers uniform thermal-mechanical energy to achieve complete polymer fusion across the porous matrix, in compliance with the visual evaluation criteria specified in the EN 868-5 standard [8].

Following the operational boundary evaluation, if quality requirements are successfully satisfied at both the upper and lower boundaries, the process setpoint is commonly defined, as an engineering convention rather than a universal normative rule, as the arithmetic mean of these two values (e.g., a lower limit of $180°C$ and an upper limit of $190°C$ produce a baseline sealing temperature of $185°C$); institutions may adopt other criteria within the validated range.

Finally, Performance Qualification (PQ) evaluates whether the validated process consistently produces compliant sterile barrier systems under actual routine operational conditions.

VII. Engineering Design Features for Preventing Delamination Failures

A. Sensing and Mechanical Hardware

Modern heat-sealing instrumentation incorporates dedicated hardware mechanisms intended to support metrological traceability and precision material handling, thereby reducing operator dependency.

- **High-Response Temperature Sensors**: Some advanced equipment embeds platinum resistance thermometers (RTDs, such as Pt100/Pt1000) directly into the heating block as an alternative to standard thermocouples. Depending on system architecture, calibration, and dynamic-response requirements, RTDs can provide high-resolution, near-continuous temperature readings that help mitigate thermal inertia; sensor choice should nonetheless be based on the specific metrological requirements of each equipment design rather than treated as a universally superior solution.
- **Independent Upper and Lower Bar Temperature Control**: Although European reference standards (EN 868-5 [8]), frequently adopted in the absence of national specifications, state that the temperature baseline can be determined by the arithmetic mean of both elements, acute thermal asymmetries between the two bars compromise sterile barrier integrity. For instance, while an average target specification of $180°C$ can be achieved through symmetric distributions ($175°C/185°C$), asymmetric profiles (e.g., $150°C$ upper and $230°C$ lower) induce uneven polymer melting and subsequent delamination.
- **Adjustable Infeed Guides and Automated Traction**: The operator simply positions the packaging edge against the input guide, after which synchronized drive belts pull the substrate forward at a locked linear speed. This design feature is intended to reduce human variability regarding the thermal exposure time.

B. Embedded Control Software

Embedded software serves as an active control instrument, enforcing compliance with critical parameters validated during qualification protocols, as mandated by the ABNT NBR ISO 11607-2 standard [3].

- **Process Window Monitoring (OQ Limits)**: During the Operational Qualification (OQ) phase, a safe operating window is assigned (e.g., $180°C$ to $185°C$). The firmware

automatically restricts machine operation if the system parameters drift outside this validated range.

- **Alarm Systems and Mechanical Interlocking (Machine Stop)**: This functionality reflects the process-monitoring and deviation-response mechanisms required by ABNT NBR ISO 11607-2 [3] for a validated sealing process, and is commonly implemented as a strict operational safeguard in commercially available equipment. If the temperature drops below a validated tolerance around the setpoint (a 2°C deviation is a common illustrative threshold in commercial equipment, though the exact value must be defined for each sterile barrier system during OQ) or if the drive velocity fluctuates, the software triggers a visual/audible alert and immediately de-energizes the traction motor, physically preventing the processing of non-compliant packaging.
- **Advanced Temperature Regulation**: Microprocessor-driven control loops (such as Proportional-Integral-Derivative - PID algorithms) mathematically calculate instantaneous heat dissipation as a pouch enters the track, dynamically modulating electrical power to the heating elements to maintain a linear thermal baseline.

C. Digital Traceability and Data Logging

Digital traceability and data logging solutions provide verifiable assurance that each sealing cycle adheres to the validated standard.

- **Supervisory Control and Data Acquisition (SCADA) Integration**: Equipment architecture may include communication ports (Ethernet, USB, or RS-232) to export real-time temperature, pressure, and dwell time data logs for every processed pouch. Should a specific batch exhibit post-processing delamination, Clinical Engineering acts as a root-cause investigator, auditing these computerized SCADA logs to correlate thermodynamic deviations with structural laminate failures, preventing speculative adjustments and ensuring data-driven troubleshooting at the precise second of execution.
- **Integrated Process Inking**: Another technological alternative involves coupling an inline ink jet printer to the output terminal, printing data such as processing date, lot number, operator ID, and a ”valid parameters” verification string directly onto the substrate. If the equipment drifts from its validated baseline, printing is instantly suspended, which yields immediate visual evidence of the error on the package itself.

D. Troubleshooting Guidance

Equipment developers provide detailed troubleshooting guidelines in their technical manuals to diagnose and mitigate active delamination failures:

- **Sealability Curve Optimization**: Technical documentation provides cross-referenced matrices correlating substrate formulation with ideal temperature and linear velocity combinations.
- **Polytetrafluoroethylene (PTFE/Teflon) Tape Replacement**: Manuals mandate the routine replacement of protective PTFE barriers. If the Teflon layer degrades, the packaging film adheres to the exposed heating bar, causing catastrophic delamination through scorching and material drawing.
- **Compulsory Calibration Cycles**: Technical instructions explicitly dictate that internal metrological sensors undergo calibration by laboratories accredited under national metrological networks (such as the RBC - Rede Brasileira de Calibração) to verify that the digital readout accurately reflects the true thermal energy transferred to the polymer matrix.

VIII. Conclusion

The safety and efficacy of medical device processing depend heavily on maintaining instrument sterility until the exact moment of clinical deployment within the surgical field. Within this framework, the heat-sealing process transcends being a mere mechanical closure step, assuming the role of a critical biomedical engineering procedure whose predictability and repeatability are guaranteed by rigorous control of critical process parameters: temperature, contact pressure, and thermal dwell time.

Operational deviations in any of these three core variables compromise the validated process window established under the guidelines of the ABNT NBR ISO 11607-2 standard [3], ultimately triggering structural delamination failures. Consequently, continuous validation and automated monitoring of sealing parameters are not simply bureaucratic or regulatory exercises mandated by ISO standards or local perioperative guidelines (SOBECC) [9]. Rather, they constitute a fundamental risk mitigation and quality assurance strategy driven by the joint efforts of CSSD nursing and Clinical Engineering.

A. Study Limitations and Research Gaps

As the recommendations are based predominantly on a literature and normative review rather than on experimental testing or case analysis in real hospital settings, claims regarding elimination of human error, direct reduction of infection rates, and superiority of specific equipment architectures should be regarded as hypotheses for future validation rather than established outcomes. This study’s main contribution is the integrated analysis of normative requirements, clinical-engineering practice, and delamination mechanisms into a single applied technical framework, complementing existing standards and technical guides that typically address these aspects separately. Adopting these recommendations in practice will also depend on each institution’s infrastructure, budget, staff training, and access to compatible equipment and consumables, which may limit or delay implementation in some CSSD settings. In summary, this review indicates that explicit control and documentation of temperature, pressure, and dwell time are consistently required across the standards analyzed. Delamination emerges as the most frequently reported critical failure, although it is rarely attributed to a

single process variable. In addition, automation and digital traceability are recurring engineering approaches aimed at reducing operator-dependent variability. The main identified research gaps are the scarcity of published experimental data directly linking specific sealing-parameter deviations to seal-strength or delamination outcomes, and the absence of studies correlating sterile barrier system performance with clinical infection indicators.

This collaborative framework connects the metrological precision of clinical instrumentation with sterile barrier integrity, which is recognized in the literature as a contributing factor to surgical site infection prevention, positioning the sterile barrier system as an important element in safeguarding patient safety and clinical outcomes. Establishing a quantitative link to Surgical Site Infection (SSI) rate reduction would require dedicated clinical and experimental studies beyond the scope of this technical review.

IX. Acknowledgments

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brazil (CAPES) – Finance Code 001 and the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) (309464/2022-6 to HTM). The authors thank Persei Sistemas Eletroeletrônicos for providing the images used in this study and for their valuable contributions that enabled a better understanding of the primary challenges in the thermal sealing process.

***Abstract*— Noise may be an important problem in medical decision making which includes establishing diagnoses, assessing conditions, or deciding upon management options among others. When medical professionals make different decisions despite being faced with the same information this can be termed noise, that is, unwanted, random variability in decision making. The focus of this work is on the analysis of statistical noise during the process of classifying the surgical complexity of cleft lip and palate, which are facial congenital malformations in fetal development. Their anatomical description involves, in general terms, the lip, the alveolus, and the palate (hard and/or soft), and may occur in isolated or combined form, unilateral or bilateral. In this work, two models that propose a classification for cleft lip and palate developed at the Comprehensive Center for Cleft Lip and Palate of Mexico (SUMA Center) were analyzed. Model 1 proposes a classification of 29 classes based on the location of the cleft, and Model 2, proposes a classification of 15 classes based on the anatomical characteristics of the cleft. The objective of this work was to evaluate the statistical noise of both classification models in a sample of 105 patients treated at the SUMA Center using ordinal coherence, increase and Shannon entropy between classes of both models. To complement the analysis, we use Spearman's rank correlation coefficient and, Kendall's tau coefficient to quantify the degree to which the ordering of classes is aligned with increasing surgical complexity. The results indicated that Model 2 exhibits lower structural statistical noise than Model 1.**

Keywords—Statistical noise, medical decision making, cleft lip and palate classification.

I. Introduction

Unwanted random variability of judgment, commonly referred to as "noise," is an inherent phenomenon in human decision-making and has been documented across a wide range of disciplines, including medicine. Unlike systematic bias, which consistently skews decisions in a particular direction, noise introduces inconsistency and unpredictability, leading to variability in outcomes even when the same information is available. One important subtype is occasion noise, which arises from transient factors associated with the moment in which a decision is made. These factors include physiological and psychological states such as stress, fatigue, hunger, cognitive load, time pressure, and overall workload. Such influences can subtly alter perception, reasoning, and judgment, thereby affecting decision outcomes [1].

In the context of medical practice, noise represents a particularly critical yet underexplored issue. Clinical decision-making involves complex cognitive processes, including diagnosis, evaluation of disease severity, and selection of treatment strategies. Variability in these decisions can have direct consequences for patient outcomes, safety, and quality of care. Despite its potential impact, the systematic measurement and characterization of noise in medicine remain limited. In clinical settings, noise may manifest when different healthcare professionals arrive at different conclusions or recommendations despite being presented with identical clinical data. This inconsistency reflects not only differences in expertise or experience but also the influence of contextual and situational factors that introduce random variability into judgment [2].

The present work focuses specifically on the analysis of statistical noise in the classification of surgical complexity in patients with cleft lip and palate. These conditions are facial congenital malformations that occur during fetal development due to the incomplete fusion of facial structures. They may affect the lip, alveolus, palate (hard and/or soft), and nasal structures, either in isolation or in combination. Their etiology is multifactorial, involving genetic predisposition as well as environmental influences such as maternal health, nutrition, and exposure to teratogens. Clinically, cleft lip and palate present with a wide spectrum of anatomical variations, ranging from mild unilateral defects to more complex bilateral and combined forms (Fig. 1).

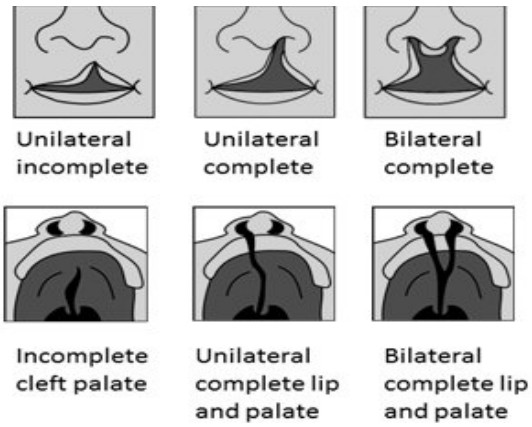

Figure 1. Cleft lip and clef palate (unilateral and bilateral) [3]

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

The anatomical characterization of these malformations typically considers three primary components: the lip, the alveolar ridge, and the palate. Each of these structures can be affected to varying degrees, resulting in significant heterogeneity in clinical presentation. This variability poses challenges for the classification of surgical complexity, as it requires clinicians to interpret anatomical features and assign them to predefined categories. Consequently, the process is susceptible to noise, particularly when classification criteria are subjective or when evaluators differ in training and experience. Understanding and quantifying this variability is essential for improving consistency in clinical assessment, optimizing treatment planning, and ultimately enhancing patient outcomes [4].

While statistical noise is traditionally associated with variability among observers or repeated decisions under identical conditions, it can also be examined from the perspective of the internal consistency of a classification system. In this context, noise may emerge when the structural organization of categories fails to preserve a coherent relationship with the variable that the classification intends to represent. Therefore, the present study focuses on the concept of structural statistical noise, defined as irregularities, discontinuities, or inconsistencies within the progression of surgical complexity levels across the classes of a classification model. This approach does not seek to evaluate inter-observer agreement, but rather the internal coherence of the classification framework itself as a decision-support instrument.

In this work, two models that propose a classification for cleft lip and palate developed at the Comprehensive Center for Cleft Lip and Palate of Mexico (SUMA Center) [5] were analyzed. Both are described as follows:

Model 1. Proposes a classification of 29 classes based on the location of the cleft in the primary palate (unilateral and bilateral), and/or in the secondary palate. It also considers clefts that occur simultaneously in both palates (primary and secondary) and groups them into cleft lip and palate with unilateral or bilateral involvement of the primary palate [6].

Model 2. Proposes a classification of 15 classes based on the anatomical characteristics of the cleft. It considers complete and incomplete clefts of the primary and secondary palate. It includes complete or incomplete bilateral clefts of both palates, and asymmetric bilateral clefts of the primary palate (a complete unilateral cleft and an incomplete unilateral cleft) [7].

By combining these classes in each model, the SUMA Center plastic surgeon team determined the surgical complexity of the clefts. Then, the corresponding model assigned a *Surgical Complexity Factor* (SCF) within a value range. Having a classification with 29/15 classes of clefts, with their respective surgical complexity factor [5, 6], means the unification of the surgeon's clinical criteria and, therefore, makes it possible to define a specific surgical management of the patient, depending on the class to which the cleft that it presents belongs to.

Therefore, the objective of this work was to evaluate the statistical noise of both cleft lip and palate classification models described above, analyzing the SCF in a sample of 105 patients treated at the SUMA Center using three approaches: ordinal coherence, increase and Shannon entropy between classes. To complement the analysis, the association between class order and mean surgical complexity values was assessed by two coefficients, Spearman's rank correlation coefficient and Kendall's tau coefficient. Both measures quantify the degree to which the ordering of classes is aligned with increasing surgical complexity

II. Methodology

A. Ordinal Coherence

Ordinal data is a qualitative data type that classifies variables in a ranked order. This kind of data is categorical and separates variables into groups based on distinct ascending or descending hierarchies. An ordinal scale is defined as a measurement scale that allows for the ranking of data based on relative comparisons but does not permit absolute comparisons or mathematical operations [8]. Agreement or coherence in ordinal data refers to the degree to which different observers or classification methods assign the same ordered category to the same observation [9].

In this work, to assess ordinal coherence, the association between the designated categories and their respective mean SCF values was examined. This procedure was grounded in the assumption that a surgical complexity-based classification framework should exhibit a monotonic pattern, where higher numerical categories correspond to progressively greater mean SCF values compared to preceding ones. Therefore, ordinal consistency reflects the extent to which the classification scheme aligns with the principle of ascending surgical complexity.

The study included 105 patients diagnosed with cleft lip and/or palate and treated at the SUMA Center [5]. For each patient, the corresponding cleft classification was assigned according to both models, and the associated Surgical Complexity Factor (SCF) was obtained. Subsequently, mean SCF values were calculated for each class by averaging the SCF values of all patients belonging to that category. These class-level mean values served as the basis for the ordinal coherence and increment analyses. Subsequently, the difference (Δ) between the mean SCF of each class and that of the preceding class was examined. Positive Δ values reflect a consistent increase in complexity, while negative Δ values signal reversals. That is, cases in which a higher-numbered class exhibits a lower mean SCF than the one before it. Each reversal was documented as a breach of ordinal consistency. This strategy enables the systematic detection of hierarchical discontinuities within the model, highlighting potential mismatches between the intended classificatory framework and the observed numerical patterns of the SCF variable.

To complement the inversion analysis, the association between class order and mean SCF values was assessed by two coefficients: Spearman's rank correlation coefficient, that is a non-parametric measure of the strength and direction of the monotonic relationship between two ranked variables [10] and, Kendall's tau coefficient, that evaluates ordinal association by quantifying the agreement between paired rankings and is

particularly robust in the presence of ties and small sample sizes [10]. Both measures quantify the degree to which the ordering of classes is aligned with increasing surgical complexity. Higher correlation values indicate stronger monotonic consistency between class designation and SCF progression.

B. Increase between Classes

The regularity of the increments between classes was evaluated based on the standard deviation of the differences in SCF values across consecutive classes. This metric provides a quantitative assessment of the dispersion in the magnitude of growth, allowing for the identification of variability patterns in the progression. In this context, a high standard deviation reflects greater inconsistency in the increments, suggesting irregular, non-monotonic, or unpredictable transitions between classes, which may indicate classification noise or instability in the underlying model. Conversely, a low standard deviation indicates that the increments are more homogeneous, reflecting a smoother and more stable progression that is closer to the expected ordinal structure. Therefore, this measure serves as an indicator of coherence in the scaling of surgical complexity, helping to evaluate whether the classification system preserves a consistent gradation between categories [2].

C. Classes Entropy

The distribution of patients among the classes was evaluated using Shannon entropy, a widely used metric that quantifies the degree of categorical dispersion within a discrete probability distribution. In this context, entropy provides a measure of how evenly patients are distributed across the different classes. Higher entropy values indicate a more uniform distribution, where patients are more evenly spread among all categories, reflecting greater heterogeneity and less dominance of any single class. In contrast, lower entropy values suggest that patients are concentrated in a limited number of classes, indicating a more imbalanced or skewed distribution.

Shannon entropy is mathematically defined by (1) [11]. It quantifies the average amount of information expected when observing the variable. The higher the entropy, the greater the uncertainty of the outcome.

$$H(X) = -\sum p(x_i) log_2(p(x_i)) \quad (1)$$

Where: $p(x_i)$ is the probability of obtaining a value x_i.

Because the two classification models contain a different number of categories (29 and 15 classes, respectively), entropy values were normalized by the theoretical maximum entropy of each model by (2). This normalization scales entropy values to the interval [0, 1], allowing direct comparison between classification systems with different numbers of classes.

$$H_N = \frac{H}{log_2(K)} \quad (2)$$

Where H is the Shannon entropy and K is the number of classes in the classification model.

D. Rationale for the Selected Indicators

The three indicators used in this study were selected because they evaluate complementary dimensions of classification consistency. Ordinal coherence assesses whether the progression of classes follows the expected monotonic increase in surgical complexity. The analysis of increments between classes evaluates the regularity of complexity transitions and identifies abrupt fluctuations that may introduce instability into the classification process. Shannon entropy characterizes how patients are distributed among the available categories, providing information about the concentration or fragmentation of the classification structure. These indicators provide an indirect assessment of statistical noise by evaluating the degree of consistency, stability, and organization exhibited by the classification models.

III. Results

The results of the analysis of the Surgical Complexity Factor (SCF) obtained by the 105 patients in the two models evaluated: Model 1 (29 classes) and Model 2 (15 classes) are presented according to the three axes of analysis calculated: ordinal coherence, increase and entropy, between classes.

A. Ordinal Coherence

The analysis of the two classification models revealed notable differences in the occurrence and magnitude of inversions (Table I). In Model 1, six inversions were detected, with negative delta values ranging from −29.67 to −6, indicating variability in the severity of these deviations. While some inversions correspond to minor decreases in the mean between consecutive classes (Δ = −6), others reflect more pronounced drops (Δ = −25, −29.67), highlighting disruptions in the expected hierarchical progression, and suggesting that the numerical ordering of classes does not consistently correspond to the intended complexity levels.

In contrast, Model 2 exhibited only three inversions, two of which are minor (Δ = −3), while one represents the largest reduction observed across both models (Δ = −36.8). Overall, Model 2 not only reduces the number and magnitude of inversions but also demonstrates a progression more closely aligned with the expected monotonic behavior.

TABLE I. SCF MEAN AND INCREASES OBTAINED BY CLASSES IN BOTH CLASSIFICATION MODELS

Model 1			Model 2		
Class	**Mean SCF**	**Δ**	**Class**	**Mean SCF**	**Δ**
1	3	3	1	3	3
2	12	9	2	7	4
3	18,5	6,5	3	9	2
4	7	**–11,5**	4	12	3
5	38,67	31,67	5	16	4
6	9	**–29,67**	6	38,67	22,67
7	23	14	7	36	**–2,67**
8	36	13	8	38	2
9	38	2	9	48	10
10	51	13	10	48	0
11	45	**–6**	11	70	22
12	20	**–25**	12	33,2	**–36,8**
15	78	58	13	58,95	25,75
16	101,33	23,33	14	80,56	21,61
17	126,17	24,83	15	77,67	**–2,9**
22	107	**–19,17**			
24	117	10			
25	140,4	23,4			
27	127,5	**–12,9**			
29	186	58,5			

These findings indicate that the structure of Model 2 provides a stronger and more reliable correspondence between class designation and surgical complexity, offering a more consistent framework for clinical classification.

To complement the inversion analysis, the association between class order and mean SCF values (Table 1) was assessed using Spearman's rank correlation coefficient and Kendall's tau coefficient.

Both models exhibited strong and statistically significant monotonic relationships indicating that higher class numbers are generally associated with greater surgical complexity (Table 2). Although the correlation coefficients were similar for both models, the analyses of ordinal inversions and increment dispersion revealed fewer local inconsistencies in Model 2, suggesting greater structural stability despite comparable overall monotonicity.

TABLE II. SPEARMAN'S RANK CORRELATION COEFFICIENT AND KENDALL'S TAU COEFFICIENT

Model	Spearman's ρ	p-value	Kendall's τ	p-value
Model 1	0.929	3.23×10^{-9}	0.811	9.06×10^{-9}
Model 2	0.903	4.13×10^{-6}	0.804	3.15×10^{-5}

B. Analysis of Increases between Classes

Comparison of the increments (Δ) in mean Surgical Complexity Factor (SCF) between consecutive classes for Model 1 and Model 2 is shown in Fig.1. Negative values indicate ordinal inversions, where a higher-numbered class exhibits a lower mean SCF than the preceding class.

Comparison of the standard deviation of class increments (σΔ) for both classification models is shown in Fig. 2. Lower values indicate more homogeneous transitions between consecutive classes and, therefore, greater structural stability of the classification framework. Model 1 presents an average standard deviation of the increments of $\sigma_{\Delta 1}$= 23.78, suggesting a more erratic progression with abrupt variations between complexity levels. In contrast, Model 2 exhibits an average standard deviation of $\sigma_{\Delta 2}$= 15.24, indicating greater stability in how complexity increases across the classes. This result complements the previous analyses and reinforces that Model 2 organizes its SCF progression scale more consistently.

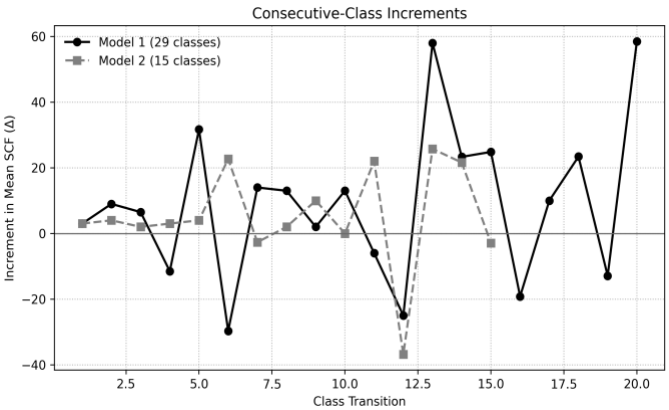

Fig. 1. Consecutive-class increments [Model 1 vs. Model 2]

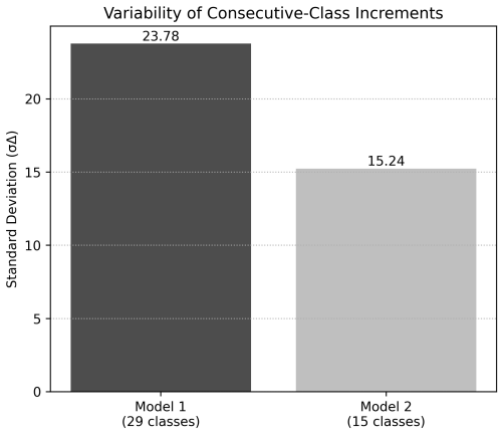

Fig. 2. Variability of Consecutive-Class Increments.

C. Classes Entropy

In this study, entropy was calculated using the observed frequencies of patients in each class of both classification models (Table III). The entropy analysis was performed using both raw and normalized Shannon entropy values. The normalized entropy was used for model comparison because the two classification systems contain different numbers of classes. Higher normalized entropy values indicate a more uniform distribution of patients among categories, whereas lower values indicate greater concentration in specific classes.

TABLE III. FREQUENCIES OF PATIENTS IN EACH CLASS OF BOTH CLASSIFICATION MODELS

Model 1		Model 2	
Class	No. patients	Class	No. patients
1	7	1	7
2	4	2	6
3	6	3	1
4	6	4	4
5	3	5	6
6	1	6	3
7	1	7	1
8	1	8	1
9	1	9	1
10	1	10	1
11	1	11	1
12	1	12	5
13	0	13	45
14	0	14	23
15	4	15	3
16	6		
17	36		
18	0		
19	0		
20	0		
21	0		
22	2		
23	0		
24	1		
25	5		
26	0		
27	2		
28	0		
29	16		

Model 1 (29 classes). Using both equations (1) and (2) this model presents:

H_{M1}= 3.67

H_{max}= log2 (29) = 4.858

$$H_{N-M1} = \frac{H}{log_2(K)} = \frac{3.67}{4.585} = 0.756$$

This result indicates that patient distribution occupies approximately 75.6% of the maximum possible dispersion, suggesting a relatively heterogeneous classification structure with moderate concentration in a limited number of categories.

Model 2 (15 clsses). Using both equations (1) and (2) this model presents:

H_{M2}=2.94.

H_{max}=log2(15) = 3.907

$$H_{N-M2} = 0.752$$

Because the two classification systems contain different numbers of categories, entropy values were normalized by their respective maximum entropy values. The resulting normalized entropies were H_{N-M1}=0.756 and H_{N-M2}=0.752. These values indicate that both models exhibit a very similar relative distribution of patients across their available categories, with differences below 1%.

IV. Discussion

The results obtained from the three analytical approaches consistently indicate that Model 2 exhibits a more organized classification structure than Model 1. The reduced number of ordinal inversions suggests that the progression of classes more closely follows the expected increase in surgical complexity. Similarly, the lower dispersion of class increments indicates a smoother transition between categories, reducing abrupt fluctuations that may complicate clinical interpretation.

The normalized entropy obtained for Model 1 indicates that patients are distributed across a considerable proportion of the available classes. Although the classification exhibits substantial dispersion, the concentration of cases in specific categories, particularly Class 17 and Class 29, prevents the distribution from reaching maximum uniformity. Consequently, the model can be characterized as moderately fragmented, with patients occupying a broad range of surgical complexity categories.

Although the raw entropy was higher for Model 1, this result is largely explained by the larger number of classes available in the classification scheme. After normalization, both models exhibited nearly identical entropy values (H_{N-M1}=0.756 and H_{N-M2}=0.752), indicating comparable levels of relative dispersion. Therefore, entropy alone does not provide evidence supporting the superiority of either model. Instead, the differences observed in ordinal inversions and increment variability become the primary indicators distinguishing the structural consistency of the two classification frameworks.

From a clinical perspective, a classification system with fewer structural inconsistencies may facilitate more reproducible decision-making processes. When class ordering reflects a coherent increase in complexity, clinicians may interpret category transitions more consistently and communicate treatment strategies more effectively. Although the present study does not evaluate surgical outcomes or inter-observer agreement, the observed reduction in structural noise may contribute to greater standardization in the assessment of cleft lip and palate severity.

A. Limitations of the Study

The findings should be interpreted considering some limitations. First, the study was conducted using a relatively modest sample of 105 patients obtained from a single clinical center. Second, some classes may contain a limited number of observations, potentially affecting the stability of mean SCF estimates. Third, the analysis focused exclusively on the internal consistency of the classification models and did not include multiple evaluators, external validation datasets, or direct measures of inter-rater reliability. Consequently, the results should be viewed as preliminary evidence of structural consistency rather than definitive proof of clinical superiority.

V. Conclusion

The present study provides preliminary evidence that Model 2 exhibits lower structural statistical noise than Model 1 when evaluated through ordinal coherence, increment regularity, and entropy-based measures. The results suggest that less fragmented classification frameworks may support more consistent representations of surgical complexity and contribute to the standardization of clinical assessment processes. Likewise, because some categories contained relatively few observations, class-level mean SCF values may be sensitive to sampling variability.

Future studies should expand the evaluation framework by incorporating larger multicenter datasets, independent clinical evaluators, and additional agreement metrics (e. g. weighted kappa coefficients). Such analysis would allow a more comprehensive characterization of decision variability and strengthen the validation of classification systems used in cleft lip and palate management.

***abstract*—The cardiovascular system can be represented through electrical analogies that establish equivalences between physiological and electrical variables, enabling the reproduction of the cardiac cycle by means of analog electronic circuits. This work presents the development of an analog electronic circuit designed to reproduce the principal cardiovascular pressure waveforms using commercially available electronic components and a simplified circuit topology, thereby facilitating its physical implementation for educational and experimental applications. The proposed circuit models the four cardiac chambers, represents the cardiac valves using diodes, incorporates the pulmonary and systemic circulations, and includes an active stage to emulate the mechanical behavior of the left ventricle. The proposed system was initially validated through circuit simulations performed in the Proteus environment and subsequently implemented on a breadboard using discrete electronic components. The experimentally acquired waveforms were compared with both the simulated responses and reference physiological pressure waveforms, demonstrating good agreement in terms of waveform morphology and temporal characteristics. These findings indicate that the proposed circuit accurately reproduces the principal features of the cardiac cycle, thereby validating the electrical analogy as an effective educational tool for Biomedical Engineering. Furthermore, the developed platform integrates concepts from cardiovascular physiology, analog electronics, and biomedical instrumentation while providing a low-cost experimental framework for future investigations and comparative analyses of physiological and pathological cardiovascular conditions.**

***Keywords*—Cardiovascular system; Analog electronic circuit; Biomedical Engineering; Biomedical instrumentation; Electrical analogy.**

I. Introduction

The cardiovascular system is responsible for transporting blood throughout the body and is primarily composed of the heart, blood vessels, and blood. Cardiac function is governed by the cardiac cycle, which consists of two main phases: diastole, during which the atria and ventricles are filled with blood while the atrioventricular valves remain open, and systole, during which the ventricles contract and eject blood into the aorta and pulmonary arteries [1]. These phases produce characteristic variations in pressure and volume within the cardiac chambers, whose assessment plays a fundamental role in the diagnosis of several cardiovascular diseases [1].

Several approaches have been proposed to investigate cardiovascular dynamics. Computational models, such as the one developed by Heldt et al. (2002), represent the cardiovascular system through mathematical equations, enabling the analysis of its response under different physiological conditions [2]. Alternatively, analog electrical models exploit the correspondence between hemodynamic variables, including pressure, flow, blood volume, vascular resistance, and vascular compliance, and their electrical counterparts, namely voltage, current, charge, resistance, and capacitance. An example is the model proposed by Montenegro (2022), in which the four cardiac chambers, the four cardiac valves represented by diodes, and the pulmonary and systemic circulations are modeled using an equivalent electrical circuit whose parameters are correlated with the geometric and mechanical properties of the cardiovascular system [3]. This model reproduces the characteristic morphology of physiological pressure waveforms, including the systolic and diastolic pressures observed in the aorta. However, it presents limitations related to electrical noise and to maintaining pressure consistency throughout the vascular network [3].

Although computational models provide accurate mathematical representations of cardiovascular dynamics, they do not allow the physical observation and manipulation of the system components. Analog electrical models, in contrast, offer a tangible representation of cardiovascular physiology but remain largely restricted to simulation environments. This limitation

arises because their component values are obtained through the direct conversion of hemodynamic parameters, resulting in electrical elements that do not correspond to commercially available components. Furthermore, the excitation sources employed in these models often require voltage levels that are incompatible with conventional laboratory instrumentation. In the model proposed by Montenegro (2022), for example, the right and left ventricular excitation sources operate with amplitudes of 20 V and 120 V, respectively. In addition, the high level of model granularity requires a large number of electrical components, increasing implementation complexity and limiting its practical realization [3]. Consequently, although these models are suitable for numerical simulation, they are difficult to implement experimentally, restricting their use as educational platforms for teaching analog electronics, electrical circuits, and cardiovascular physiology.

Motivated by these limitations, the present work proposes the development of a physical analog electronic circuit capable of reproducing the behavior of the cardiovascular system using commercially available electronic components. The proposed circuit represents the four cardiac chambers, namely the right atrium, right ventricle, left atrium, and left ventricle, together with the corresponding cardiac valves and the pulmonary and systemic circulations. The design was based on the lumped-parameter model proposed by Montenegro (2022), in which each vascular segment is represented by equivalent electrical elements whose parameters are derived from physiological characteristics, including vessel length, cross-sectional area, wall thickness, and elastic modulus [3]. To enable practical implementation, the original model was simplified by concentrating the hemodynamic properties of each circulatory segment into a reduced number of equivalent electrical elements. This approach substantially reduces circuit complexity while preserving the characteristic systolic and diastolic pressure waveforms under normal physiological conditions. As a result, the proposed circuit provides an inexpensive experimental platform suitable for educational applications and future research in cardiovascular modeling.

II. Methodology

A. Methodological Overview

The development of this work followed a structured methodology comprising theoretical analysis, circuit design, simulation, hardware implementation, and experimental validation. Figure 1 summarizes the methodological workflow adopted in this study, illustrating the sequence of stages and the relationship between them.

The first stage consisted of establishing the electrical representation of the cardiovascular system by defining the analogies between physiological and electrical quantities. In this representation, blood flow is analogous to electric current, while pressure is represented by voltage. This electro-hemodynamic correspondence enables the development of analog electronic circuits capable of reproducing the pressure waveforms observed throughout the cardiovascular cycle.

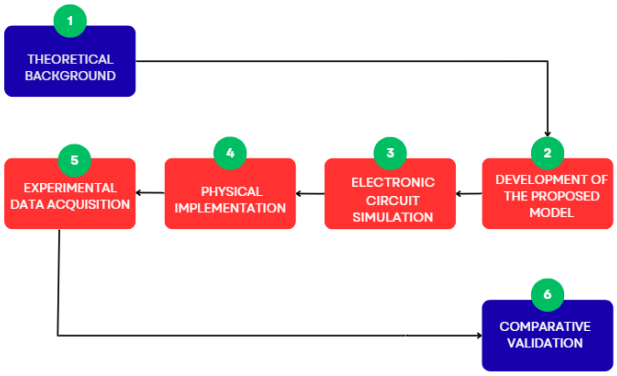

Figura 1: Flowchart illustrating the methodological steps adopted in the development of this study, from the theoretical background to the experimental validation of the proposed circuit.

B. Lumped-Parameter Method

A rigorous description of blood flow in a vessel requires partial differential equations in which pressure and flow vary simultaneously with time and along the vessel length [2], [8]. The lumped-parameter method simplifies this formulation by assuming that, within a vascular segment sufficiently short compared with the wavelength of the pressure pulse, spatial variations can be neglected [2], [8]. Consequently, each segment is represented by a single set of lumped parameters, and the resulting mathematical model is described by ordinary differential equations that are formally equivalent to those governing an RLC electrical circuit [2], [3]. This equivalence constitutes the basis of the electro-hemodynamic analogy.

In this approach, each vascular segment is represented by a block composed of three electrical elements whose values are determined from the geometric and mechanical properties of the vessel, including its length, inner radius, wall thickness, and elastic modulus. The electrical resistance represents the viscous dissipation that opposes blood flow, the inductance represents the inertia of the blood mass accelerated during ventricular ejection, and the capacitance represents vascular compliance, corresponding to the ability of the vessel wall to expand and store blood volume.

The principal advantage of the lumped-parameter method is its flexibility, allowing the cardiovascular system to be represented with different levels of anatomical detail. Increasing the number of vascular segments improves the physiological fidelity of the model but also increases the number of electrical components, making physical implementation considerably more complex. For this reason, the present work adopts a simplified representation of the cardiovascular system, which is described in the following section.

C. Windkessel Model

The Windkessel model represents the simplest application of the lumped-parameter method, in which the systemic circulation is described using equivalent electrical elements [3], [8].

In this work, the two-element Windkessel model, composed of a peripheral vascular resistance and an arterial compliance, was adopted because it is sufficient to reproduce the characteristic systolic and diastolic pressure waveforms under normal physiological conditions while reducing the complexity of the physical implementation [8]. The characteristic resistance of the aorta was retained in the model, whereas the inductive element was omitted because the inductance values obtained from the lumped-parameter formulation are extremely small, making their physical implementation of limited practical significance [3]. The mathematical behavior of the adopted model is described by (1).

$$C\frac{dP(t)}{dt} + \frac{P(t)}{R} = Q(t) \tag{1}$$

where $P(t)$ represents the arterial pressure, $Q(t)$ represents the blood flow rate, C denotes the arterial compliance, and R denotes the peripheral vascular resistance.

D. Electro-Hemodynamic Analogy

The analog electronic circuit was developed based on the correspondence between physiological variables and equivalent electrical quantities. This electro-hemodynamic analogy allows the cardiovascular system to be represented by conventional electrical components while preserving its fundamental dynamic behavior.

Blood pressure is represented by electrical voltage, since both quantities act as the driving force responsible for producing flow in their respective systems. Likewise, blood flow is represented by electrical current because both describe the transport of a conserved quantity through a conductive medium.

Vascular resistance is represented by an electrical resistor. In the cardiovascular system, vascular resistance opposes blood flow and is mainly determined by vessel diameter and blood viscosity. Similarly, an electrical resistor limits the flow of electric current by opposing the movement of electric charge.

Arterial compliance is represented by a capacitor. Physiologically, arterial compliance corresponds to the ability of blood vessels to expand during ventricular ejection and to release the stored blood volume during diastole, thereby attenuating pressure fluctuations. In the electrical circuit, the capacitor performs an analogous function by storing and releasing electrical charge, smoothing voltage variations and reproducing the elastic behavior of the arterial walls.

Finally, the cardiac valves are represented by diodes. Heart valves ensure unidirectional blood flow by opening and closing according to the pressure difference between adjacent cardiac chambers. Likewise, a diode allows electrical current to flow in only one direction, preventing reverse current and accurately reproducing the valve function within the electrical model.

III. Development of the Proposed Model

Based on the lumped-parameter method and the electro-hemodynamic analogies described in the previous section, an analog electronic circuit was developed to physically reproduce the behavior of the four cardiac chambers, as well as the pulmonary and systemic circulations. The proposed model follows the physiological blood flow pathway, comprising the right atrium, right ventricle, pulmonary circulation, left atrium, left ventricle, and systemic circulation, as illustrated in the complete schematic shown in Fig. 2.

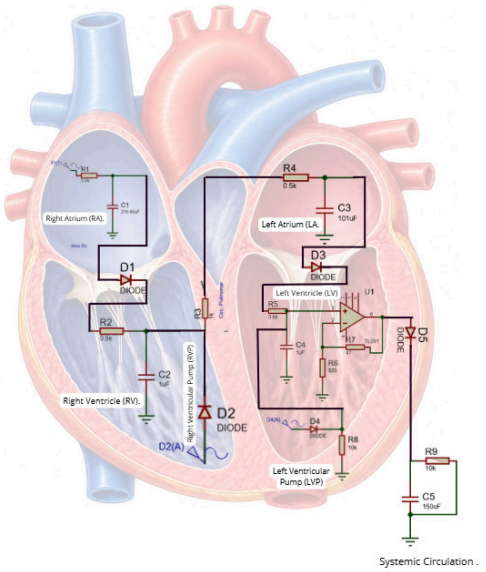

Figura 2: Proposed electronic circuit superimposed on the cardiac anatomy, highlighting the correspondence between each circuit block and the cardiac chamber or vascular compartment it represents. Source: Prepared by the author (2026).

The second modification involved the cardiac chambers. Passive RC blocks were retained for the right atrium, right ventricle, and left atrium, whereas the left ventricle was implemented as an active circuit based on a TL081 operational amplifier. This modification constitutes the principal contribution of the proposed model, as it provides sufficient signal amplification to reproduce the characteristic amplitude and slope of the left ventricular pressure waveform, which cannot be accurately generated using a passive RC network alone.

These simplifications were introduced to obtain a circuit that is both physically feasible to implement and suitable for educational and experimental applications while preserving the characteristic pressure waveforms at the physiologically most relevant locations, namely the right ventricle, left atrium, and left ventricle, instead of reproducing the entire vascular tree.

A. Division into the Four Cardiac Chambers

The right atrium, right ventricle, and left atrium were implemented as first-order RC networks, each composed of a series resistor and a capacitor connected in parallel with the output. These networks reproduce the charging and discharging behavior analogous to the pressure-volume relationship of the corresponding cardiac chamber. The electrical components associated with each chamber are listed in Table I.

The left ventricle was implemented as an active circuit based on a TL081 operational amplifier. The circuit comprises the input resistor R5 (0.5 kΩ) and the feedback network formed by C4, R6 (820 Ω), and R7 (47 Ω). This configuration amplifies the signal generated by the left atrium and actively reproduces the characteristic left ventricular pressure waveform.

The systemic circulation was represented by a two-element Windkessel model composed of resistor R9 (10 kΩ), corresponding to the peripheral vascular resistance, connected in parallel with capacitor C5 (150 μF), which represents the arterial compliance.

Tabela I: Circuit components and their respective physiological representation.

Component	Value	Physiological representation
R1	0.5 kΩ	Resistance of the right atrium
C1	216.45 μF	Compliance of the right atrium
D1	—	Tricuspid valve
R2	0.5 kΩ	Resistance of the right ventricle
C2	1 μF	Compliance of the right ventricle
D2	—	Pulmonary valve (RV pump)
R3	1 kΩ	Pulmonary vascular resistance
R4	0.5 kΩ	Resistance of the left atrium
C3	101 μF	Compliance of the left atrium
D3	—	Mitral valve
R5	0.5 kΩ	Input resistance of the left ventricle
C4	1 μF	Feedback capacitor of the left ventricle
R6	820 Ω	Feedback resistor of the left ventricle
R7	47 Ω	Feedback resistor of the left ventricle
U1 (TL081)	—	Operational amplifier of the left ventricle
D4	—	LV pump diode
R8	10 kΩ	Resistance associated with the LV pump
D5	—	Aortic valve
R9	10 kΩ	Peripheral vascular resistance
C5	150 μF	Arterial compliance

B. Use of Diodes as Valves

Each cardiac valve was represented by a diode positioned to conduct current only in the physiological direction of blood flow while blocking reverse flow when the downstream pressure exceeds the upstream pressure. The correspondence between the diodes and the cardiac valves is summarized in Table II.

Tabela II: Diodes used as cardiac valves in the circuit.

Component	Valve	Location
D1	Tricuspid valve	Between the right atrium and the right ventricle
D3	Mitral valve	Between the left atrium and the left ventricle
D5	Aortic valve	Between the left ventricle and the systemic circulation
D2	Pulmonary valve	Between the right ventricle and the pulmonary circulation

It should be noted that the Right Ventricle Pump (RVP) block simulates blood ejection from the right ventricle into the pulmonary circulation. In the proposed circuit, diode D2 performs the dual function of rectifying the sinusoidal excitation signal and reproducing the action of the pulmonary valve. In contrast, the reference model presented in [3] represents the pulmonary valve as an independent diode separate from the right ventricular pump. This modification constitutes an additional simplification of the proposed circuit, reducing the number of components without compromising its intended physiological behavior.

C. Ventricular Excitation Sources ("Pumps")

In addition to the passive RC networks, the proposed circuit incorporates three sinusoidal voltage sources. The first source excites the right atrium with an amplitude of 100 mV, an offset of 300 mV, and a frequency of 250 mHz, representing the venous return that supplies blood to the heart and initiates the simulated cardiac cycle.

The remaining two sources reproduce the active contraction of the ventricles. The Right Ventricle Pump (RV Pump) emulates the pressure generation associated with right ventricular contraction, whereas the Left Ventricle Pump (LV Pump) reproduces the corresponding mechanism in the left ventricle. Physiologically, ventricular contraction generates the pressure required to eject blood into the pulmonary and systemic circulations, a process that cannot be reproduced using passive electrical elements alone.

This approach follows the same principle adopted in the reference model [3], in which the “Right Ventricle - Pump” and “Left Ventricle - Pump” blocks employ sinusoidal voltage sources associated with diodes to reproduce ventricular contraction. In that model, both sources operate at a frequency of 1.2 Hz (72 beats per minute), with amplitudes of 20 V and 120 V for the right and left ventricles, respectively.

In the proposed circuit, the excitation mechanism was simplified to facilitate physical implementation. The RV Pump consists of an AC voltage source combined with a 7.04 V DC source and a series diode, whereas the LV Pump is composed of a sinusoidal voltage source and a diode. Both excitation sources operate at a frequency of 1.2 Hz. Their amplitudes were reduced to 2 V for the RV Pump, with a 700 mV offset, and 12 V for the LV Pump, with a 700 mV offset and a phase angle of 0°. This scaling preserves the original 6:1 amplitude ratio between the left and right ventricular excitation sources while reducing the operating voltage to a range compatible with the physical implementation of the proposed circuit.

D. Ventricular Excitation Sources ("Pumps")

In addition to the passive RC networks, the proposed circuit incorporates three sinusoidal voltage sources. The first source excites the right atrium with an amplitude of 100 mV, an offset of 300 mV, and a frequency of 250 mHz, representing the venous return that supplies blood to the heart and initiates the simulated cardiac cycle.

The remaining two sources reproduce the active contraction of the ventricles. The Right Ventricle Pump (RV Pump) emulates the pressure generation associated with right ventricular contraction, whereas the Left Ventricle Pump (LV Pump) reproduces the corresponding mechanism in the left ventricle. Physiologically, ventricular contraction generates the pressure required to eject blood into the pulmonary and systemic circulations, a process that cannot be reproduced using passive electrical elements alone.

This approach follows the same principle adopted in the reference model [3], in which the “Right Ventricle - Pump” and “Left Ventricle - Pump” blocks employ sinusoidal voltage sources associated with diodes to reproduce ventricular contraction. In that model, both sources operate at a frequency of 1.2 Hz (72 beats per minute), with amplitudes of 20 V and 120 V for the right and left ventricles, respectively.

In the proposed circuit, the excitation mechanism was simplified to facilitate physical implementation. The RV Pump consists of an AC voltage source combined with a 7.04 V DC source and a series diode, whereas the LV Pump is composed of a sinusoidal voltage source and a diode. Both excitation sources operate at a frequency of 1.2 Hz. Their amplitudes were reduced to 2 V for the RV Pump, with a 700 mV offset, and 12 V for the LV Pump, with a 700 mV offset and a phase angle of 0°. This scaling preserves the original 6:1 amplitude ratio between the left and right ventricular excitation sources while reducing the operating voltage to a range compatible with the physical implementation of the proposed circuit.

IV. Results and Discussion

This section presents the pressure waveforms obtained at the nodes corresponding to the cardiac chambers from two complementary stages: computational simulations performed in Proteus and experimental measurements acquired from the physical implementation on a protoboard. The simulated and experimental waveforms were compared with the expected physiological pressure profiles of each cardiac chamber to evaluate the ability of the proposed circuit to reproduce cardiovascular dynamics. As a reference for the analyses presented in the following sections, Fig. 6 shows the physiological pressure waveforms of the cardiac cycle used for comparison with the signals generated by the proposed circuit.

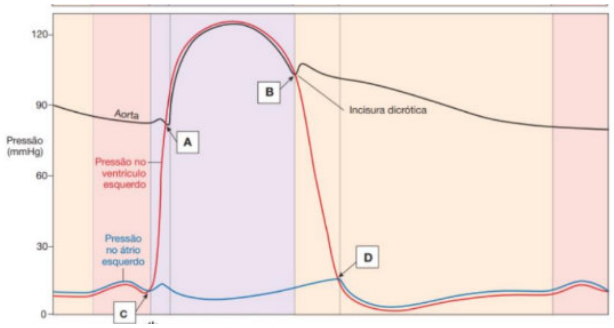

Figura 3: Reference physiological pressure curves of the left cardiac cycle, illustrating the relationship between pressure and volume. Adapted from [6].

A. Right Ventricular Pressure

Figure 5 compares the right ventricular pressure waveform obtained from the physiological reference, the Proteus simulation, and the experimental measurements. For comparison purposes, all waveforms were normalized, allowing their morphological characteristics to be evaluated independently of their amplitudes. It should be noted that the physiological waveform

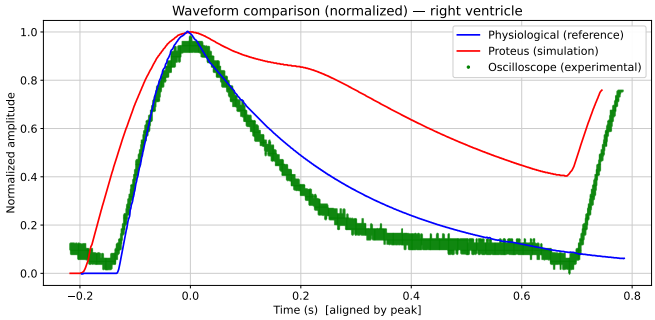

Figura 4: Normalized comparison of the right ventricular pressure waveform obtained from the schematic physiological reference, the Proteus simulation, and the experimental measurements, aligned at the systolic peak. Source: Prepared by the author (2026), based on the Proteus simulation, the experimental measurements, and the physiological reference derived from the literature.

is schematic and was constructed from values reported in the literature.

Under normal physiological conditions, right ventricular pressure ranges from approximately 2 to 5 mmHg during diastole and reaches about 25 mmHg during systole, reflecting the relatively low resistance of the pulmonary circulation. In the Proteus simulation, the signal varied from 0.4 V to 2.06 V, corresponding to approximately 20 mmHg according to the adopted conversion of 1 V to 10 mmHg, which is consistent with the expected physiological range.

The normalized comparison demonstrates that the experimental waveform closely follows both the simulated signal and the physiological reference, preserving the rapid pressure increase during systole and the gradual decrease during diastole. Minor differences, including a slightly delayed peak and a steeper decay in the experimental waveform, are attributed to the limited sampling rate of the acquisition system and to the tolerances of the electronic components used in the physical implementation. Overall, these results indicate that the proposed circuit adequately reproduces the characteristic dynamics of right ventricular pressure.

B. Left Atrial Pressure

Figure 6 compares the left atrial pressure waveform obtained from the physiological reference, the Proteus simulation, and the experimental measurements acquired using an oscilloscope. For comparison purposes, all waveforms were normalized to emphasize their morphological characteristics, whereas the quantitative analysis is based on the measured voltage values.

Unlike ventricular pressure, left atrial pressure exhibits a characteristic waveform composed of distinct pressure waves associated with the different phases of the cardiac cycle. In the present work, however, the physiological reference was intentionally simplified to represent only the overall variation in atrial pressure throughout the cardiac cycle, consistent with

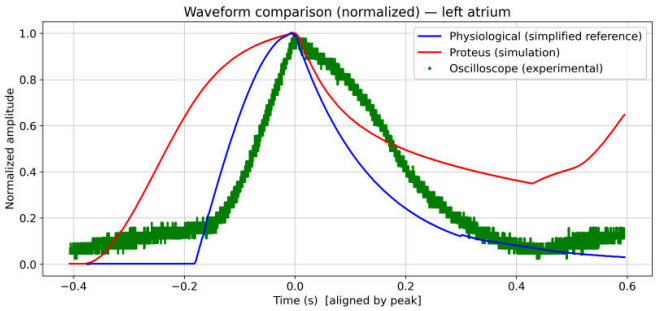

Figura 5: Normalized comparison of the left atrial pressure waveform obtained from the schematic physiological reference, the Proteus simulation, and the experimental measurements. The reference waveform represents the overall variation in atrial pressure without explicitly reproducing the individual atrial pressure waves. Source: Prepared by the author (2026), with the physiological reference based on [5].

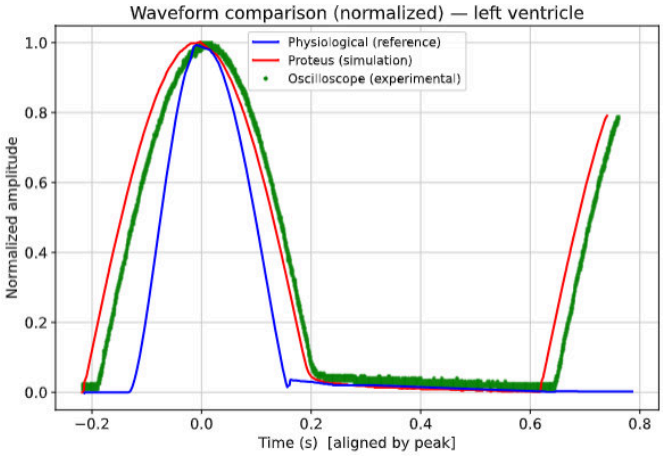

Figura 6: Normalized comparison of the pressure waveform at the output of the Left Ventricular Pump (LVP), which serves as the excitation source for the left ventricle, obtained from the Proteus simulation and the experimental measurements, aligned at the waveform peak. Source: Prepared by the author (2026).

the objective of reproducing the global behavior of the cardiac chambers rather than the detailed atrial pressure components.

In the Proteus simulation, the left atrial signal ranged from 0.4 V to 1.72 V, reaching its maximum value at approximately 0.41 s. This timing is consistent with the expected delay between atrial and ventricular activity during the cardiac cycle. The experimentally measured signal varied from 0.54 V to 1.35 V, with a period of approximately 0.83 s, confirming the stable and periodic operation of the proposed circuit.

Comparison of the normalized waveforms reveals good agreement between the simulated and experimental results, with both preserving the overall morphology of the simplified physiological reference. Minor discrepancies, including a slightly delayed rising edge and a steeper decay in the experimental waveform, are primarily attributed to the limited sampling rate of the acquisition system and to the tolerances of the electronic components used in the prototype. Despite these differences, the close agreement between the simulated and experimental waveforms indicates that the proposed circuit successfully reproduces the overall temporal evolution of left atrial pressure.

C. Pressure at the LV Pump Output

Figure 7 compares the waveform measured at the output of the Left Ventricular Pump (LVP), which serves as the excitation source for the active left ventricular stage, between the Proteus simulation and the experimental measurements. This signal provides the excitation required to reproduce the pressure generated during left ventricular contraction. For comparison purposes, both waveforms were normalized between 0 and 1 to emphasize their morphological characteristics, whereas the quantitative analysis is based on the measured voltage values.

In the Proteus simulation, the excitation signal varied from approximately 0 V to 12 V, reaching its peak at about 0.21 s before gradually decreasing throughout the remainder of the cardiac cycle. According to the conversion adopted in the model (1 V $\equiv$ 10 mmHg), the peak value corresponds to approximately 120 mmHg, consistent with the physiological left ventricular systolic pressure.

Experimentally, the measured signal ranged from approximately 0 V to 8.5 V and exhibited a well-defined peak followed by a gradual decay during each cardiac cycle, confirming the stable and periodic operation of the excitation stage. Although the measured peak amplitude was lower than that predicted by the simulation because of component nonidealities, circuit losses, and limitations of the acquisition system, the waveform morphology and periodicity were preserved.

The close agreement between the simulated and experimental waveforms indicates that the proposed excitation stage reliably reproduces the driving signal required by the active left ventricular model. Consequently, this signal provides the appropriate excitation for generating the left ventricular pressure waveform discussed in the following subsection.

D. Left Ventricular Pressure

Figure 8 compares the normalized left ventricular pressure waveforms obtained from the physiological reference, the Proteus simulation, and the experimental measurements acquired using an oscilloscope. The left ventricular pressure corresponds to the output of the active stage implemented with the TL081 operational amplifier. To facilitate the comparison of waveform morphology independently of amplitude and temporal offsets, all signals were normalized to the range of 0 to 1 and aligned at the systolic peak ($t = 0$ s).

The physiological reference waveform was analytically constructed from cardiac-cycle timing parameters reported in the literature and therefore does not correspond to an experimental recording. A cardiac cycle duration of approximately

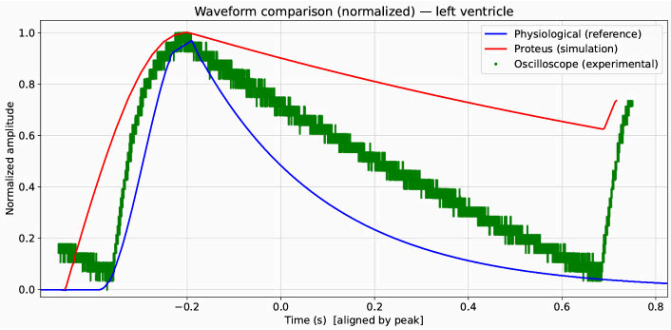

Figura 7: Normalized comparison of the left ventricular pressure waveform obtained from the physiological reference, the Proteus simulation, and the experimental measurements, aligned at the systolic peak ($t = 0$ s). The physiological reference waveform was analytically constructed from cardiac-cycle timing parameters reported in the literature (cardiac cycle of 0.8 s, systole of 0.3 s, diastole of 0.5 s, and isovolumetric relaxation of 0.06 s) and does not correspond to an experimental recording. Source: Prepared by the author (2026).

0.8 s (75 bpm), consisting of a ventricular systole of 0.3 s, a diastole of 0.5 s, and an isovolumetric relaxation period of approximately 0.06 s, was adopted [7]. The experimentally measured period was approximately 0.836 s, corresponding to a heart rate of about 72 bpm, which lies within the normal resting physiological range.

The simulated and experimental waveforms closely reproduce the systolic rising phase and the pressure peak, showing good agreement with the physiological reference during ventricular contraction. The principal difference is observed during diastole. Whereas physiological left ventricular pressure decreases rapidly at the end of systole because of isovolumetric relaxation, both the simulated and experimental waveforms exhibit a gradual pressure decay.

This behavior is characteristic of arterial pressure described by the Windkessel model adopted for the systemic circulation, in which the diastolic pressure follows an approximately exponential decay [8]. Consequently, the proposed circuit reproduces the systolic ejection dynamics and peak timing with good agreement, whereas the relaxation phase predominantly reflects the dynamics of the arterial compartment rather than the rapid decrease of true intraventricular pressure. This observation is consistent with the theoretical assumptions adopted in the circuit design and indicates that the proposed model reproduces arterial hemodynamics more accurately than the detailed intraventricular pressure profile.

E. Final Considerations

The differences observed between the simulated and experimental waveforms were consistent across all analyzed cardiac chambers. The experimental signals exhibited a slightly delayed rising edge, a steeper decay during the relaxation phase, and a higher noise level than the simulated waveforms. These differences are attributed primarily to the limited sampling rate of the acquisition system and to the tolerances of the electronic components, which introduce variations in the circuit time constants that are not present in the idealized simulation.

The diastolic phase of the left ventricle deserves particular attention. Whereas physiological intraventricular pressure decreases abruptly following systole because of isovolumetric relaxation, the simulated and experimental waveforms display a gradual decay characteristic of arterial pressure. This behavior is consistent with the two-element Windkessel model adopted for the systemic circulation, whose response is governed by an exponential discharge of the arterial compliance. Consequently, the proposed circuit accurately reproduces the systolic pressure generation and peak timing, while the relaxation phase is dominated by the response of the arterial compartment.

The main contribution of the proposed model becomes evident when compared with previous studies. Computational cardiovascular models [2], [4] provide accurate representations of hemodynamic behavior but are restricted to numerical simulations and cannot be directly implemented as physical systems. Analog electrical models, such as that proposed by Montenegro [3], also remain primarily simulation-oriented because they require a large number of components, excitation voltages of 20 V and 120 V, and electrical component values that are not commercially available, making practical implementation difficult.

In contrast, the proposed circuit adopts a simplified topology that prioritizes physical implementation while preserving the characteristic pressure waveforms at the principal cardiac chambers. By reducing the vascular network to its essential elements, eliminating impractical inductive components, scaling the excitation voltages to laboratory levels, and employing commercially available components, the proposed model provides a practical experimental platform for demonstrating the fundamental principles of cardiovascular hemodynamics.

V. Conclusion

This work presented the development and experimental validation of an analog electronic circuit capable of reproducing the principal pressure dynamics of the cardiovascular system using commercially available components. Based on the lumped-parameter method, the two-element Windkessel model, and electro-hemodynamic analogies, a simplified version of the reference model proposed by Montenegro [3] was developed by reducing the systemic circulation to an equivalent block, eliminating inductive elements, and scaling the excitation voltages to values compatible with laboratory implementation.

The results obtained from both the Proteus simulations and the experimental prototype demonstrated good agreement with the expected physiological pressure waveforms. The measured pressure levels were consistent with the adopted conversion factor of 1 V to 10 mmHg, corresponding to approximately 20 mmHg for the right ventricle and 120 mmHg for the left ventricle. The differences observed between the simulated

and experimental results are consistent with the limitations of the acquisition system and the tolerances of the electronic components used in the prototype.

Compared with previously reported analog models, the proposed circuit offers the advantage of physical realizability while maintaining the principal hemodynamic characteristics of the cardiovascular system. Consequently, it constitutes a practical platform for teaching cardiovascular physiology, validating lumped-parameter models, and supporting experimental activities in biomedical and electronic engineering.

Future work includes improving the representation of intraventricular pressure during diastole, expanding the vascular network while maintaining practical implementation, employing higher-speed data acquisition systems, developing a printed circuit board version of the prototype, and incorporating quantitative waveform similarity metrics, such as the Pearson correlation coefficient and the root mean square error (RMSE), to complement the qualitative analysis.

***Abstract*—Dengue is a viral disease transmitted by the bite of infected female *Aedes aegypti* mosquitoes that represents a significant global public health challenge, particularly during pregnancy, when infection may result in severe maternal and fetal complications. This study investigates the impact of antiviral treatment on dengue viral dynamics throughout pregnancy using a within-host mathematical modeling approach. The proposed model consists of a system of ordinary differential equations describing the interactions among viral particles, susceptible monocytes, infected monocytes, and T lymphocytes, while incorporating the effects of antiviral therapy on viral replication. Numerical simulations were implemented in Python to evaluate treatment administration during different stages of pregnancy, namely the first, second, and third trimesters. Parameter values were adapted to account for physiological and immunological changes occurring throughout gestation. The results found in this work, indicate that pregnant women are more vulnerable to severe infection, particularly during the second trimester, due to reduced immune activity. Furthermore, the results also show that the proposed antiviral administration substantially decreases viral load and accelerates viral clearance, reducing the risk of adverse outcomes associated with dengue infection during pregnancy, such as Dengue Hemorrhagic Fever (DHF), especially when early administrated.**

***Index Terms*—dengue, mathematical modeling, antiviral treatment, pregnancy.**

I. Introduction

Dengue is a mosquito-borne viral disease caused by the dengue virus (DENV), which belongs to the *Flaviviridae* family and is primarily transmitted by infected female mosquitoes of the genus *Aedes*. This disease is considered one of the most significant arbovirus diseases worldwide, affecting millions of individuals annually, especially in tropical and subtropical regions [1]. The DENV infection can manifest simple symptoms or progress to severe forms characterized by plasma leakage, hemorrhagic manifestations, and organ dysfunction, associated with the occurrence of Dengue Hemorrhagic Fever (DHF), which represents a major challenge to public health systems [2].

After transmission, the virus initially infects immune cells, particularly monocytes, where viral replication occurs. The progression of the infection is strongly influenced by the interaction between viral particles and the host immune response [3]. Among the most relevant cellular populations involved in this process are susceptible monocytes, infected monocytes, and T lymphocytes, which play a fundamental role in controlling viral replication and eliminating infected cells. The balance between viral proliferation and immune activity determines the severity and duration of the disease [4].

Pregnancy introduces substantial physiological and immunological changes that may alter the course of dengue infection. To ensure fetal tolerance and proper gestational development, the maternal immune system undergoes adaptations that modify the activity and distribution of immune cells throughout the trimesters [5]. These alterations can influence the host's ability to control viral infections, potentially increasing susceptibility to severe outcomes, such as Dengue Hemorrhagic Fever (DHF). Dengue infection during pregnancy has been associated with adverse maternal and fetal complications, including preterm birth, low birth weight, fetal distress, and, in severe cases, maternal or neonatal death [6].

Despite the growing incidence of dengue worldwide, there is currently no widely established specific antiviral therapy for routine clinical use [7]. In this case, mathematical models provide a valuable framework for evaluating the potential effectiveness of therapeutic approaches, allowing researchers to investigate treatment outcomes under different biological conditions and intervention schedules. The mathematical model proposed in this work incorporates the interactions between viral particles, susceptible monocytes, infected monocytes, and T lymphocytes, while accounting for physiological changes associated with different gestational stages. Therefore, this study investigates the impact of antiviral treatment on dengue viral dynamics during pregnancy through a mathematical and computational approach, aiming to contribute to the advancement of personalized medicine and reduce the incidence of severe outcomes associated with DENV infection in pregnant women.

II. Literature Background

A. Immune Populations Involved in Dengue Infection

The progression of dengue infection is strongly influenced by the interaction between the dengue virus (DENV) and the host immune system. Following transmission through

the bite of an infected mosquito, viral particles enter the bloodstream and initially target susceptible immune cells, particularly monocytes, macrophages, and dendritic cells. These cells serve as primary sites for viral replication, contributing to the dissemination of the virus throughout the body [3]. The immune components involved in the DENV infection dynamics are represented in Figure 1.

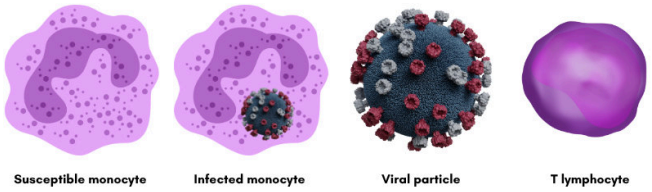

Fig. 1. Immune cells involved in DENV infection

Monocytes play a central role in dengue pathogenesis. Once infected, they become viral factories capable of producing and releasing new viral particles, thereby increasing the viral load. The number of infected monocytes is directly associated with the progression of the infection and the activation of the immune response. At the same time, susceptible monocytes are continuously recruited and exposed to viral particles, creating a dynamic interaction between viral replication and immune defense [3]. Once, susceptible monocytes are infected by a viral particle, cytotoxic T cells, such as T lymphocytes, recognize and eliminate infected cells, reducing viral dissemination, while helper T cells coordinate immune activity through the production of cytokines and the activation of other immune cells [4].

The balance between viral replication within infected monocytes and the immune response mediated by T lymphocytes largely determines disease severity. A robust and well-regulated immune response promotes viral elimination, whereas impaired or delayed immune activity may allow prolonged viral replication and increase the risk of severe clinical manifestations [4]. Therefore, understanding the interactions among viral particles, susceptible monocytes, infected monocytes, and T lymphocytes is essential for developing mathematical models capable of describing the dengue disease dynamics and evaluating potential therapeutic interventions.

B. Female Immune System During Pregnancy

Pregnancy is characterized by profound physiological, hormonal, and immunological adaptations that are essential for maintaining fetal development, being described in literature as a major immunosuppressive period. Since fetal development requires substantial maternal physiological and immunological adaptations to meet its nutritional and hormonal demands, pregnancy depends on a finely regulated balance between immune tolerance and immune protection. This higher immunological activity is particularly important during the first and third trimesters, when the maternal immune system is initially adapting to the presence of the fetus and later preparing the body for labor and delivery [8]. In this case, a decrease in immune activity can be observed throughout the second trimester of pregnancy, when the T lymphocyte production stimulated by the amount of infected monocytes rate in the maternal body reaches the lowest point, indicating a period of bigger immunosuppression and risk for contracting severe forms of the DENV infection caused disease, such as DHF, as observed in Figure 2.

During the first trimester of pregnancy, there is an increase in the population dynamics of T lymphocytes, once the pregnant body is initially recognizing the fetus as a potential immune threat. However, during the second trimester, there is a significant decrease in the immunological activities of the pregnant body, lowering the amount of T lymphocytes pregnant women's blood stream, indicating a major immunosuppressive period. Finally, during the third trimester, there is a gradual increase on the immunological defenses during pregnancy, raising the amount of T lymphocytes in the blood stream, preparing the maternal body for labor and delivery [8].

As a consequence, pregnant women may exhibit increased susceptibility to severe outcomes following dengue infection. The reduced immune activity observed particularly during the second trimester can facilitate viral replication and prolong the persistence of infected cells, resulting in higher viral loads and an increased risk of complications [9]. These gestational immune adaptations have motivated the development of mathematical models capable of incorporating pregnancy-specific immunological conditions into the analysis of dengue infection dynamics. By considering trimester-dependent variations in immune parameters, computational models can provide a more realistic representation of viral dynamics and help evaluate therapeutic interventions, such as antiviral treatments, in pregnant populations [9] [10].

III. Methods

The methodology adopted in this study consists of the development of a within-host mathematical models to describe the dynamics of DENV infection during pregnancy. First, a system of ordinary differential equations (ODEs) was formulated to represent the interactions among susceptible monocytes ($s(t)$), infected monocytes ($i(t)$), viral particles ($v(t)$), and T lymphocytes ($z(t)$). The parameters used to build the mathematical models were obtained from literature, and the initial conditions of all state variables were defined at the beginning of the simulation, with time set to $t = 0$, representing the initial stage of infection. Subsequently, a mathematical model that describes antiviral treatment was incorporated into the system of ODEs by modifying parameters associated with specific stages of the viral life cycle. The resulting system of equations provides a quantitative framework for investigating the progression of dengue infection and evaluating the effectiveness of the proposed therapeutic strategy. The model is numerically solved using the third-order Runge–Kutta method implemented in Python, allowing the simulation of viral and immune dynamics over time for non-pregnant women and pregnant women while accounting for their distinct biological and immunological characteristics. Finally, the temporal profiles of the model

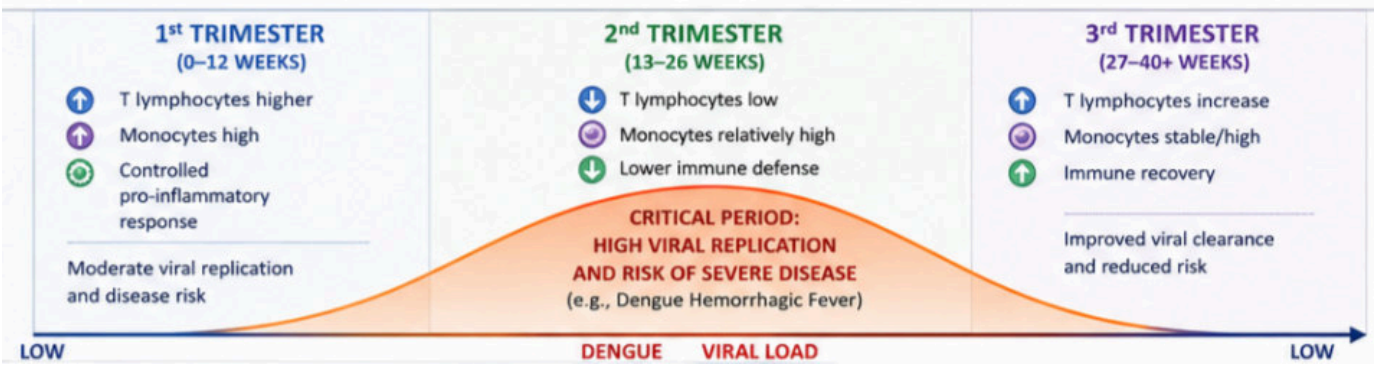

Fig. 2. Immunological dynamics during DENV infection throughout pregnancy.

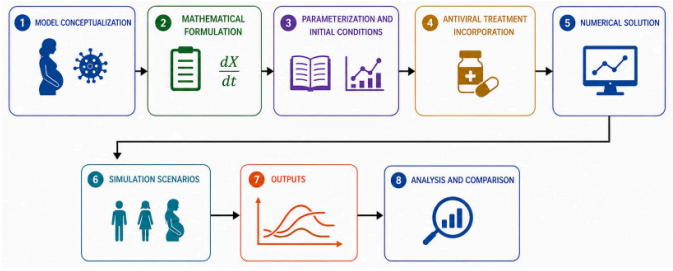

Fig. 3. Representation of the methodology used to obtain the results for the impact of DENV antiviral treatment during pregnancy.

variables were analyzed and compared to assess the impact of antiviral treatment under the investigated scenarios. The complete methodological workflow is summarized in Fig. 3.

A. Mathematical Modeling of Dengue Infection and Antiviral Treatment

Mathematical modeling has become an important tool for understanding the complex interactions between pathogens and the host immune system. In the context of dengue infection, within-host models describe the progression of the disease inside an infected individual by representing the interactions among viral particles, susceptible cells, infected cells, and immune cells through a system of equations formed by ordinary differential equations [11].

This within-host approach allows the investigation of biological mechanisms that are difficult to observe directly in experimental studies. By incorporating the main cellular populations involved in DENV infection, these models provide a quantitative framework for analyzing viral replication, immune activation, and disease progression over time. Furthermore, numerical resolution implemented in computational simulations enable the evaluation of this within-host dynamics according to different therapeutic strategies and physiological conditions without exposing patients to potential risks [12].

Among the immune populations commonly considered in dengue mathematical models are susceptible monocytes, infected monocytes, viral particles, and T lymphocytes. The interaction between these cellular populations and viral particles can be represented mathematically through ODEs that describe the rates of cell infection, viral production, immune activation, and cellular death. Such models make it possible to quantify how variations in immune parameters influence viral dynamics and disease severity. In addition, the incorporation of antiviral treatment into the model allows the investigation of its effects on viral load reduction and immune response enhancement [12]. In this work, the immune parameters of pregnancy required for these mathematical models are taken from literature and express the life and death dynamics of the immune cells described. The initial values, such as the values that represent the viral dynamics of dengue infection during pregnancy, are shown in Table I [10].

The temporal evolution of each cellular population is represented through differential equations that account for biological processes such as monocyte production and replication, viral infection of susceptible monocytes, viral replication, immune-mediated clearance of infected cells and viral particles, and the activation and proliferation of T lymphocytes. In addition, antiviral treatments are incorporated into the model through parameters that modify specific stages of the viral life cycle.

1) Mathematical Model for Susceptible Monocytes: The variable number of susceptible monocytes over the course of DENV infection (1) is determined by the monocyte production rate, minus the natural monocyte depletion rate, represented by $\alpha s(t)$, and minus the rate at which susceptible monocytes become infected through interactions with viral particles, represented by $\alpha s(t)v(t)$.

$$\frac{ds(t)}{dt} = \mu - \alpha s(t) - \alpha s(t)v(t) \tag{1}$$

With this equation, it becomes possible to predict the amount of monocytes susceptible to DENV infection in the maternal body's bloodstream. According to this rate, it is possible to numerically represent the initial amount for susceptible monocytes, and the monocyte recovery rate, meaning infected monocytes that are successfully neutralized by the maternal body's immune response coordinated by T lymphocytes, which can be used as an indicator of the

TABLE I
IMMUNOLOGICAL PARAMETERS

Symbols	Immunological Parameters		
	Meaning	***Initial Values***	***Pregnancy Values***
μ	Monocyte replication rate	80	120
α	Monocyte death rate	3	3
a	Viral infection rate	0.003	0.003
κ	Monocyte regeneration rate	20	20
γ	Virus release rate	0.8	0.8
ν	Infected monocyte clearance rate	0.001	0.001
β_1	Monocyte infection period	1/0.5	1/0.5
δ	T-lymphocyte lifespan	365	365
η	T-lymphocyte production rate	0,265	0,20
c	Stimulation rate of ν induced by infected monocytes	0.01	0.01
d	T-lymphocyte production stimulated by infected monocytes	250	1st tri. = 0.0179; 2nd tri. = 0.0168; 3rd tri. = 0.0321
s(t)	Susceptible monocytes	250	1st tri. = 490; 2nd tri. = 606; 3rd tri. = 908
i(t)	Infected monocytes	10	10
v(t)	Viral particles	165	165
z(t)	T lymphocytes	2000	1700

effectiveness of the proposed antiviral treatment.

2) Mathematical Model for Infected Monocytes: The dynamics of the infected monocyte population (2) is governed by the conversion of susceptible monocytes into infected monocytes through interactions with viral particles, represented by $\alpha s(t)v(t)$, and by the clearance of infected monocytes at a rate proportional to their infection period, which is represented by β_1 (3).

$$\frac{di(t)}{dt} = \alpha s(t)v(t) - \beta_1 i(t) - \nu i(t)z(t) \tag{2}$$

$$\beta_1 = \beta + \frac{\eta\nu}{\delta} \tag{3}$$

With these equations, it is possible to predict the amount of infected monocytes in the maternal bloodstream. From this rate it is possible to numerically estimate the viral particles production score, which flows from the resulting product of the monocyte infection-period rate and the infected monocyte population $\beta_1 i(t)$, counterbalanced by the elimination of infected monocytes through both natural cell death and T lymphocyte-mediated immune clearance, represented by $\nu i(t)z(t)$.

3) Mathematical Model for T Lymphocytes: The number of T lymphocytes over the period of DENV infection (4) is determined by the T-lymphocyte production rate $c_1 i(t)$, where the parameter c_1 is determined in (5), plus the amount of T lymphocytes produced by the stimulus contact with infected monocytes $di(t)z(t)$, minus the score for the natural death of T lymphocytes $\delta z(t)$.

$$\frac{dz(t)}{dt} = c_1 i(t) + di(t)z(t) - \delta z(t) \tag{4}$$

$$c_1 = c + \frac{d\eta}{\delta} \tag{5}$$

These equations represent the dynamics of T-lymphocyte number and production through the course of DENV infection. They make it possible to quantify both the natural production of T lymphocytes and the additional production stimulated by contact with infected monocytes. The resulting T-lymphocyte population number provides a quantitative measure of the adaptive immune response and can be used to investigate its association with disease severity.

4) Mathematical Model for Viral Particles: The number of viral particles present in the host during DENV infection (6) is determined by the viral production rate $\kappa i(t)$, minus the viral clearance rate $\gamma v(t)$, which accounts for both the natural degradation of viral particles and the elimination of infected monocytes, minus the loss of viral particles resulting from their entry into susceptible monocytes $\alpha s(t)v(t)$, as these particles are no longer part of the free viral population.

$$\frac{dv(t)}{dt} = \kappa i(t) - \gamma v(t) - \alpha s(t)v(t) \tag{6}$$

This equation makes it possible his equation makes it possible to determine the temporal evolution of the viral population by quantifying viral production, viral clearance, and the infection of susceptible monocytes. The resulting viral load provides a quantitative measure of infection progression and is the main score used to evaluate the effectiveness of the proposed antiviral treatment.

5) Mathematical Model for Antiviral Treatment: The mathematical model that represents the effect of the antiviral treatment (7) is based on the same equation used to model the viral particles' population, with the addition of the parameter ρ. Prior to treatment administration, ρ assumes a value of 1, corresponding to the untreated infection dynamics, keeping the equation's results untouched. Following antiviral administration, ρ is set to 0, reflecting the complete activation of the antiviral mechanism incorporated into the model.

$$\frac{dv(t)}{dt} = (1-\rho)\kappa i(t) - \gamma v(t) - \alpha s(t)v(t) \tag{7}$$

With this equation, it becomes possible to model the dynamics of DENV infection with the impact of antiviral treatment specifically considering the amount of viral particles present in the host's bloodstream. The resulting system of ODEs is shown in (8).

$$\begin{cases} \frac{ds(t)}{dt} = \mu - \alpha s(t) - \alpha s(t)v(t) \\ \frac{di(t)}{dt} = \alpha s(t)v(t) - \beta_1 i(t) - \nu i(t)z(t) \\ \frac{dz(t)}{dt} = c_1 i(t) + di(t)z(t) - \delta z(t) \\ \frac{dv(t)}{dt} = (1-\rho)\kappa i(t) - \gamma v(t) - \alpha s(t)v(t) \end{cases} \tag{8}$$

IV. Results

This section presents the computational results obtained from the within-host mathematical model of DENV infection in pregnant women undergoing antiviral treatment. The simulations were performed considering antiviral administration on the first, second, and third day of infection, allowing the evaluation of its effects on viral dynamics throughout the course of the disease, considering the immunological parameters associated with pregnancy, as well as the biological differences observed throughout the three trimesters of gestation.

When administrated in the first day of infection, the proposed antiviral treatment produced the most pronounced reduction in viral load among all evaluated scenarios, considering all three trimester of gestation. Although the viral population increased during the initial stage of infection, the treatment rapidly limited viral replication, resulting in an early decline in viral particles, as observed in Figure 4.

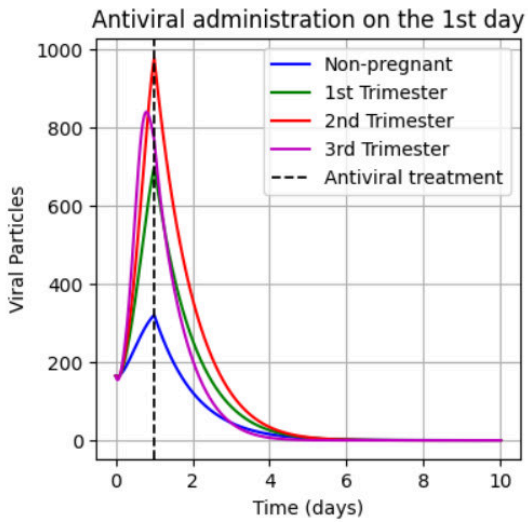

Fig. 4. Antiviral treatment administrated on the first day of infection.

In this graphic, the second trimester (red curve) exhibited the highest viral peak, followed by the third trimester (purple curve), the first trimester (green curve), and non-pregnant women (blue curve). Despite these differences, all groups showed a rapid decrease in viral load after treatment, reaching nearly complete viral clearance within approximately five days. These findings indicate that early antiviral intervention, preferably on the first day of infection, substantially improves infection control, particularly under the immunosuppression conditions observed during pregnancy.

When the antiviral treatment is initiated on the second day of infection, viral replication continues for a longer period before therapeutic intervention, resulting in higher viral peaks than those observed with first-day administration, as seen in Figure 5.

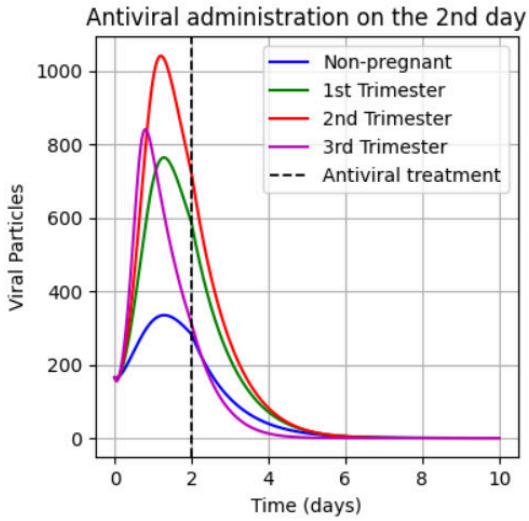

Fig. 5. Antiviral treatment administrated on the second day of infection.

In this graphic, the second trimester again presented the highest viral load, followed by the third and first trimesters, whereas non-pregnant women maintained the lowest viral concentrations throughout the infection. After treatment initiation, all curves exhibited a progressive decline, demonstrating the effectiveness of the proposed antiviral strategy. However, compared with treatment on the first day, viral clearance occurred more slowly, emphasizing the importance of minimizing delays in antiviral administration.

The delayed administration of the antiviral treatment presented on Figure 6 allowed viral replication to progress for a longer period, producing the highest viral burdens among the evaluated treatment schedules.

In the graphic presented in Figure 6, the second trimester remained the most susceptible condition, exhibiting the greatest viral peak, while the third trimester showed intermediate viral levels, followed by the first trimester and non-pregnant women. Although antiviral administration successfully reduced viral load in all groups, the decline occurred later than in the previous scenarios, reflecting the prolonged period of uncontrolled viral replication before treatment. Nevertheless, complete viral clearance was still achieved, demonstrating that the proposed antiviral therapy remained effective even when administered after the early phase of infection.

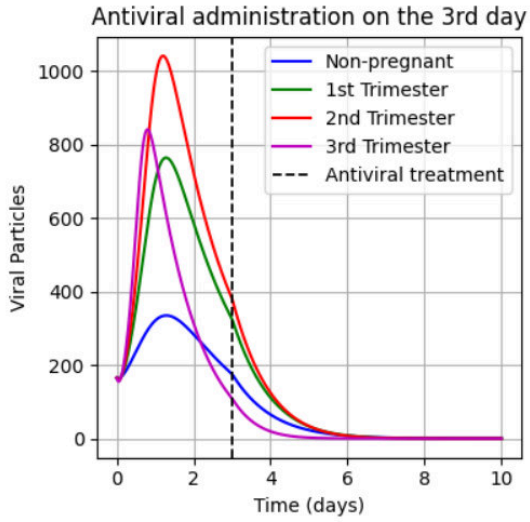

Fig. 6. Antiviral treatment administrated on the third day of infection.

Finally, all results show that the proposed antiviral treatment is most effective when administered early in the course of infection, ideally on the first day following DENV exposure, as observed on Figure 4. Under this condition, a more pronounced reduction in viral load is observed, resulting in faster viral clearance and a lower peak concentration of viral particles, as shown in Figures 5 and 6. These findings highlight the importance of early diagnosis and prompt therapeutic intervention in controlling dengue infection during pregnancy.

V. Conclusion and Discussion

The proposed antiviral strategy proved to be effective across all gestational trimesters and under all treatment initiation times evaluated in this study. In every simulated scenario, antiviral administration contributed to a reduction in viral load, indicating its potential as a therapeutic approach for mitigating the progression of DENV infection in pregnant women.

Among the three gestational stages analyzed, the second trimester presented the highest viral loads, suggesting a period of increased susceptibility to developing more severe forms of dengue, which are frequently associated with the occurrence of DHF. This behavior may be associated with the greater degree of immunosuppression observed during this phase of pregnancy, which favors viral replication and persistence within the host. However, even under the conditions considered for each trimester, the proposed antiviral treatment remained effective in reducing viral particle density and improving infection control.

These findings reinforce the importance of considering pregnancy-specific immunological characteristics when developing therapeutic strategies for dengue infection. Personalized antiviral approaches tailored to the immunological profile of each gestational stage may improve treatment outcomes and contribute to reducing the incidence of severe dengue manifestations, currently associated with the occurrence of DHF. Such reductions could help prevent pregnancy-related complications and minimize adverse effects on fetal development, thereby improving maternal and fetal health outcomes.

A potential future improvement of the proposed model is the incorporation of the DENV incubation period, which corresponds to the time period between viral infection and the onset of clinical symptoms. Including this stage would provide a more realistic representation of the disease progression, since antiviral treatment is typically initiated only after symptom onset and clinical diagnosis. By accounting for this delay in treatment administration, future simulations could more accurately assess the therapeutic effectiveness of antiviral interventions under realistic conditions and provide more reliable support for clinical decision-making.

VI. Acknowledgment

The authors would like to acknowledge the support provided to this study by the National Council for Scientific and Technological Development (CNPq) through an Undergraduate Research Scholarship.

***Resumo*—** A avaliação cognitiva de crianças com Paralisia Cerebral (PC) permanece um desafio clínico, uma vez que limitações motoras e sensoriais podem ocultar o real potencial cognitivo. Este trabalho propõe uma abordagem modular baseada em Redes Neurais Artificiais (RNAs) para classificar o desempenho cognitivo a partir de dados do aplicativo Desenvolve®, como suporte à decisão clínica. Fundamentado no Guia Portage, o Desenvolve® sistematiza a avaliação de dezenove habilidades cognitivas e gera perfis de desenvolvimento infantil. A base experimental incluiu 52 crianças com PC, entre dois e seis anos, do Centro de Referência UEAFTO/UEPA. O fluxo metodológico envolveu pré-processamento, codificação e divisão dos dados em treinamento, validação e teste, com uso de dados simulados exclusivamente no treinamento para maior robustez. A abordagem utilizou seis RNAs independentes, baseadas em Perceptron de Múltiplas Camadas, cada uma dedicada a um domínio cognitivo. Os modelos alcançaram acurácias entre 93,33% e 100% na base de teste, evidenciando elevada capacidade de generalização. Os resultados indicam que a estratégia modular é promissora como ferramenta complementar de apoio à decisão clínica, auxiliando na análise do desenvolvimento infantil sem substituir o julgamento terapêutico.

Palavras-chave—paralisia cerebral, aplicativo Desenvolve, redes neurais artificiais, desenvolvimento cognitivo, suporte à decisão clínica.

I. INTRODUÇÃO

A avaliação do desenvolvimento infantil constitui um processo complexo e multifacetado, que demanda instrumentos sensíveis e adequados para captar as nuances do progresso psicomotor e cognitivo, especialmente em crianças com condições clínicas específicas. Entre essas condições, destaca-se a Paralisia Cerebral (PC), definida como um grupo de desordens motoras permanentes e não progressivas, resultantes de lesões ou anomalias no desenvolvimento do cérebro durante os primeiros estágios da vida [1]. Tais lesões comprometem significativamente o controle motor e a coordenação, manifestando-se por meio de espasticidade, movimentos involuntários, fraqueza muscular e alterações no equilíbrio [2].

No ambiente clínico, a avaliação cognitiva de crianças com PC enfrenta desafios significativos, uma vez que a disfunção neuromotora pode interferir na auto exploração e na capacidade de interpretar estímulos ambientais [2]. Além disso, a maioria dos instrumentos tradicionais de avaliação exige respostas verbais ou motoras complexas que podem não refletir a real capacidade intelectual de pacientes com graves limitações na fala e na escrita manual [3].

Considerando este cenário observa-se um crescente interesse pelo uso de tecnologias computacionais no apoio à avaliação clínica, especialmente aquelas capazes de lidar com dados complexos e multidimensionais. Nesse contexto, insere-se o aplicativo Desenvolve® [4], uma ferramenta concebida para a avaliação e estimulação do desempenho cognitivo de crianças com deficiências neuromotoras. O protocolo adotado pelo *software* fundamenta-se em referenciais clássicos, como o Guia Portage, que sistematiza comportamentos e habilidades cognitivas e motoras em faixas etárias que abrangem do nascimento aos seis anos [2], [5]. O Desenvolve® é estruturado em 127 telas interativas que abrange dezenove habilidades cognitivas [4]. O aplicativo facilita a coleta e a organização de dados da avaliação cognitiva, gerando relatórios quantitativos que apresentam o número bruto de acertos e erros, além de percentis de rendimento categorizados por perfis etários típicos [4], [6].

Entretanto, em determinados contextos clínicos, a interpretação desses dados organizados pode tornar-se complexa. Dependendo da abordagem adotada, a leitura puramente descritiva dos resultados pode não captar adequadamente as nuances inerentes ao desempenho de pacientes com desenvolvimento atípico [7]. Quando as informações não são consideradas de forma integrada, a interpretação quantitativa dos acertos pode não refletir plenamente as capacidades ou dificuldades específicas do paciente, demandando consideração adicional do contexto da avaliação.

Além disso, o modelo analítico atual concentra-se predominantemente em habilidades isoladas. Essa fragmentação pode demandar uma interpretação manual intensa e exaustiva por parte do profissional a fim de obter uma visão global do paciente. Tal condição exige um maior esforço para cruzar múltiplas variáveis simultaneamente, o que possibilita diferentes interpretações diagnósticas a depender do nível de experiência do avaliador [2], [3]. Assim, a síntese e a interpretação integrada desses dados não são tarefas triviais na prática clínica, evidenciando a necessidade de abordagens mais sistematizadas e contextualizadas.

Diante deste contexto, este trabalho propõe uma abordagem modular considerando seis classificadores de desempenho baseados em Redes Neurais Artificiais Perceptron de Múltiplas camadas especializadas para cada domínio cognitivo do aplicativo Desenvolve®, visando auxiliar a interpretação dos resultados e fornecer suporte técnico à decisão clínica por meio da integração de variáveis contextuais.

II. PROTOCOLO E APLICATIVO DESENVOLVE®

O aplicativo Desenvolve® é um instrumento científico concebido para a avaliação e estimulação do desempenho cognitivo de crianças com deficiências neuro-motoras. Fruto de uma investigação científica iniciada em nível de mestrado e consolidada em tese de doutorado, a ferramenta evoluiu de protocolos originais em pranchas de papel para uma plataforma digital multiplataforma. Atualmente, o *software* vem sendo aplicado em contextos de pesquisa e atendimentos clínicos na Unidade de Ensino e Assistência de Fisioterapia e Terapia Ocupacional (UEAFTO) da Universidade do Estado do Pará (UEPA), tratando-se de uma tecnologia de uso acadêmico e institucional, não disponível comercialmente. O protocolo adotado pelo *software* fundamenta-se no Guia Portage, que sistematiza comportamentos e marcos do desenvolvimento infantil do nascimento aos seis anos [2], [5].

Diferente de avaliações qualitativas, o sistema permite a coleta sistemática de registros em 127 telas interativas que abrangem 19 habilidades cognitivas, entre elas: percepção de objetos do cotidiano, percepção de tamanho, percepção de sequência, noção de espaço, percepção auditiva, identificação de ações, identificação de formas e associação de iguais e diferentes. Para garantir a acessibilidade de pacientes com graves comprometimentos motores, o *software* utiliza um sistema de varredura (escaneamento) aliado a acionadores adaptados (toque, sopro ou movimento de cabeça), assegurando que o impedimento físico não mascare o real potencial cognitivo da criança [8], [9], [10].

As 19 habilidades cognitivas podem ser agrupadas em seis aspectos fundamentais (A1 a A6), respeitando a hierarquia de complexidade, conforme apresentado na Tabela I.

TABELA I
ASPECTOS COGNITIVOS FUNDAMENTAIS
CHECADOS PELO INSTRUMENTO DE AVALIAÇÃO

Aspectos cognitivos	**Habilidades**
A1 - Percepção visual	Se o indivíduo (criança) identifica e associa cores, formas, tamanho, objetos do cotidiano, letras e números, se o indivíduo (criança) identifica "igual", "diferente" etc...
A2 - Percepção auditiva	Se o indivíduo (criança) possui compreensão do comando de forma correta e se discrimina sons de animais, de objetos domésticos e relaciona a palavra ao objeto.
A3 - Percepção espacial	se o indivíduo (criança) identifica conceitos de "grande'", "pequeno", "em cima", "em baixo", "dentro", "fora", "compridos", "curtos", "primeiro", "segundo", "terceiro", "último".
A4 - Percepção e sequência	De ações, numérica, alfabética, temporal e tamanho
A5 - Percepção de esquema corporal	Se a criança identifica partes do corpo.
A6 - Outros	Se a criança completa figuras. Se a criança possui percepção de tempo. Se a criança possui percepção de escrita e leitura.

III. REDES PERCEPTRON DE MÚLTIPLAS CAMADAS

As Redes Neurais Artificiais (RNA) constituem modelos matemáticos computacionais inspirados na estrutura neural de organismos inteligentes, capazes de refinar o conhecimento adquirido a partir de estímulos do ambiente através de um processo iterativo de aprendizagem [11], [12]. A característica que torna o uso dessas redes relevante para aplicações na área da saúde é a sua capacidade de lidar com a não-linearidade e com múltiplas variáveis de forma simultânea [12], [13].

As Redes Perceptron de Múltiplas Camadas (MLP) representam uma evolução dos modelos neurais simples, sendo caracterizadas por uma arquitetura do tipo *feedforward* e completamente conectada [11], [12]. A estrutura básica de uma MLP é dividida em três componentes fundamentais: a camada de entrada, que recebe e distribui os sinais de estímulo; uma ou mais camadas ocultas (ou intermediárias), onde o processamento pesado ocorre; e a camada de saída, que fornece a resposta final do modelo para o problema proposto [11]. O diferencial técnico desta arquitetura reside na utilização de funções de ativação não-lineares nas camadas ocultas, o que permite à rede mapear relações complexas e separar padrões que não seriam distinguíveis por modelos lineares [11], [12].

O processo de aprendizagem das redes MLP segue o paradigma de aprendizado supervisionado, utilizando majoritariamente o algoritmo de retropropagação do erro (*Backpropagation*) [11]. O objetivo final do treinamento é minimizar o erro quadrático médio na saída da rede, ajustando os parâmetros internos para que a rede adquira a capacidade de generalização, ou seja, consiga produzir resultados corretos mesmo para dados que não foram apresentados durante a fase de treinamento da rede [11], [12].

IV. METODOLOGIA

A pesquisa foi conduzida em etapas sequenciais, organizadas em *pipeline*, garantindo o processamento das variáveis do protocolo do Guia Portage em ambiente digital. O fluxograma geral da metodologia proposta é apresentado na Fig. 2.

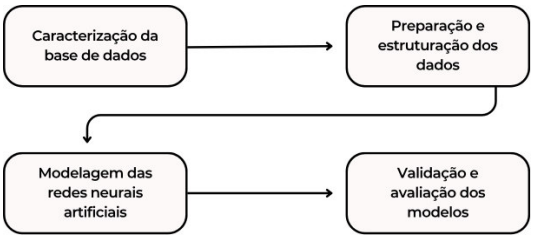

Fig. 2. Fluxograma geral da metodologia proposta.

Diferentemente de uma abordagem global com um único classificador neural, optou-se pelo desenvolvimento de classificadores dedicados para processar o desempenho de forma segmentada por domínios cognitivos (A1 a A6). Essa estratégia visa oferecer uma base estruturada para o suporte à decisão clínica, auxiliando o profissional na análise quantitativa das variáveis de cada aspecto, sem substituir o julgamento terapêutico.

A. Caracterização e Partição da Base de Dados

A base de dados é constituída por registros secundários de 52 pacientes com diagnóstico de Paralisia Cerebral, com idades entre 2 e 6 anos, coletados por terapeutas ocupacionais no Centro de Referência UEAFTO, da Universidade do Estado do Pará — UEPA (ALVES DE OLIVEIRA, 2010). Os estudos que fundamentaram a coleta original e o desenvolvimento do protocolo foram aprovados

pelo Comitê de Ética em Pesquisa do Núcleo de Medicina Tropical da Universidade Federal do Pará — UFPA, sob protocolo nº 049/2003 CEP/NMT.

Para o desenvolvimento dos modelos, os registros foram submetidos a um processo de partição *Holdout* [12]. O conjunto de treinamento foi inicialmente composto por 22 registros reais, sendo complementado com dados simulados para corrigir o desbalanceamento de classes e estabilizar o aprendizado das redes frente ao volume limitado da amostra clínica inicial. Ao final deste processo, o conjunto foi balanceado para um total de 99 registros [12]. Os conjuntos de validação (15 registros) e teste (15 registros) foram compostos integralmente por dados clínicos reais e inéditos, garantindo que a eficácia final do modelo fosse aferida apenas frente a evidências clínicas concretas.

Os registros simulados foram construídos de forma sistemática, utilizando as habilidades e o número de telas do aplicativo Desenvolve®, seguindo os marcos do desenvolvimento infantil [2]. A Tabela II sintetiza o perfil de desempenho por classe utilizado para a geração desses dados.

TABELA II
PERFIL DE DESEMPENHO POR CLASSE PARA GERAÇÃO DE DADOS

Classe	Característica dos registros
1	Alto desempenho (80% a 100% de acertos) nos marcos compatíveis com a idade.
2	Desempenho intermediário (50% a 80% de acertos) nos marcos compatíveis com a idade.
3	Baixo desempenho (0% a 50% de acertos) nos marcos compatíveis com a idade.

B. Preparação e Estruturação dos Dados

Esta seção detalha o procedimento de transformação dos registros brutos do aplicativo Desenvolve® em vetores numéricos estruturados para o processamento computacional. O fluxo de preparação foi desenhado para converter o desempenho clínico em variáveis quantitativas, respeitando a organização por aspectos cognitivos e marcos de desenvolvimento previstos no protocolo.

A modelagem adotada define a entrada de cada modelo classificador com base na estrutura do protocolo de avaliação, que distribui as habilidades em quatro faixas etárias principais: dois a três, três a quatro, quatro a cinco e cinco a seis anos. O vetor de entrada utiliza codificação *one-hot* para identificação da faixa etária, entradas de desempenho em habilidades específicas e entradas agregadas por faixa (médias aritméticas de acertos), oferecendo à rede um contexto adicional sobre o rendimento em cada nível de desenvolvimento.

A variável de saída representa o resultado da análise integrada do desempenho cognitivo, convertida por arredondamento para umas das três categorias discretas apresentadas na Tabela II. Para a quantificação, as variáveis foram convertidas em uma escala de razão proporcional entre 0 e 1, calculada pela divisão entre o número de telas acertadas e o total de telas executadas. Adotou-se o valor -1 para identificar a ausência de execução de tarefas, diferenciando o desempenho nulo (erro) da ausência de registro (não realização), preservando a integridade da estrutura dos dados coletados.

C. Modelagem das Redes Neurais Artificiais

A pesquisa utilizou Redes Neurais Artificiais (RNAs) do tipo Perceptron de Múltiplas Camadas (MLP), implementadas em ambiente MATLAB® utilizando a função *feedforwardnet* do *Deep Learning Toolbox*. A estrutura de cada rede foi composta por três camadas:

- Camada de entrada: Constituída por um número de neurônios igual ao vetor de variáveis definido para cada aspecto. Para o tratamento de dados ausentes (codificados como -1), a topologia de entrada foi expandida através da concatenação de uma máscara binária que identifica a ocorrência de valores nulos. Dessa forma, o número real de neurônios na camada de entrada corresponde ao dobro da dimensionalidade original de cada vetor.
- Camada oculta: Camada intermediária responsável pelo processamento, submetida a variações experimentais para identificação da melhor topologia. Nesta camada, utilizou-se a função de ativação não-linear

Tangente Hiperbólica Sigmóide (*tansig*), que permite à rede mapear relações complexas entre as variáveis de desempenho.

- Camada de saída: Composta por um neurônio, responsável por gerar um valor numérico posteriormente convertido, por meio de arredondamento, para as classes 1, 2 e 3.

O treinamento das redes seguiu o paradigma supervisionado utilizando o algoritmo Levenberg-Marquardt [15], [16]. Como critério de interrupção do ajuste dos pesos sinápticos, adotou-se a técnica de *Early Stopping* (parada antecipada), fundamentada no monitoramento do erro no conjunto de validação. Para mitigar a instabilidade da inicialização aleatória dos pesos sinápticos, adotou-se uma estratégia de múltiplas execuções independentes (*seeds*). O processo experimental consistiu na variação sistemática do número de neurônios na camada oculta (10, 20, 40, 60, 80 e 100 neurônios), realizando-se 500 iterações de treinamento para cada configuração e selecionando-se o modelo com melhor acurácia no conjunto de validação.

D. Métricas de Desempenho

A acurácia na base de dados de validação foi adotada como a métrica principal para a definição da melhor arquitetura para cada um dos seis aspectos. Complementarmente, para aferição do desempenho dos modelos frente a dados reais e inéditos, foram obtidas as matrizes de confusão e calculadas as métricas de precisão, sensibilidade (*Recall*) e *F-score*.

V. RESULTADOS

A. Desempenho Global dos Modelos

A seleção das arquiteturas com melhores desempenhos fundamentou-se no critério de maior acurácia no conjunto de validação, priorizando, em caso de equivalência técnica, o modelo com maior poder de generalização no conjunto de teste e menor complexidade estrutural. A Tabela IV apresenta o desempenho global dos classificadores selecionados após diversos treinamentos, onde se variou os neurônios na camada escondida para inicializações de pesos diferentes (*seed)*.

TABELA IV
DESEMPENHO GLOBAL DOS CLASSIFICADORES POR ASPECTO COGNITIVO

Aspecto	**Neurônios**	***Seed***	**Treino**	**Validação**	**Teste**
A1	10	70	98,99%	100%	93,33 %
A2	20	1	97,98%	100%	100%
A3	40	292	98,99%	100%	93,33 %
A4	10	5	98,99%	100%	93,33 %
A5	10	1	100%	100%	100%
A6	20	7	100%	100%	93,33 %

Fonte: Elaborado pelo autor.

A interpretação sistêmica dos resultados, após os diversos treinamentos, permite agrupar os classificadores em dois perfis técnicos distintos. O primeiro grupo, composto pelos aspectos A2, A4 e A5, apresentou elevada estabilidade e generalização consistente durante os treinamentos, indicando padrões funcionais robustos e fronteiras clínicas claras no protocolo. Destaca-se o Aspecto A5 (Esquema Corporal), que preservou acerto integral (100%) em todas as fases experimentais devido à sua baixa dimensionalidade e regras determinísticas.

O segundo grupo, que integra os Aspectos A1, A3 e A6, revelou maior sensibilidade arquitetural durante os treinamentos. O sucesso da classificação foi estritamente dependente do ajuste fino da densidade da camada oculta para mitigar o fenômeno de sobreajuste (*overfitting*). Apesar da maior complexidade e heterogeneidade funcional, esses modelos mantiveram acurácias de teste superiores a 93%, validando a eficácia da modelagem modular mesmo em cenários de alta dimensionalidade.

C. Análise de desempenho dos modelos na base de teste

As Fig. 3 a Fig. 8 apresentam as matrizes de confusão para os classificadores considerando a base de teste e a Tabela V apresenta as métricas de Precisão, *F-score* e Sensibilidade para cada modelo.

Nos domínios A2 (Percepção Auditiva) e A5 (Esquema Corporal), observou-se acerto integral de todos os registros reais (diagonal principal). Para os demais aspectos (A1, A3, A4 e A6), os desvios de classificação ocorreram exclusivamente entre classes adjacentes. Nos Aspectos A1 e A3, registrou-se um único desvio onde a Classe 2 foi classificada como Classe 1. Já nos domínios A4 e A6, ocorreu um único erro de classificação na qual instâncias da Classe 1 foram atribuídas à Classe 2.

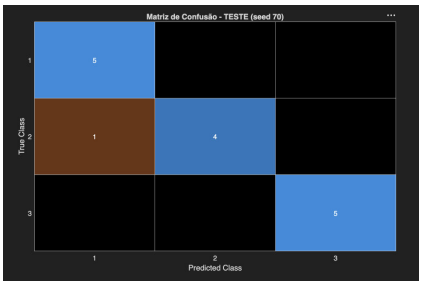

Fig. 3. Matriz de confusão para a base de teste – Aspecto A1.

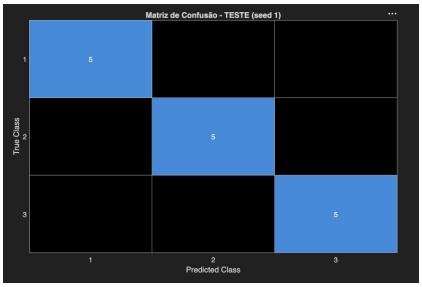

Fig. 4. Matriz de confusão para a base de teste – Aspecto A2.

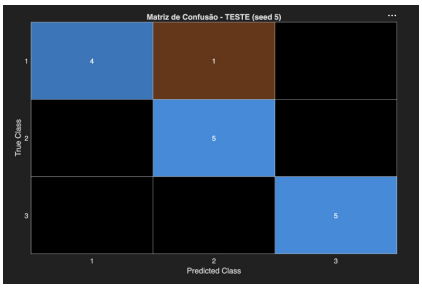

Fig. 6. Matriz de confusão para a base de teste – Aspecto A4.

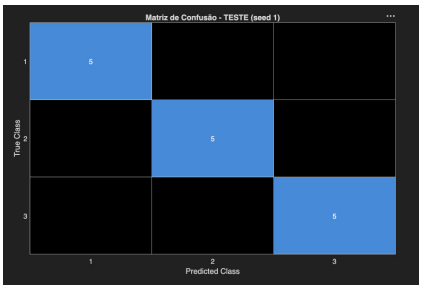

Fig. 7. Matriz de confusão para a base de teste – Aspecto A5.

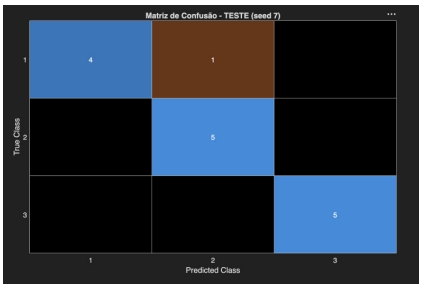

Fig. 8. Matriz de confusão para a base de teste – Aspecto A6.

TABELA V
MÉTRICAS GLOBAIS DE DESEMPENHO NA BASE DE TESTE

Aspecto	**Precisão**	**Sensibilidade**	***F-score***
A1	94,44%	93,33%	93,27%
A2	100%	100%	100%
A3	94,44%	93,33%	93,27%
A4	94,44%	93,33%	93,27%
A5	100%	100%	100%
A6	94,44%	93,33%	93,27%

Fonte: Elaborado pelo autor.

A análise da Tabela V indica que o modelo apresenta alto desempenho, com valores elevados de precisão, sensibilidade e *F-score*. A precisão elevada sugere baixa ocorrência de falsos positivos, indicando que o sistema raramente atribui incorretamente uma classe. Por outro lado, a sensibilidade ligeiramente inferior aponta para a presença de alguns falsos negativos, mostrando que nem todos os casos reais são identificados corretamente. O *F-score* confirma o equilíbrio entre as métricas, indicando ausência de viés significativo. Além disso, os erros ocorrem apenas entre classes adjacentes, reduzindo seu impacto clínico. Assim, mesmo quando há classificações incorretas, estas permanecem próximas do valor real. Apesar dos bons resultados, destaca-se a importância da análise conjunta com o terapeuta, uma vez que o sistema deve ser utilizado como ferramenta de apoio à decisão. A interpretação profissional é essencial para contextualizar os resultados e garantir uma avaliação mais precisa e individualizada.

VI. DISCUSSÃO

A. Contribuições da Metodologia

A principal contribuição deste trabalho reside na implementação de uma estratégia modular, que segmentou o desenvolvimento cognitivo em

classificadores especializados para cada aspecto do protocolo Desenvolve®. Em substituição a uma rede única e generalista, o emprego de MLPs dedicadas permitiu que cada modelo assimilasse as propriedades específicas de seu respectivo aspecto clínico, elevando a capacidade de adaptação do sistema às nuances de cada aspecto avaliado.

Os resultados evidenciam que as MLPs conseguiram identificar padrões funcionais a partir dos registros de avaliação com sólida capacidade de generalização frente a dados reais e inéditos. A metodologia comprova ser capaz de converter registros brutos em informações estruturadas, confirmando a utilidade de algoritmos de aprendizado de máquina em contextos de saúde infantil ao oferecer um suporte complementar que otimiza a carga de análise manual e proporciona uma visualização mais ágil e estruturada do perfil do paciente, sem substituir o julgamento clínico essencial ao cuidado.

B. Limitações do Estudo

A amostra clínica desta pesquisa é composta por registros de 52 pacientes reais, o que reflete as complexidades inerentes à coleta de dados em ambientes clínicos altamente especializados. Este volume amostral impõe desafios ao treinamento de modelos de Redes Neurais Artificiais, que demandam bases robustas para o mapeamento de padrões funcionais complexos. Em decorrência da limitação amostral inicial, o emprego de dados simulados constituiu uma estratégia necessária para equalizar as classes e assegurar a estabilidade da otimização dos pesos sinápticos durante o treinamento.

Contudo, esta técnica foi aplicada sob rigorosa salvaguarda metodológica, restringindo o uso de dados simulados exclusivamente ao conjunto de treinamento. Dessa forma, as etapas importantes de validação e teste permaneceram fundamentadas integralmente em registros de pacientes reais, garantindo a fidedignidade dos resultados. Adicionalmente, deve-se considerar que o sistema foi desenvolvido sobre a estrutura específica do protocolo Desenvolve®, o que vincula a eficácia atual dos classificadores à organização e aos marcos de desenvolvimento deste instrumento.

C. Implicações Clínicas

Na prática assistencial, a metodologia proposta oferece um suporte estratégico ao profissional de saúde, otimizando a organização do elevado volume de dados coletados durante os atendimentos com o aplicativo Desenvolve®. Ao processar de forma integrada o desempenho da criança nos diferentes aspectos cognitivos (A1 a A6), o sistema favorece a interpretação funcional das variáveis, proporcionando uma visão ágil, estruturada e sistêmica do perfil do paciente. É fundamental destacar que a tecnologia atua estritamente como um recurso de apoio e sistematização, fornecendo subsídios técnicos que auxiliam a análise do terapeuta sem substituir sua sensibilidade e *expertise* no processo avaliativo.

O potencial clínico desta abordagem estende-se ao acompanhamento evolutivo, permitindo que o profissional monitore o progresso terapêutico de forma sistemática e longitudinal ao longo do tempo. Em ambientes multiprofissionais, a ferramenta estabelece uma base técnica comum para a discussão de casos, apoiando a tomada de decisão por meio de dados organizados e fundamentados nos marcos do desenvolvimento infantil. Esse suporte tecnológico auxilia no direcionamento de intervenções personalizadas, garantindo que as metas terapêuticas estejam rigorosamente alinhadas às reais necessidades e capacidades demonstradas pela criança em cada etapa de seu amadurecimento.

D. Trabalhos Futuros

A continuidade desta pesquisa aponta para a necessidade de expansão da base clínica, buscando a inclusão de registros provenientes de novos centros de reabilitação. A realização de validações multicêntricas permitirá que os modelos representem uma diversidade ainda maior de perfis funcionais, ampliando a capacidade de generalização do sistema em diferentes contextos clínicos.

No âmbito tecnológico, os trabalhos futuros podem explorar a avaliação de outras arquiteturas neurais, como redes recorrentes ou modelos baseados em *ensembles*, visando o refinamento contínuo da precisão classificatória. Além disso, a integração da metodologia com sistemas de gestão clínica e a expansão para outros protocolos de avaliação funcional permitirão que a inteligência artificial ofereça um suporte ainda mais abrangente, possibilitando o acompanhamento da trajetória evolutiva do paciente de maneira mais sistemática e organizada.

VII. CONCLUSÃO

A aplicação do *pipeline* metodológico evidenciou a viabilidade técnica do uso de Redes Neurais Artificiais (MLP) para a classificação do desempenho cognitivo em crianças com Paralisia

Cerebral. Os classificadores demonstraram eficácia na estratificação dos níveis de rendimento cognitivo, consolidando a modelagem modular por aspectos como uma estratégia robusta para o suporte à decisão clínica.

Esta síntese reitera que a eficácia da Inteligência Artificial nesta pesquisa é reflexo da consistência estrutural do instrumento de avaliação, validando a convergência entre algoritmos de aprendizado de máquina e marcos de desenvolvimento clínico. Conclui-se que a metodologia modular proposta tem potencial como ferramenta complementar de apoio à decisão, podendo auxiliar o profissional na análise de variáveis multidimensionais e no acompanhamento do desenvolvimento infantil de crianças com PC, sem, no entanto, substituir o julgamento terapêutico.

***Abstract*—Este trabalho apresenta uma análise comparativa entre os controladores RST e GPC aplicados ao controle da flexão do joelho via Estimulação Elétrica Funcional (FES). Utilizando o modelo musculoesquelético Leg6Dof9Musc no ambiente OpenSim integrado ao MATLAB, o sistema foi identificado por um modelo ARX. Os resultados indicam que ambas as estratégias são estáveis para o rastreamento de trajetórias. Contudo, o GPC demonstrou superioridade, apresentando convergência mais rápida, menor erro no regime transitório e resposta visualmente mais suave, consolidando-se como a técnica mais promissora para reabilitação motora.**

***Index Terms*—FES, GPC, RST, OpenSim, Flexão do Joelho, Modelagem Musculoesquelética, Identificação de Sistemas (ARX).**

I. Introduction

Diversas estratégias de controle vêm sendo propostas para aplicações em FES, incluindo controladores PID, adaptativos, robustos e preditivos. Entre essas abordagens, o Controle Preditivo Generalizado (Generalized Predictive Control – GPC) destaca-se por utilizar um modelo matemático da planta para prever o comportamento futuro do sistema e determinar, a cada instante de amostragem, a sequência ótima de ações de controle. Essa característica permite melhorar o rastreamento da trajetória desejada, reduzir erros de seguimento e minimizar os efeitos das não linearidades presentes no sistema neuromuscular [4]. Outra estratégia amplamente empregada em sistemas discretos é o controlador RST, baseado em alocação de polos por meio de polinômios, que apresenta simplicidade de implementação, estabilidade e bom desempenho no acompanhamento de referências [5]. Nos últimos anos, o avanço das ferramentas computacionais de modelagem musculoesquelética tem possibilitado o desenvolvimento e a validação de algoritmos de controle em ambientes virtuais antes de sua aplicação experimental. Entre essas ferramentas, o OpenSim destaca-se como uma plataforma de código aberto amplamente utilizada para simulação biomecânica, permitindo representar com elevado grau de realismo a dinâmica dos músculos, articulações e segmentos corporais. A utilização desse ambiente reduz custos experimentais, aumenta a reprodutibilidade dos estudos e possibilita avaliar diferentes estratégias de controle em condições controladas [6]. Além disso, revisões recentes destacam que a modelagem musculoesquelética associada a técnicas avançadas de controle constitui uma das principais tendências para o desenvolvimento de sistemas inteligentes de reabilitação motora personalizados [7]. Apesar dos avanços observados na literatura, ainda são escassos os estudos que realizam uma comparação direta entre estratégias de controle baseadas em GPC e RST aplicadas à Estimulação Elétrica Funcional para movimentos de flexão do joelho utilizando modelos musculoesqueléticos computacionais. Essa lacuna limita a compreensão das vantagens e limitações de cada abordagem no contexto da reabilitação motora assistida por FES. Dessa forma, este trabalho apresenta uma análise comparativa entre os controladores GPC e RST aplicados ao controle em malha fechada da flexão do joelho induzida por Estimulação Elétrica Funcional. Para isso, foi utilizado o modelo musculoesquelético Leg6Dof9Musc, implementado na plataforma OpenSim e integrado ao MATLAB para identificação do sistema, projeto dos controladores e realização das simulações computacionais. O desempenho das estratégias é avaliado por meio da capacidade de rastreamento da referência e das características da resposta dinâmica, contribuindo para o desenvolvimento de sistemas de reabilitação motora mais precisos, robustos e eficientes.

Reconhecimento ao CNPq, por meio do Edital nº 25/2020 - Projeto 445435/2020-8, pelo auxílio Financeiro no desenvolvimento da pesquisa.

II. Materiais e Métodos

A. Arquitetura do sistema proposto

A metodologia proposta foi desenvolvida em ambiente computacional integrando o software MATLAB® ao OpenSim®. A interface MATLAB/OpenSim utilizou o solver *ode45*, com tempo de amostragem de $0{,}02\,\mathrm{s}$ para aquisição e processamento dos dados. O MATLAB foi empregado para a identificação da planta, implementação dos algoritmos de controle e processamento dos resultados, enquanto o OpenSim foi utilizado para representar a dinâmica musculoesquelética do membro inferior humano e simular a resposta biomecânica à Estimulação Elétrica Funcional (FES).

Inicialmente, o modelo musculoesquelético foi excitado por sinais de entrada previamente definidos, permitindo a obtenção dos dados necessários para a identificação do sistema. A partir do modelo identificado, foram projetados os controladores RST e GPC, os quais foram avaliados em malha fechada por meio de simulações computacionais.

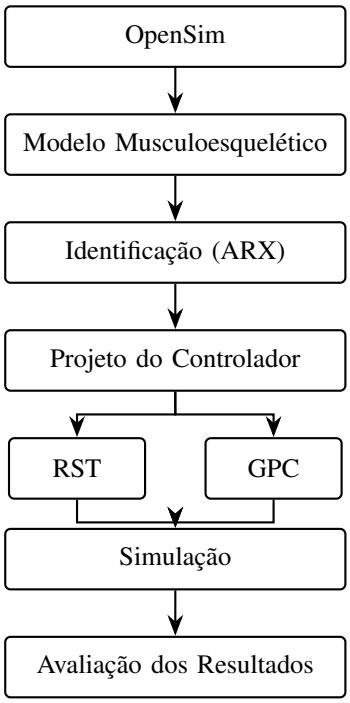

Fig. 1. Fluxograma geral da metodologia.

B. Modelo musculoesquelético

Foi utilizado o modelo não-linear Leg6Dof9Musc, disponibilizado na biblioteca do OpenSim [9]. Esse modelo representa o membro inferior humano por meio de seis graus de liberdade e nove músculos responsáveis pelos principais movimentos do quadril, joelho e tornozelo.

O estudo concentrou-se na flexão do joelho produzida pela estimulação elétrica aplicada ao músculo bíceps femoral, sendo o ângulo articular utilizado como variável de saída do sistema.

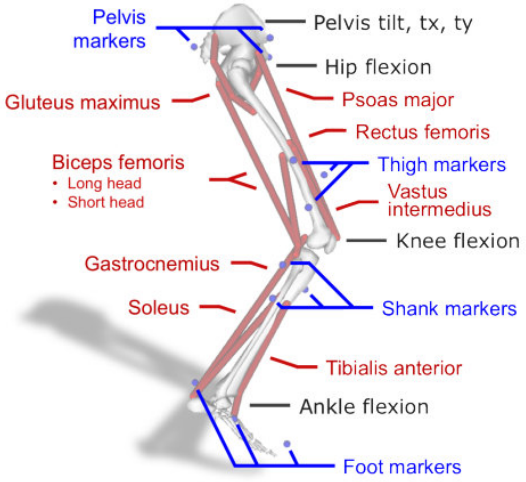

Fig. 2. Modelo musculoesquelético Leg6Dof9Musc utilizado nas simulações, representando o membro inferior com seis graus de liberdade e nove músculos

C. Identificação do sistema

A identificação da planta foi realizada em ambiente MATLAB utilizando dados obtidos a partir do OpenSim. Para garantir excitação persistente, empregou-se um sinal Pseudo Random Binary Sequence (PRBS) durante a coleta de dados.

A amplitude e a frequência do sinal PRBS foram definidas a partir de uma análise prévia da dinâmica do sistema. Inicialmente, foi aplicado um sinal degrau de amplitude 0,5 ao músculo bíceps femoral, sendo observada uma frequência dominante de aproximadamente $1{,}6\,\mathrm{Hz}$. Com base nessa resposta, o PRBS foi configurado com 7 células, amplitude entre 0,3 e 0,7, período de bit $T_b = 0{,}2\,\mathrm{s}$ e duração de 30 s. A adequação espectral do sinal foi verificada por meio da Transformada Rápida de Fourier (FFT), de forma a garantir conteúdo energético na faixa dinâmica de interesse do sistema. Ressalta-se que o modelo ARX obtido constitui uma aproximação linear válida em torno da região de operação excitada pelo sinal de identificação.

A estrutura do modelo identificado é baseada em modelos auto-regressivos com entradas exógenas (ARX).

$$A(q^{-1})y(k) = B(q^{-1})u(k) + e(k) \tag{1}$$

onde

- $u(k)$ representa o sinal de estimulação elétrica;
- $y(k)$ representa o ângulo de flexão do joelho;
- $e(k)$ representa o erro de modelagem.

Os polinômios do modelo são definidos por

$$A(q^{-1}) = 1 + a_1 q^{-1} + a_2 q^{-2} + \cdots + a_n q^{-n} \tag{2}$$

$$B(q^{-1}) = b_1 q^{-1} + b_2 q^{-2} + \cdots + b_m q^{-m} \tag{3}$$

Os parâmetros foram estimados pelo método dos mínimos quadrados não-recursivo, seguindo os critérios clássicos de identificação de sistemas [10]. O modelo apresentou um índice

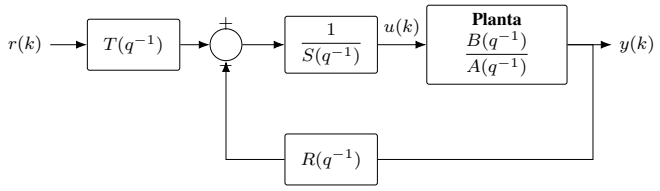

Fig. 3. Estrutura do controlador RST em tempo discreto.

de ajuste de aproximadamente 90,84%, indicando boa capacidade de representar a dinâmica da flexão do joelho em torno do ponto de operaçao dos dados coletados.

D. Projeto do controlador RST

Após a identificação da planta, foi projetado um controlador RST em tempo discreto pelo método de alocação de pólos. A lei de controle é dada por

$$R(q^{-1})u(k) = T(q^{-1})r(k) - S(q^{-1})y(k) \tag{4}$$

Os polinômios do controlador foram determinados por meio da solução da Equação Diofantina

$$A(q^{-1})R(q^{-1}) + B(q^{-1})S(q^{-1}) = A_c(q^{-1}) \tag{5}$$

em que $A_c(q^{-1})$ representa o polinômio característico escolhido de acordo com o comoportamento dinâmico desejado para o sistema de malha fechada.

A alocação dos polos foi definida a partir das especificações de desempenho desejadas para a resposta em malha fechada. A partir do polinômio característico resultante, obtiveram-se os polos

$$z_{1,2} = 0{,}9448 \pm j\,0{,}2225$$

e

$$z_{3,4} = 0{,}9065 \pm j\,0{,}0533.$$

O critério de projeto considerou a definição dos polos dominantes a partir dos requisitos de amortecimento e velocidade de resposta. Os polos adicionais foram escolhidos de modo a apresentar dinâmica mais rápida e menor influência sobre o comportamento dominante da resposta.

E. Projeto do controlador GPC

O controlador GPC foi desenvolvido com base no modelo CARIMA

$$A(q^{-1})y(k) = B(q^{-1})u(k-1) + \frac{e(k)}{\Delta} \tag{6}$$

em que

$$\Delta = 1 - q^{-1} \tag{7}$$

A função custo utilizada é

$$J = \sum_{j=N_1}^{N_2} (r - \hat{y})^2 + \lambda \sum_{j=1}^{N_u} (\Delta u)^2 \tag{8}$$

em que N_1 e N_2 representam, respectivamente, os limites inferior e superior do horizonte de predição; N_u corresponde ao horizonte de controle; $r(k+j)$ representa a trajetória de referência; $\hat{y}(k+j|k)$ corresponde à saída predita no instante $k+j$, com base nas informações disponíveis no instante k; $\Delta u(k+j-1)$ representa a variação incremental do sinal de controle; e λ é o fator de ponderação associado ao esforço de controle. Valores maiores de λ penalizam variações mais intensas da ação de controle, enquanto valores menores atribuem maior prioridade ao rastreamento da referência.

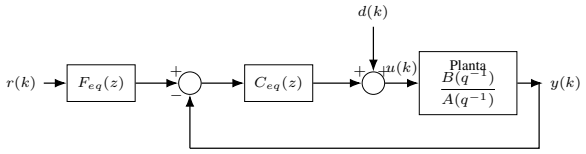

Fig. 4. Estrutura equivalente do controlador GPC em tempo discreto.

A estrutura interna do GPC pode ser representada por uma configuração equivalente de dois graus de liberdade (2DOF), na qual $C_{eq}(z)$ corresponde ao controlador equivalente e $F_{eq}(z)$ ao filtro equivalente associado ao caminho da referência.

Nessa representação, $F_{eq}(z)$ atua no pré-processamento da referência, enquanto $C_{eq}(z)$ reúne de forma compacta a dinâmica interna do controlador preditivo. Essa forma equivalente permite descrever a relação entre referência, ação de controle e saída da planta de maneira mais simples e adequada à apresentação do método.

$$M(z) = (K_e H - K_f)\,(zI - A + DH)^{-1}, \tag{9}$$

obtêm-se

$$C_{eq}(z) = -\left[\left([M(z)D - K_e]\,\Delta^{-1}\right)^{-1}(1 - M(z)B)\right]^{-1}, \tag{10}$$

e

$$F_{eq}(z) = -\left([M(z)D - K_e]\,\Delta^{-1}\right)^{-1} K_r \Delta^{-1}, \tag{11}$$

em que $\Delta = 1 - z^{-1}$.

F. Critérios de avaliação

O desempenho dos controladores foi avaliado a partir da capacidade de rastreamento da referência, da estabilidade da resposta, do comportamento durante o regime transitório e da presença de sobresinal. Também foi analisado qualitativamente o comportamento do sinal de controle ao longo da simulação.

A comparação entre as estratégias foi realizada considerando a resposta do ângulo de flexão do joelho em relação à trajetória de referência e as características transitórias observadas após as mudanças de referência.

III. Resultados e Discussões

A. Validação do modelo identificado

Após a etapa de identificação, o modelo ARX foi validado por meio da comparação entre sua resposta e a resposta do modelo musculoesquelético implementado no OpenSim. A Figura 5 apresenta o resultado dessa validação.

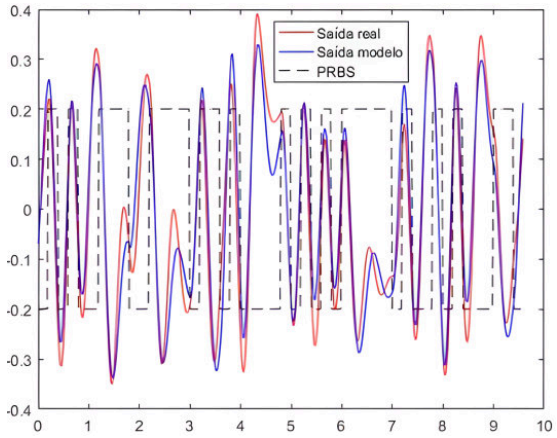

Fig. 5. Validação do modelo ARX

A partir da Figura 5 verifica-se que o modelo capturou a dinâmica do sistema em torno do ponto de operação dos dados coletados. O índice de ajuste (fit) obtido foi de aproximadamente 90,84%, indicando que o modelo ARX representa adequadamente a dinâmica da flexão do joelho para as condições consideradas neste estudo.

Esse resultado é fundamental para o desenvolvimento dos controladores, uma vez que tanto o controlador RST quanto o GPC dependem da qualidade do modelo identificado para produzir ações de controle compatíveis com a dinâmica da planta.

Além disso, a boa capacidade de representação do modelo reduz erros decorrentes da identificação e aumenta a confiabilidade das simulações realizadas em malha fechada.

B. Avaliação do controlador RST

Após a validação da planta identificada, foi implementado o controlador RST para o controle da flexão do joelho.

Conforme apresentado na Figura 6, o controlador RST foi capaz de conduzir o sistema até a referência desejada, mantendo estabilidade durante toda a simulação. A resposta apresenta comportamento compatível com a metodologia de alocação de polos empregada no projeto do controlador.

Observa-se, entretanto, que durante o regime transitório ocorre uma aproximação mais gradual da referência. Além disso, foi observada a ocorrência de sobresinal após as mudanças de referência, com duração aproximada de 1 s.

Mesmo apresentando esse comportamento, o controlador demonstrou ser uma alternativa viável para o controle da flexão do joelho induzida por FES, proporcionando resposta estável ao sistema.

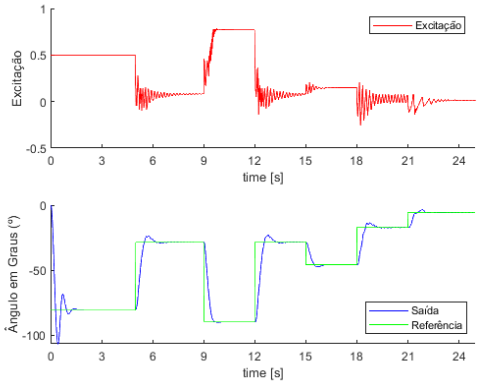

Fig. 6. Resposta temporal do controlador RST.

C. Avaliação do controlador GPC

Na sequência, foi avaliado o desempenho do Controle Preditivo Generalizado (GPC).

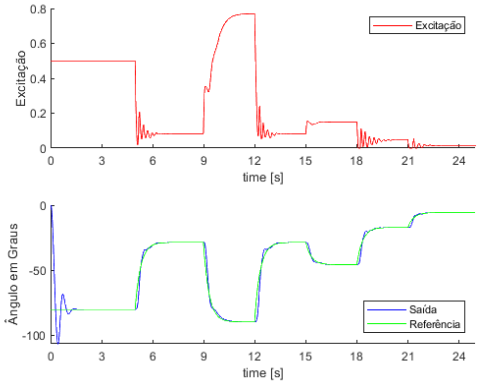

Fig. 7. Resposta temporal do controlador GPC.

A Figura 7 mostra que o controlador GPC também foi capaz de acompanhar a trajetória de referência de forma estável. A amplitude apresentada corresponde ao sinal de controle calculado pelo controlador nas condições simuladas e não representa, por si só, os limites fisiológicos máximos da estimulação. Os limites físicos da atuação dependem da forma de normalização e da implementação da excitação no modelo musculoesquelético.

Visualmente, observa-se uma aproximação mais rápida da referência durante o regime transitório, além de uma resposta mais suave ao longo da simulação. Esse comportamento é coerente com a estratégia preditiva empregada pelo controlador, que utiliza um modelo interno da planta para calcular, a cada instante de amostragem, a ação de controle que minimiza uma função de custo previamente definida.

Essa característica permite ao GPC antecipar o comportamento futuro do sistema, favorecendo um rastreamento mais eficiente da referência.

Para o controlador GPC, não foi observada a ocorrência de sobresinal nas condições simuladas, indicando comportamento

transitório mais suave em comparação ao controlador RST.

D. Comparação entre as estratégias de controle

A comparação direta entre as duas estratégias é apresentada na Figura 8.

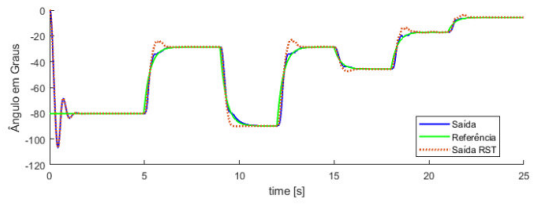

Fig. 8. Comparação entre as respostas obtidas pelos controladores RST e GPC.

A análise visual da Figura 10 evidencia que ambos os controladores foram capazes de estabilizar o sistema e realizar o rastreamento da referência proposta.

Entretanto, observa-se que o controlador GPC apresenta menor erro durante o regime transitório e uma resposta mais uniforme ao longo do movimento de flexão do joelho. Em contrapartida, o controlador RST apresenta uma convergência mais gradual até a referência, mantendo, porém, estabilidade durante toda a simulação.

No contexto da Estimulação Elétrica Funcional, uma resposta mais suave e com menor erro transitório pode contribuir para uma aplicação mais eficiente da estimulação elétrica, favorecendo o controle do movimento articular e reduzindo oscilações indesejadas.

Os resultados obtidos apresentam tendências consistentes com trabalhos correlatos da literatura. Em sistemas de estimulação elétrica em malha fechada, estratégias de controle preditivo têm demonstrado potencial para melhorar o acompanhamento de tarefas motoras [3]. De forma semelhante, nas condições avaliadas neste trabalho, o GPC apresentou aproximação mais rápida da trajetória de referência e comportamento transitório mais suave.

Por outro lado, a aplicação de controladores RST em sistemas de reabilitação motora baseada em FES já foi investigada para movimentos de quadril e joelho, demonstrando a viabilidade dessa estratégia para o controle de movimentos articulares [8]. No presente estudo, o RST também foi capaz de manter a estabilidade e realizar o rastreamento da referência, embora tenha apresentado convergência mais gradual e ocorrência de sobresinal durante o regime transitório.

Esses comportamentos também são coerentes com os fundamentos das duas estratégias. O GPC utiliza um modelo interno da planta para prever seu comportamento futuro e determinar as ações de controle a partir da minimização de uma função de custo [4], enquanto o RST baseia-se na alocação dos polos da malha fechada [5]. Dessa forma, as diferenças observadas nas simulações são compatíveis com as características teóricas descritas na literatura.

Diferentemente dos trabalhos citados, que analisam individualmente estratégias preditivas ou baseadas em alocação de polos, o presente estudo realiza uma comparação direta entre GPC e RST sob as mesmas condições de simulação e utilizando a mesma planta musculoesquelética, permitindo evidenciar de forma mais direta as diferenças de comportamento entre as duas estratégias.

Como limitação, os controladores foram projetados a partir de um modelo linear identificado em uma região específica de operação, enquanto a dinâmica neuromuscular associada à FES apresenta não linearidades e variações fisiológicas não explicitamente representadas, incluindo a fadiga muscular. Como trabalhos futuros, pretende-se avaliar os controladores diante dessas condições, incorporar modelos de fadiga e investigar estratégias adaptativas de estimulação, além de realizar validações com dados experimentais.

IV. Conclusão

Este trabalho realizou uma análise comparativa entre as estratégias de controle RST e GPC aplicadas à flexão do joelho induzida por Estimulação Elétrica Funcional (FES), utilizando um modelo musculoesquelético complexo no ambiente integrado MATLAB e OpenSim

Os principais pontos conclusivos são:

- **Validação do Modelo:** O processo de identificação do sistema por meio de um modelo ARX e sinais PRBS mostrou-se altamente eficaz, atingindo um índice de ajuste (*fit*) de aproximadamente 90,84%, o que confirma que o modelo foi capaz de representar com precisão a dinâmica biomecânica da flexão do joelho, fornecendo uma base sólida para o projeto dos controladores.
- **Desempenho dos Controladores:** Ambas as estratégias demonstraram ser alternativas viáveis e estáveis para o controle em malha fechada. O controlador RST garantiu estabilidade, embora tenha apresentado uma convergência mais gradual e um regime transitório menos responsivo.
- **Melhor comportamento transitório nas condições simuladas:** O Controle Preditivo Generalizado (GPC) destacou-se por apresentar um melhor rastreamento da trajetória de referência, com menor erro durante o regime transitório e uma resposta visualmente mais suave e uniforme ao longo da simulação. Essa comportamento é atribuída à sua capacidade inerente de utilizar um modelo interno para antecipar o comportamento futuro do sistema e otimizar as ações de controle em tempo real.
- **Impacto na Reabilitação:** No contexto da reabilitação motora, a resposta mais suave do GPC sugere uma aplicação de estímulos mais eficiente, o que pode contribuir para a redução de oscilações indesejadas e um melhor controle do movimento articular em pacientes com disfunções motoras.

Em suma, o estudo demonstrou que a utilização de ferramentas de simulação como o OpenSim permite a validação robusta de algoritmos de controle avançados, reduzindo riscos e custos experimentais. Os resultados posicionam o GPC como a técnica mais promissora para futuras implementações experimentais e clínicas de sistemas de FES personalizados e precisos.

AGRADECIMENTOS

Ao apoio do Programa de Pós-Graduação em Engenharia Elétrica da Universidade Federal do Ceará (PPGEE/UFC), por meio do Grupo de Pesquisa em Automação, Controle e Robótica (GPAR), pelo suporte científico e infraestrutura disponibilizada para o desenvolvimento deste trabalho. Agradecemos também às agências de fomento Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) e Fundação Cearense de Apoio ao Desenvolvimento Científico e Tecnológico (FUNCAP) pelo apoio à pesquisa.

***Abstract*—Developing a model for cell culture is a challenging task, because single cells have a certain response to the environment, and the same cell line in a culture with millions of cells has a different response for the same environment. Therefore, a robust model requires complicated mathematical equations with a large set of parameters and variables that, when not properly implemented, could mislead researchers to design a process that fails to achieve the simulated results. This study has the goal of developing a structured segregated model in Unreal Engine (UE) to predict the growth curves (GCs) of the cell lines CHO, Vero, and some of their sublines. The proposed computational model (CM) relies on the simulation of cell behavior to emerge the mathematical equations presented in the literature. Its parameters were set using data from experiments of different cell lines and the well-established knowledge about their characteristics, such as glucose consumption rate, maximum cell density in adherent or suspension culture, and lag phase estimation. The evaluation of the model was done by calculating the absolute relative error, $|\delta|$, the non-absolute relative error, δ, and the mean absolute error (MAE) at each time point. The doubling time and the average growth rate were also used for the analysis. The results showed that the model, with an absolute relative mean error of $|\bar{\delta}| = 0.77 \pm 0.127$, was able to simulate, on average, the early stages of culture growth (i.e., the lag phase and the beginning of exponential growth), $|\bar{\delta}|_{early} = 0.168 \pm 0.031$, better than the last stage of exponential growth, $|\bar{\delta}|_{last} = 2.426 \pm 0.393$. These results indicate that *in vitro* cells cease the division process before reaching the maximum cell density, avoiding the scarcity of nutrients in the medium and the stress increasing originated from spatial limitation. Although numerous biological, chemical, and physical factors may influence cell culture behavior, the evaluated model, even with its limited set of parameters, demonstrates potential to simulate in a short-term period the aspects of cell culture behavior growth. The use of UE enabled a more fluid development of the model itself, and —being based on C++— offered the flexibility and robustness needed to optimize the computational power required to cell culture simulation.**

***Index Terms*—computational model, structured segregated model, cell culture, growth curve, Unreal Engine**

I. Introduction

Mathematical and computational models of cell culture are an important feature for the biotechnological industry and academic research because they can reduce waste of resources when used properly. Having the ability to simulate the cell culture allows researchers to evaluate a myriad of scenarios economically and quickly. Most of the models are based on mathematical equations and describe the cell population statistically.

According to [1], there are four main types of cell culture models: unstructured unsegregated model, unstructured segregated model, structured unsegregated model, and structure segregated model.

The unstructured unsegregated model uses a more simplistic cell representation. This model simulates the cell population as a unique entity that refers to an average cell, so the model does not consider the intracellular variances between individuals and the different aspects of the cells such as age, shape, weight, and size [2]. In other words, the cell population is composed of cells with the same intracellular characteristics, shape, size and all of them are at the same age at the same time. Nonetheless, this model is largely used for the simplification of the mathematical equations, allowing a direct evaluation of the response of the culture to different conditions [3].

The unstructured segregated model enables a simulation of a heterogeneous cell population, where each cell has age, weight or size individually defined. These properties variances are ruled by statistical distribution models, such as the Population Balance Models (PBM) [4]. The PBM allows the population heterogeneity to be represented in a more concise approach. Compared with the unstructured unsegregated model it increases the mathematical complexity of the simulation, because the equations need to take into account the cell variation in the population and in the period of cultivation. Even with the increasing difficulty yielded by the model complexity for mathematical solution and parameters estimation, new mathematical tools and the advanced monitoring techniques of cellular processes made the application of this type of model possible outside the academic environment.

The structured unsegregated model treats the cell population as if all the cells present identical values for identification characteristics, such as age, size and weight. Although, the cells present a distinguishable intracellular structures. In other words, the cell population is a representation of the same cell (i.e., same age, same size, and same weight) in different stages that are precisely defined by the knowledge of the dynamic relation between the intracellular structures and processes and the boundary conditions of the culture medium. The depth of this knowledge allows the intracellular characteristics be more

granular simulating the principal biochemistry processes of the metabolism [5].

The structured segregated model reaches the most precise simulation of the cell culture. It represents a heterogeneous cell population, in which each cell is individually characterized, and presents individual intracellular structures [6]. This approach leads to a robust representation of the diversity of the physiological behavior of cells with their own structures and metabolic pathways interacting with the boundary conditions of their microenvironment [7]. Although this great accuracy in the complexity of the cell culture has a high price to pay because of the complexity of the mathematical formulation and the determination of the parameters. Because of these requirements the structured segregated model is rarely used.

To support the development of computational models capable of reproducing and visualizing cell culture dynamics, appropriate simulation platforms are required. UE is a graphic engine utilized for game development and creation of visual effects. It is based on C++, a programming language well-known for its robust library and its optimization capabilities. Its development environment is prepared to use the GPU of the computer; this enables the usage of the GPU to help the simulation and calculation of some aspects of computational modeling. In addition, the implementation of a Graphical User Interface (GUI) is trivial using this editor.

In this context, the goal of this work is to develop a CM implemented in UE that offers the level of granularity presented in a structured segregated model, simulating the cell behavior individually through logical conditions and simple mathematical equations (i.e., equations with few variables and parameters). Therefore, mitigating the issues of applying complicated mathematical formulation observed in the structured segregated models that restrict the usage of this type of modeling.

II. Methods

A. Collecting data from literature

To evaluate the robustness of the CM, studies meeting the following criteria were selected: research involving cell culture that included a graphical representation for the GC; at least one of the GC studied was of a non-carcinogenic cell line; the initial glucose concentration and the initial culture medium volume were reported; the culture container had to be reported; the type of cultivation had to be mentioned (e.g., batch, fed-batched suspension culture, or continuous suspension culture).

Access to raw cell count data was initially considered as an inclusion criterion. However, due to the difficulty of obtaining such data from published studies, this criterion was eventually discarded. Instead, to compare the model generated data with the experimental data, we extract the experimental observation from the graphs retrieved from the website of the publisher. To reduce the analytical problem raised by this approach, we applied an appropriate order-of-magnitude scaling in the simulation data to match the experimental data extracted.

To extract the experimental observations, we used a note app to draw lines from each time entry parallel to its opposed axis (i.e., the time entries were on the x-axis, and their lines were parallel to the y-axis that contained the cell density entries). Then, we estimated the cell density values using the intersection point between the GC and the lines, and the reference values presented on the y-axis. We sought the highest resolution image available to decrease the estimation error. However, we acknowledge that even with the highest resolution possible, the extracted experimental observation contained considerable uncertainty that directly affect the accuracy evaluation of the comparison measurements taken in this study.

The magnitude scaling was achieved by manipulating the simulation data values using the scale set in the experimental observation graphs. For example, Pan et al [9] (2017) presented the experimental observations of GC on a graph with the y-axis set in total viable cells, where each unit of the y-axis corresponded to 10^9 cells/bioreactor. Therefore, we took the simulation data given in cells $\cdot$ mL^{-1} and converted the value to total viable cells/bioreactor, multiplying the simulation data by the total volume given by the authors, then dividing the result by 10^9.

We also defined the time horizon represented by the CM. The model simulated the first 2–3 days of *in vitro* cell culture, corresponding to the biological time experienced by the *in silico* cell population (not to be confused with the computational runtime of the simulation).

B. The structured segregated behavioral computational model

The structured segregated behavioral classification of the CM means that the model simulated the behavior of each cell individually with its own characteristics and its own internal processes (i.e., the cell can be identified individually by its own age, volume, shape, and stage of cell cycle with its own internal clock). The flowchart of the model is shown in Fig. 1

The model was developed in UE. Therefore, rather than expending effort on the manual implementation of GUI libraries and GPU acceleration in a standard C++ development environment (e.g., Visual Studio Code or Xcode), we were able to focus exclusively on model development and on exploring the intended simulations using the CM.

C. Setting the parameters for the model

The parameters of interest focused on the lag phase of cells cultured under both suspension and adherent conditions, glucose consumption rate for basal metabolism and biomass synthesis for cell division, maximum cell density per volume or surface area, seeding cell density, simulation time horizon, glucose concentration in the medium, total surface area or volume of the container.

The values of the parameters listed above were defined using the following. The information from the article (e.g., initial volume or area of cultivation, period of cultivation, glucose concentration, seeding density), and the characteristics of the cell line used in the experiment (e.g., maximum cell density, lag phase period, glucose consumption rate) were extracted from the literature.

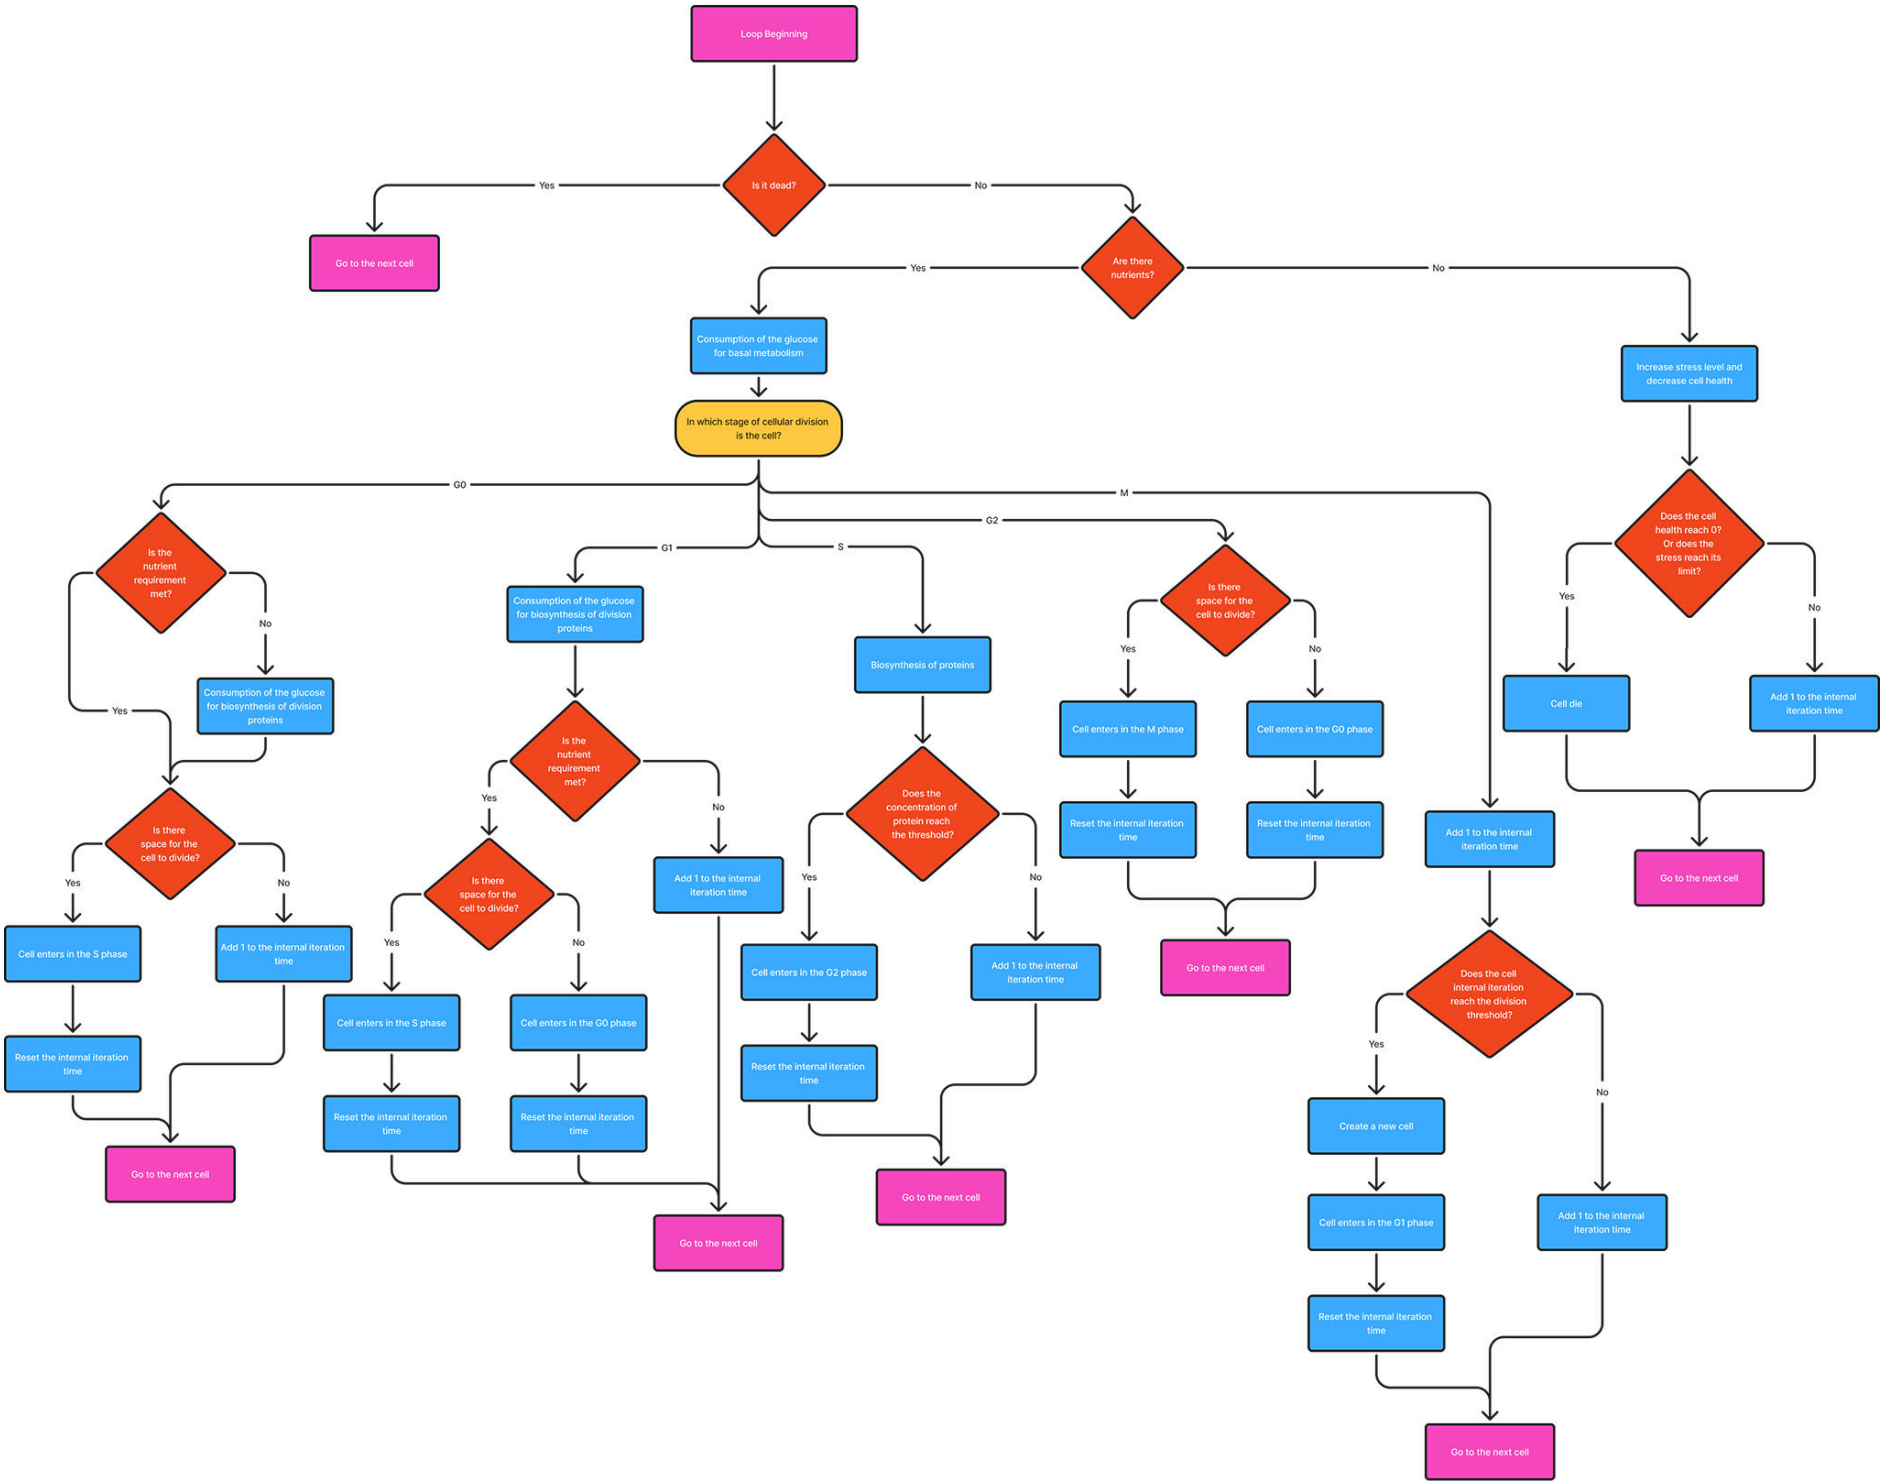

Fig. 1. Flowchart of the model cell behavior during the simulation. The internal iteration time refers to the internal clock of each cell.

To achieve heterogeneity in the cell population, cell characteristics in well-defined intervals were defined, and the CM chose pseudo-randomly a value in the range—using the Mersenne Twister algorithm that is natively supported in C++ and in the UE. This algorithm received the bound limits as input. The formulas applied to calculate the parameter bounds were:

$$\text{lower bound} = \text{literature datum} – 0.2 \times \text{literature datum} \quad (1)$$

$$\text{upper bound} = \text{literature datum} + 0.2 \times \text{literature datum} \quad (2)$$

The authors assumed that the characteristics followed a Gaussian distribution.

Because the glucose consumption rate per cell is extremely low (on the order of 10^{-15} mol · cell^{-1} · min^{-1}), both the glucose consumption parameter and the glucose concentration in the culture medium were scaled by a factor of 10^{13} as a numerical scaling strategy. This scaling was necessary because, given the numerical precision adopted by UE (approximately six decimal places), these values would otherwise be treated as zero during the computations. Although this limitation could be overcome by modifying the numerical representation or by implementing a scientific mathematics library with higher precision, such modifications were unnecessary, as the proposed scaling strategy preserved the intended cell behavior throughout the simulations.

The units adopted throughout the simulation were: mL for volume; mm^2 for surface area; cells · mL^{-1} for cell density; min for the simulation time step and lag phase duration; mol for glucose concentration; and mol · cell^{-1} · min^{-1} for the glucose consumption rate.

Based on the values of the parameters related to culture environment (e.g., volume of the container, seeding cells density) the number of simulations was selected to ensure that users could complete the simulation within a reasonable computational time. The environment parameters values for each simulation taken from the experiments are presented in Table I; the parameters values of cell characteristics taken from the literature are shown in Table II; and the general parameters applied in all simulations are listed in Table III.

D. Treating the simulation data

The simulation data was treated with biostatistics functions to calculate the growth rate of the cell population and the doubling time of each culture. Each experimental condition was simulated three times, the mean value was used as a scatter point, and the deviation of the simulation results was presented using the error bar. Data analysis was done in Python using pandas, numpy, matplotlib, and scipy libraries for the treatment, visualization, and manipulation of the experimental and simulation data. To maintain the same number of collected points in both groups, the authors took only the entries of the simulation data that met the time interval of the experimental entries observed (e.g., 24 h, 48 h, 72 h). Therefore, prevent statistical discrepancies related to the number of sample data

of each group. Based on the sample data, the non-absolute relative error, $\delta(t)$, was determined using the following formula:

$$\delta(t) = (y_s(t) - y_e(t))/y_e(t) \tag{3}$$

For the absolute relative error, $|\delta(t)|$, the formula applied was:

$$|\delta(t)| = |y_s(t) - y_e(t)|/y_e(t) \tag{4}$$

The MAE was calculated using the following formula:

$$\text{MAE} = \frac{1}{n}\sum_{t=1}^{n} |y_e(t) - y_s(t)| \tag{5}$$

where $y_s(t)$ is the simulation value at time t, $y_e(t)$, the experimental value at the same time, and n is the number of time steps. For the estimation of the doubling time of each GC, the formula applied was as follows.

$$T_d = (\Delta t \times log(2))/(log(X_{max}/X_0)) \tag{6}$$

where T_d is the doubling time in hours, Δt is the incubation time in hours, X_{max} is the maximum value of cell density reached in this period, and X_0, the initial cell density (i.e., the seeding density), both densities in cells · mL^{-1} or cells · mm^{-2}. In order to calculate the mean growth rate, the following formula was used:

$$\mu = log(X_T/X_0)/\Delta t \tag{7}$$

where μ is the mean growth rate of the culture in cells · ml^{-1} · h^{-1}, X_T is the cell density at the last collected point in cells · mL^{-1}, X_0, the seeding density in cells · mL^{-1} and Δt is the incubation time in hours.

The results were expressed in mean of the simulation values ± standard error of the mean (SEM).

III. Results and Discussion

Our analysis focused on the initial 2-3 days of cultivation in order to avoid misinterpretation of the process and the impact of renewing the culture medium on the GC, ending the simulation before the medium change in the experiments. Another reason for this time interval was to be able to simulate different cell lines and different experimental settings to demonstrate that the CM did not overfit a unique cell line under specific conditions. The total time required to simulate each replicate was 12 days, approximately. Due to the time cost of running all simulations, each experimental condition was simulated only three times. This decision prioritized the evaluation of all experimental conditions rather than increasing the number of replicates per condition. Even because without raw data, we could not calculate the SEM of the experimental observations, then the number of replicates does not have the expected statistical weight for the comparison, contributing to the decision to limit the number of replicates to the minimum required to represent the results as mean value ± SEM. In addition, the evaluation of the MAE indicated that the addition of more data sets would not change expressively the prediction performance of the CM in all experimental conditions evaluated. The Table IV shows the MAE with the standard deviation, σ, of all possible combinations of the data sets.

TABLE IV

[14]	CHO GS46	0.385 ± 0.059	0.416 ± 0.03	0.364 ± 0.052	0.38 ± 0.082	$\times 10^9$

For the purpose of this study, the model is limited to simulate a certain group of characteristics large enough to allow heterogeneity in the *in silico* population. This decision enabled us to simulate different cell lines without the depth of knowledge necessary to set all the model parameters presented for each line (the fixed parameters were listed in Table III). The authors believe that heterogeneity reduces the possibility of overfitting; therefore, it was fundamental that the limited group of attributes could represent some cell line differences.

The difference of the proposed CM is the approach to emerging the complexity of the mathematical formulation based on the individual cell behavioral response. This enables it to simulate the cell culture as a structured segregated model without the application of complicated mathematical equations. To accomplish this goal, our work was to simulate *in silico* cell heterogeneity throughout the distribution of biological characteristics of the cell line—lag phase period and nutrient consumption rates—and the stochastic phenomena related to cell division, mainly the biosynthesis of proteins.

For the biological characteristics, we used equations 1 and 2 to obtain the intervals of values that were input for the Mersenne Twister algorithm. The Empirical Rule establishes that approximately 68% of the data is in the interval of the first standard deviation, σ_1. So using data from the literature, which is frequently given as a mean value, and getting $\sigma_1 = 0.2\times$literature data, it was possible to generate a representative interval for the characteristics (shown in Table II), discarding potential extreme behavior that could create abnormalities in the simulation data.

To achieve the stochastic characteristic of proteins biosynthesis for cell division, the authors used the differential equation proposed by Biswas and Brenner [8] (2024). This approach treats the metabolic process as an Ornstein-Uhlenbeck process (i.e., a stochastic process of threshold crossing event), allowing

the model to simulate the progress of the cell cycle in a more natural and less deterministic way.

The similarity between the simulation results and the experimental data (i.e., the prediction capacity of the model) was evaluated by calculating the MAE, and the absolute and non-absolute relative errors. Furthermore, to hypothesize about the impact of CM fixed parameters in the simulated GC, we calculated the growth rate and doubling time of the cultures (Table V).

TABLE V
COMPARISON OF GROWTH RATE AND DOUBLING TIME. EXPERIMENTAL (e) AND SIMULATION (s)

[13]	Vero (adherent)	0.0174	0.0335 $\pm$0.0025	39.8372	20.6636 $\pm$1.4314
[14]	CHO GS46	0.0261	0.0415 $\pm$0.0015	26.5581	16.6902 $\pm$0.5799

The mean absolute relative error of the CM, which is $|\bar{\delta}| = 0.77 \pm 0.127$, shows that, for the entire simulated period of all conditions, the model had a tendency to overestimate the experimental data by approximately 77%. It is important to highlight that because of the different units of the collected data, we decided not to use the average MAE (i.e., the mean value of the MAE calculated for each experimental condition) since it retains the unit of the analyzed data. On first look, we could conclude that the CM did not achieve a good prediction of culture growth. However, looking for the general stages presented in a culture growth curve individually (e.g., lag phase, log phase), we found that at early stages —lag phase and the first portion of the log phase (around the first 36 hours)— the CM predicted, on average, the culture growth with an error estimation of the experimental observations around 17%, $|\bar{\delta}|_{early} = 0.168 \pm 0.031$ (as shown in Fig. 2). Using the non-absolute relative error, we found that in some conditions the model underestimated the culture growth, and in others, it overestimated the growth behavior of the cells, as can be seen in Fig. 3. How to improve the prediction in this scenario of mix estimations will be discussed later.

Now, looking at the last stages —the second portion of the log phase— of the simulations, the CM had a poor prediction of the GCs, it overestimated the experimental data, on average, by approximately 242.6%, $|\bar{\delta}|_{last} = 2.426 \pm 0.393$. In other words, *in silico* cell cultures were almost 2.5-fold more dense than *in vitro* cell cultures. We hypothesize that cells cease division prior to reaching their maximum density, halting population growth. Possible explanations for this may involve reduced nutrients in the medium and spatial

limitation, parameters included in this work. However, other parameters can be related, such as contact inhibition [15], pH alteration [16], accumulation of toxic metabolites [17], [18], among others, which were not considered in this exploratory analysis. The possibility that more replications would improve the average CM prediction without adjusting the parameters was discarded because of the low variance presented in the MAE of the combination of data sets, as discussed earlier. So, a large number of replications would probably not avoid those significant overestimations observed, even with the cells inner characteristics varying pseudo-randomly. The authors believe

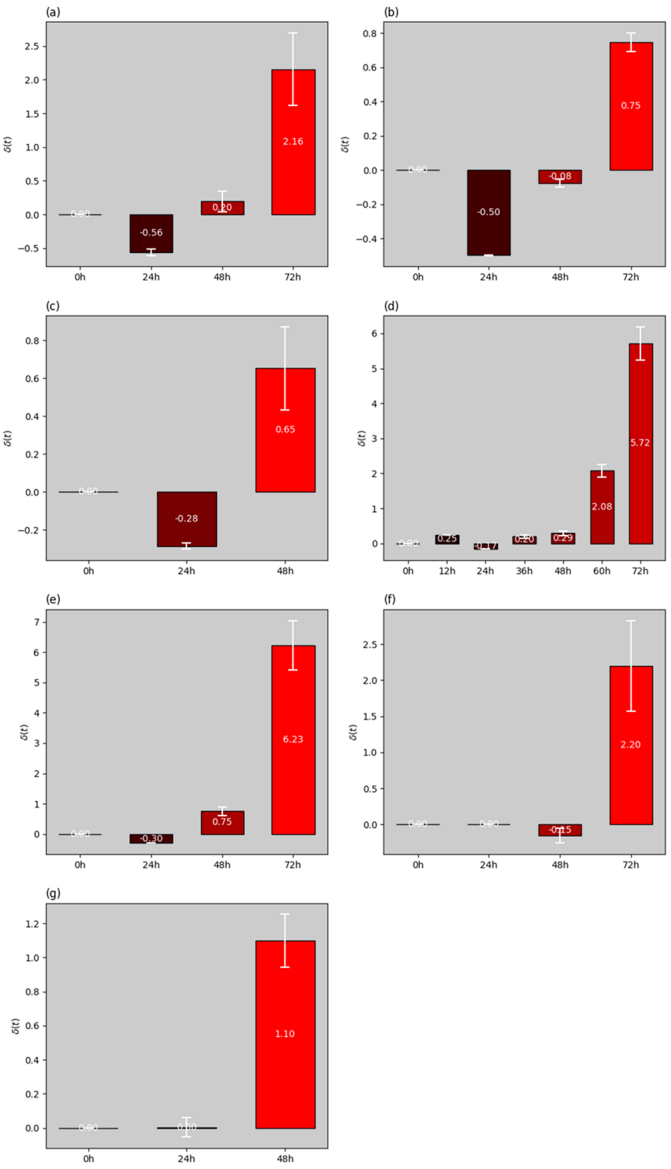

Fig. 3. Non-absolute relative error of the cell number of the simulation data at each period of time. (a) CHO-BC® cells [9]; (b) CHO-DG44 cells [10]; (c) CHO-K1 cells [11]; (d) Vero ATCC-CCL-81 cells [12]; (e) and (f) Vero ATCC-CCL-81 cells in suspension and adherent culture, respectively, [13]; (g) CHO-GS46 cells [14].

that adjusting only the parameters of interest could reduce the CM overestimation of the final cell density, but probably the early stages would suffer an error prediction increase.

However, it is already established in the literature that environmental cues to induce halt of cell division are more complex than just the number of cells in the vicinity of each cell and the availability of nutrients. For this study, we chose not to increase the number of parameters under evaluation because the raw experimental data were not available.

The aforementioned non-absolute error of the simulations, illustrated in Fig. 3, is the key to establish a strategy to improve the prediction power of the CM. These data can clarify how the fixed parameters impacted the simulation. The first two parameters presented in Table III —cell health range and senescent death rate range— do not needed any adjustment in the scenarios used in this work, because the period of cultivation selected were the initial stages, when the cells, theoretically, could not reach yet the number of divisions required to enter in senescence, and the health is only a representation of the cell to endure damage and stressful conditions before entering in apoptosis or necrosis. The G2 and Mitotic phases duration parameters are another pair of values that does not need any adjustment in the CM framework used for two reasons, the values used are well-known in the literature, representing the average duration of each phase in a mammalian animal cell; and because in the future framework of the model, these phases logic will be refined to simulate the cellular division process using mechanical and spatial feedback of the *in silico* cell in division and its surrounding. The variables related to stress of the cell will also be improved through the implementation of boundary conditions of the signaling context presented in cellular cultures. All the parameters already mentioned are not included in our hypothetical solution for solve the overall overestimation of the CM.

For us, the variables of the Ornstein-Uhlenbeck process and the variable of glucose concentration required for cellular division were the fixed parameters responsible for the prediction capability achieved by the CM. The glucose concentration required represents in a simplistic way the volume that the *in silico* cell must achieve to pass the checkpoint of G1 phase. In other words, this parameter represents how much glucose oriented to biomass production the cells need to synthesize and duplicate its protein mass as one of the conditions required for the cell to enter in the DNA duplication process. Therefore, this value can lead the model to overestimate the volume needed for the specific cell line to divide if it is greater than the actual volume required; or it can lead the model to underestimate the volume needed if it is smaller than the actual volume. In the simulations made for this study, we think that the fixation of this variable contributes to the overall overestimation of the model, mainly because this variable was not linked to the actual size of the *in silico* cell (i.e., the cell volume did not increase as the protein mass increases), so the negative feedback given by the available space around the cell for its growth and division did not regulate glucose uptake and proteins synthesis. The absence of this type of feedback leads to a theoretical growth rate greater than the actual growth rate of the cell line. In the case of the experimental conditions simulated, the simulation growth rate overestimated, on average, the experimental growth rate by 167.7%. In other words, the *in silico* cells divided 1.7x faster than the *in vitro* cells (Fig. 4A). Furthermore, the variables of the Ornstein-Uhlenbeck process will directly affect proteins synthesis. The protein α threshold rate will impact, for example, the protein mass required for the cell to divide. A larger rate will lead to a great threshold value fluctuation because of the restoring force of this stochastic process; also, different cell lines present different rate values (as can be seen in Fig. 4). The restoring force variable impacts

how fast the protein threshold returns to its center. And the initial values of the protein α concentration and its threshold can lead the CM to underestimate or overestimate how much the cell needs to grow for its division. These variables impact the speed of the culture growth and its doubling time. Looking at the doubling time of the *in silico* and *in vitro* culture, we can conclude that the values used for the threshold rate and the restoring force lead the CM to underestimate the protein mass required for cellular division in these cell lines, so the *in silico* cells were able to divide faster than the *in vitro* cells, as the *in vitro* population needed 80.5% more time, on average, to double when compared to the *in silico* population (Fig. 4B).

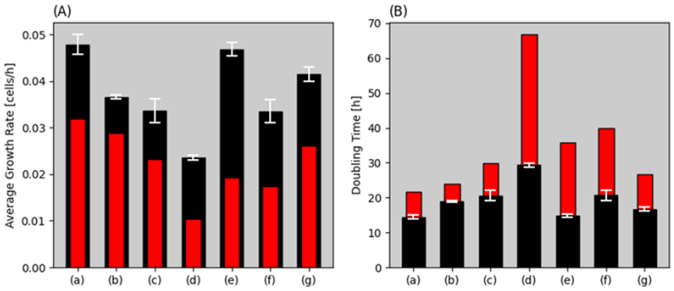

Fig. 4. Comparison of the average growth rate (A) and comparison of the doubling time (B) of the simulation data (black bars) and the experimental data (red bars). (a) CHO-BC® cells presented in [9]; (b) CHO-DG44 cells presented in [10]; (c) CHO-K1 cells presented in [11]; (d) Vero ATCC-CCL-81 cells presented in [12]; (e) and (f) Vero ATCC-CCL-81 cells in suspension and adherent culture, respectively, presented in [13]; (g) CHO-GS46 cells presented in [14].

Future work should include the cultivation of the cell lines simulated in order to validate the CM through the F-test methodology proposed by [1]. Further investigations should also explore alternative values for the parameters that remained unchanged in the present study. The future CM framework can become able to support bioreactor simulations, enabling the evaluation of production performance and the identification of optimal operating strategies to achieve target product yields with high accuracy while avoiding excessively complex mathematical formulations. Ultimately, the model is intended to simulate cell 3D culture to generate and analyze vasculature geometries capable of sustaining the cells.

IV. Conclusion

The current framework of the CM evaluated in this study demonstrated the potential to reproduce the short-term GC of different cell lines. However, its predictive performance decreases over extended simulation periods. In the future, with further improvement in the simulation of metabolic processes and the implementation of cellular mechanical simulation, the proposed model could achieve the potential to evaluate different culture scenarios and support researchers in estimating suitable strategies for their specific objectives.

***Abstract*—Dengue is a major public health concern in tropical and subtropical countries due to its high incidence and recurrent outbreaks. Despite its significant impact, treatment remains primarily supportive, highlighting the need for effective antiviral strategies. This study employs mathematical modeling and computational simulations to evaluate and compare the effects of two antiviral approaches against dengue infection. The results demonstrated that early antiviral administration prevented sustained viral replication and markedly reduced viral load in both sexes compared with the untreated condition. In the female simulations, antiviral ρ produced the most pronounced reduction in viral load immediately after treatment initiation, whereas antiviral ψ promoted faster elimination of residual viral particles during the later stages of infection. In the male simulations, antiviral ψ showed greater reduction in the viral load , while antiviral ρ provided a rapid initial decrease in viral load. In both sexes, delaying treatment initiation from the first to the second day resulted in higher viral peaks and slower viral elimination, reducing the overall therapeutic benefit. These findings demonstrate that sex-specific immunological characteristics influence antiviral efficacy and highlight the potential value of incorporating sex-related parameter variation into within-host dengue modeling.**

***Index Terms*—dengue; mathematical modeling; antiviral therapy; T lymphocytes; viral dynamics.**

I. Introduction

The dengue virus (DENV) is one of the most significant arboviral diseases affecting global public health, particularly in tropical and subtropical regions. The disease belongs to the *Flaviviridae* family and is primarily transmitted by the *Aedes aegypti* female mosquito, whose proliferation is favored by environmental and climatic conditions such as high temperatures and intense rainfall [13]. In Brazil, (DENV) exhibits an endemic pattern with recurrent epidemic outbreaks and remains a major challenge for public health systems due to its high incidence and socioeconomic impact [1], [11]. Despite its considerable burden, dengue management remains predominantly supportive and symptomatic, highlighting the need for effective therapeutic interventions. Mathematical and computational models have become valuable tools for understanding the within-host dynamics of viral infections, allowing the investigation of interactions between viral particles, infected cells, and immune components, as well as the evaluation of potential treatment strategies [3], [6]. Among the immune components involved in dengue infection, T lymphocytes play a central role in both viral clearance and disease pathogenesis. These cells contribute to the recognition and elimination of infected cells and regulate antiviral responses through cytokine production, significantly influencing the progression and outcome of dengue virus infection [2], [9]. Furthermore, immune responses may vary among individuals due to biological factors, including sex-related differences, which can affect disease progression and treatment efficacy [7], [8]. Recent studies have proposed different antiviral approaches to control dengue infection. One strategy, represented by antiviral ρ (rho), acts directly on free viral particles, reducing viral load and limiting viral dissemination throughout the host [5]. The second antiviral strategy, represented by the parameter ψ, enhances immune-mediated viral clearance by increasing the effectiveness of the host immune response. Rather than directly inhibiting viral production, ψ increases the rate at which free viral particles are eliminated [3]. Since these antiviral strategies target different aspects of the infection process, comparing their effects on dengue within-host dynamics may provide important insights into the development of more effective and personalized therapeutic interventions. Therefore, the present study aims to analyze and compare the effects of antivirals ρ and ψ on the within-host dynamics of dengue infection through mathematical modeling and computational simulations, considering their impacts on viral load and T lymphocyte populations in both men and women.

II. Literature Background

A. Immune Cells Involved in Dengue Infection

The course of dengue infection results from a complex interplay between dengue virus (DENV) replication and the host immune response, this viral infection dynamics are represented in Fig. 1. After inoculation by an infected *Aedes aegypti* mosquito, the virus enters the circulation and rapidly encounters immune cells that are susceptible to infection, especially monocytes, macrophages, and dendritic cells. These

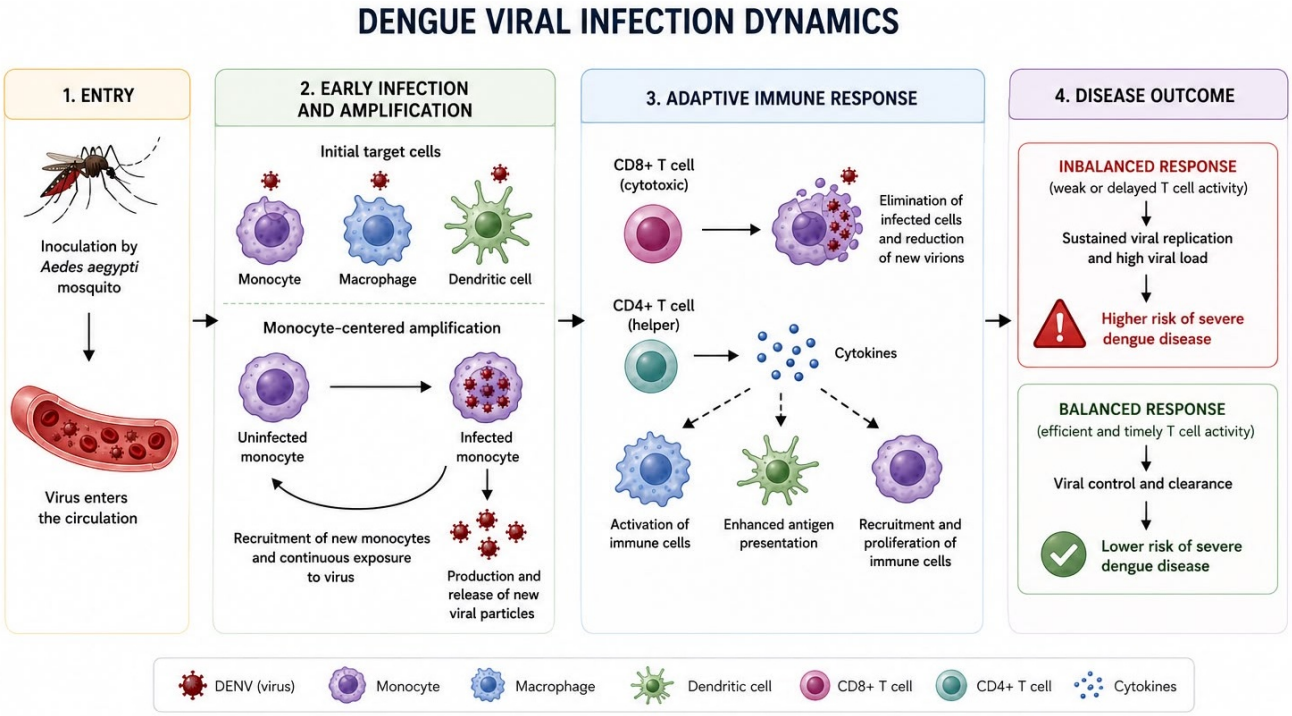

Fig. 1. DENV infection dynamics.

cells not only constitute the initial targets of DENV but also provide a favorable environment for viral multiplication and dissemination within the host [2].

Among these immune cells, monocytes are specifically important in the establishment and progression of infection. Following viral entry, infected monocytes actively produce and release new viral particles, contributing to the amplification of viral load. Meanwhile, uninfected monocytes continue to be recruited and become exposed to circulating virions, generating a continuous cycle of infection and cellular turnover [10].

The adaptive immune response, especially that mediated by T lymphocytes, is essential for limiting viral spread. Cytotoxic T lymphocytes eliminate infected cells and reduce the production of new virions, whereas helper T cells orchestrate immune activity by secreting cytokines and promoting the activation of additional immune populations [2]. Consequently, the efficiency of T-cell-mediated responses has a direct impact on the control of dengue infection.

Disease outcome depends largely on the equilibrium established between viral expansion and immune-mediated clearance. Efficient and timely activation of T lymphocytes favors viral control and contributes to infection resolution. In contrast, inadequate or delayed immune responses may permit sustained viral replication, thereby increasing the likelihood of severe clinical outcomes [2], [10]. Therefore, characterizing the interactions among viral particles, susceptible monocytes, infected monocytes, and T lymphocytes is fundamental for constructing mathematical models that accurately represent dengue within-host dynamics and for assessing the potential efficacy of antiviral interventions.

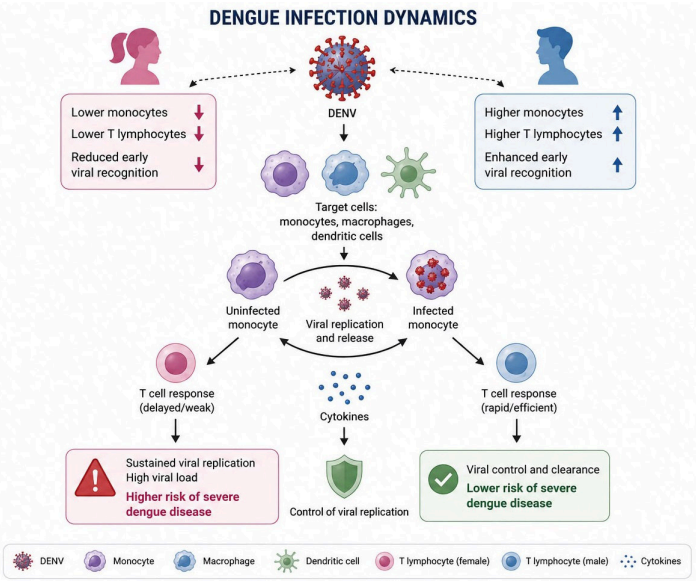

Fig. 2. sex-related differences assumed in the mathematical model

B. Female Immune System

The female immune system exhibits complex and dynamic characteristics that can significantly influence the progression of viral infections, as represented in Fig. 2. In general, women tend to develop different innate and adaptive immune responses than men due to differences in immune regulation and hormonal influences, which can affect both susceptibility to infections and therapeutic outcomes [8]. Nevertheless,

in the present mathematical model, females were assigned lower initial populations of T lymphocytes, which play a fundamental role in controlling viral replication by recognizing and eliminating infected cells and coordinating antiviral responses through cytokine production [2], and monocytes, therefore, characterizing lower rates of monocyte production and viral recognition compared to men [7]. Consequently, reduced availability of these immune cells may compromise the efficiency of viral clearance efficiency and contribute to increased vulnerability during dengue infection, particularly when antiviral treatment is delayed [7]. These findings highlight the importance of considering sex-related immunological differences in mathematical models of dengue infection and in the development of personalized therapeutic strategies, especially those aimed at preserving or increasing T-lymphocyte populations [2], [7], [8].

C. Male Immune System

The male immune system presents distinct immunological characteristics that can influence the progression and control of viral infections, as demonstrated in Fig. 2. Overall, men tend to exhibit less intense innate and adaptive immune responses than women, resulting in differences in susceptibility, disease progression, and responses to therapeutic interventions [8]. Nonetheless, in the mathematical model, male individuals were characterized by higher viral-recognition compared with women thereby presenting increased rates of T lymphocytes,responsible for limiting viral replication through the recognition and elimination of virus-infected cells [2], and increased initial rates of monocyte populations production compared with women [7]. These characteristics may contribute to a more efficient early immune response and greater capacity to control viral replication. Consequently, these findings emphasize the importance of considering sex-related differences in immune dynamics when developing mathematical models of dengue infection and evaluating antiviral strategies [2], [7], [8].

III. Methods

A. Mathematical Modeling of Immune Cells

The present study employed mathematical modeling based on ordinary differential equations (ODEs) and computational implementations developed in Python to investigate the immune dynamics of young adults of both sexes during dengue infection and under antiviral treatment, this course of the methodology used in the study is represented by Fig. 3. The model describes the temporal evolution of infection and immune responses by simulating viral load and immune cell populations [3], [12].

1) Equations: Four state variables were considered: $v(t)$, representing the concentration of free viral particles; $s(t)$, the population of susceptible monocytes; $i(t)$, the population of infected monocytes; and $z(t)$, the population of T lymphocytes.

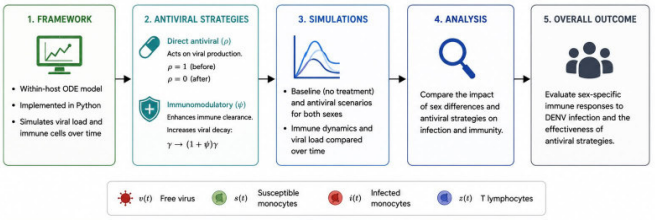

Fig. 3. Representation of the methodology used to obtain the results.

The parameters k and (γ) denote the viral replication rate and the natural clearance rate of free viral particles, respectively.

$$\begin{cases} \dfrac{dv}{dt} = ki(t) - \gamma v(t) - as(t)v(t) \\ \dfrac{ds}{dt} = \mu - \alpha s(t) - as(t)v(t) \\ \dfrac{di}{dt} = as(t)v(t) - \beta_1 i(t) - \psi i(t)z(t) \\ \dfrac{dz}{dt} = \eta + c_1 i(t) + di(t)z(t) - \delta z(t) \end{cases} \tag{1}$$

For all simulations, the initial conditions $v(0)$=165 and $i(0)$=10, together with the parameters k =20, a=0.003, and (γ=0.8), were assumed to be identical for both sexes. In contrast, the initial populations of susceptible monocytes $s(t = 0)$ and T lymphocytes $z(t = 0)$, as well as the monocyte production rate (μ), the T-lymphocyte production rate (η), and the viral recognition parameter (d), were adjusted according to sex-specific immunological characteristics [7], [8].

TABLE I
Model Parameters Modified by Sex.

Modified Elements	$s(t=0)$	$z(t=0)$	μ	η	d
Women	480	1700	120	0.20	0.01
Men	500	1800	130	0.21	0.02

2) Mathematical Model for Antiviral Treatment: The system of ordinary differential equations was based on previously proposed mathematical models of dengue within-host dynamics and immune interactions [3], [6]. Two antiviral strategies were incorporated into the model. The first, represented by the parameter (ρ), acts directly on free viral particles, reducing viral load and limiting viral dissemination. Following a previous approach, (ρ = 1) before treatment administration and (ρ = 0) after antiviral administration, representing the inhibition of viral production [5].

$$\frac{dv(t)}{dt} = (1-\rho)\kappa i(t) - \gamma v(t) - \alpha s(t)v(t) \tag{2}$$

The second antiviral strategy is represented by the parameter (ψ), which does not act directly on viral particles. Instead, it enhances the host immune system's ability to eliminate the virus by increasing the immune-mediated viral clearance rate. Specifically, (ψ) acts as a multiplicative factor on the natural viral decay coefficient, (γ), intensifying the viral removal term by a factor of (1+ψ). Consequently, the equation governing the dynamics of free viral particles becomes: [3].

$$\frac{dv(t)}{dt} = ki(t) - (1+\psi).\gamma v(t) - as(t)v(t) \qquad (3)$$

where the term ((1+ψ)γ v(t)) represents the enhanced elimination of viral particles mediated by the host immune response. This immuno modulatory strategy strengthens the natural defenses of the organism and contributes indirectly to the control of dengue infection.

Results

The simulation results demonstrate that early antiviral administration substantially reduces viral load in both sexes when compared with the untreated condition. In all simulated scenarios, antiviral therapy effectively interrupted sustained viral replication, resulting in a more rapid decline in viral particle concentration following treatment initiation. Furthermore, the two antiviral strategies evaluated exhibited distinct therapeutic profiles throughout the course of infection, indicating that their mechanisms of action differentially influence viral clearance dynamics.

In the female simulations, antiviral administration on the first day of infection produced a pronounced reduction in viral load shortly after the peak of infection. The antiviral ρ, which directly inhibits viral production, promoted the greatest decrease in viral load during the early post-treatment period. In contrast, the antiviral ψ, which enhances immune-mediated viral elimination, exhibited comparable efficacy during the initial phase of treatment but achieved a slightly faster reduction in residual viral load during the later stages of infection, as observed in Fig. 4.

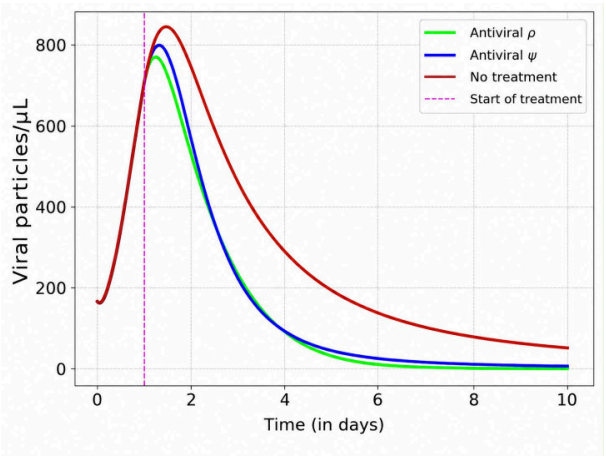

Fig. 4. Antiviral treatment administrated on the first day of infection in women.

.

When treatment initiation was delayed until the second day, both antiviral strategies remained effective; however, the therapeutic benefit was attenuated because viral replication had already progressed substantially before intervention, as presented in Fig. 5.

A similar pattern was observed in the male simulations. Early treatment initiation, as seen in Fig 6 markedly restricted

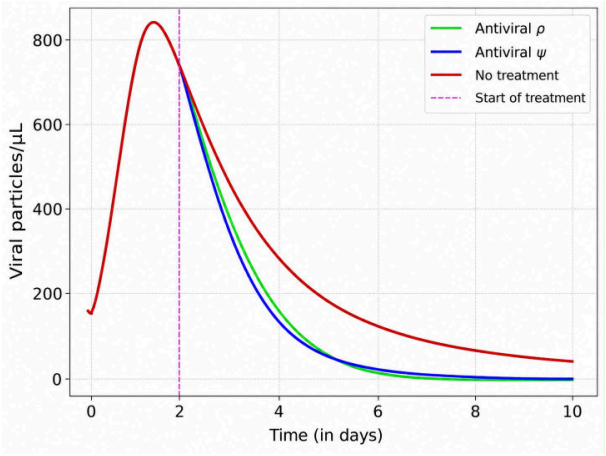

Fig. 5. Antiviral treatment administrated on the second day of infection in women.

infection progression and shortened the duration of elevated viral load relative to the untreated condition. In contrast to the female simulations, antiviral ψ exerted a stronger immediate effect following administration, whereas antiviral ρ enhanced viral clearance during the declining phase of infection, resulting in lower viral levels during the later stages.

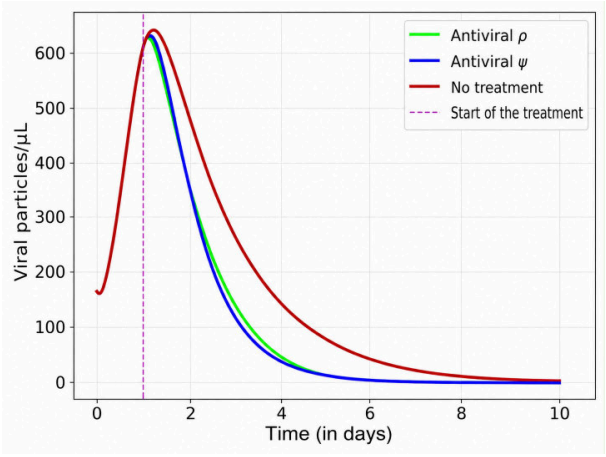

Fig. 6. Antiviral treatment administrated on the first day of infection in men.

The delayed administration of treatment until the second day, represented by Fig. 7 reduced the efficacy of both antiviral strategies, emphasizing the importance of early therapeutic intervention for optimal viral control.

Conclusion and Discussion

The comparison between sexes further revealed that female simulations exhibited higher peak viral loads than male simulations, reflecting the sex-specific immunological parameters incorporated into the mathematical model. Despite these differences, both sexes responded favorably to antiviral therapy, with treatment initiated on the first day consistently producing superior outcomes. Overall, both antiviral strategies substantially improved viral control compared with the untreated scenario.

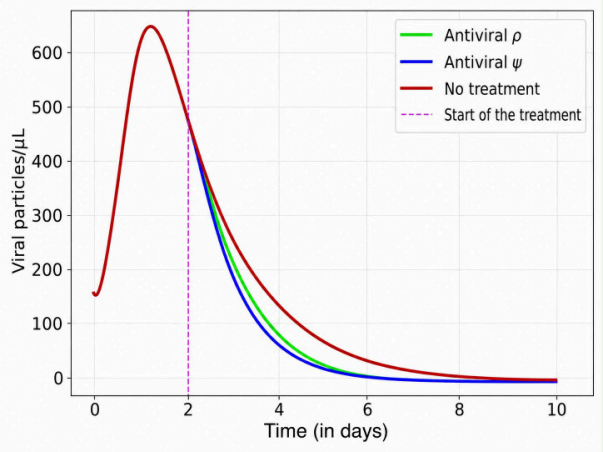

Fig. 7. Antiviral treatment administrated on the second day of infection in men.

However, the comparative analysis suggests that the optimal therapeutic approach may differ according to biological sex. Specifically, antiviral ρ produced the greatest overall reduction in viral load in the female simulations, whereas antiviral ψ achieved slightly greater efficacy during the later stages of infection in the male simulations. These findings indicate that sex-related immunological and physiological differences can influence antiviral performance and, consequently, therapeutic outcomes. Therefore, the present results support the development of sex-specific and personalized antiviral strategies to maximize treatment efficacy in dengue virus infection.

***Abstract*—This study presents and applies the comparison of a technique based on the magnitude and phase metrics as well as the linear correlations and amplitudes of computed muscle activations (CMA) and lower limb surface electromyography (sEMG) during different stretch-shortening cycle. CMA algorithm is based on data fusion from external kinematic and dynamic direct measurements for inverse dynamics with subject specific musculoskeletal model, static optimization and 2nd order polynomial cost function to address muscle redundancy. The magnitude (M) and phase (P) metrics proved adequate for the comparison of CMA based on sEMG. Thus, despite different nature of CMA and sEMG, presented methods pave the way for improvement of both techniques, namely with different optimization strategies, cost functions, muscles and movements applied at larger samples to assess multimodal comparison.**

Keywords—computed muscle activations, sEMG, lower limb, muscle SSC

I. Introduction

Natural human movement is the result of the integration by the neuromusculoskeletal system starting at the neural sum of the excitatory and inhibitory inputs from each motoneuron, the integration of all the motor twitches for the muscle recruitment, the sum of the agonist and antagonist muscle actions at each joint, and the combination of the synergistic joint actions towards a common goal [1]. Muscle stretch-shortening cycle (SSC) is a natural phenomenon involved in gait, running and jumping, with lower limb muscle contraction immediately preceded by the muscle stretch for efficient submaximal and powerful maximal action [2-4]. Thus, despite lower limb muscle SSC can be observed in gait and running, its higher expression and accessibility is performed on maximum vertical jump with long countermovement (CM) at countermovement jump (CMJ) and drop jump (DJ) with short CM for comparison with squat jump (SJ) and no CM [5-6].

Muscles, as the active components responsible under the control of the central nervous system (CNS) for the necessary actions to produce natural human movement are typically assessed using noninvasive surface electromyography (sEMG). Despite isolated concentric and excentric actions have received larger research effort, muscle SSC corresponds to a natural human action, with sEMG assessment issues at dynamic conditions.

More recently, computed muscle actions (CMA) from inverse dynamics, with subject specific musculoskeletal modeling and simulations (MSK-MS) based on optimization techniques, have arisen to address muscle redundancy issues, with an open question on the most adequate cost function for realistic muscle tendon unit (MTU) action prediction at different CM and SSC. For this reason, we have performed a comparison study of the lower limb CMA from personalized MSK-MS with corresponding sEMG towards validation at different CM and SSC. According to different nature of CMA and sEMG, complementary analysis was used for comparison at each signal category, namely the phase/magnitude metrics [7], the Pearson correlations and the amplitudes/dispersions.

II. Materials and Methods

A. Trial tests

A total of 54 trials were assessed using subject-specific musculoskeletal digital models, including three repetitions each of the countermovement jump (CMJ), drop jump (DJ), and squat jump (SJ). The sample is composed by a group of six sports and physical education students with ages 20-24 years old, body masses 60-84 kg and heights 1.69-1.86 m. None of the participants presented any pathology or had undergone specialized sports training. The study was approved CAE200903 by the ISMAI scientific committee 01/03/2009 and the ethical standards were followed on human experimentation in agreement with the Helsinki Declaration of 1975, as revised in 2000 and 2008. Participants were explained on the study purpose and procedures and signed written informed consent

Reflective adhesive markers were positioned at the skin surface over palped anatomic joints. These included the right and left acromioclavicular joints at the shoulders (RSHO /LSHO), anterior superior iliac spines at the hip (RASI/LASI), knees femoral epicondyles (RKNE/LKNE), lateral malleoli at the ankles (RANK/LANK), heels calcanei (RHEE/LHEE), and the distal ends of the second metatarsals at the toes (RTOE/LTOE). In addition, Aqua-Wet gel Skintact F55 electrodes were placed in a bipolar arrangement according to SENIAM guidelines for surface electromyography (sEMG) recording of selected lower-limb muscles, namely *vastus medialis* (VM), *rectus femoris* (RF), *vastus lateralis* (VL), *gastrocnemius lateralis* (GL), and *gastrocnemius medialis* (GM).

During the experimental trials, ground reaction forces and moments were collected at a sampling frequency of 1000 Hz using an AMTI BP2416-4000 CE force platform (Advanced Mechanical Technology Inc., Watertown, MA) connected to an AMTI Mini Amp MAS-6 amplifier. Simultaneously, sEMG synchronized signals were acquired at 2000 Hz and transmitted through a 32-channel Biotell 99 telemetry system (Glonner Electronic GmbH). Video recordings were captured at 100 Hz after external synchronization using two JVC GR-VL9800 camera system (JVCKENWOOD Corporation, Kanagawa, Japan), positioned 4 m from the subjects and aligned parallel to the sagittal plane at anterior and posterior locations.

B. Signal processing

Ground reaction forces and force moments were resampled at 100 Hz to match with the image acquisition frequency. The integration of each 2D camera image with the calibration system was performed using direct linear transformation (DLT), and the 3D coordinates of the reflective markers were tracked using Simi Motion 3D Version 7.5.280 (Simi Reality Motion Systems GmbH, Germany). The obtained 3D Cartesian coordinates were filtered in the time domain using a bidirectional second-order low-pass Butterworth filter with a 12 Hz cut-off frequency, applied in both forward and reverse directions to prevent phase distortion, as described by [1]. Raw sEMG signals were normalized relative to the maximum voluntary contraction (MVC), rectified, and subsequently filtered using a second-order low-pass Butterworth filter with 5.0 Hz cut-off frequency applied bidirectionally to avoid phase shift and generating the sEMG linear envelope.

C. Computed muscle actions

Inverse kinematics was implemented using AnyBody Version 8.1.2 Modeling System (AnyBody Technology A/S, Aalborg, Denmark) and articular cartesian coordinates to obtain lower limb joint angles, angular velocities and accelerations. Inverse dynamics was performed from the joint angular kinematics and ground reaction forces / force moments using multi-articular dynamics and obtaining lower limb joint moments of force. Based on joint moments of force, the musculoskeletal geometry and muscle properties, the CMA were calculated, as presented at Fig. 1, using static optimization and polynomial $p = 2$ cost function along with computed muscle control to minimize the error between the model and the experimental joint angles / angular velocities with time iteration and direct dynamics.

Applied musculoskeletal model was the full human body model with 432 degrees of freedom (DOF) and eleven segments for the lower limb, corresponding to the pelvis, femurs, tibias, talus and feet, with 4 joints on each limb, 3 DOF spherical joints at the hips, and 1 DOF hinge joints at the knees, the talocrural, and the subtalar joints, with the patella's positions defined as a function of the knee angle as defined by De Pieri et al. [8].

The model is composed by a total of 55 muscular actuators divided by 169 Hill type elements based on TLEM (Twente lower extremity model) data [9-10]. According to the relevance for the present study, data was selected on the number of elements, type of the path (WS - wrapping surface), type of the origin and insertion sites (Point, Line (order)), mass (g) and volume (ml) for the selected muscle actuators *gastrocnemius lateralis* (GL), *gastrocnemius medialis* (GM), *rectus femoris* (RF), *vastus lateralis inferior* (VLi), *vastus lateralis superior* (VLs), *vastus medialis inferior* (VMi), *vastus medialis mid* (VMm) and *vastus medialis superior* (VMs) presented at Tab. 1.

TABLE I. DATA FROM THE SELECTED MUSCLE ACTUATORS

Muscle	# Elem.	Path	Origin	Insertion	Mass (g)	Vol. (ml)
GL	1	WS	Point	Point	54	54
GM	1	WS	Point	Point	111	107
RF	2	WS	Point	Line (2)	118	114
VLi	6	WS	Line (2)	Line (3)	84	84
VLs	2	WS	Line (2)	Point	338	330
VMi	2	WS	Line (3)	Line (3)	47	46
VMm	2	WS	Line (3)	Line (3)	87	88
VMs	4	WS	Line (2)	Point	111	112

D. Comparison at CMA and sEMG

1) Magnitude and phase diferences

The comparisons within CMA and within sEMG were performed based on two different types of metrics: (*i*) a set of flexible metrics corresponding to the phase and magnitude differences, and (*ii*) a set of standard metrics, namely the Pearson correlations and the amplitude comparison. The goal is to perform the validation based on two different methods, to assess the adequacy of each method and its results.

Regarding the flexible metrics, the comparison of computed muscle activations (CMA) for selected muscle groups *gastrocnemius lateralis* (GL), *gastrocnemius medialis* (GM), *rectus femoris* (RF), *vastus lateralis inferior* (VLi), *vastus lateralis superior* (VLs), *vastus medialis inferior* (VMi), *vastus medialis mid* (VMm) and *vastus medialis superior* (VMs) from the TLEM musculoskeletal model was performed, using the magnitude (M) and the phase (P) metrics as defined in (1)-(5) for $m = 1, \dots, 9$ and $n = m + 1, \dots, 9$.

$$v_{mm} = 1/(t_2 - t_1) \int_{t_1}^{t_2} CMA_m^2(t)\, dt \quad (1)$$

$$v_{nn} = 1/(t_2 - t_1) \int_{t_1}^{t_2} CMA_n^2(t)\, dt \quad (2)$$

$$v_{mn} = 1/(t_2 - t_1) \int_{t_1}^{t_2} CMA_m(t)\, CMA_n(t)\, dt \quad (3)$$

$$M = \sqrt{v_{nn}/v_{mm}} - 1 \quad (4)$$

$$P = 1/\pi \cos^{-1}\left(v_{mn}/\sqrt{v_{mm} v_{nn}}\right) \quad (5)$$

As for the surface EMG signals, the same metrics were used to compare the phase and the magnitude within sEMG signals. These are for the $sEMG_i$ signals ($i = 1, \dots, 5$) of selected lower limb muscles *vastus medialis* (VM), *rectus femoris* (RF), *vastus lateralis* (VL), *gastrocnemius lateralis* (GL) e *gastrocnemius medialis* (GM), using the magnitude M and the phase P metrics presented in (6)-(10) for $i = 1, \dots, 5$ and $j = i + 1, \dots, 5$.

$$v_{ii} = 1/(t_2 - t_1) \int_{t_1}^{t_2} sEMG_i^2(t)\, dt \quad (6)$$

$$v_{jj} = 1/(t_2 - t_1) \int_{t_1}^{t_2} sEMG_j^2(t)\, dt \quad (7)$$

$$v_{ij} = 1/(t_2 - t_1) \int_{t_1}^{t_2} sEMG_i(t)\, sEMG_j(t)\, dt \quad (8)$$

$$M = \sqrt{v_{jj}/v_{ii}} - 1 \quad (9)$$

$$P = 1/\pi \cos^{-1}\left(v_{ij}/\sqrt{v_{ii} v_{jj}}\right) \quad (10)$$

2) Linear correlations and amplitudes

Regarding the standard metrics, for each pairwise comparison within CMA and within sEMG, the bivariate linear Pearson correlations were computed by the least squares method. As for the amplitudes, these were compared between trials for the location and dispersion measures through the mean and standard deviation of each muscle activity both on computed CMA and measured sEMG for each trial.

III. Results

A. Comparison of CMA

Illustrative time profiles of CMA for one of the performed trials on CMJ, DJ and SJ are presented at Fig. 2.

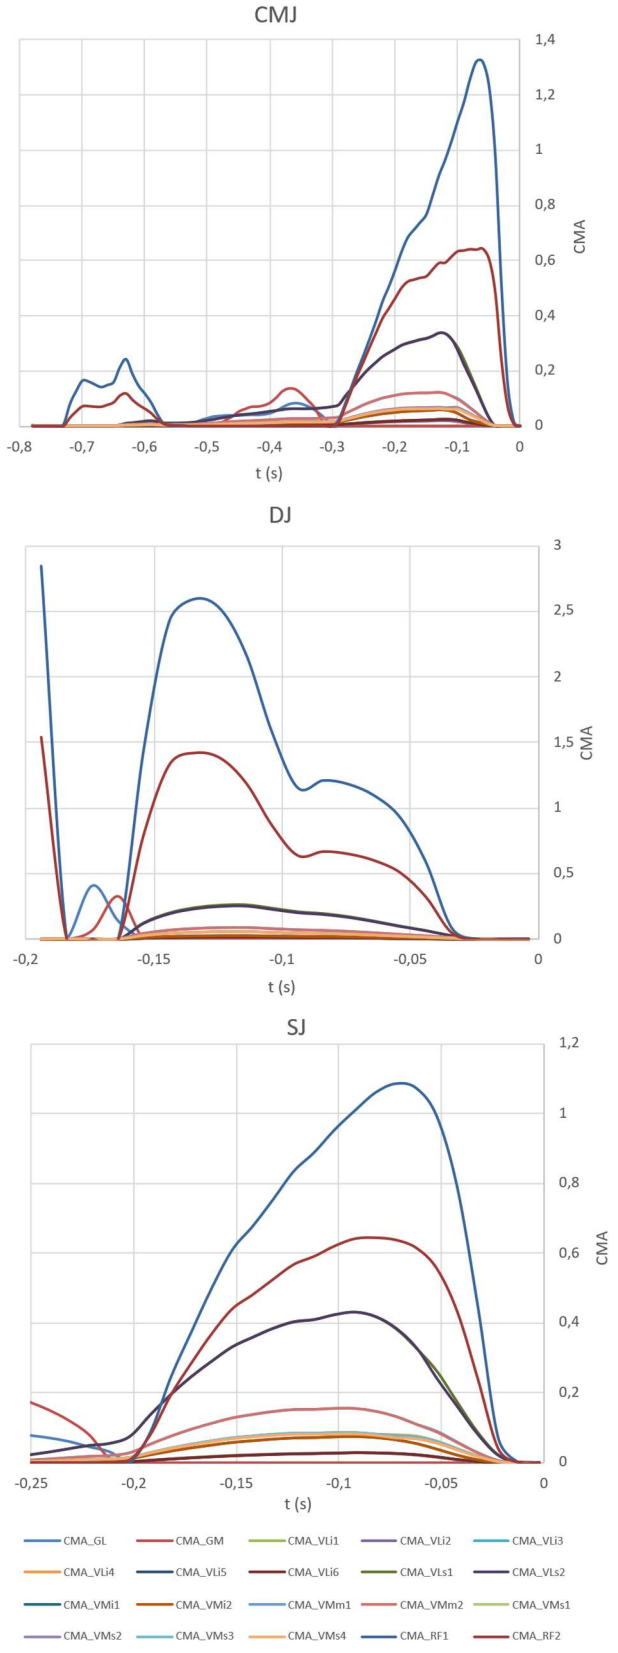

Fig. 2 Illustrative CMA of the main muscle groups for one performed trial of CMJ, DJ and SJ respectively.

1) CMA magnitude and phase diferences

The magnitude differences M presented higher means and standard deviations at CMJ, DJ and SJ for the groups RF, VLs, VMm and VMs in relation to GL and GM ($p < 0.05$)*, with lower amplitudes of CMA in GL and GM, as well as higher magnitudes M for VLi-VLs ($p < 0.05$)* corresponding to higher amplitudes of CMA for VLs relative to VLi, in Tab. 2.

*Statistically significant differences ($p < 0.05$)

2) CMA correlations and amplitudes

The associations between CMA signals for the muscle groups showed, as presented at Fig. 3, a common trend to the various types of countermovement CMJ, DJ and SJ, with higher positive correlations ($p < 0.05$)* for the gastrocnemius GL–GM, the rectus femoris RF1–RF2, and the vastus lateralis and medialis VL–VM, followed by the rectus femoris with the vastus lateralis and vastus medialis RF–VL and RF–VM, corresponding to agonist behaviour. On the other hand, the associations between the gastrocnemius (GL, GM) with the rectus femoris (RF) and the vastus lateralis and medialis (VL and VM) show negative correlations, corresponding to an antagonistic behaviour, as illustrated at Fig. 3.

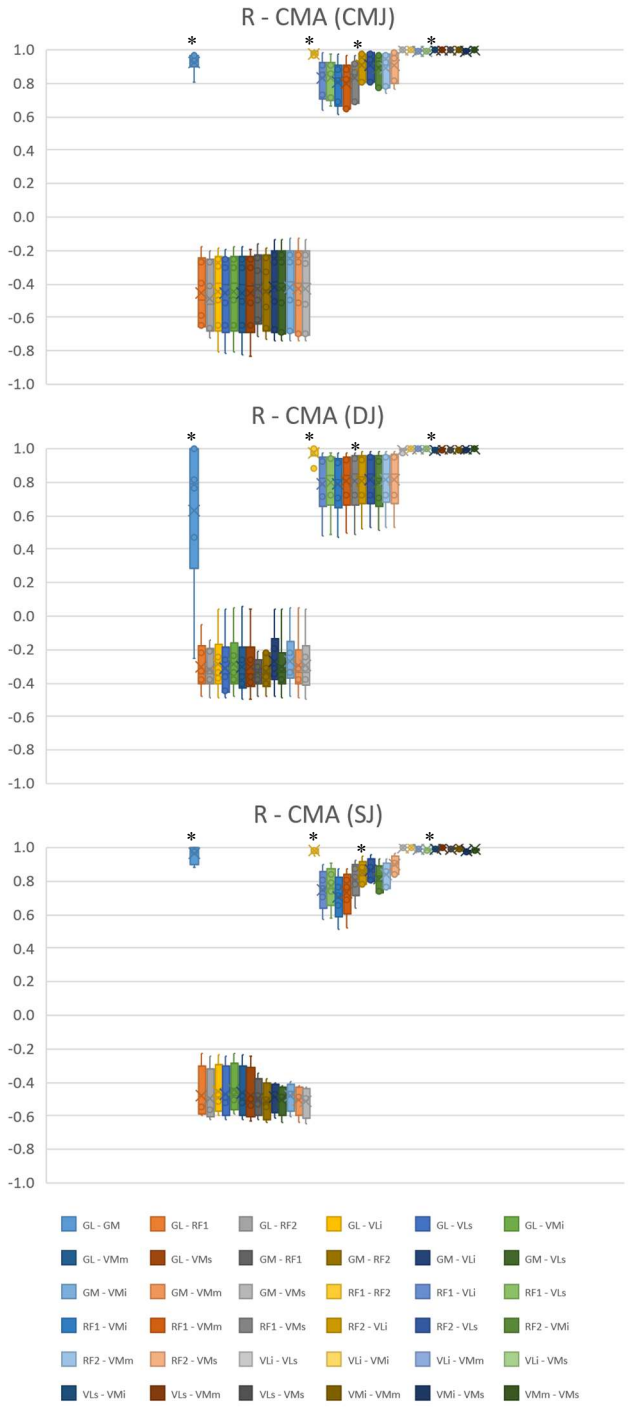

Fig. 3 Correlations of the CMA for the main muscle groups during CMJ, DJ and SJ respectively

The computed muscle activations CMA presented higher mean values ($p < 0.05$)* for RF than VLs muscle, both larger to the other muscles groups, as well as higher values for the DJ when compared with the SJ, both of which were higher than the CMJ, as shown in Tab. 4.

TABLE IV. MEAN AND STANDARD DEVIATION OF CMA AT CMJ, DJ AND SJ.

CMA	CMJ	DJ	SJ

*Statistically significant differences ($p < 0.05$)

Regarding the comparison of the results from the CMA magnitude differences M and the means of the corresponding CMA, both metrics presented consistent higher M and mean CMA values for the quadriceps muscles in relation to the gastrocnemius. Nevertheless, whereas the M metrics at each CM type involves the relative magnitude of the total CMA time series, as presented in (1)-(4), the CMA mean values involves the comparison of the absolute mean values, contributing for additional detection of the differences among CM, with higher values at DJ and short CM in relation to SJ without CM, both higher than CMJ with long CM.

The phase differences P of the computed CMA and the bivariate correlations of the corresponding CMA presented a systematic agreement among different CM, with lower phase differences P and higher bivariate correlations for the muscles at the same groups namely GL-GM and the VL-VM, with a second cluster of intermediate phase differences P and bivariate correlations at RF-VL and RF-VM, in contrast to larger phase differences and lower bivariate correlations at the antagonistic muscle groups of GL, GM with RF, VL, and VM, thus pointing for computed muscle control CMA to implement the lower limb synergistic and antagonistic muscle behaviour along with the ability of the phase differences and bivariate correlations to consistently capture this systematic behaviour.

B. *Comparison of sEMG*

Illustrative time profiles of sEMG for selected performed trials of CMJ, DJ and SJ are presented at Fig. 4.

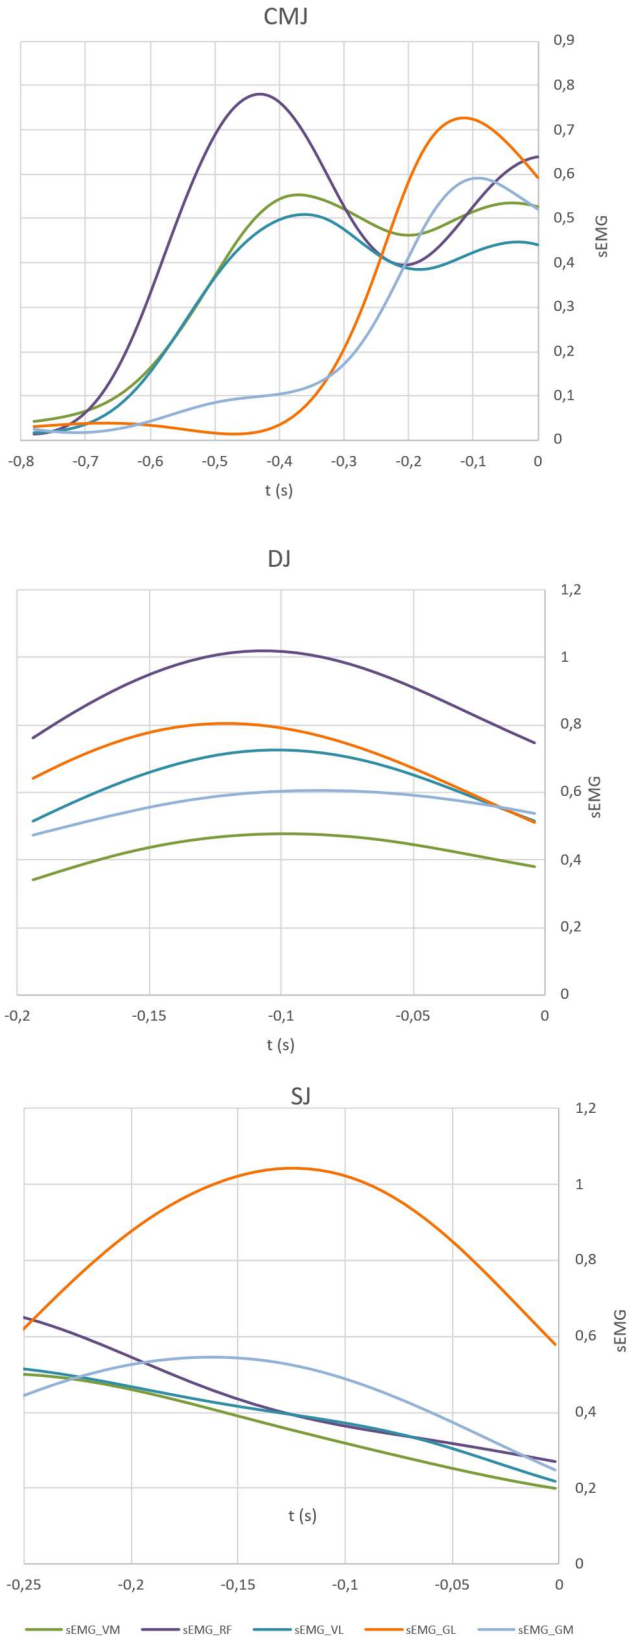

Fig. 4 Illustrative examples of sEMG for the main muscle groups for one performed trial of CMJ, DJ and SJ respectively.

1) *sEMG magnitude and phase diferences*

Based on obtained results for the magnitude M, resulting from comparison of sEMG signals, presented in Tab. 5, we highlight the higher values ($p < 0.05$)* of M for VM – RF shared by CMJ, DJ and SJ corresponding to greater amplitudes of RF relative to VM for the different types of CM. DJ further presented higher negative magnitudes ($p < 0.05$)* for RF-VL, RF-GL and RF-GM corresponding to higher amplitudes of RF relative to VL, GL and GM. Finaly, SJ presented higher negative magnitudes ($p < 0.05$)* for RF-VL and RF-GM corresponding to higher amplitudes of RF relative to VL and GM, and higher positive magnitudes for VL-GL, corresponding to higher amplitudes of GL relative to VL at SJ, with higher standard deviation on SJ for VM-GL, RF-GL and VL-GL corresponding to higher dispersion across different trials in the absence of CM.

TABLE V. MEAN AND STANDARD DEVIATION FOR THE PAIRWISE MAGNITUDE DIFERENCE $|M|$ BETWEEN MUSCLES SEMG AT CMJ, DJ, SJ.

***M* - sEMG**	**CMJ**	**DJ**	**SJ**
VM – RF	0.456 ± 0.513*	0.570 ± 0.698*	0.512 ± 0.244*
VM - VL	0.026 ± 0.201	-0.192 ± 0.334	-0.267 ± 0.263
VM - GL	-0.084 ± 0.350	-0.205 ± 0.319	0.071 ± 0.882
VM - GM	-0.164 ± 0.228	-0.211 ± 0.221	-0.228 ± 0.342
RF – VL	-0.213 ± 0.316	-0.415 ± 0.333*	-0.493 ± 0.263*
RF – GL	-0.266 ± 0.419	-0.468 ± 0.232*	-0.202 ± 0.802
RF – GM	-0.341 ± 0.322	-0.471 ± 0.128*	-0.452 ± 0.342*
VL - GL	-0.098 ± 0.265	0.095 ± 0.628	0.411 ± 0.755*
VL - GM	-0.166 ± 0.16	0.081 ± 0.472	0.074 ± 0.297
GL - GM	-0.028 ± 0.212	0.086 ± 0.330	-0.123 ± 0.343

*Statistically significant differences ($p < 0.05$)

Regarding the results of the phase difference P in the comparison among sEMG signals, presented in Tab. 6, it was possible to detect a generalized trend for all comparisons, with higher means and standard deviations in CMJ relative to DJ and SJ ($p < 0.05$)*, corresponding to lower phase agreement of acquired sEMG signals at long CM in relation to the short CM and in the absence of CM.

TABLE VI. MEAN AND STANDARD DEVIATION FOR THE PAIRWISE PHASE DIFERENCE $|P|$ BETWEEN MUSCLES SEMG AT CMJ, DJ, SJ.

***P* - sEMG**	**CMJ**	**DJ**	**SJ**
VM - RF	0.121 ± 0.128*	0.019 ± 0.013	0.070 ± 0.058

GL - GM	0.066 ± 0.055*	0.037 ± 0.035	0.034 ± 0.019

*Statistically significant differences ($p < 0.05$)

2) sEMG correlations and amplitudes

In terms of the associations between the sEMG signals assessed on the basis of bivariate correlations relating to the selected muscle groups from the lower limbs, CMJ showed a general trend towards higher correlation values and lower dispersion ($p < 0.05$)* compared with DJ and SJ for all the muscle pairs presented in Fig. 5. Higher correlations were also detected ($p < 0.05$)* for RF–VL across the various types of countermovement (CMJ, DJ and SJ) and for GL–GM in CMJ and SJ, as well as lower correlation levels for RF–GL, RF–GM and VL–GL in CMJ, DJ and SJ.

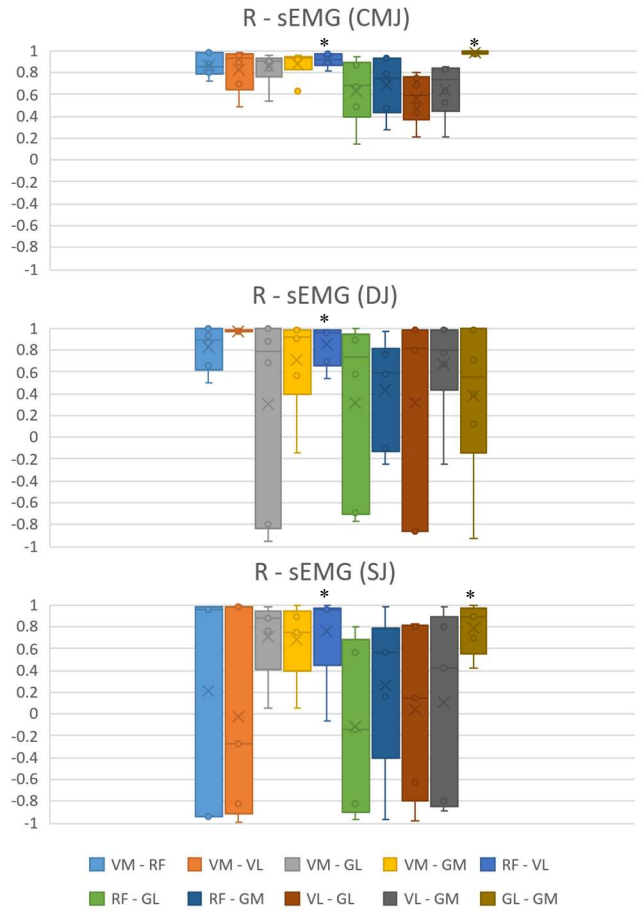

Fig. 5 Correlations of the sEMG signals for the main muscle groups during CMJ, DJ and SJ respectively

The sEMG registered signals for the selected lower limb muscles presented higher mean values ($p < 0.05$)* for DJ compared with SJ, and both were higher than CMJ (Tab. 7). DJ also showed greater variability than CMJ, with both being higher than SJ. Furthermore, RF showed higher sEMG mean values when compared with the other selected lower limb muscle groups.

TABLE VII. MEAN AND STANDARD DEVIATION OF SEMG AT CMJ, DJ AND SJ.

sEMG	CMJ	DJ	SJ
VM	0.381 ± 0.167	0.684 ± 0.395*	0.486 ± 0.136
RF	0.572 ± 0.338*	1.031 ± 0.487*	0.740 ± 0.283*
VL	0.342 ± 0.174	0.588 ± 0.313*	0.395 ± 0.117
GL	0.259 ± 0.224	0.539 ± 0.218*	0.503 ± 0.248
GM	0.250 ± 0.172	0.568 ± 0.265*	0.424 ± 0.158

Regarding the comparison of the results from the sEMG magnitude M and the corresponding sEMG mean values, both metrics presented higher activity ($p < 0.05$) for the RF muscle, pointing to the consistency of both metrics in agreement with detected results for the CMA analysis. Additionally, direct comparison of the mean sEMG led to detection of a detailed differentiation for the assessed muscle groups, with transversal higher values at DJ in relation to SJ, and both higher than CMJ. Finaly, the sEMG phase differences led to detection of higher P values at CMJ, with higher mean of sEMG bivariate correlations at CMJ and the lower limb synergistic muscles in relation to the antagonistic.

IV. DISCUSSION AND CONCLUSIONS

The results of the comparison of CMA activations led to the detection of higher M magnitudes in CMJ, DJ and SJ for the quadriceps muscle groups RF, VLs, VMm and VMs compared to the gastrocnemius GL and GM in line with the results of the comparison of sEMG activations. Similarly, with regard to the P phase difference, CMJ, DJ, and SJ showed higher values among the RF, VL, and VM muscle groups of the quadriceps in relation to the gastrocnemius GL and GM, with a second group of intermediate phase differences P between VL and VM compared to RF, and reduced phase differences between VL and VM. The magnitude and phase metrics thus allowed us to detect in CMJ, DJ, and SJ a greater association between the CMA activations of muscles belonging to the same muscle groups.

Additionally, the correlations between CMA activations with higher values detected between the gastrocnemius muscles GL-GM on the one hand, and between the quadriceps muscles RF1-RF2, VL-VM, RF-VL, and RF-VM on the other, point to the quantitative validation of the agonist behavior between the muscles of the same group, just as the negative correlations detected between the CMA activations of GL, GM with RF, VL, VM point to the validation of the antagonist behavior indicated by the respective CMA temporal profiles.

Focusing specifically on the comparison between sEMG signals, the greatest difference in magnitude M was registered between VM-RF for CMJ, DJ and SJ with higher RF values compared to VM. Additionally, DJ showed differences with higher sEMG magnitudes for RF relative to VL, GL, GM, as well as SJ with higher magnitude differences for RF relative to VL, GM, thus pointing to a generalized trend of higher sEMG activity in RF relative to the other muscle groups, with some variations between CMJ, DJ and SJ. Regarding the P phase difference between sEMG activations, the higher values detected in CMJ compared to DJ and SJ may be associated with the longer duration of the impulse phases at long CM, with the higher simultaneity of muscle recruitment in DJ and SJ related to the lower naturalness of the DJ and SJ impulses compared to CMJ.

The bivariate correlations between the sEMG signals of the selected muscles in the lower limbs allowed us to differentiate long CM in CMJ with higher correlation levels compared to short CM in DJ, and at the absence of the countermovement in SJ. Additionally, the higher correlation levels detected between RF-VL for CMJ, DJ, and SJ, and GL-GM for CMJ and SJ, point to agonist behavior between muscles of the same group, as opposed to the antagonist behavior between muscles of different groups associated with the lower correlation values detected between RF-GL, RF-GM, and VL-GL for CMJ, DJ, and SJ.

Regarding the mean values of the sEMG signals for the selected muscles of the lower limbs, a trend was observed with higher values in DJ relative to SJ and CMJ, as well as higher values for RF relative to VM, VL, GL, and GM at DJ, SJ, and CMJ. These trends were additionally registered for the CMA activations with higher mean values at DJ relative to SJ and CMJ, as well as higher values in RF1, RF2 relative to VLs1, VLs2, and both higher than the other muscles VMm, VMi, VMs, VLi, GL, and GM. Similarly, the correlations between sEMG activations with higher values for long CM in CMJ relative to DJ and SJ presented greater amplitudes for synergist muscles belonging to the same muscle group and lower amplitudes for the antagonistic muscles belonging to different muscle groups, in line with what was detected for the correlations between the corresponding CMA activations. The sEMG and CMA activations also showed alignment with respect to higher amplitudes in DJ and SJ compared to CMJ, with greater simultaneity of muscle recruitment for short CM and in the absence of CM compared to long CM, as well as higher mean sEMG and CMA values in RF compared to the other lower limb muscles selected for analysis.

Thus, the correlations between the muscle activations separately applied to each of the sEMG and CMA measures allowed for better detection of synergistic activations between muscles of the same muscle group and antagonistic activations between muscles of different groups, as well as the greater degree of synergy assessed through correlations with higher values for long CM. Finally, the amplitudes assessed based on the average values of the sEMG and CMA signals led to the detection, by both methods, of greater activity for the rectus femoris, as well as higher intensities for short CM on DJ and without CM on SJ in relation to long CM on CMJ.

According to the obtained results, it is possible to point out the magnitude and phase metrics as adequate for comparing sEMG and CMA activations related to the same muscle groups, based on the differences in amplitudes and time lag assessed on each of the methods, while separately at each of the sEMG measurements and computed CMA, the assessments of correlations and amplitudes allow for a more detailed analysis.

sEMG and CMA are distinct quantities, obtained through different methods. Thus, while sEMGs correspond to muscle activations collected via surface electromyography, CMAs correspond to muscle activations calculated from inverse dynamics, based on optimization criteria used to address the issue of muscle redundancy. Thus, while sEMG signals relate to the activations of the active muscle components, the CMA calculated through the computed muscle control relate to the muscle-tendon unit (MTU) as a whole, corresponding to the association of the three components, the contractile elements (CE) of the muscle in parallel with the passive elements (PE), both in series with the tendon. These differences in the approaches also support the predominance of positive correlations between sEMG activations as opposed to the CMAs positive correlations of synergist muscles and negative correlations for antagonist muscles. The similarities between CMAs for the different types of countermovement CMJ, DJ, and SJ can thus be associated with the type of model and the optimization conditions applied at the MSK-MS, while the differences between CMs at the sEMG patterns result from a process associated with the direct measurement of muscle activity recorded at the skin surface in explosive movements such as the CMJ, DJ and SJ.

According to the redundancy of muscle actions at each joint and the agonistic and antagonistic activations in response to increased external load, as well as the existence of upper limits of muscle load, with the distribution of the higher force levels among the largest muscles, the second-order polynomial optimization criterion was used, prioritizing on the one hand the efficiency corresponding to the minimization of energy expenditure and considering the muscle volume that favours the activation of larger muscles, ensuring the non-linear nature of the activation without excessively penalizing a single muscle and contributing to the overall energy economy in stereotyped movements, while on the other hand reconciling the existence of synergies and allowing a considerable level of overload of the larger muscles.

The comparison of CMA activations using sEMG measurements based on magnitude and phase metrics is thus presented as a form of evaluation, towards improving the techniques and parameters used with a view to the realistic calculation of CMA, as well as the use of a greater number of sEMG measurement channels for validation of the obtained CMA. In addition to the increase on the number of channels for the sEMG signals acquisition, the utilization of different cost functions, namely the min/max and the polynomial with different degrees, can contribute to the objective of realistic CMA predictions taking into account the different nature of the sEMG and CMA signals for the selection of the comparison metrics, with the correlations and amplitudes proving adequate for the analysis at each of the measured sEMG and computed CMA, with the need for more flexible metrics such as the magnitude M and phase P for direct comparison between CMA and sEMG.

***Abstract*—Teaching computational cardiac electrophysiology is challenging due to the mathematical complexity of biophysical models and the dependence on high-performance computing infrastructures. To address these barriers, this work presents a free, interactive, and fully client-side web simulator designed for educational purposes. Methodologically, the application employs a hybrid acceleration architecture: it utilizes Web Workers for robust multithreaded numerical integration in 0D and 1D environments, and leverages the WebGPU API to execute highly parallelized spatial computations for 2D reaction-diffusion models directly on the user's hardware. Performance benchmarks demonstrate that the WebGPU implementation achieves execution speedups of up to $395\times$ compared to standard CPU processing. These optimizations enable the real-time visualization of phenomena such as spiral waves and source-sink mismatch on personal computer hardware. Early user feedback highlights the tool's intuitive interface as an effective way to lower the barrier to entry for exploring electrophysiological concepts, motivating future formal studies on its pedagogical impact.**

***Index Terms*—computational electrophysiology, web simulator, education, cardiac modeling, WebGPU**

I. Introduction

Computational modeling has revolutionized the understanding of cardiac electrophysiology by enabling the simulation of complex scenarios that approximate clinical reality [1]. These tools offer predictive capabilities regarding cardiac conditions and the mechanisms of arrhythmias without the need for invasive procedures [2].

Despite this potential, the widespread adoption of computational tools in educational environments faces significant challenges. The models rely on the numerical solution of ordinary differential equations (ODEs) and partial differential equations (PDEs) [3], which imposes a steep learning curve. Furthermore, high-fidelity simulations frequently demand high-performance computing and specialized knowledge in information technology for the installation and configuration of software environments [4]. This complexity creates a barrier for students and medical educators who wish to experiment with biophysical models without the need to manage complex infrastructures.

In this context, web-based solutions have emerged as an alternative to mitigate accessibility issues. Some approaches use WebGL and WebGPU to accelerate calculations through the GPU [5], [6], while others offer web interfaces for established *backends*, such as OpenCARP [7]. However, these solutions may still demand high computational resources or rely on server-side processing.

Thus, this work presents a fully client-side web simulator designed for educational purposes. Developed with React, the tool leverages WebGPU to optimize demanding simulations, while utilizing Web Workers for parallel processing as a robust fallback. This architecture ensures the simulator remains entirely functional even on devices without WebGPU support, without ever relying on server-side processing. By simplifying the execution and visualization of electrophysiological models, the tool eliminates the need for advanced programming skills or specific hardware configurations. This approach seeks to bridge the gap between mathematical complexity and accessibility, allowing students to explore cardiac dynamics in an intuitive manner. Furthermore, the simulator is provided as an open-source tool with versioned source code and a clear license to ensure reproducibility, browser compatibility, accessibility, and long-term maintenance.

II. Related Works

The development of computational tools for cardiac electrophysiology has traditionally focused on high-performance computing (HPC) environments. Established software packages like openCARP [7] offer robust, state-of-the-art simulation capabilities for clinical and research applications. However, their reliance on command-line interfaces, complex dependencies, and server-side processing creates a steep learning curve that limits their use in undergraduate education.

To address accessibility, web-based solutions have gained traction. Kaboudian et al. [5] demonstrated the potential of WebGL for interactive simulations of complex ionic models, while Rosales et al. [6] recently explored WebGPU to achieve fast simulations of cardiac electrophysiology. While these works successfully leverage client-side GPU acceleration, they are often tailored towards advanced research visualization rather than pedagogical exploration.

The simulator presented in this work distinguishes itself by wrapping the high-performance capabilities of WebGPU within an intuitive, React-based educational interface. It prioritizes ease of use, dynamic parameter adjustment, and imme-

diate visual feedback, bridging the gap between raw computational power and pedagogical utility without requiring specialized hardware. Compared to these existing platforms, our approach emphasizes cross-browser compatibility and minimal resource consumption, offering an accessible implementation of established models with transparent acceleration specifically tailored for pedagogical use.

III. Modeling Cardiac Electrophysiology

The simulation of cardiac electrical activity in this work is based on solving mathematical models that describe both individual cellular excitation and the propagation of the electrical wave through the tissue.

A. Cellular Models

The cardiac action potential (AP) is the fundamental cellular event that triggers the contraction of the heart. It is characterized by a rapid depolarization of the cell membrane, followed by a plateau phase and a subsequent repolarization. To represent this dynamics, the simulator implements three widely used models in the literature: the Mitchell-Schaeffer model, the Minimal Model, and the ten Tusscher model.

The Mitchell-Schaeffer model [8] is a simplified two-variable model designed to capture the fundamental properties of restitution dynamics and the generation of arrhythmias, such as electrical alternans, with low computational cost. The state of the cell is described by the transmembrane potential (v) and a gating variable (h) that regulates the refractoriness of the cell.

The Minimal Model [9] is a more robust formulation composed of four state variables (u, v, w, s). It was developed to accurately reproduce the action potential shape and the properties of different cell types (endocardium, epicardium, and mid-myocardium).

The ten Tusscher model [10] is a detailed biophysical formulation of the human ventricular myocyte. Unlike simplified phenomenological models, it provides a comprehensive description of the underlying ionic currents, pumps, and exchangers. This level of detail allows for the investigation of specific ion channel dysfunctions and complex physiological behaviors.

The behavior of each cell is governed by a system of Ordinary Differential Equations (ODEs). For the numerical solution of this system, the simulator adopts a hybrid approach aiming for a balance between accuracy and stability. The potential variable (v) is integrated using the Forward Euler method [11]. Conversely, the gating variables (h in the MS model; v, w, s in the Minimal Model; and the multiple gating variables in the ten Tusscher model) are integrated using the Rush-Larsen method [12]. The Rush-Larsen method is used for these variables because, by assuming the voltage is constant during the time step, it allows the use of the analytical solution for the gating variable. This guarantees unconditional stability for this part of the system, thereby allowing for larger time steps than the standard Euler method would permit.

B. Electrical Tissue Propagation Model

To model the electrophysiological activity of the tissue, the monodomain model [3] is used. This model assumes that the cardiac tissue behaves as a functional syncytium, where the intracellular and extracellular spaces have proportional conductivities. The propagation of the transmembrane potential is described by a reaction-diffusion partial differential equation (PDE) coupled with the cellular reaction model:

$$\chi \left(C_{\mathrm{m}} \frac{\partial V}{\partial t} \right) + (I_{\mathrm{ion}} + I_{\mathrm{s}}) = \nabla \cdot (\sigma \nabla V), \tag{1}$$

$$\frac{\partial \eta}{\partial t} = f(V, \eta, t), \tag{2}$$

where χ is the surface-to-volume ratio of the cells (mm^{-1}), C_{m} is the membrane capacitance per unit area ($\mu\mathrm{F\,mm}^{-2}$), V is the transmembrane potential, and η is the state variable vector of the cellular model. The term I_{ion} represents the sum of the transmembrane ionic currents (given by the cellular models described previously), I_{s} is the external stimulus current, and σ is the electrical conductivity ($\mathrm{mS\,mm}^{-1}$) of the tissue. At the domain boundaries, no-flux Neumann boundary conditions are applied ($\partial V/\partial n = 0$), ensuring that the system is electrically isolated.

The monodomain equation is solved using the Finite Difference Method (FDM) [11] on a uniform Cartesian grid. The spatial Laplacian operator ($\nabla^2 V$) in two dimensions is approximated using a standard 5-point central difference stencil:

$$\nabla^2 V_{i,j} \approx \frac{V_{i+1,j} + V_{i-1,j} + V_{i,j+1} + V_{i,j-1} - 4V_{i,j}}{\Delta x^2} \tag{3}$$

where Δx represents the uniform spatial resolution ($\Delta x = \Delta y$). To enforce the no-flux boundaries, a ghost-node approach is implemented. During each integration step, the voltage values of the boundary nodes are mirrored to the fictitious nodes outside the domain. The temporal evolution is subsequently solved using the explicit Forward Euler scheme, with the time step Δt strictly bounded by the Courant-Friedrichs-Lewy (CFL) stability condition.

IV. Architecture and Implementation

The application interface was developed modularly using React [13], while styling was implemented with Tailwind CSS [14]. A critical aspect of democratizing educational tools is ensuring cross-device compatibility. Leveraging Tailwind's utility-first framework, the simulator features a fully responsive layout that dynamically adapts to various screen resolutions, including tablets and smartphones. This allows students to access, configure, and run models directly from their mobile web browsers, providing an unprecedented level of portability for ubiquitous learning environments.

However, since solving ODEs and PDEs entails high computational costs, executing these calculations on the main browser thread—especially on mobile processors—would inevitably cause the interface to freeze. To ensure interactivity and performance, a hybrid client-side acceleration architecture

was adopted. For computationally intensive spatial propagation, the simulator leverages the WebGPU API to execute highly parallelized calculations directly on the user's graphics processing unit (GPU). Historically, web-based GPU acceleration relied on WebGL, which forced developers to disguise mathematical state variables as RGB pixel colors within textures, executing calculations via graphics rendering pipelines. Conversely, WebGPU natively introduces Compute Shaders written in the WebGPU Shading Language (WGSL), designed specifically for general-purpose GPU (GPGPU) computing. The computations are performed using 32-bit floating-point precision, which is standard for WebGPU and sufficient for educational visualizations, though strict hardware-dependent variations must be considered.

In this implementation, the simulation domain is discretized and mapped to GPU workgroups. Each thread uses its global invocation ID to fetch the local state of a specific grid node from structured Storage Buffers, computes the spatial Laplacian, integrates the gating variables, and writes the updated state back to memory. To avoid the severe performance penalty of continuously transferring large state matrices between the GPU VRAM and the CPU (readbacks) during each integration time step, the simulator implements an alternating double-buffer strategy natively within the device memory. Data is only read back to the CPU asynchronously when real-time visualization rendering is required, ensuring that the heavy computational loop runs at maximum hardware throughput.

For 0D and 1D simulations, or as a robust fallback for devices lacking WebGPU support, a multithreaded architecture using Web Workers [15] was implemented, ensuring that numerical integration is seamlessly processed in the background CPU threads. Real-time rendering of the simulations required intense graphical optimizations. For 0D and 1D simulations, the Chart.js library [16] was used in conjunction with a *downsampling* technique. For 2D propagation under the Web Worker fallback, the solution involves direct pixel manipulation via the HTML5 Canvas API [17].

V. Simulator Overview

The graphical interface was designed to offer full control over simulation parameters without compromising visual clarity[1]. As depicted in Figure 1, the environment is divided into an intuitive side panel for configuration and a main central canvas for real-time dynamic charting.

In the specific example shown in Figure 1, the simulator is running the 0D Mitchell-Schaeffer model under a single-stimulus protocol. The tool seamlessly plots both the Transmembrane Potential (V) and the corresponding gating variable (h) simultaneously. This allows students to directly observe the mathematical and physiological relationship between these variables: following the stimulus injection, the cell rapidly depolarizes, while the gating variable immediately drops, visually illustrating the onset of the cellular refractory period.

[1]The web simulator can be accessed at: https://web-simulator.github.io.

The ability to toggle the visibility of distinct state variables and instantly observe the impact of modifying core parameters provides a highly interactive feedback loop. This immediate visual response effectively eliminates the "black-box" nature often associated with traditional command-line simulation environments.

A. Restitution Analysis and Action Potential Duration (0D)

Beyond standard transmembrane potential plotting, the simulator features a dedicated module for theoretical Restitution Analysis. By applying a programmed S1-S2 pacing protocol across a broad sweep of coupling intervals, the underlying simulation engine programmatically calculates the Action Potential Duration (e.g., APD_{90}) and the preceding Diastolic Interval (DI) for each cycle.

These internally extracted metrics are utilized to dynamically generate and plot the APD restitution curve (Figure 2). This feature allows students to immediately visualize the slope of the restitution curve without needing external analytical software. Understanding this slope is a crucial pedagogical step, as slopes greater than 1 are mathematically and clinically associated with the onset of electrical alternans and subsequent wave propagation instability.

B. One-Dimensional Cable Equation (1D)

The one-dimensional (1D) module extends the cellular models to a cable geometry, allowing the study of wave propagation and the calculation of Conduction Velocity (CV). The ten Tusscher biophysical model is particularly highlighted in this environment, as illustrated in Figure 3.

In the 1D setting, students can observe spatiotemporal phenomena such as the dispersion of repolarization and the onset of unidirectional waveblock under rapid pacing. Given the computational complexity of the ten Tusscher formulation—which comprises dozens of state variables and coupled ionic gates—the client-side WebGPU and multithreaded architecture provided by the simulator becomes strictly necessary to allow real-time interaction with the cable's stimulation parameters. In addition to standard line charts plotting transmembrane potential over time, the 1D module offers a spatiotemporal heatmap visualization (Figure 4). This color-mapped representation displays the tissue cable along the x-axis and time along the y-axis, providing an intuitive, global view of wave propagation, conduction velocity variations, and blockages at a single glance.

C. Two-Dimensional Electrical Wave Propagation

The transition to two-dimensional simulations, highly optimized by the WebGPU integration, enables the study of complex reentrant mechanisms. Figure 5 illustrates the sequential formation of an arrhythmia (spiral breakup) using the Mitchell-Schaeffer model. The sequence begins with an initial planar wavefront triggered at the lateral domain border (a). A premature S2 stimulus is then applied during the vulnerable refractory window (b), leading to the formation of an organized reentrant spiral wave (c). Due to the restitution

properties configured in the model, the wave eventually undergoes spiral breakup, fragmenting into multiple disorganized wavelets simulating ventricular fibrillation (d).

Beyond rendering the Transmembrane Potential (V) in real-time, the 2D module incorporates advanced spatial mapping visualization capabilities, fully supporting tissue heterogeneity (transmurality). By configuring the tissue with distinct cellular action potential phenotypes, such as mapping the Mid-myocardium starting at 30% and the Epicardium at 60% of the domain width, students can visualize the physiological consequences of transmural dispersion.

Figure 6 presents these capabilities using the Minimal Model. The Local Activation Time (LAT) map (a) displays color-coded isochrones indicating the exact moment the depolarization wavefront reaches each tissue node, which is highly pedagogical for identifying conduction delays. Similarly, the spatial Action Potential Duration (APD) map (b) highlights the explicit boundaries and differences in repolarization times across the endocardial, mid-myocardial, and epicardial layers, a fundamental substrate for arrhythmogenesis.

In pathological scenarios, tissue structure plays a crucial role. Figure 7 presents the effect of diffuse fibrosis on wave propagation, creating non-conducting barriers that fragment the wavefront.

Finally, the source-sink mismatch phenomenon [18] is depicted in Figure 8. This phenomenon occurs when the excitatory charge generated by depolarizing cells (the active "source") is insufficient to raise the membrane potential of the adjacent resting cells (the passive "sink") above the activation threshold. In this simulation, wave propagation is guided through a narrow fibrotic isthmus that suddenly expands into a broader healthy tissue region. The narrow isthmus restricts the number of active source cells, while the sudden structural expansion presents a massive electrotonic load. As demonstrated in the figure, the charge provided by the wavefront is rapidly drained by the large mass of resting cells, resulting in a severe conduction delay and ultimately causing a unidirectional block, a known precursor to reentrant arrhythmias.

D. Performance Benchmarks

To quantitatively evaluate the computational efficiency of the proposed hybrid architecture, performance benchmarks were conducted across two distinct hardware profiles: a standard desktop (Intel Core i5-9400F, 16GB RAM, NVIDIA GTX 1660) and a high-performance workstation (Intel Core i5-12400F, 16GB RAM, NVIDIA RTX 4070). The tests consisted of running the 2D Minimal Model for a biological simulation time of 1000 ms, utilizing a fixed spatial resolution ($\Delta x = 0.1$ mm) and a fixed integration time step ($\Delta t = 0.1$ ms).

To isolate the variable of computational load, the grid size was progressively increased from 128×128 to 1024×1024 nodes. The execution time (from initialization to the rendering of the final state) was measured for both the multithreaded CPU approach (Web Worker) and the highly parallelized GPU approach (WebGPU).

As shown in Tables I and II, the pure JavaScript implementation (Web Worker CPU) scales poorly as the grid size in-

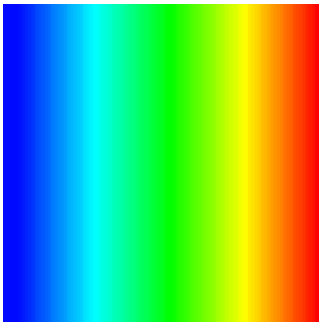
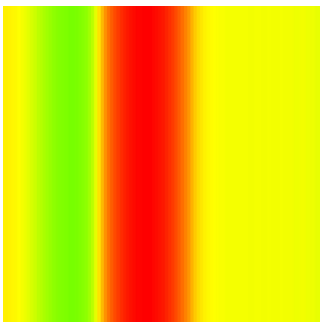
TABLE I: Personal Computer Benchmark



Grid Size	CPU Time (s)	GPU Time (s)	Speedup
128×128	21.14	1.74	$\sim$12x
256×256	82.16	2.23	$\sim$37x
512×512	329.58	2.80	$\sim$117x
1024×1024	1377.00	5.05	$\sim$272x

TABLE II: Workstation Benchmark



Grid Size	CPU Time (s)	GPU Time (s)	Speedup
128×128	16.00	0.95	$\sim$17x
256×256	61.00	1.38	$\sim$44x
512×512	247.00	1.64	$\sim$150x
1024×1024	1060.00	2.68	$\sim$395x

creases. Even on the modern i5-12400F processor, simulating a grid with over one million nodes required nearly 18 minutes (1060 seconds), rendering high-resolution 2D simulations highly impractical for interactive classroom environments.

In contrast, the WebGPU implementation effectively exploits the massively parallel nature of the reaction-diffusion equations. On the GTX 1660, the GPU execution time scaled remarkably well, remaining at roughly 5 seconds for the largest grid. When utilizing the laboratory-grade RTX 4070, the simulation completed in 2.68 seconds, yielding a maximum

speedup of nearly $395\times$ compared to its CPU counterpart. These results demonstrate the simulator's capability to deliver fluid, real-time interactivity on accessible hardware. Future work must include rigorous benchmarking with multiple repetitions, as well as mathematical validation of convergence against trusted ODE and PDE reference solutions, reporting temporal and spatial errors, stability limits, and boundary tests over multiple parameter sets.

E. Simulator Evaluation

To gather initial feedback on the usability of the tool, the simulator underwent an informal evaluation by a preliminary sample of users ($N = 5$), comprising undergraduate students and professors. Data collection was performed through an

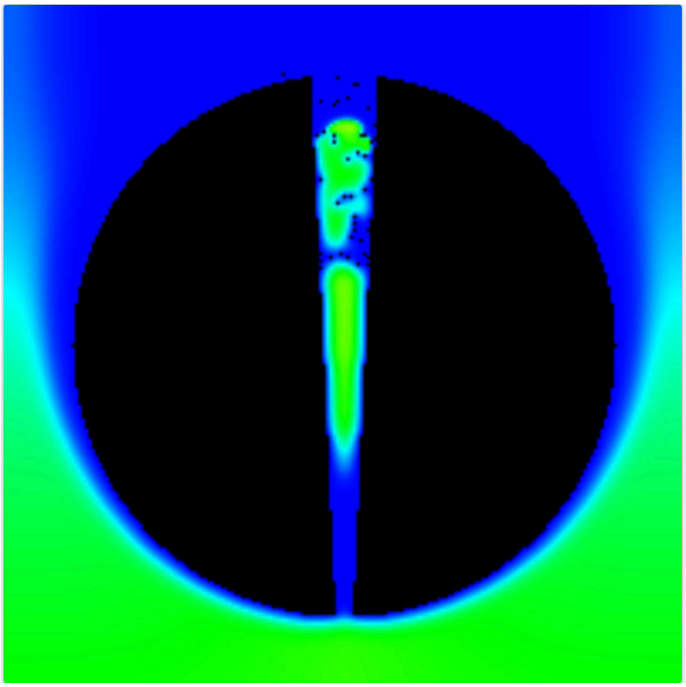

Fig. 8: Simulation of the *source-sink mismatch* phenomenon through a narrow isthmus.

anonymous ad-hoc form, utilizing a 1-to-5 Likert scale to evaluate different aspects of the interface, alongside open-ended questions for qualitative feedback.

The initial quantitative results indicated user satisfaction regarding the interface. Across the responses, users provided positive scores in metrics including the ease of navigation between different mathematical models, the clarity of parameter input fields, and the ease of understanding the 1D and 2D graphical visualizations. From a qualitative perspective, users reported that the tool facilitates the visualization of abstract concepts, highlighting the 2D propagation and Source-Sink modules as particularly useful.

While these findings are encouraging, this preliminary assessment lacks the scope to objectively quantify the educational impact of the tool. A controlled pre-post comparative teaching study is necessary to formally evaluate actual learning outcomes.

A noted limitation is the hardcoded nature of the mathematical models. Future work will focus on integrating a dynamic model parser capable of interpreting standardized formats, such as CellML, allowing users to import and simulate any published cellular model without modifying the application's source code. Additionally, extending the WebGPU compute pipeline to support three-dimensional (3D) anatomical geometries represents the next milestone in bridging the gap between educational tools and advanced research environments.

Overall, the initial evaluation indicates that the simulator serves as an accessible implementation of established models, though further structural validation is required.

VI. Conclusion

This work presented an interactive web simulator dedicated to teaching cardiac electrophysiology. The adoption of a hybrid acceleration architecture, combining WebGPU for highly parallelized spatial computations and Web Workers for robust multithreaded numerical integration, enabled the fluid execution of complete mathematical models entirely within the browser, eliminating the need for costly hardware infrastructures. The results demonstrated the tool's capability to visually reproduce cellular heterogeneity and pathological dynamics, such as spiral waves and fibrosis-induced conduction blocks. Consequently, the application shows promise in achieving its goal of lowering the barriers to accessing computational modeling. Future efforts will focus on rigorous mathematical verification and formal pedagogical assessments through comparative teaching studies.

***Resumo*—Este estudo apresenta o desenvolvimento e a validação de um fluxo de trabalho computacional para a geração de gêmeos digitais cardíacos, integrando dados anatômicos de ressonância magnética (RM) e registros eletrofisiológicos *ex vivo* obtidos por meio de um sistema de perfusão de Langendorff. O fluxo de trabalho proposto abrange o processamento morfológico tridimensional, uma simulação biomecânica de expansão passiva para o corregistro espacial e a calibração da dinâmica celular com base no mapeamento óptico. Para reconstruir o complexo QRS, adotou-se uma abordagem híbrida: a inferência das velocidades de condução e dos pontos de ativação no endocárdio utilizando a equação Eikonal otimizada pelo algoritmo de Evolução Diferencial, seguida por uma simulação biofísica através da equação do monodomínio. Os resultados demonstram que a etapa de inferência reproduziu o comportamento eletrofisiológico experimental, alcançando coeficientes de correlação elevados. Embora o modelo do monodomínio tenha apresentado divergências morfológicas residuais devido à premissa de homogeneidade celular transmural, o alinhamento das velocidades de condução confirmou a validade da propagação espacial. Esse fluxo de trabalho consolida uma plataforma para a eletrofisiologia cardíaca personalizada, impulsionando o desenvolvimento de ensaios clínicos *in silico* e apoiando a redução da experimentação animal em pesquisas biomédicas.**

***Palavras-chave*—Gêmeo Digital, Equação Eikonal, Monodomínio, Simulação Computacional.**

I. Introdução

As doenças cardiovasculares representam uma das principais causas de mortalidade globalmente [3]. Na busca por estratégias diagnósticas e terapêuticas mais eficazes, a medicina de precisão tem se apoiado cada vez mais na modelagem computacional. Neste contexto, o conceito de gêmeo digital cardíaco emerge como uma representação computacional capaz de integrar dados anatômicos, fisiológicos e hemodinâmicos para emular a dinâmica do órgão de forma individualizada, abrindo novos horizontes para o planejamento terapêutico e para a predição de risco [6], [7].

Para a investigação detalhada dos mecanismos arritmogênicos e da eletrofisiologia cardíaca basal sem interferência sistêmica, o modelo de coração isolado e perfundido retrogradamente de Langendorff constitui um padrão experimental bem estabelecido [8]. Contudo, a tradução direta de sinais elétricos adquiridos *ex vivo*, como o mapeamento óptico panorâmico de fluorescência [5] e eletrogramas de superfície, para um gêmeo digital cardíaco apresenta desafios matemáticos e computacionais significativos. O principal gargalo reside na resolução do problema inverso: estimar a velocidade de condução elétrica no tecido e mapear os locais de ativação mais precoces no endocárdio a partir de sinais elétricos globais [19].

A simulação computacional da propagação do potencial de ação no miocárdio é realizada através da resolução de equações diferenciais acopladas, como os modelos do bidomínio ou do monodomínio [10], [11]. Embora esses modelos forneçam alta fidelidade biofísica e capturem a dinâmica não linear das correntes iônicas, a personalização direta de seus parâmetros topológicos e elétricos é um processo iterativo cujo custo computacional é frequentemente proibitivo. Em contrapartida, modelos de ordem reduzida baseados na equação Eikonal permitem o cálculo rápido dos tempos de ativação local (LAT), viabilizando o uso de algoritmos metaheurísticos para a inferência paramétrica de propriedades ventriculares essenciais [19], [20].

Neste contexto, o presente estudo propõe o desenvolvimento e a validação de um *pipeline* computacional híbrido para a geração de um gêmeo digital cardíaco de coelho. A metodologia integra dados estruturais de ressonância magnética (RM) combinados a uma simulação mecânica de expansão passiva para garantir o corregistro espacial preciso com a fotogrametria do órgão [9]. Após o alinhamento geométrico, a modelagem Eikonal associada ao algoritmo de Evolução Diferencial (DE) é utilizada para inferir as velocidades de condução macroscópicas e os locais de ativação mais precoces (*root nodes*) diretamente a partir do complexo QRS extraído dos eletrogramas experimentais.

Por fim, os parâmetros anatômicos e de condução inferidos são transpostos para um simulador de monodomínio para emular a despolarização tecidual utilizando um modelo celular [13]. O objetivo principal é demonstrar que a integração metodológica do processamento de imagens, da modelagem biomecânica passiva e da inferência Eikonal oferece uma plataforma eficiente para calibrar simulações biofísicas complexas. A consolidação deste *pipeline* tecnológico visa impulsionar a confiabilidade dos ensaios clínicos *in silico*, aprimorando o teste de fármacos cardiovasculares e mitigando a dependência de modelos animais na pesquisa biomédica primária.

II. Materiais e Métodos

A. Protocolo Experimental e Aquisição de Dados

Os protocolos experimentais conduzidos neste estudo foram aprovados pelo Comitê de Ética no Uso de Animais (CEUA) local, sob o protocolo número 3947230519. Utilizou-se uma fêmea de coelho da raça Nova Zelândia (massa corporal de 3,1 kg; dimensões cardíacas de $3,5 \times 2,5$ cm e peso do órgão de 8,0 g). A indução anestésica foi realizada com cloridrato de buprenorfina (0,05 mg/kg) via injeção intramuscular. Após 30 minutos, administrou-se uma combinação de cetamina (100 mg/kg) e xilazina (14 mg/kg), seguida pela infusão intravenosa de heparina (1.250 U/kg). A extração do coração foi realizada via toracotomia esquerda, seguida por sua imediata canulação em um sistema de perfusão de Langendorff. O órgão foi perfundido retrogradamente pela aorta utilizando uma solução de Krebs modificada, mantida a 37,5 °C e oxigenada com carbogênio (95% de O_2 e 5% de CO_2).

1) Ressonância Magnética: Os dados de ressonância magnética (RM) foram adquiridos utilizando um sistema Siemens MAGNETOM de 7 Tesla. Para garantir a estabilidade geométrica durante o escaneamento, o coração foi acomodado em um recipiente preenchido com espuma e Fomblin, um fluido que também foi injetado nas câmaras cardíacas para evitar a flutuação e mitigar artefatos de imagem (Fig. 1).

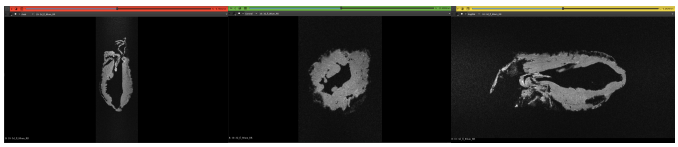

Figura 1. Cortes de RM adquiridos nas visões sagital, coronal e axial.

2) Mapeamento Óptico Panorâmico: Para a reconstrução da superfície cardíaca e análise da dinâmica elétrica, realizou-se o mapeamento óptico panorâmico empregando o corante fluorescente sensível à voltagem Di-4-ANBDQPQ (V_m). A excitação do tecido foi obtida utilizando seis LEDs de cor vermelho profundo (650 nm). A fluorescência emitida foi captada por três câmeras de alta velocidade (HB-1800-S, Emergent Technologies), operando a 500 frames/s com uma resolução de 1600×1000 pixels. As câmeras foram equipadas com lentes de 25 mm e filtros de passagem longa de 715 nm, posicionadas a 120° umas das outras para garantir a cobertura total do órgão (Fig. 2).

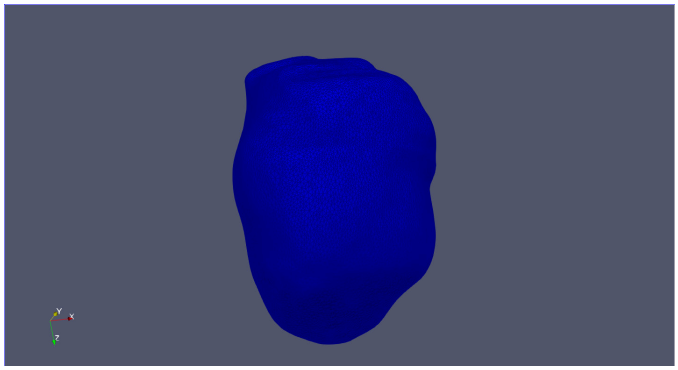

Figura 2. Imagem da superfície geométrica reconstruída via fotogrametria.

3) Eletrocardiografia: Para o registro dos sinais elétricos, o coração foi submerso em um tanque hexagonal customizado, preenchido com uma solução de sacarose (23 mM de NaCl e 260 mM de sacarose) (Fig. 3). O sistema de aquisição consistiu em 60 eletrodos de superfície organizados em matrizes, distribuídos estrategicamente pelas faces do tanque. Os dados foram registrados utilizando um módulo de aquisição de 64 canais (RHD 64, Intan Technologies), permitindo a coleta de eletrogramas espaciais de alta densidade (pseudo-ECG) a uma taxa de amostragem de 4 kHz. Adicionalmente, a dinâmica elétrica celular obtida a partir do experimento permitiu a extração do sinal do potencial de ação da superfície epicárdica (Fig. 4).

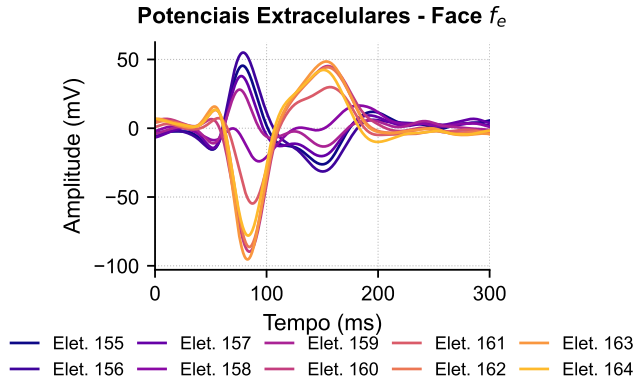

Figura 3. Registro temporal das leituras dos eletrodos de superfície no interior do tanque hexagonal.

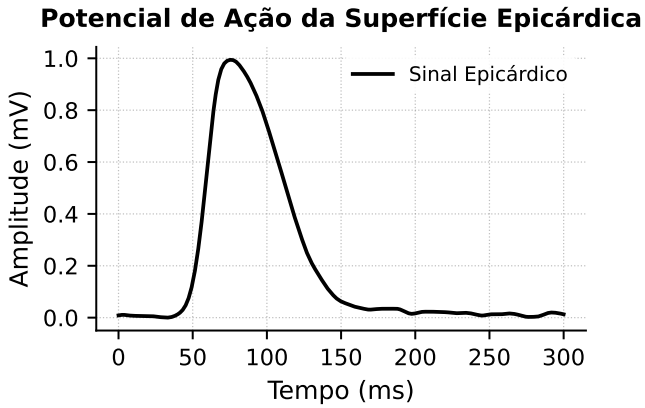

Figura 4. Sinal do potencial de ação extraído da superfície epicárdica.

B. Modelagem Computacional do Gêmeo Digital

1) Segmentação e Processamento Anatômico: A representação volumétrica dos ventrículos foi reconstruída a partir dos dados de RM utilizando o software 3D Slicer [12] por meio do algoritmo semi-automático *Grow from Seeds*. O processo de segmentação delimitou o volume ventricular, estabelecendo barreiras de contenção nas regiões atriais e na fronteira externa inferior do ventrículo direito.

Para corrigir artefatos de degrau decorrentes da resolução espacial e do espaçamento entre as fatias, um protocolo de filtragem morfológica (*Smoothing*) foi aplicado exclusivamente à máscara ventricular. Esse procedimento combinou operações de fechamento (*Closing*), para selar cavidades intersticiais internas, e operações de abertura (*Opening*), para remover ruído de fundo e aglomerados de voxels isolados. Por fim, um filtro Gaussiano com desvio padrão (tamanho do kernel) de 0,3 mm foi aplicado para garantir a continuidade geométrica e a suavidade da superfície (Fig. 5).

A superfície suavizada resultante (no formato STL) foi importada para o Autodesk Meshmixer [2] para refinamento topológico. Inicialmente, um corte planar transversal (*Plane Cut*) foi executado na região basal para remover irregularidades anatômicas remanescentes. Subsequentemente, a malha foi submetida a um relaxamento de superfície (*Smooth*) com a restrição de preservação de fronteiras (*Preserve Group Borders*) ativada, prevenindo o arredondamento indesejado da recém-criada borda basal. Por último, o modelo foi particionado em superfícies de contorno independentes para facilitar a imposição de condições de contorno em simulações futuras (Fig. 6).

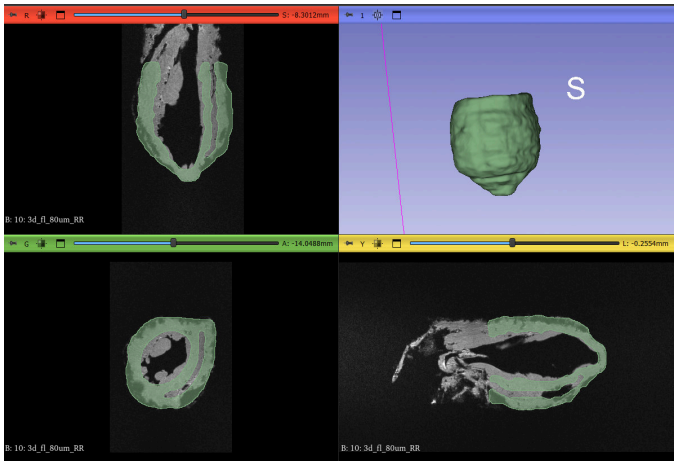

Figura 5. Máscara 3D resultante após a aplicação do algoritmo Grow from Seeds e dos processos de suavização morfológica.

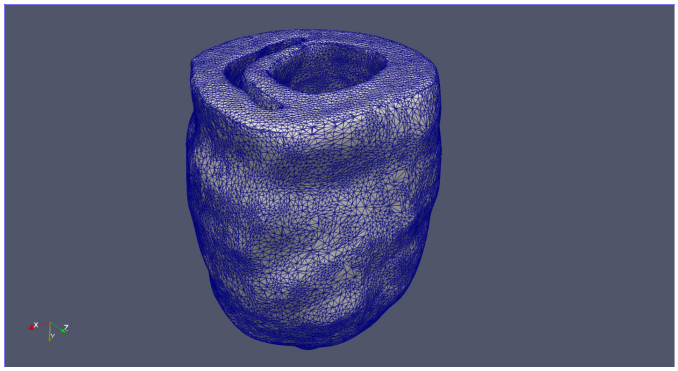

Figura 6. Modelo 3D refinado detalhando a topologia processada e as superfícies de contorno isoladas.

2) Geração da Malha Diastólica e Simulação Mecânica: Após o isolamento das superfícies de contorno, utilizou-se um *script* customizado baseado no software Gmsh para gerar a malha tridimensional de elementos finitos, com parâmetros de comprimento característico definidos no intervalo de $[0,5; 1,0]$ (Fig. 7).

Para reconstruir a geometria diastólica correspondente ao estado de pressão fisiológica durante o experimento, conduziu-se uma simulação mecânica de insuflação passiva utilizando o software Cardiax [9]. Uma pressão endocárdica de 1 kPa foi aplicada ao longo de 10 incrementos de carga, com restrição de deslocamento ao longo do eixo z para os nós pertencentes ao plano basal. O comportamento passivo do tecido miocárdico foi modelado pela lei constitutiva de Guccione [4], configurada

com os seguintes parâmetros: $C = 0,6$ kPa, $b_f = 6,62$, $b_t = 3,65$, $b_{fs} = 2,65$, e um módulo de bulk (penalidade de incompressibilidade) de $\kappa = 200$ kPa. A validação espacial do modelo deformado foi realizada através do corregistro com a superfície de referência obtida via fotogrametria (Fig. 8).

Por fim, versões de elementos finitos e de volumes finitos da malha diastólica foram geradas utilizando o software de código aberto *InSilicoHeartGen* [21] com resoluções espaciais iguais a $500\mu m$ e $200\mu m$, respectivamente. A malha grosseira de elementos finitos foi então utilizada para as simulações de inferência de parâmetros de condução, enquanto a malha refinada de volumes finitos foi empregada na etapa de calibração do modelo celular.

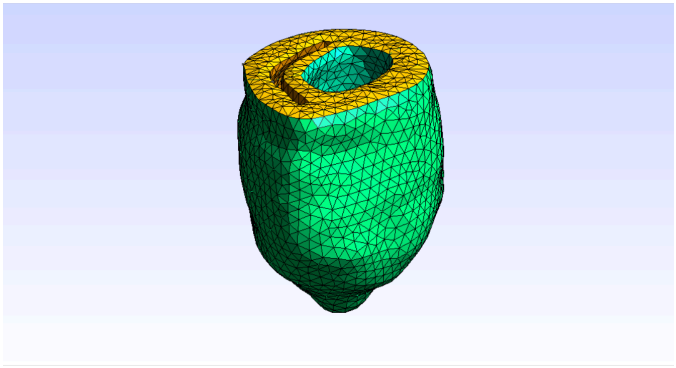

Figura 7. Malha de elementos finitos inicial pré-expansão gerada utilizando o GMSH.

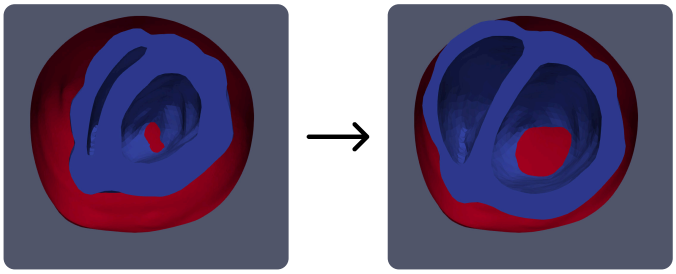

Figura 8. Em azul: malha volumétrica deformada após a simulação mecânica de insuflação no Cardiax; em vermelho: superfície de referência obtida por fotogrametria.

3) Inferência de Parâmetros de Condução (Eikonal): A reprodução computacional dos eletrogramas de superfície (pseudo-ECG) requer a caracterização precisa da velocidade de condução tissular e da distribuição espacial dos locais de ativação mais precoces (*root nodes*), o que aproxima o acoplamento da rede de Purkinje no miocárdio. O modelo Eikonal foi resolvido utilizando uma versão adaptada do software de código aberto CARDIAC-DIGITAL-TWIN-PURKINJE [19], que utiliza numericamente o algoritmo de Dijkstra aplicado à malha ventricular tetraédrica tridimensional para calcular os Tempos de Ativação Local (LAT).

A função objetivo (*discrepancy*) utilizada para guiar a minimização do problema inverso baseou-se em uma métrica combinada do Erro Quadrático Médio (RMSE) e do Coeficiente de Correlação de Pearson (PCC). Os sinais experimentais, extraídos da janela temporal restrita ao complexo QRS, foram pré-processados a uma frequência de amostragem de 1000 Hz, submetidos a um filtro passa-banda de 0,001 a 100 Hz e calculados diferencialmente para os canais 160 a 164 em relação ao eletrodo de referência 155 (GND).

A otimização do espaço paramétrico foi conduzida utilizando um algoritmo metaheurístico misto de Evolução Diferencial (DE) [15]. O algoritmo evolutivo foi configurado com uma população de 256 indivíduos, taxa de mutação (F) de 0,5, probabilidade de cruzamento (CR) de 0,8 e uma semente aleatória fixada em 42, operando por até 5000 gerações.

Além disso, não consideramos uma camada subendocárdica uniformemente rápida nesta configuração e inferimos apenas as três velocidades de condução anisotrópicas ao longo das fibras cardíacas: fibra (longitudinal), folha (transversal) e normal (transmural). A orientação das fibras foi calculada utilizando o software *InSilicoHeartGen* [21]. O espaço de busca global para as variáveis de condução e topologia anatômica foi delimitado da seguinte forma:

- Velocidade longitudinal (fibra): $[0,010; 0,100]$ cm/ms
- Velocidade transversal (folha): $[0,010; 0,060]$ cm/ms
- Velocidade transmural (normal): $[0,010; 0,040]$ cm/ms
- Número de *root nodes*: $[5; 15]$ locais de ativação mais precoces, assumindo uma distribuição *a priori* baseada em uma média de 10 nós.

4) Calibração do Modelo Celular: A precisão das simulações de propagação elétrica em nível tecidual depende da fidelidade da dinâmica iônica intracelular. Para tanto, empregou-se o *Minimal Model* [13], uma formulação fenomenológica que descreve o potencial de ação (PA) cardíaco por meio de quatro variáveis de estado (u, v, w, s). Registros experimentais de mapeamento óptico indicaram uma duração do PA de aproximadamente 100 ms.

A calibração paramétrica foi guiada por uma análise de sensibilidade global de Sobol [14], a qual identificou os parâmetros u_u, τ_{so1} e τ_v^+ como os principais determinantes da variância morfológica da curva do PA. A otimização desse subespaço paramétrico foi executada via Evolução Diferencial, utilizando a biblioteca PyMOO [16]. A função objetivo foi projetada para minimizar a divergência do APD90, complementada por um refinamento morfológico baseado na minimização do erro na norma L_2 entre os traçados simulado e experimental. Por fim, assumiu-se a premissa de homogeneidade celular transmural, aplicando-se o mesmo modelo otimizado globalmente em células epicárdicas, mesocárdicas e endocárdicas.

5) Simulação Eletrofisiológica (Monodomínio): Com os parâmetros anatômicos, de condução e celulares devidamente calibrados, a simulação espacial do tecido miocárdico foi realizada resolvendo-se a equação do monodomínio através do simulador de eletrofisiologia cardíaca MonoAlg3D [10], [11]. O *Minimal Model* [13] calibrado foi acoplado à formulação do monodomínio e resolvido sobre a malha biventricular diastólica utilizando uma discretização espacial de $200\mu m$. Previamente a isso, foram atribuídas à geometria as orientações das fibras miocárdicas.

Para refletir os resultados obtidos a partir da inferência computacional, a matriz de condutividade anisotrópica foi configurada no MonoAlg3D com os seguintes valores escalares: condutividade longitudinal (fibra) $\sigma_l = 5,29041 \times 10^{-5}$, transversal (folha) $\sigma_t = 3,53419 \times 10^{-5}$ e transmural (normal) $\sigma_n = 1,17339 \times 10^{-5}$. O mapeamento entre as velocidades de condução inferidas pelo modelo Eikonal e as condutividades do tecido no monodomínio foi realizado através de simulações unidimensionais em um cabo, empregando-se a rotina *tuneCV* no simulador MonoAlg3D [22].

A simulação da propagação elétrica, configurada com uma resolução espacial de 200 μm e um passo de integração no tempo de 0,02 ms, foi desencadeada pela ativação sequencial de nove pontos de ativação mais precoces (*root nodes*) mapeados durante o processo de inferência. Estes estímulos, modelados como domínios esféricos com um raio de 800μm, foram ativados de forma assíncrona (no intervalo entre $t = 1$ ms e $t = 25$ ms) utilizando os LATs calculados provenientes do processo de inferência.

III. Resultados

A. Alinhamento e Geometria da Malha

A validação do alinhamento geométrico e da expansão mecânica foi realizada de forma qualitativa, comparando-se a malha volumétrica simulada com o modelo de referência externo gerado por fotogrametria (Fig. 9). Embora os modelos apresentem forte concordância espacial global, observa-se que a geometria simulada extrapola os limites da fotogrametria em regiões localizadas.

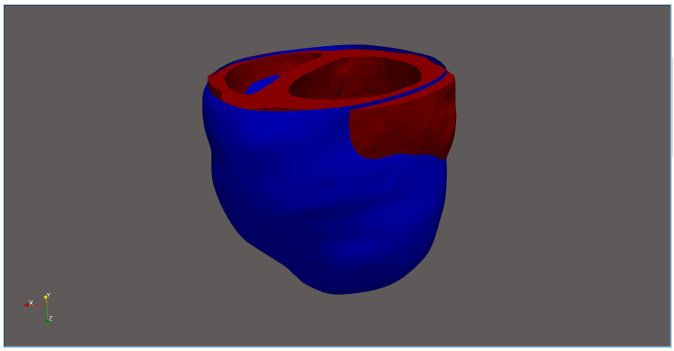

Figura 9. Em vermelho: malha volumétrica deformada após a simulação mecânica; em azul: superfície de referência obtida via fotogrametria.

B. Dinâmica Celular e Potencial de Ação

A otimização do modelo celular gerou uma curva com uma taxa de despolarização (fase 0) visivelmente mais acentuada em comparação ao sinal registrado (Fig. 10). Esta divergência morfológica inicial é bem fundamentada na literatura e atribuída ao efeito de espalhamento de fótons inerente aos sistemas de mapeamento óptico. Esse fenômeno induz uma integração espacial da fluorescência, resultando em um prolongamento artificial do *upstroke* medido [17]. Apesar dessa distorção conhecida na fase de ativação inicial, a Duração do Potencial de Ação (APD) foi ajustada, convergindo para a faixa de 100 ms e assegurando a fidelidade temporal necessária para as simulações em nível tecidual.

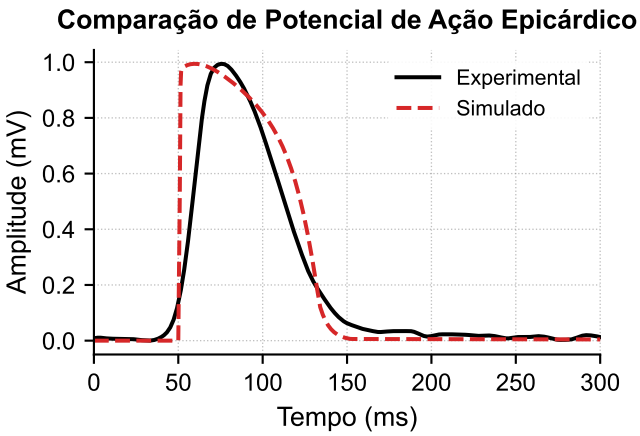

Figura 10. Em vermelho: PA simulado após a otimização (*Minimal Model*). Em azul: PA experimental (mapeamento óptico).

C. Eletrogramas

A acurácia dos eletrogramas de superfície simulados foi quantificada em relação aos sinais experimentais utilizando duas métricas: o Erro Quadrático Médio Normalizado (NRMSE) e o Coeficiente de Correlação de Pearson (PCC). Para a extração adequada dos sinais, selecionou-se um subconjunto de cinco eletrodos de interesse (identificados como derivações 160 a 164). Suas diferenças de potencial foram calculadas utilizando a derivação 155 como referência comum (terra/GND). Para viabilizar a comparação morfológica e considerar as variações de impedância no meio condutor, as amplitudes dos sinais simulados e inferidos foram normalizadas pico a pico em relação aos dados experimentais. A Fig. 11 detalha as formas de onda resultantes para este subconjunto e seus respectivos parâmetros estatísticos.

A análise quantitativa revela que o pseudo-ECG simulado diretamente pela equação do monodomínio apresentou divergências de amplitude aceitáveis (média de $29,6\%$) e valores ideais de PCC (média de $0,80$). Contudo, observou-se um desempenho notavelmente inferior para o eletrodo 160, que registrou um PCC de $0,55$, sugerindo limitações localizadas na inferência e na distribuição espacial dos *root nodes*. Em contrapartida, os sinais reconstruídos pelo processo de inferência Eikonal demonstraram capacidade de reproduzir o comportamento eletrofisiológico experimental. Esta formulação resultou em uma mitigação generalizada do erro de amplitude (baixo NRMSE) e em alta fidelidade morfológica, evidenciando a eficácia do mapeamento espacial dos parâmetros de condução gerado pela inferência.

IV. Discussão

Este estudo demonstra a viabilidade do desenvolvimento de um gêmeo digital cardíaco através da integração de dados anatômicos de ressonância magnética com registros eletrofisiológicos extraídos de um sistema de perfusão de Langendorff. A

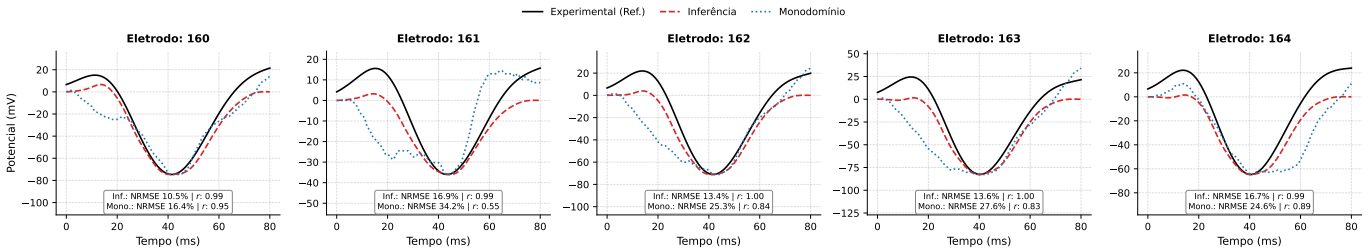

Figura 11. Comparação temporal de 5 eletrodos epicárdicos e métricas de correlação. Preto: pseudo-ECG experimental. Vermelho tracejado: sinal reconstruído via inferência (Eikonal). Azul pontilhado: sinal simulado utilizando o modelo do Monodomínio.

metodologia proposta reconstruiu com sucesso as propriedades morfológicas do órgão e reproduziu a progressão temporal da despolarização ventricular. Além disso, os parâmetros de velocidade de condução tissular inferidos pelo método inverso alinharam-se com a literatura eletrofisiológica estabelecida para o modelo de coelho [18], atestando a validade fenotípica da formulação Eikonal empregada na otimização.

O modelo exibe desvios esperados que destacam o impacto das simplificações assumidas em relação ao sistema biológico. No domínio biomecânico, a simulação de expansão passiva aplicou uma carga de pressão uniforme através das cavidades ventriculares. A extrapolação geométrica localizada observada em relação à superfície de fotogrametria reflete a ausência de um carregamento hemodinâmico assimétrico. A aplicação de gradientes diferenciais de pressão fisiológica para os ventrículos esquerdo e direito apresenta-se como a abordagem corretiva ideal para simulações mecânicas futuras, a fim de garantir a conformidade absoluta do contorno epicárdico.

No domínio elétrico, diferenças morfológicas residuais foram observadas entre os eletrogramas simulados pelo modelo do monodomínio e a referência experimental. Diferentemente do estado estacionário resolvido pela equação Eikonal, o monodomínio captura interações não lineares da dinâmica iônica. Portanto, a falta de heterogeneidade eletrofisiológica transmural (diferenciando células endocárdicas, mesocárdicas e epicárdicas) negligencia variações intrínsecas na forma e na duração dos potenciais de ação locais, impactando diretamente a reconstrução morfológica fina dos sinais de superfície.

As limitações na reprodução da dinâmica elétrica também refletem restrições computacionais durante a etapa de inferência. A otimização de parâmetros concentrou-se em um subconjunto de canais, deixando de lado a totalidade dos dados disponíveis na matriz de 60 eletrodos da montagem experimental. A incorporação do mapeamento elétrico completo no problema inverso poderia aprimorar a resolução espacial da predição, mitigando ainda mais os erros de amplitude (NRMSE). Contudo, a escalabilidade deste processo é dificultada por custos computacionais proibitivos; essa mesma barreira forçou a simplificação da rede de Purkinje. A restrição quantitativa de pontos de ativação no endocárdio (*root nodes*) foi uma imposição técnica necessária para prevenir uma explosão combinatória no espaço de busca do algoritmo de otimização.

Para mitigar essas limitações, trabalhos futuros podem priorizar a incorporação da heterogeneidade miocárdica e a expansão do domínio anatômico para abranger o coração inteiro (átrios e ventrículos). Esta integração estrutural, combinada com o desenvolvimento de redes de Purkinje topologicamente mais precisas e específicas para coelhos, permitirá a emulação do ciclo elétrico completo. Tais aprimoramentos estenderão o escopo do gêmeo digital cardíaco muito além da validação do complexo QRS, viabilizando o estudo detalhado das ondas P e T e, consequentemente, a gênese de arritmias impulsionadas por anomalias de repolarização. Além disso, investigações futuras devem considerar a implementação de um modelo celular específico para coelhos, como o modelo de Mahajan, que replica com precisão a dinâmica do potencial de ação cardíaco em altas frequências de estimulação [23].

V. Conclusões

O *pipeline* computacional estabelecido neste trabalho apresenta uma estrutura promissora para a geração de gêmeos digitais cardíacos personalizados. Através do acoplamento sequencial do processamento de imagens, da simulação mecânica de expansão passiva e da otimização eletrofisiológica guiada por dados experimentais, foi possível recriar o comportamento elétrico do miocárdio com um alto grau de similaridade espacial e temporal. O sucesso na recuperação das velocidades de condução e a fidelidade da propagação confirmam a eficácia da abordagem híbrida, que combina o problema inverso Eikonal com simulações biofísicas do monodomínio. A maturação destas metodologias apresenta um potencial considerável para impulsionar a transição tecnológica em direção aos ensaios clínicos *in silico*, aprimorando a eficácia dos testes farmacológicos e apoiando o princípio ético fundamental de reduzir o uso de modelos animais na pesquisa biomédica.

***Abstract*—The use of portable Large Language Models (pLLMs) for sentiment analysis offers a cost-effective and private alternative to Large Language Models (LLMs), yet their operational stability against subtle prompt variations remains critical. This study investigates the prompt sensitivity of five open-source LLMs: Llama3.2 (3B), Phi-4 (14B), LLaVA (7B), Mistral (7B), and DeepSeek-R1 (8B), when performing valence evaluations. Performance was modeled using mean absolute error (MAE), root mean squared error (RMSE), and Pearson's correlation coefficient (r), while response validity was analyzed separately. The sample standard deviation of MAE across prompt configurations was used as the primary descriptive indicator of prompt sensitivity. `Phi-4` had the lowest mean errors and MAE variation, with** $\mathrm{MAE} = 1.07 \pm 0.15$, $\mathrm{RMSE} = 1.33 \pm 0.16$, **and** $r = 0.82 \pm 0.04$, **while returning valid responses in 82.00% of calls. Among the four pLLMs, `Mistral` had the lowest mean errors and MAE variation, with** $\mathrm{MAE} = 1.11 \pm 0.27$, $\mathrm{RMSE} = 1.42 \pm 0.28$, **and** $r = 0.73 \pm 0.06$, **while returning valid responses in 91.09% of calls. These findings suggest the need for an in-depth baseline study when selecting specific models for sentiment analysis pipelines, as different LLMs exhibit contrasting levels of operational volatility.**

I. Introduction

The advancement of large language models (LLMs) has established them as important tools for complex linguistic analysis [1]. Despite their usefulness, a notable challenge remains: small variations in the phrasing of prompts can lead to substantially different outputs. This sensitivity to word ordering and instruction styling has been documented as a core vulnerability in modern language models [2]. While this responsiveness allows for performance optimization through careful prompt engineering [3], it also introduces a degree of instability. The study of response variability and model uncertainty in LLM-based sentiment analysis has also been comprehensively reviewed by Herrera-Poyatos et al. [4], who categorized the primary sources of inconsistencies and discussed theoretical mitigation strategies.

Furthermore, deploying LLMs at scale can be both cost-prohibitive and time-consuming, making the adoption of freely available, smaller language models, such as portable Large Language Models (pLLMs), a viable alternative. Particularly due to their reduced computational overhead (less than 10 Billion parameters) and enhanced data privacy [5]. However, while recent literature demonstrates that pLLMs can effectively assist in text-based sentiment analysis [1], the effects of minor prompt variations on their outputs remain largely underexplored.

The objective of this study is to systematically investigate prompt sensitivity in four pLLMs and one local reference model when performing text-based sentiment evaluation on a positivity scale.

II. Methods

To quantify this continuous dimension of positiveness, our evaluation utilizes the valence domain of Self-Assessment Manikin (SAM) scale. Originally developed by Margaret Bradley and Peter Lang [6], the SAM scale is a non-verbal pictorial questionnaire designed to directly measure an individual's emotional response to a given stimulus. By adapting this human-centric framework to a numerical scale for computational evaluation, we establish a standardized baseline that allows language models to map textual sentiments onto a spectrum spanning from highly negative to highly positive [7].

A. Dataset

Participants in the original study [8] rated a series of English lemmas on a 9-point scale in three emotional dimensions: valence, arousal, and dominance. While the full publicly available dataset contains 13,915 words, the present study focuses exclusively on the valence dimension

and utilizes a representative subset of 140 words. This word set is exactly the same as the one established in our prior study [7]. In that work, the sampling procedure was designed to select words systematically from the original dataset sorted by valence, picking lemmas at intervals of 100 words with an added random jitter of +1 or −1.

B. Large Language Models

The models were selected based on the Hugging Face leaderboard rankings available in November 2025: `Phi-4` (14B) and the four pLLMs `Llama3.2` (3B), `LLaVA` (7B), `Mistral` (7B), and `DeepSeek-R1` (8B) [9], [10]. We evaluate the comparative performance of the five models across slightly different instructional prompts. Hereinto, the term *five evaluated models* refers to the complete set, whereas *four pLLMs* excludes `Phi-4`, because its 14 billion parameters exceed the 10-billion-parameter threshold adopted for the pLLM group. All models were run locally via the Ollama framework on a workstation equipped with an Intel i9 processor, 128 GB of RAM, and an NVIDIA RTX 4090 GPU (24 GB VRAM).

C. Parameters

To ensure the reproducibility and minimize variance, all models were used with a deterministic configuration. The specific parameters, available in the Ollama framework, are detailed in Table I.

Setting the temperature to 0 decreases the responses variance, while a fixed seed of 42 was applied to stabilize the internal state of the random number generator.

TABLE I
OLLAMA FRAMEWORK PARAMETERS THAT ENSURE REPRODUCIBILITY

Parameter	Value
temperature	0
seed	42
num_predict	500

The num_predict parameter was limited to 500 tokens as a safeguard against infinite generation loops. This behavior was observed in some models, which occasionally produced redundant symbols or emojis rather than a concise response. By enforcing this limit, the system reduces the risk of resource exhaustion and helps maintain the processing of subsequent words.

D. Prompt Engineering

To systematically assess the models' architectural robustness when performing the same affective task under slightly altered instruction sets, a two-phase cross-evaluation framework was established. In the first phase, each of the selected local LLMs acted as a *generator*. They were tasked with generating five semantic variations of the baseline prompt inherited from previous literature [7]. To ensure generation alignment, the models received the following meta-prompt:

> *Write only 5 similar prompts that mean the same, but with different words, as the given prompt: How positive or negative is this word on a 1-9 scale? Answer only with a facial emoji and a number, with 1 being "very negative" and 9 "very positive". Here is the word: {word}*

This procedure yielded a final pool of 25 unique machine-engineered prompts (five variations across five generator models), while the `num_predict` inference parameter was left at its default behavior to avoid constraining the generation length during this initial phase. The authors jointly inspected the 25 prompts and considered them semantically equivalent for the target task.

In the second phase, these 25 prompts were deployed as a standardized test suite. Every prompt was cross-evaluated by all five local LLMs acting as *evaluators*. This full matrix configuration resulted in 25 distinct prompts × 5 evaluator models = 125 unique evaluation lines for each evaluated term. Given our sample dataset of 140 target words, the pipeline executed a total of 17,500 (125×140) local `ollama` API calls.

Due to the unconstrained nature of text generation in smaller architectures, a validation filter was implemented to parse the outputs. Responses that failed to provide the mandatory quantitative rating were labeled as invalid and subsequently discarded.

E. Metrics

These $17.5k$ calls were classified by prompt (instruction generated), the generator model (the prompt author), and the evaluator model (the model that interprets the prompts and provides the final ratings).

Each prompt–evaluator configuration comprised 140 word evaluations. The experiment comprised 125 prompt–evaluator configurations. Numerical metrics and regression fits were calculated only for configurations with sufficient valid responses. Following the statistical analysis from the previous studies, we conducted an ordinary least squares (OLS) linear regression for each calculable configuration. The resulting regression lines were presented across six panels as a descriptive visualization of model performance under slightly different instructions.

For every calculable prompt–evaluator configuration, predicted valence $\hat{y}_i$ was compared with the human rating y_i using mean absolute error (MAE) and root mean squared error (RMSE). Pearson's correlation coefficient (r) quantified linear association between model predictions and human ratings.

MAE, RMSE, and r were summarized using their mean and sample standard deviation across prompt configurations. The sample standard deviation of MAE was selected as the primary descriptive indicator of prompt sensitivity. It was interpreted together with mean MAE so that consistent but inaccurate responses were not characterized as robust performance.

A response was considered valid when its parsed numerical value was between 1 and 9, inclusive. Missing values, nonnumeric outputs, and values outside this interval were classified as invalid. Invalid responses were excluded from the numerical analyses and were not replaced with estimated values. The success rate is the percentage of valid responses returned by an evaluator model relative to its total number of calls (25 prompts $\times$140 words = 3.5k calls).

To determine whether the observed differences in agreement with human valence ratings were statistically supported, the calculated metrics were compared in all pairs of evaluator models. For each word and evaluator, the valid predictions obtained across the 25 prompt configurations were averaged, producing one estimate per model for each word. MAE and RMSE were calculated between these prompt-averaged predictions and the human ratings, while Pearson's r measured their linear association. Each of the ten possible model pairs was then compared by paired bootstrap resampling of the words, using 10,000 replicates and seed 42. Bootstrap percentile confidence intervals and two-sided bootstrap p-values were calculated, and Holm's procedure was applied across the ten model comparisons separately for each metric. Differences were considered statistically supported when $p_{\text{Holm}} < 0.05$.

III. Results

A. Prompt Variation

The 25 prompts differed in wording and in the emphasis placed on output format. Table II presents one prompt from each generator.

TABLE II
Examples of prompts generated by the large language models

Model	Prompt
`DeepSeek-R1`	Rate the sentiment of this word from 1 to 9, using a facial emoji. 1 is very negative, 9 is very positive.
`Llama3.2`	What's the emotional tone of this word? Rate it from 1 to 9, where 1 is "very negative" and 9 is "very positive".
`LLaVA`	Please rate this word on a scale of 1 to 9, with 1 being "extremely negative" and 9 "extremely positive", using a facial emoji.
`Mistral`	Rate the tone of this word on a 1-9 scale, where 1 is "very negative" and 9 is "very positive". Please respond with an emoji and a number.
`Phi-4`	Using a 1-9 scale, where 1 is very negative and 9 is very positive, how would you express the sentiment of this word? Provide a facial emoji and a number.

B. Success Rate

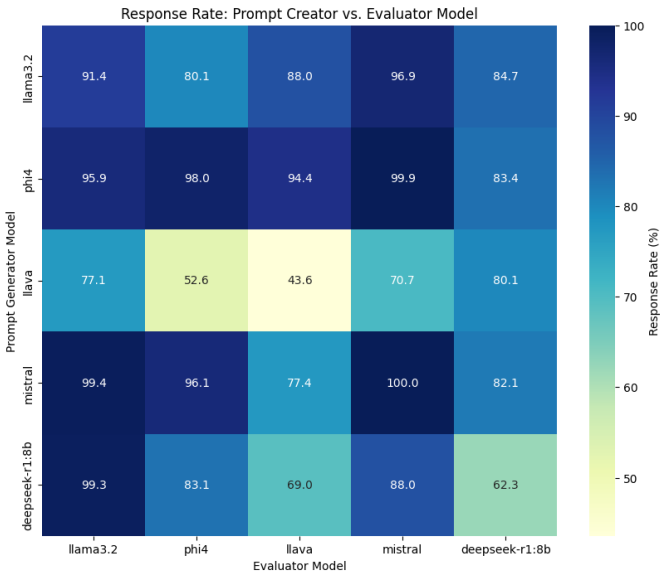
The 25 prompts were used to trigger 17.5k ollama calls. Only 83.7% were classified as usable. Table III shows the success rate of each evaluator model.

TABLE III
Models success rate responding to the prompts

Evaluator Model	Valid	Invalid	Success Rate (%)
`DeepSeek-R1` (8B)	2749	751	78.54
`Llama3.2` (3B)	3242	258	92.63
`LLaVA` (7B)	2607	893	74.49
`Mistral` (7B)	3188	312	91.09
`Phi-4` (14B)	2870	630	82.00

To further examine the performance dynamics, Figure 1 presents a cross-evaluative heatmap of response success rates. In this visualization, each element cell at row n and column m represents the success rate of prompts generated by model n when evaluated by model m. This mapping reveals significant variances in how different models interact during the evaluation task.

Response validity also varied by prompt generator and individual prompt. The `LLaVA`-generated block yielded 2,269 valid responses in 3,500 calls (64.83%), the lowest validity among the five generator blocks, whereas the `Phi-4`-generated block yielded 3,301 valid responses (94.31%). `LLaVA-P2` (the second prompt generated by `LLaVA`, provided in Table II) yielded 377 valid responses in 700 calls (53.86%); when this prompt was evaluated by `LLaVA`, all 140 responses were invalid. Across the 25 individual prompts, `DeepSeek-R1-P1` (the first prompt generated by `DeepSeek-R1`, provided in Table II) had the lowest aggregate validity, with 317 valid responses in 700 calls (45.29%).



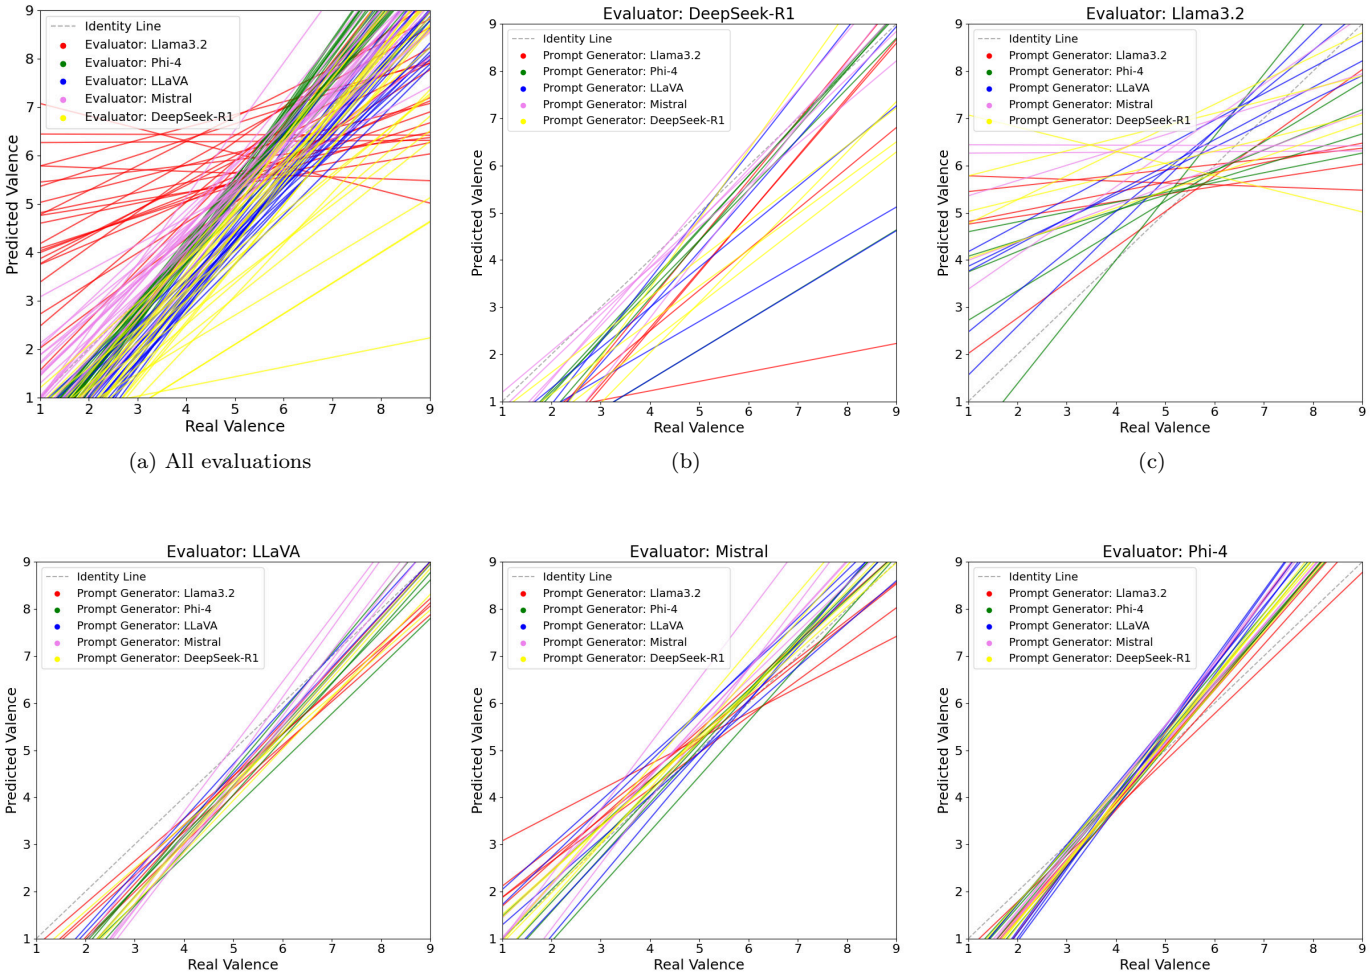


Fig. 1. Heatmap of response success rates (%) across different Large Language Models. Each cell (n,m) represents the percentage of valid responses generated by model m (Evaluator) when prompted with instructions authored by model n (Generator).

(a) All evaluations (b) (c)

(d) (e) (f)

Fig. 2. Comparison of affective evaluation performance across different prompt variations. The panels display results for: (a) all aggregated models, classified by the evaluator model, each color represents a model; (b,c,d,e,f) responses given by the models `DeepSeek-R1` (8B), `Llama3.2` (3B), `LLaVA` (7B), `Mistral` (7B) and `Phi-4` (14B), respectively, classified by the generator prompt.

C. Affective Valence Responses

The performance of the models in terms of linear alignment with human-rated valence is illustrated in Figure 2. The figure presents the linear regression fits for each prompt–evaluator pairing. Figure 2a displays the aggregated trend for each model acting as an evaluator. These regressions provide a descriptive visualization of variation across the evaluated configurations.

D. Absolute Error and Correlation

Table IV summarizes MAE, RMSE, and Pearson's correlation coefficient r by evaluator across prompt configurations. `Phi-4` showed the lowest average MAE and RMSE, together with the highest average Pearson correlation. Among the four pLLMs, `Mistral` had the lowest mean errors and the highest mean correlation.

TABLE IV
DESCRIPTIVE PERFORMANCE OF EVALUATOR MODELS ACROSS CALCULABLE PROMPT–EVALUATOR CONFIGURATIONS. MAE, RMSE, AND PEARSON'S CORRELATION COEFFICIENT (r) ARE REPORTED AS MEAN ± SAMPLE STANDARD DEVIATION ACROSS PROMPT CONFIGURATIONS.

Evaluator	MAE	RMSE	r
`Phi-4`	1.07 ± 0.15	1.33 ± 0.16	0.82 ± 0.04
`Mistral`	1.11 ± 0.27	1.42 ± 0.28	0.73 ± 0.06
`LLaVA`	1.44 ± 0.56	1.76 ± 0.52	0.72 ± 0.05
`DeepSeek-R1`	2.07 ± 0.70	2.51 ± 0.71	0.54 ± 0.15
`Llama3.2`	1.52 ± 0.28	1.96 ± 0.32	0.32 ± 0.23

E. Paired Model Comparisons

The descriptive differences in MAE, RMSE, and Pearson's correlation coefficient do not, by themselves, establish whether the evaluated models differed beyond the variation associated with the set of words. Pairwise

TABLE V

PAIRED COMPARISONS AMONG EVALUATOR MODELS. DIFFERENCES ARE CALCULATED AS THE FIRST MODEL MINUS THE SECOND. THE 95% CONFIDENCE INTERVALS ARE UNADJUSTED BOOTSTRAP PERCENTILE INTERVALS; p-VALUES WERE HOLM-ADJUSTED ACROSS THE TEN COMPARISONS SEPARATELY FOR EACH METRIC. ROWS ARE ORDERED BY DECREASING HOLM-ADJUSTED p-VALUE FOR PEARSON CORRELATION.

Contrast	**MAE**			**RMSE**			**Pearson's r**		
	Δ	**95% CI**	p_{Holm}	**Δ**	**95% CI**	p_{Holm}	**Δ**	**95% CI**	p_{Holm}

comparisons were therefore performed to determine which differences were statistically supported under the common set of 25 prompts.

Tables IV and V address different but complementary questions. Table IV summarizes metrics calculated separately for each calculable prompt–evaluator configuration and describes both average performance and variation across prompt configurations. In contrast, Table V compares evaluator models using one prompt-averaged prediction for each word and model. Consequently, the paired differences reported in Table V are not obtained by directly subtracting the descriptive means reported in Table IV.

For each model pair, signed differences in Pearson's correlation coefficient, MAE, and RMSE were computed. The reported 95% confidence intervals are percentile intervals derived from the bootstrap distributions. After Holm adjustment, five comparisons showed statistically supported differences in correlation: `Llama3.2` had a lower correlation than each of the other four evaluators, while `Phi-4` had a higher correlation than `DeepSeek-R1`. No statistically supported correlation differences were observed for the remaining five model pairs.

IV. Discussion

Changes in prompt formulation were associated with variation in both numerical agreement and response validity, indicating that phrasing mattered under the evaluated conditions. However, the magnitude and nature of this effect depended on the outcome considered. MAE and RMSE measured agreement with the human valence scale, Pearson's r measured preservation of linear ordering, and success rate measured adherence to the required response format. These dimensions did not vary uniformly across models and should therefore be interpreted separately.

The sample standard deviation of MAE across prompt configurations was used as the primary descriptive indicator of prompt sensitivity. By this indicator, `Phi-4`, included as a local reference model rather than as a pLLM, showed the lowest prompt sensitivity. Among the four pLLMs, `Mistral` showed the lowest MAE variation, whereas `DeepSeek-R1` showed the highest variation across all five evaluated models. Moreover, this ordering was not reproduced for correlation variability, for which `Llama3.2` showed the largest variation, reinforcing that prompt sensitivity depends on the performance dimension considered.

The paired comparisons qualify the descriptive ordering observed in Table IV. `Phi-4` had the lowest descriptive errors and the highest mean correlation, whereas `Mistral` had the corresponding best descriptive values among the four pLLMs. However, none of the paired differences between these two models in MAE, RMSE, or correlation was statistically supported after Holm adjustment. Their numerical ordering therefore does not establish superior numerical performance for either model.

In the error-based paired comparisons, `Mistral` had lower MAE and RMSE than `LLaVA`, but the analysis provided no evidence of a difference in correlation. Thus, `Mistral`'s estimates were closer to the human ratings without establishing a difference in the models' preservation of word ordering. Response validity further distinguished them: `Mistral` returned valid responses in 91.09% of calls, compared with 74.49% for `LLaVA`. `DeepSeek-R1` also illustrated the distinction between error and validity: its MAE and RMSE were higher than those of `Phi-4`, `LLaVA`, and `Mistral`, while 78.54% of its responses were valid.

As shown in Table V, `Llama3.2` had lower correlation than each of the other evaluators after Holm adjustment (all $p_{\text{Holm}} = 0.002$). This pattern is consistent with our previous study, in which `Llama3.2` also exhibited the weakest correlation with human valence ratings under a single prompt configuration [1]. By extending the evaluation to 25 prompt configurations, the present findings show that the lower linear association was not eliminated by the prompt variations examined here. This recurrence should be interpreted cautiously as consistency across the evaluated settings, rather than as evidence of the model's general adequacy or inadequacy for valence evaluation.

The paired comparisons and the prompt-sensitivity

analysis address complementary questions. The low p_{Holm} values indicate that the correlation computed from the prompt-averaged predictions of `Llama3.2` differed from those of the other evaluators, but they do not directly quantify sensitivity to prompt variation. At the same time, `Llama3.2` returned the highest proportion of valid responses (92.63%), showing that consistent adherence to the requested numerical format did not imply close agreement with the human ratings.

Response validity varied across prompt–evaluator combinations. As shown in Figure 1, the `LLaVA`-generated block had the lowest generator-block validity, and `LLaVA` returned no valid numerical response in the 140 calls using `LLaVA-P2`. This configuration had no calculable MAE and was omitted from the across-configuration summary, possibly reducing the observed MAE variation for `LLaVA`. Nevertheless, `DeepSeek-R1-P1` had the lowest aggregate validity across evaluators. Both prompts requested a 1–9 rating and mentioned a facial emoji but did not explicitly require a numerical value in the response. However, because wording and output-format requirements were not varied independently, these observations do not establish that the emoji instruction caused the invalid responses.

The study was restricted to 140 isolated English words obtained from a single public dataset. The 25 prompts were generated from one baseline prompt by the same five models subsequently used as evaluators. Although the prompts were considered semantically equivalent for the target task, some variations placed different emphasis on the required response format, making it difficult to fully separate sensitivity to wording from failures to follow the instructions. Results attributed to a generator block describe only the five existing prompts in that block and do not establish an evaluator-independent ability to generate prompts.

The paired comparisons assess differences between evaluator models under the complete set of existing prompts; they do not constitute statistical comparisons between individual prompts or prompt generators. Averaging valid responses for each word provided a common basis for comparison but summarized variation among the 25 prompts, and the number of valid responses contributing to each average could differ between models. The findings should therefore be interpreted together with response validity and remain limited to the evaluated words, prompts, models, and inference settings.

V. Conclusion

The results show that changes in prompt wording were associated with variation in numerical agreement and response validity, although these outcomes represented distinct aspects of model behavior. Using the sample standard deviation of MAE as the primary descriptive indicator, `Phi-4`, the local reference model, showed the lowest observed prompt sensitivity across calculable configurations; `Mistral` showed the lowest among the four pLLMs, whereas `DeepSeek-R1` showed the highest across the five evaluated models. In terms of mean performance, `Phi-4` also had the lowest MAE and RMSE and the highest correlation, whereas `Mistral` had the corresponding lowest mean errors and highest mean correlation among the four pLLMs. The paired analysis did not support differences between `Phi-4` and `Mistral` in MAE, RMSE, or correlation after Holm adjustment. `Llama3.2` returned the largest proportion of valid responses but had the lowest mean correlation.

These findings should not be interpreted as establishing a single overall ranking of the evaluated models. This work indicates that relying solely on mean performance metrics may mask the operational volatility of LLMs. Model selection depends on the relative importance assigned to numerical error, linear association, response validity, and computational portability. The conclusions are limited to the 140 isolated English words, 25 prompts, five locally executed models, and inference settings evaluated in this study.

Future work should evaluate prospectively constructed paraphrases in which semantic content, scale anchors, and output format remain constant while only linguistic phrasing is varied. The framework can also be extended to other languages, contextualized texts, and emotional dimensions of the SAM scale, such as arousal and dominance.

***Abstract*—Pulmonary hypertension (PH) is a condition associated with low survival rates, and its standard diagnostic procedure is highly invasive. The objective of this work is to develop a method capable of estimating the parameters for pulmonary arterial tree flow models in patients with PH based on their hemodynamic waveforms. To this end, a pulmonary arterial tree was segmented from computed tomography angiography images of pigs with induced PH and was used to create the arterial flow model using openBF software. An inverse solver based on the generalized Tikhonov regularization was implemented to estimate the hemodynamic parameters of the model from pressure and velocity measurements in one of the main pulmonary arteries. The pulmonary arterial tree geometry was successfully reconstructed from the angiography images, and the proposed parameter estimation method yielded satisfactory results, although full convergence was not achieved for all parameters when multiple parameters were estimated simultaneously. The generalized Tikhonov regularization method proved suitable for parameter estimation in PH patient models.**

I. Introduction

Pulmonary hypertension (PH) is a highly lethal condition (mean survival of 2.8 years) [1], characterized by excessively elevated pulmonary arterial pressure in comparison with the level of cardiac output [2].

PH is classified into 5 clinical groups, according to the root cause of the disease: Pulmonary Arterial Hypertension; PH due to left-sided heart disease; PH due to chronic lung disease; Chronic Thromboembolic PH; and PH due to unclear and/or multifactorial mechanisms [3]. Furthermore, it is also classified as: 'pre-capillary", 'isolated post-capillary", or "combined pre- and post-capillary"; depending on the values of mean pulmonary arterial pressure (mPAP), pulmonary capillary wedge pressure (PCWP), and pulmonary vascular resistance (PVR) [1].

Although other tools are used to estimate the clinical probability of the condition or exclude possible causes, right heart catheterization is still the tool used to confirm the disease, despite being highly invasive [3].

Electrical impedance tomography (EIT) is a non-invasive tool based on electrical impedance variation to obtain bedside thoracic images [4], [5]. In addition, it has shown promise for the diagnosis of pathologies affecting pulmonary hemodynamics.

Studies have demonstrated the possibility of using EIT for pulmonary hemodynamic assessment under PH conditions. Correlations have been observed between the probability of PH presence, the severity of the condition, survival [6], [7], and systolic pulmonary arterial pressure with data obtained via EIT [8], [9]. However, the diagnostic power of EIT is linked to the possibility of obtaining absolute lung images (rather than relative ones), since it would be possible to detect an adverse condition without the need for comparison with images acquired prior to the onset of alterations [4], [10].

The main challenge in obtaining absolute images is the greater susceptibility to artifacts caused by modeling errors, as well as the need for improved image reconstruction algorithms [4]. To overcome this challenge, refined impedance models and prior information are required [4].

The possibility of using an anatomical atlas to obtain clinically meaningful thoracic images via EIT has already been demonstrated under conditions such as pneumothorax, atelectasis, pleural effusion, and pressure variations during mechanical ventilation [10]. An anatomical atlas of the upper part of the head has also been constructed and may be used for diagnostic purposes [11]. Furthermore, several pulmonary arterial tree models under the effects of PH have already been developed in order to better understand the hemodynamics of

this condition [12]–[16].

In summary, this work focuses on calibrating an arterial hemodynamic model using pressure and velocity waveforms obtained from swine, so that, in the future, it can be used as *a priori* information for the detection and monitoring of PH in patients. This represents the first step toward the application of EIT for this purpose.

II. Methodology

The algorithm developed to estimate the characteristics of the pulmonary arterial tree from its hemodynamic waveforms was divided into two parts. First, an algorithm capable of generating hemodynamic waveforms was developed. Subsequently, the inverse problem was addressed using Tikhonov regularization.

Finally, the algorithm was tested using both a simplified model and a model reconstructed from computed tomography angiography (CTA) images of pigs with experimentally induced PH (Project No. 2349/2025, approved by the Animal Research Ethics Committee (CEUA) of the School of Medicine, University of São Paulo).

A. Algorithm

The algorithm was implemented in Python (version 3.10.16; developed by the Python Software Foundation) [17] using Visual Studio Code (version 1.100.2; developed by Microsoft) [18].

To define the problem configuration (e.g., vessels and characteristics to be estimated in the inverse problem, vessels and waveforms measured in the forward problem, regularization parameter, Gauss-Newton step length, etc.), a configuration file in YAML format was created, from which the algorithm imports the required information.

The Reynolds number was calculated in both the forward and inverse problem solutions using the blood viscosity and density specified in the arterial network file (μ and ρ_b, respectively), twice the vessel radius specified in the configuration file or estimated after solving the inverse problem (represented by the diameter d), and the average flow velocity obtained from openBF (v), as shown in Eq. (1) [19]. The openBF software is described in Section II-A1.

$$\mathrm{Re} = \frac{v \cdot d \cdot \rho_b}{\mu} \tag{1}$$

For the model reconstructed from CTA images, the external pressure acting on each vessel was calculated for both the forward and inverse problems using the hydrostatic pressure equation (2), where ρ_w represents the density of water, g is the gravitational acceleration, and h is the vessel depth [20].

$$P_h = \rho_w g h \tag{2}$$

The density of water was used because its value is close to that of blood and serves as an approximation of the density of the surrounding tissues and fluids.

The depth of each vessel segment was determined from the distance between its midpoint and the highest midpoint within the model. The model was reoriented to different anatomical positions by multiplying the original coordinate matrix by a rotation matrix about the (x)-axis (3), where ω denotes the counterclockwise rotation angle.

$$\mathbf{R}(\omega) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos(\omega) & -\sin(\omega) \\ 0 & \sin(\omega) & \cos(\omega) \end{bmatrix} \tag{3}$$

Fig. 1 illustrates the different anatomical orientations of the pig and the corresponding orientation of Blender's local coordinate system.

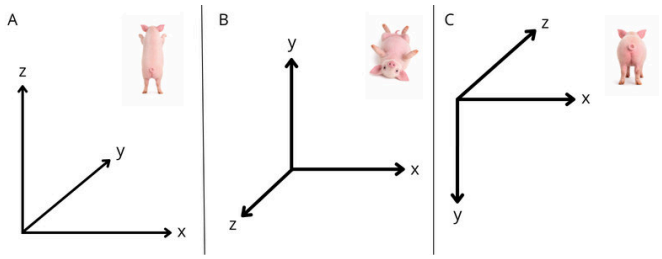

Fig. 1. New orientation of Blender's local coordinate system and the corresponding anatomical orientations of the pig. (A) Standing position; (B) Supine position; (C) Prone position. The pig images were generated using artificial intelligence.

1) Forward problem: The forward problem was solved using the hemodynamic simulation software openBF, developed by Dr. Alessandro Melis under the supervision of Dr. Alberto Marzo at the INSIGNEO Institute, where it was also validated [21]. This software is a one-dimensional blood flow solver based on the MUSCL numerical scheme and written in the Julia programming language [22], [23].

Although accuracy is reduced in the vicinity of heart valves and vascular bifurcations, one-dimensional (1D) simulations have a low computational cost, enabling the simulation of the entire cardiovascular system [23].

The model was derived from the Navier–Stokes equations under several simplifying assumptions: blood was considered an incompressible Newtonian fluid, and arteries were modeled as long, slender, elastic tubes [23].

Blood may be considered a Newtonian fluid, i.e., a fluid with constant viscosity, when simulating flow in large arteries without stagnation regions and at shear rates above $1{,}00 \times 10^2\ \mathrm{s}^{-1}$ [23], [24]. Furthermore, openBF can be used to simulate flow in short vessel segments, provided that the flow entering each segment is assumed to be fully developed, thereby neglecting the fluid transition region.

Despite these simplifications, the governing equations are capable of reproducing pulse wave propagation and reflection phenomena [23].

As input, the software requires a YAML file containing the characteristics of the vascular network to be simulated and a DAT file containing the vessel inlet boundary conditions. The output consists of hemodynamic waveforms at five locations along each simulated vessel [22], [23]. In the present study,

only the pressure and velocity waveforms at the midpoint of each vessel were used.

After generating the waveforms with openBF, noise was added to the simulated data to avoid committing the inverse crime. The inverse crime occurs when the same computational mesh is used both to generate and reconstruct the data. In this case, the absence of noise leads to a perfect reconstruction, which is unrealistic in practical applications [25]. The noise was generated from a normal distribution, with a standard deviation equal to a specified percentage of the total amplitude of each waveform.

2) Inverse Problem: This project was based on the Tikhonov regularization method to solve the inverse problem relating the hemodynamic waveforms of the pulmonary circulation to the characteristics of the arterial tree.

The need for this method arises from the fact that the inverse problem under investigation contains noise in the measured data, may fail to satisfy the Hadamard conditions (i.e., it may be ill-posed) and may also be ill-conditioned [26].

The Hadamard conditions are [27]:

- A solution exists for all admissible data;
- The solution is unique for all admissible data;
- The solution depends continuously on the data.

In an ill-conditioned problem, small variations in x can lead to large changes in $f(x)$ [28]. For a linear system $\mathbf{Ax} = \mathbf{b}$, the condition number of matrix $\mathbf{A}$ provides a useful indication of the uncertainty associated with the solution before the application of a numerical algorithm [29]. Assuming that $\mathbf{A}$ is a square and invertible/non-singular (full-rank) matrix, its condition number can be computed using Equations 4 and 5 [28].

$$\kappa(\mathbf{A}) = \|\mathbf{A}\|\|\mathbf{A}^{-1}\| \tag{4}$$

$$\kappa(\mathbf{A}) = \frac{\sigma_1}{\sigma_m} \tag{5}$$

A well-conditioned problem typically has a condition number of $\kappa = 1, 10, 10^2$, whereas an ill-conditioned problem may have $\kappa = 10^6, 10^{16}$ [28].

Regularization methods improve the stability of inverse problem solutions and enhance the suppression of undesirable noise [30]. The inclusion of a regularization parameter $\mathcal{R}_k > 0$ provides a balance between model fitting and solution stability. Larger values of $\mathcal{R}_k$ lead to more stable solutions, whereas smaller values prioritize data fitting. Since the problem addressed here is nonlinear, the regularization parameter varies between iterations; therefore, the subscript k is used to indicate the corresponding iteration [31].

The main advantage of the Tikhonov regularization method over other approaches, such as the Levenberg–Marquardt and Gauss-Newton methods, is the incorporation of a reliable estimate of the unknown parameters to constrain the solution space [26].

This method seeks to minimize the objective function given by (6) [26], where $\mathbf{z}$ represents the measured (observed) data, $\mathbf{h}'(\boldsymbol{\theta})$ is the linearized *a posteriori* model response (see (7)), $\boldsymbol{\theta}$ denotes the *a posteriori* parameters, and $\boldsymbol{\theta}^*$ is a reliable estimate of the parameters. In (7), $\mathbf{h}(\boldsymbol{\theta}_k)$ corresponds to the model response at the current iteration, and $\mathbf{J}(\boldsymbol{\theta}_k)$ is the Jacobian matrix evaluated at the current parameter vector $\boldsymbol{\theta}_k$. The matrices $\mathbf{W}_1$ and $\mathbf{W}_2$ are weighting matrices used to balance the different magnitudes of the data and parameters, respectively [26].

$$F(\boldsymbol{\theta}) = \frac{1}{2}\left\{\|(\mathbf{z} - \mathbf{h}'(\boldsymbol{\theta}))\|^2_{\mathbf{W}_1} + \mathcal{R}_k^2\|(\boldsymbol{\theta} - \boldsymbol{\theta}^*)\|^2_{\mathbf{W}_2}\right\} \tag{6}$$

$$\mathbf{h}'(\boldsymbol{\theta}) = \mathbf{h}(\boldsymbol{\theta}_k) + \mathbf{J}(\boldsymbol{\theta}_k).(\boldsymbol{\theta} - \boldsymbol{\theta}_k) \tag{7}$$

The search for the optimal parameter at each iteration is performed using (8), obtained from the minimization of the objective function in (6) [26].

$$\begin{aligned}\hat{\boldsymbol{\theta}}_{k+1} = \hat{\boldsymbol{\theta}}_k + \alpha_k &\left(\mathbf{J}_k^T\mathbf{W}_1\mathbf{J}_k + \mathcal{R}_k^2\mathbf{W}_2\right)^{-1} \\ &\cdot\left(\mathbf{J}_k^T\mathbf{W}_1(\mathbf{z} - \mathbf{h}(\hat{\boldsymbol{\theta}}_k)) - \mathcal{R}_k^2\mathbf{W}_2(\hat{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*)\right)\end{aligned} \tag{8}$$

The parameter $\alpha_k > 0$ is the Gauss-Newton step length and determines the magnitude of the parameter update at each iteration. The subscript k identifies the iteration to which the parameter corresponds [31].

In this project, $\mathbf{W}_1$ was defined as a diagonal matrix whose elements correspond to the inverse of the noise variance associated with each dataset. Specifically, the first 100 diagonal entries correspond to the inverse variance of the noise added to the 100 arterial pressure data points (Pa), whereas the last 100 entries correspond to the inverse variance of the noise added to the 100 velocity data points ($\mathrm{m/s}$).

The matrix $\mathbf{W}_2$ was defined as an identity matrix with dimensions equal to the number of estimated parameters.

The Jacobian matrix was evaluated numerically using finite differences, since a major challenge in solving nonlinear inverse problems is the accurate evaluation of derivatives [32]. Each parameter was perturbed individually, and the resulting changes in the pressure and velocity waveform vector $\mathbf{h}$ were used to estimate the partial derivatives (9). These derivatives were then assembled into the Jacobian matrix (10).

$$\frac{\partial \mathbf{h}(\theta_i)}{\partial \theta_i} = \lim_{\Delta\theta_i \to 0} \frac{\mathbf{h}(\theta_i + \Delta\theta_i) - \mathbf{h}(\theta_i)}{\Delta\theta_i} \tag{9}$$

$$\mathbf{J} = \frac{\partial \mathbf{h}}{\partial(\theta_1, \ldots, \theta_n)} = \begin{bmatrix} \dfrac{\partial h_1}{\partial \theta_1} & \cdots & \dfrac{\partial h_1}{\partial \theta_n} \\ \vdots & \ddots & \vdots \\ \dfrac{\partial h_{200}}{\partial \theta_1} & \cdots & \dfrac{\partial h_{200}}{\partial \theta_n} \end{bmatrix} \in \mathbb{R}^{200\times n}. \tag{10}$$

Since the estimated parameters $\hat{\boldsymbol{\theta}}_k$ must always remain positive, the logarithm of the desired characteristics was estimated instead of the characteristics themselves. For example, rather than estimating the vessel length L, the parameter x was

estimated, where $x = \ln(L)$. In addition, the parameter update at each iteration was constrained to a maximum variation of 10%.

Several methods have been described in the literature for determining the Gauss-Newton step length (α_k) and the Tikhonov regularization parameter ($\mathcal{R}_k$).

In this project, for the Gauss-Newton step length, both a fixed parameter ($\alpha_k = 0.7$) and an adaptive determination based on the satisfaction of the Armijo, Wolfe, and strong Wolfe conditions were investigated. In the latter case, the selected α_k is the smallest value in the sequence $(1, \frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \dots)$ that satisfies the corresponding conditions.

The search direction $\mathbf{p}_k$ is defined according to (11).

$$\begin{aligned}\mathbf{p}_k = &\left(\mathbf{J}_k^T\mathbf{W}_1\mathbf{J}_k + \mathcal{R}_k^2\mathbf{W}_2\right)^{-1} \\ &\cdot\left(\mathbf{J}_k^T\mathbf{W}_1\big(\mathbf{z} - \mathbf{h}(\hat{\boldsymbol{\theta}}_k)\big) - \mathcal{R}_k^2\mathbf{W}_2\big(\hat{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*\big)\right)\end{aligned} \tag{11}$$

Therefore, (8) can be rewritten as (12).

$$\hat{\boldsymbol{\theta}}_{k+1} = \hat{\boldsymbol{\theta}}_k + \alpha_k\mathbf{p}_k \tag{12}$$

Accordingly, the Armijo condition is given by (13), where c_1 is a constant between 0 and 1 [26], typically chosen as a small value such as 1×10^{-4}, which was the value adopted in this work [33]. The function F denotes the objective function defined in (6). The gradient of F is given by (14) and (15) [26].

$$F(\hat{\boldsymbol{\theta}}_k + \alpha_k\mathbf{p}_k) \leq F(\hat{\boldsymbol{\theta}}_k) + c_1\alpha_k\nabla F(\hat{\boldsymbol{\theta}}_k)^T\mathbf{p}_k \tag{13}$$

$$\nabla F(\hat{\boldsymbol{\theta}}_k) = -\mathbf{J}_k^T\mathbf{W}_1(\mathbf{z} - \mathbf{h}(\hat{\boldsymbol{\theta}}_k)) + \mathcal{R}_k^2\mathbf{W}_2(\hat{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*) \tag{14}$$

$$\begin{aligned}\nabla F(\hat{\boldsymbol{\theta}}_k + \alpha_k\mathbf{p}_k) &= \nabla F(\hat{\boldsymbol{\theta}}_{k+1}) \\ &= -\mathbf{J}_{k+1}^T\mathbf{W}_1\big(\mathbf{z} - \mathbf{h}(\hat{\boldsymbol{\theta}}_{k+1})\big) \\ &\quad + \mathcal{R}_{k+1}^2\mathbf{W}_2\big(\hat{\boldsymbol{\theta}}_{k+1} - \boldsymbol{\theta}^*\big).\end{aligned} \tag{15}$$

The Wolfe conditions combine the Armijo condition with the curvature condition defined in (16), ensuring that the criterion is not satisfied by arbitrarily small values of α_k [26]. The constant c_2 is chosen between c_1 and 1 and is typically set to 0.9 when a Newton or quasi-Newton method is used to determine the search direction $\mathbf{p}_k$, and to 0.1 when a nonlinear conjugate gradient method is employed [33]. In this study, $c_2 = 0.9$ was adopted.

$$\nabla F(\hat{\boldsymbol{\theta}}_k + \alpha_k\mathbf{p}_k)^T\mathbf{p}_k \geq c_2\nabla F(\hat{\boldsymbol{\theta}}_k)^T\mathbf{p}_k \tag{16}$$

For the strong Wolfe conditions, (16) is replaced by (17), thereby imposing a reduction in the absolute value of the directional derivative [26]. Strong Wolfe conditions are recommended only when the objective function is smooth [34].

$$|\nabla F(\hat{\boldsymbol{\theta}}_k + \alpha_k\mathbf{p}_k)^T\mathbf{p}_k| \leq c_2|\nabla F(\hat{\boldsymbol{\theta}}_k)^T\mathbf{p}_k| \tag{17}$$

A fixed Tikhonov regularization parameter (using several fixed values) was also evaluated, as well as regularization parameters determined by the following methods: L-curve [35], Discrepancy Principle [36], Generalized Cross-Validation (GCV) [37], Composite Residual and Smoothing Operator (CRESO) [38], Zero-Crossing [39], and U-Curve [40].

The L-curve method consists of plotting the solution norm against the residual norm (defined in (18) and (19), respectively) on logarithmic scales and identifying the value of $\mathcal{R}_k$ corresponding to the point of maximum curvature on the graph [41]. The method may fail when the curve is excessively smooth and can be computationally expensive because the norms must be evaluated for a large range of $\mathcal{R}_k$ values [30], [31].

$$\text{Solution norm} = \|(\boldsymbol{\theta} - \boldsymbol{\theta}^*)\|_{\mathbf{W}_2} \tag{18}$$

$$\text{Residual norm} = \|(\mathbf{z} - \mathbf{h}'(\boldsymbol{\theta}))\|_{\mathbf{W}_1} \tag{19}$$

The Discrepancy Principle aims to reduce the squared residual norm until it becomes consistent with the noise level present in the measured data, thereby avoiding model overfitting [32]. Since reducing the regularization parameter generally decreases the residual norm, the selected value of $\mathcal{R}_k$ should be large enough to prevent overfitting but not so large as to cause excessive regularization. Therefore, it must satisfy the condition described in (20), where ϕ denotes the number of measured data points (in this case, $\phi = 200$). Originally, the squared residual norm should equal $\phi\sigma^2$, where σ^2 is the noise variance. However, since the norm is already weighted by $\mathbf{W}_1$, which incorporates the variance, this term can be omitted [46], [47]. Given the difficulty of satisfying the equality, the squared residual norm closest to ϕ was chosen.

$$\|\mathbf{z} - \mathbf{h}'(\boldsymbol{\theta})\|_{\mathbf{W}_1}^2 = \phi \tag{20}$$

Although the method is computationally inexpensive, it tends to produce overly smooth solutions [31], and its performance depends on a reliable estimate of the noise level [30].

In the GCV method, the optimal parameter $\mathcal{R}_k$ is the one that minimizes the function defined in (21), where "trace" denotes the sum of the diagonal elements of the matrix inside the parentheses, and the matrix $\mathcal{A}$ is defined in (22) [41].

$$\mathcal{G}(\mathcal{R}_k) = \frac{\|\mathbf{z} - \mathbf{h}'(\boldsymbol{\theta})\|_{\mathbf{W}_1}^2}{\left[\frac{1}{\phi}\operatorname{trace}(\mathbf{I} - \mathcal{A})\right]^2} \tag{21}$$

$$\mathcal{A}(\mathcal{R}_k) = \mathbf{J}_k(\mathbf{J}_k^T\mathbf{W}_1\mathbf{J}_k + \mathcal{R}_k^2\mathbf{W}_2)^{-1}\mathbf{J}_k^T\mathbf{W}_1 \tag{22}$$

This method does not require prior knowledge of the noise level [37]; however, locating the minimum of the function can be difficult when it lies within a very flat region [31].

When applied to Tikhonov regularization, the CRESO method determines the optimal parameter as the first local maximum of the function defined in (23) [41]. The main

challenges associated with this method are the computation of the derivative and the identification of the function maximum.

$$\mathcal{C}(\mathcal{R}_k) = \frac{d}{d\mathcal{R}_k^2}\left(\mathcal{R}_k^2\|(\boldsymbol{\theta}-\boldsymbol{\theta}^*)\|_{\mathbf{W}_2}^2 - \|(\mathbf{z}-\mathbf{h}'(\boldsymbol{\theta}))\|_{\mathbf{W}_1}^2\right) \tag{23}$$

In the Zero-Crossing method, the optimal regularization parameter $\mathcal{R}_k$ is assumed to be the value at which the residual norm and the regularization-weighted solution norm are equal, as shown in (24) [39]. Johnston and Gulrajani (1997) defined the optimal parameter as the one corresponding to the smallest root of the function, and the absence of a root occurs only in the hypothetical case where the data are noise-free [39].

$$\mathcal{B}(\mathcal{R}_k) = \mathcal{R}_k^2\|(\boldsymbol{\theta}-\boldsymbol{\theta}^*)\|_{\mathbf{W}_2}^2 - \|(\mathbf{z}-\mathbf{h}'(\boldsymbol{\theta}))\|_{\mathbf{W}_1}^2 = 0 \tag{24}$$

In the U-Curve method, the optimal regularization parameter $\mathcal{R}_k$ is the one corresponding to the global minimum of the function defined in (25), which may also be represented on a log-log scale [41]. The method may fail if the minimum region is excessively broad, making it difficult to identify the global minimum [41].

$$\mathcal{U}(\mathcal{R}_k) = \frac{1}{\|(\mathbf{z}-\mathbf{h}'(\boldsymbol{\theta}))\|_{\mathbf{W}_1}^2} + \frac{1}{\|(\boldsymbol{\theta}-\boldsymbol{\theta}^*)\|_{\mathbf{W}_2}^2} \tag{25}$$

The stopping criterion for the Tikhonov regularization iterations was defined as three consecutive iterations with less than 1% variation between successive solutions.

The initial estimate of the method ($\boldsymbol{\theta}_0$) was set to 50% of the true solution value, while the prior estimate ($\boldsymbol{\theta}^*$) was set to 95% of the true solution value.

B. Models

1) Simple Model: A simplified model consisting of three vessels connected by a single bifurcation was constructed for the initial testing of the algorithm. Some of its configuration parameters were obtained from a Circle of Willis model recommended in the openBF documentation [42]. These included the inlet volumetric flow-rate waveform, the rheological properties of blood, the numerical scheme parameters, the order of magnitude of the vessel characteristics, and the resistance and compliance values used in the two-element Windkessel (WK) models.

In this model, the wall thickness, length, and radius of vessel 2 were estimated from the pressure and velocity waveforms measured in vessel 1. In addition, the parameters of the two-element Windkessel (WK) model were estimated, with the proximal resistance estimated independently for vessels 2 and 3, whereas a single compliance value was estimated and shared by both vessels.

2) Model Obtained from Image Segmentation: The pulmonary arterial tree model affected by PH was reconstructed from computed tomography angiography (CTA) images of experimentally induced PH pigs, obtained through a collaboration with the Laboratory of Medical Investigation LIM-09, University of São Paulo. Image segmentation was performed using 3D Slicer [43] and Blender [44].

Vessel radius and length were extracted from the segmentation, while wall thickness was calculated by openBF from the vessel radius. External pressure was determined using the proposed algorithm, a parabolic velocity profile was assumed, and the initial Young's modulus was set to $8{,}757\,81 \times 10^3\,\mathrm{Pa}$ based on literature values for Group 3 PH patients (chronic obstructive pulmonary disease) [45]. Initial orders of magnitude for the 3-element Windkessel (WK) parameters were derived from the Circle of Willis model, as these represented the key parameters that are difficult to estimate.

Pressure and velocity waveforms from the pulmonary trunk were used to estimate the Young's modulus, length, and radius of the left pulmonary artery, together with the three WK parameters for all vessels. Both homogeneous (uniform across vessels) and heterogeneous (differ between the left and right sides) WK configurations were evaluated, considering prone and supine animal positions.

III. Results and Discussion

The simplified model was built using the characteristics described in Tables I, II, and III.

TABLE I
CHARACTERISTICS OF VESSEL 1 IN THE SIMPLIFIED ARTERIAL TREE MODEL

Parameter $\boldsymbol{\theta}$	**Value**
Wall thickness, h0	$1{,}63 \times 10^{-3}\,\mathrm{m}$
Length, L	$2 \times 10^{-1}\,\mathrm{m}$
Constant radius, R0	$1{,}2 \times 10^{-2}\,\mathrm{m}$
Young's modulus, E	$4{,}000\,00 \times 10^5\,\mathrm{Pa}$
Velocity profile, gamma_profile	2 (Laminar flow)
External pressure, Pext	$0\,\mathrm{Pa}$

TABLE II
CHARACTERISTICS OF VESSEL 2 IN THE SIMPLIFIED ARTERIAL TREE MODEL

Parameter $\boldsymbol{\theta}$	**Value**
Wall thickness, h0	$1{,}83 \times 10^{-3}\,\mathrm{m}$
Length, L	$1 \times 10^{-1}\,\mathrm{m}$
Constant radius, R0	$1{,}12 \times 10^{-2}\,\mathrm{m}$
Young's modulus, E	$4{,}000\,00 \times 10^5\,\mathrm{Pa}$
WK proximal resistance, R1	$5{,}430\,000\,000 \times 10^9\,\mathrm{Pa \cdot s/m^3}$
WK distal resistance, R2	$0\,\mathrm{Pa \cdot s/m^3}$
WK compliance, Cc	$1{,}27 \times 10^{-10}\,\mathrm{m^3/Pa}$
Velocity profile, gamma_profile	2 (Laminar flow)
External pressure, Pext	$0\,\mathrm{Pa}$

CT angiography image segmentation enabled the extraction of vessel lengths and radii, which were divided into sections represented by different colors in Fig. 2.

For the simplified model, the forward simulation in openBF converged after 100 cardiac cycles and required approximately 45 s. The Reynolds number was approximately 32, indicating laminar flow.

TABLE III
CHARACTERISTICS OF VESSEL 3 IN THE SIMPLIFIED ARTERIAL TREE MODEL

Parameter $\boldsymbol{\theta}$	**Value**
Wall thickness, h0	$1{,}93 \times 10^{-3}\,\mathrm{m}$
Length, L	$3 \times 10^{-1}\,\mathrm{m}$
Constant radius, R0	$6{,}2 \times 10^{-3}\,\mathrm{m}$
Young's modulus, E	$4{,}000\,00 \times 10^{5}\,\mathrm{Pa}$
WK proximal resistance, R1	$5{,}430\,000\,000 \times 10^{9}\,\mathrm{Pa \cdot s/m^3}$
WK distal resistance, R2	$0\,\mathrm{Pa \cdot s/m^3}$
WK compliance, Cc	$1{,}27 \times 10^{-10}\,\mathrm{m^3/Pa}$
Velocity profile, gamma_profile	2 (Laminar flow)
External pressure, Pext	$0\,\mathrm{Pa}$

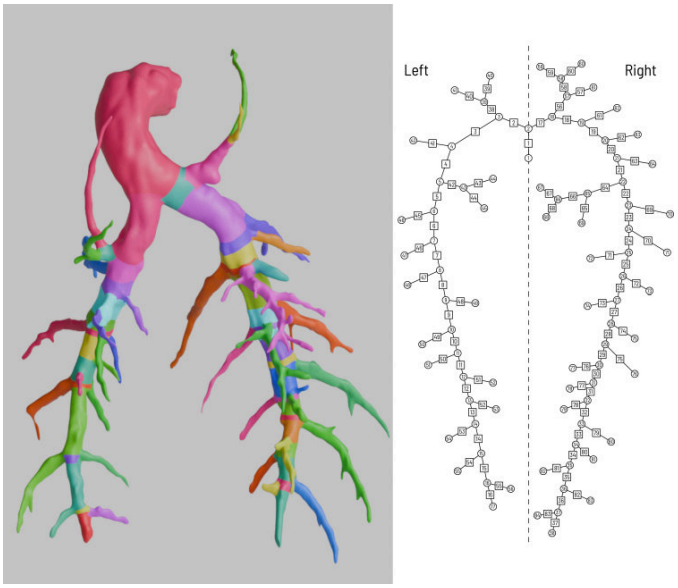

Fig. 2. Pulmonary arterial tree of a pig with induced PH. Each color represents a vessel subdivision. In the image on the right, each square corresponds to a subdivision, whereas each circle represents a junction node between adjacent subdivisions.

For the image-based model, the forward simulation converged after only 2 cardiac cycles and required approximately 7 s. The Reynolds number was approximately 291, also indicating laminar flow.

The faster convergence of the image-based model is likely due to the use of physiological vessel dimensions obtained from pigs with PH and Young's modulus values taken from the literature.

The condition number of matrix $\mathbf{A}_k$, defined in (26), was evaluated to assess the uncertainty of the inverse solution. Tikhonov regularization proved effective, as the matrices associated with all solved problems were well conditioned.

$$\mathbf{A}_k = (\mathbf{J}_k^T \mathbf{W}_1 \mathbf{J}_k + \mathcal{R}_k^2 \mathbf{W}_2) \tag{26}$$

For all inverse problem simulations, the Reynolds number remained low, confirming laminar flow.

The convergence of the inverse problem was primarily assessed through the relative difference between the estimated and true parameter values at each iteration. Consequently, the results depended on the method used to determine α_k and $\mathcal{R}_k$, the estimated parameters, and the pig posture.

For the simplified model, only method combinations involving at least one fixed parameter were evaluated because the longer openBF simulation time resulted in more than one hour per iteration when both parameters were determined. In contrast, all possible method combinations were evaluated for the image-based model.

The minimum value of α_k was set to 1×10^{-2}, since smaller values introduced excessive numerical instability.

The different methods for determining α_k showed no significant differences. Their performance depended mainly on the estimated parameters and the inverse problem configuration.

In contrast, the methods used to determine $\mathcal{R}_k$ produced substantially different results. The L-curve, GCV, and Zero-crossing methods provided the best overall performance, although none was consistently successful for all cases investigated.

The Discrepancy Principle, CRESO, and U-curve methods resulted in insufficient regularization, leading to poor parameter estimates. For the Discrepancy Principle, the squared residual norm remained far from ϕ during the first iterations, regardless of the value of $\mathcal{R}_k$, which may explain its poor performance. CRESO was evaluated using the first local maximum (original method), the last local maximum (as suggested by [41]), and by computing the derivative with respect to $\mathcal{R}_k$ instead of $\mathcal{R}_k^2$; however, all approaches produced insufficient regularization. Likewise, the U-curve method did not produce the expected U-shaped curves, even on a log-log scale.

The Zero-crossing method performed well for the simplified model. However, it produced excessive regularization for all image-based model configurations, causing all solutions to converge to the prior estimate $\boldsymbol{\theta}^*$.

Table IV summarizes the different configurations used to estimate the model parameters and the best combinations of methods for determining α_k and $\mathcal{R}_k$. The abbreviations are defined in Table II. Overall, the manual selection of fixed values for the regularization parameter $\mathcal{R}_k$ proved to be the most effective approach. This strategy reduces computational effort by eliminating the need to evaluate a wide range of candidate values to identify those satisfying the criteria described in Section II. Furthermore, it provided more reliable parameter estimates.

Table V presents the relative differences between the best estimated solution and the true parameter values for each case. The proposed inverse problem achieved complete or near-complete convergence for only some of the estimated parameters, whereas the remaining parameters showed larger deviations from the true solution. Although this behavior is common in inverse problems, it highlights the importance of evaluating the reliability of each estimated parameter before accepting the solution. The lack of a universally reliable method introduces uncertainty when applying the proposed approach to real cases. Nevertheless, the methodology can be reproduced for configurations identical to those investigated

TABLE IV
BEST COMBINATIONS OF OPTIMIZATION METHODS FOR DETERMINING THE OPTIMAL α_k AND REGULARIZATION PARAMETER $\mathcal{R}_k$.

Model	Estimated Parameters	Posture	Best optimization method
Simplified	h0, L, R0	N/A	Armijo + $\mathcal{R}_k = 500$
	R1, Cc	N/A	$\alpha_k = 0.7$ + L-curve/ GCV/ Zero-crossing or $\alpha_k = 0.7$/Armijo/ Wolfe/Strong Wolfe + $\mathcal{R}_k = 1000$
Image-based	E, L, R0	Supine	$\alpha_k = 0.7$/Armijo/Wolfe/ Strong Wolfe + $\mathcal{R}_k = 500$
		Prone	$\alpha_k = 0.7$/Armijo/Wolfe/ Strong Wolfe + $\mathcal{R}_k = 600$
	R1, R2, Cc Homogeneous	Supine	Strong Wolfe + $\mathcal{R}_k = 8$
		Prone	Armijo + L-curve
	R1, R2, Cc Heterogeneous	Supine	Wolfe + GCV
		Prone	Wolfe + $\mathcal{R}_k = 10$

TABLE V
APPROXIMATE RELATIVE DIFFERENCE BETWEEN THE SOLUTION AND THE TRUE VALUE.

Model	Estimated Parameters	Posture	Approximate Relative Difference of the Solution (%)
Simplified	h0, L, R0	N/A	h0: 6%; L: 4% and R0: 2%.
	R1, Cc	N/A	R1 (vessels 1 and 2): 0% and Cc: 5%.
Image-based	E, L, R0	Supine	E: 6%; L: 3% and R0: 1%.
		Prone	E: 6%; L: 3% and R0: practically 0%.
	R1, R2, Cc Homogeneous	Supine	R1: 0%; R2: 5% and Cc: 5%.
		Prone	R1: 0%; R2: 7% e Cc: 8%.
	R1, R2, Cc Heterogeneous	Supine	R1 Right: 0%; R1 Left: 2%; R2 (Right and Left): 5% and Cc (Right and Left): 6%.
		Prone	R1 Right: 5%; R1 Left: practically 0%; R2 Right: 0%; R2 Left: practically 0%; Cc (Right and Left): 7%.

in this study, i.e., with the same estimated parameters and anatomical posture.

IV. CONCLUSION

The inverse problem relating pulmonary arterial hemodynamic waveforms under PH to the characteristics of the arterial tree was successfully solved using Tikhonov regularization. The application of this method, together with strategies such as transforming the estimated parameters into the logarithmic domain, resulted in a well-conditioned inverse problem despite the large differences in parameter magnitudes.

The methods used to determine the step length α_k (Armijo, Wolfe, and strong Wolfe conditions) performed similarly, with no single method consistently outperforming the others. Regarding the methods for determining the Tikhonov regularization parameter $\mathcal{R}_k$, only the L-curve, GCV, and Zero-Crossing methods showed promising performance. However, as no single combination of optimization and regularization methods proved to be consistently superior across all problem configurations, it is suggested that fixing a value for the parameter $\mathcal{R}_k$, combined with either fixing α_k or applying different conditions to it, is the best approach.

The results presented in this study are expected to provide insight into both the strengths and limitations of applying Tikhonov regularization to calibrate hemodynamic models of the pulmonary arterial tree affected by PH.

Future work includes evaluating the convergence of the inverse solution using other fixed values of α_k and extending the proposed methodology to human arterial models.

***Abstract*—The production of personalized plantar orthoses faces significant barriers due to the high cost of clinical equipment for capturing plantar pressure. As an alternative, this work investigates the technical limits of simplified computational models for human gait simulation, aiming to map the feasibility of a low-cost numerical approach for sizing these structures. The methodology involved developing simulations in ANSYS software, employing the Ogden hyperelastic model to represent the foot's soft tissue in a continuous geometry without the internal bone component. Dynamic impact tests were performed using the LS-DYNA solver to represent the specific moments of gait where dynamic loads exceed the static state. Results revealed that the absence of an internal bone structure leads to excessive geometric deformations and an artificial flattening of the plantar arch during the simulated impact. The study concludes that while the simplified continuous model fails to replicate real gait kinematics, it fulfills a crucial scientific role by delimiting the boundaries of biomechanical modeling, proving that the inclusion of the skeletal structure is mandatory for realistic gait simulation and effective orthosis design.**

***Index Terms*—gait simulation, Ogden model, plantar orthoses, numerical simulation**

I. Introduction

The manufacturing of personalized plantar orthoses is traditionally a process dependent on high-cost equipment and expensive commercial materials. In a scenario where gait asymmetries frequently lead to injuries and conventional design relies on costly static measurements, numerical simulation and 3D manufacturing emerge as viable alternatives to reduce costs and optimize projects.

Gait analysis is fundamental for assessing functional independence, diagnosing pathologies and designing assistive devices in medical, rehabilitative and sports contexts. The reliability of gait simulation as a research tool has been further reinforced by validation studies such as those conducted by Baxter et al. [1]. Their work demonstrated that gait simulators, when driven by population-specific in vivo inputs can successfully replicate the kinematics of the ankle, subtalar and talonavicular joints. These findings are particularly significant for orthotic and surgical design, as they prove that simulation platforms can accurately reproduce not only mean population patterns but also individual variability. However, experimental trials are often limited by the high number of sessions required to test multiple conditions, such as varying speeds and carried loads or by the physical burden of sensors on the subject [2]. Recent advancements in biomechanical modeling have produced high-fidelity simulators capable of replicating human gait with remarkable accuracy. Notable examples include the forward dynamic model developed by Ito et al. [3], which incorporates a detailed skeletal structure of 23 bones to simulate foot-ground interactions during the stance phase, which require up to 14 hours of supercomputing time. Likewise, Minagawa et al. [4] employed anatomically precise bone and ligament representations to investigate joint stability under various stress conditions. While these models provide deep insights into internal tissue loading, their implementation often requires high computational power. Nevertheless, a model more accessible and with low-cost numerical tools for plantar orthosis design is an excellent auxiliary tool for plantar orthosis design.

This study presents a feasibility analysis of simplified computational models for human gait simulation. The research investigates the technical limits of replacing complex anatomical structures with the adoption of a continuous geometry without bone components. To ensure mechanical fidelity, the soft tissue was represented using the 1st-order Ogden hyperelastic model, which is capable of capturing the non-linear strain-stiffening behavior of plantar fat.

Using ANSYS software and the LS-DYNA solver for transient dynamic analysis, this work aims to map the numerical stabilization and convergence of this low-cost proposal. By delimiting the boundaries of simplified biomechanical modeling, this research provides essential criteria for the development of accessible tools for plantar orthosis sizing and design.

II. Theoretical Background

This section establishes the biomechanical and mathematical principles used to evaluate human gait and the mechanical behaviour of plantar tissues through numerical simulation.

A. Gait biomechanics and plantar pressure distribution

Human gait is a cyclic activity composed of repetitive patterns, primarily divided into stance and swing phases [2]. For precise orthotic design, the stance phase is further categorized into six stages: Heel Strike, Foot Flat, Mid-Stance, Heel Off, Terminal Stance and Toe Off (see Fig. 1). While conventional orthotic design often relies on static measurements, the highest force concentrations occur during locomotion, where the body weight is abruptly transferred over small areas of the foot. During these moments, dynamic loads can reach twice the magnitude of those observed in a static posture [3]. Computational simulation allows for the assessment of joint torques and internal stresses in these conditions, which are otherwise difficult to reproduce or measure experimentally.

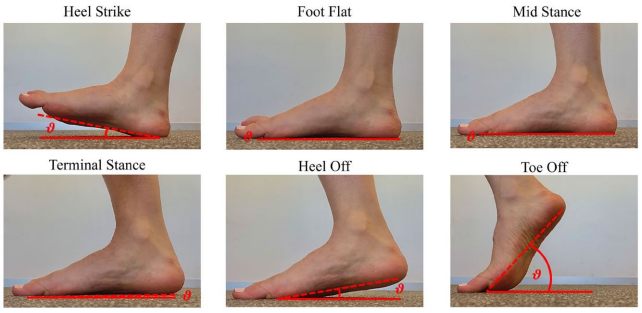

Fig. 1: Visual scheme of gait stages [5]

Plantar pressure distribution is a critical parameter for identifying high-risk zones where abnormal pressure peaks are directly linked to musculoskeletal injuries and complications like diabetic foot ulcers. During a normal step, the Center of Pressure follows a specific trajectory, typically progressing from the heel medially to the midfoot and then to the hallux during the propulsive phase [3, 6].

B. Ogden hyperelastic constitutive model

The representation of plantar soft tissues, such as the fat pad, requires numerical models capable of capturing complex non-linear mechanical behaviours. Unlike linear elastic materials, biological tissues exhibit strain-stiffening, a phenomenon where the material becomes progressively more rigid as it undergoes compression. To replicate this in a Finite Element environment, the Ogden hyperelastic model is widely employed [3].

The Ogden hyperelastic model is widely utilized in soft tissue biomechanics due to its high capacity to capture non-linear and isotropic strain response under large deformations [7, 8]. The strain energy density function is expressed as

$$W = \sum_{i=1}^{N} \frac{\mu_i}{\alpha_i} \left(\lambda_1^{\alpha_i} + \lambda_2^{\alpha_i} + \lambda_3^{\alpha_i} - 3\right), \tag{1}$$

where N represents the order of the model and μ_1 and α_i are empirical parameters of the materials. λ_i represent the principal stretch ratios of the material.

While high-fidelity models often combine the Ogden formulation with viscoelastic properties to account for time-dependent responses [3], this work adopts a simplified 1st-order approach to maintain computational efficiency for orthosis design. However, comparative tests with linear materials (e.g., structural steel) demonstrate that using the Ogden model is mandatory; linear models fail to account for the large local deformations necessary to generate realistic pressure maps, highlighting the importance of hyperelasticity in biomechanical simulations.

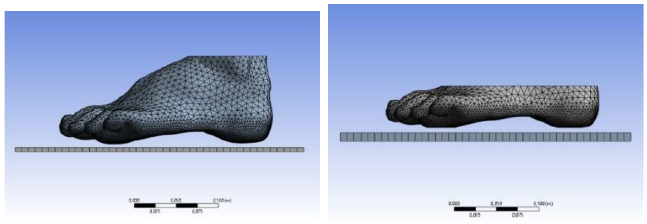
III. Methodology

This section details the methodological approach used to investigate the feasibility of computational human gait simulation without relying on clinical force-capture machinery. The study employs a purely numerical framework focused on a simplified geometric model of the human foot.

A. Geometry and Material properties

The 3D geometric domain was obtained from a surface scan available on the GrabCAD library [9]. The model represents a male adult foot with a length of 251.37 mm and a maximum width of 108.74 mm, corresponding to approximately a size 40/41 (EU). Before simulation, the mesh underwent surface smoothing to remove scanning artifacts. The final domain was discretized using tetrahedral elements (8 mm global, 3 mm plantar refinement).

Two material scenarios were defined for comparison:



- Plantar Soft Tissue: Represented by the 1st-order Ogden hyperelastic constitutive model. This model is essential for capturing the non-linear behavior and large deformations of biological tissues under compression. The parameters used were $\mu_1 = 0.026$ MPa and $\alpha_1 = 0.523$ [10]. It is critical to note that while values of $\alpha_1 > 1$ typically model strain-stiffening behavior under compression, the adopted parameter of $\alpha_1 = 0.523$ mathematically

results in a non-linear strain-softening effect under large compressive strains. As observed in the results, this material response further facilitated the rapid deformation and eventual collapse of the plantar arch during dynamic trials.

- Control Material: Structural Steel was used as a linear elastic material to evaluate the influence of extreme stiffness on stress distribution and to isolate the effects of geometric deformation.

B. Numerical setup and simulation scenarios

The domain was discretized using tetrahedral elements with a global size of 8 mm. A local mesh refinement was applied to the plantar surface, reducing element size to 3 mm to ensure higher accuracy in contact regions, as shown in Fig. 2.

(a) (b)

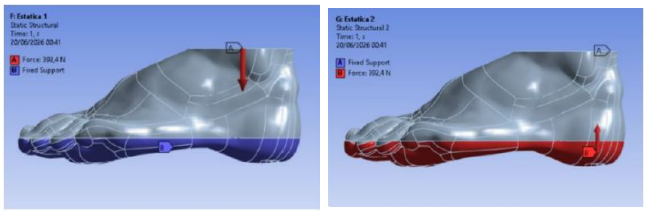


Fig. 2: Geometric representation of the foot: (a) geometry adopted in Cases 1-5 and (b) in Case 6.

The loading parameters assumed a standard adult mass of 80 kg, resulting in a design load of 392.4 N (40 kg – half human representative weight) for a single foot. Simulations were performed using ANSYS software, divided into Static Structural analysis and LS-DYNA transient dynamic analysis to represent the gait impact where dynamic loads exceed static states.

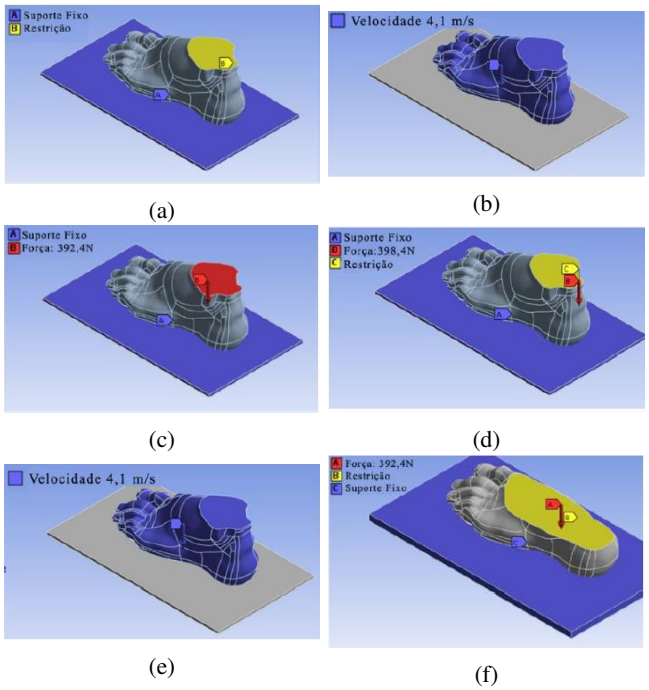
Six study cases were established to evaluate numerical stabilization and pressure distribution:

- Static scenarios:
  - Case 1 (Superior Load and Plantar Fixation): Fixed support on the sole with a vertical force applied to the top of the leg (see Fig. 3a);
  - Case 2 (Plantar Load and Superior Fixation): Fixed support on the top of the leg with a distributed force applied perpendicularly to the sole (see Fig. 3b).
- Dynamic impact scenarios:
  - Case 3 (Pure Inertial Impact): Pure inertial impact with constant force of 392.4 N (see Figs. 4a, showing the fixed support in blue and movement restriction in yellow; and 4b, showing the foot uniform velocity of 4.1 m/s);
  - Case 4 (Restricted Motion Impact): Restricted motion (blocking vertical and horizontal translations at the top) with damping controls to stabilize numerical oscillations (see Fig. 4c, showing the fixed support in blue and applied force in red);
  - Case 5 (Guided Motion with Damping): Guided motion adding an initial velocity of 4.1 m/s to the Case 4 configuration to represent high-intensity running impact speed (see Figs. 4d, showing the fixed support in blue, force in red and movement restriction in yellow; and 4e, showing foot velocity);
  - Case 6 (Reduced Geometric Domain): Reduced geometry version using the same conditions as Case 5 to optimize processing time (see Fig. 4f, showing the fixed support in blue, movement restriction in yellow and applied force in red).

To simulate the foot-ground interaction during impact, a Surface-to-Surface contact formulation was implemented in LS-DYNA. The interface utilized a static friction coefficient of $\mu_s = 0.6$ and a dynamic friction coefficient of $\mu_d = 0.4$, representing typical contact conditions between human skin (or elastomeric orthotic materials) and a rigid floor.

(a) (b)

Fig. 3: Boundary conditions in static cases: (a) Case 1, superior load applied at the ankle (highlighted in red) with fixed plantar support (highlighted in blue); (b) Case 2, plantar load applied at the heel (highlighted in red) with fixed superior support.

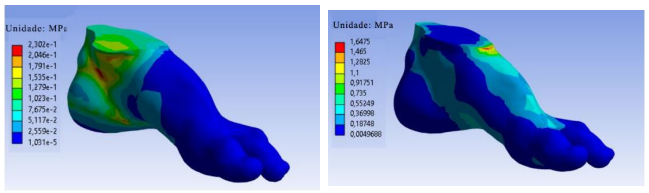


IV. Results

This section presents the results of the numerical simulations performed in ANSYS categorized into static structural analyses and transient dynamic impact tests. The primary objective was to evaluate the stability of the simplified computational model and its capacity to predict plantar pressure distribution using the Ogden hyperelastic model.

A. Static analysis and numerical response

The initial phase tested two constraint arrangements under a constant load of 392.4 N to determine the mechanical response of the simplified model. The velocity of 4.1 m/s is here correctly classified as high-intensity running impact, as typical walking (gait) speeds range between 1.2 and 1.4 m/s [3]. This extreme condition was chosen to test the numerical limits of the simplified geometry:

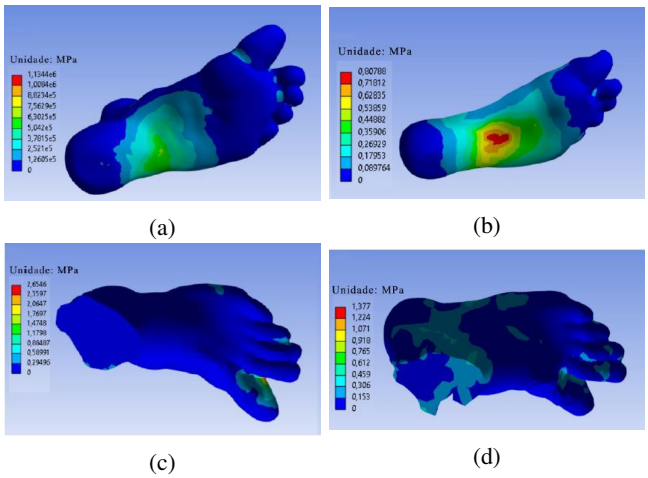


- Case 1: Applying the load at the ankle with a fixed sole resulted in artificial numerical locking. Because the plantar surface was completely restricted, the stress flow at the contact interface was nullified, concentrating instead at the nearest geometric discontinuities and preventing the natural compression of the hyperelastic tissue (see Fig. 5a);

(a) (b) (c) (d) (e) (f)

Fig. 4: Boundary conditions in dynamic cases: (a)-(b) Case 3, (c) Case 4, (d)-(e) Case 5 and (f) Case 6.

- Case 2: Inverting the arrangement caused deformation energy to migrate away from the sole and toward the plantar arch and the anterior ankle transition zone. This behavior indicates that the continuous geometry, when pulled in this configuration, concentrates stress at superior discontinuities, simulating the stretching of dorsal support tissues rather than plantar compression (see Fig. 5b).



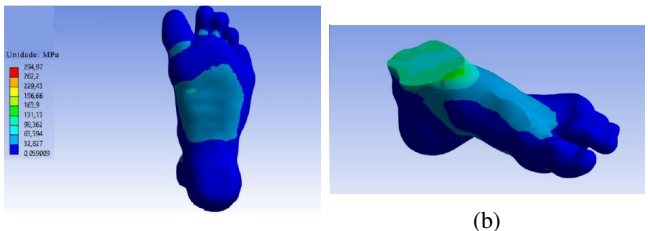
(a) (b)

Fig. 5: Results for pressure distribution along the foot for (a) Case 1 and (b) Case 2.

The comparison established that for transient stages, the model requires freedom of movement at the base to generate biologically coherent pressure maps through mutual compression against the orthotic surface.

B. Dynamic impact analysis

The impact simulations revealed that a model consisting exclusively of hyperelastic soft tissue lacks the structural stiffness required to reproduce human foot biomechanics during ground contact. While Cases 3 and 6 provided clear numerical outputs (see Figs. 6a and 6b), Cases 4 and 5 exhibited severe stabilization issues (see Figs. 6c and 6d). The absence of internal rigid components meant the model suffered from excessive geometric deformations, which compromised system stability and produced mechanical responses divergent from realistic gait patterns.



(a) (b) (c) (d)

Fig. 6: Results for impact simulation for (a) Case 3, (b) Case 6, (c) Case 4 and (d) Case 5.

C. Comparative Analysis: Linear vs. Hyperelastic Material

To isolate the effects of the Ogden constitutive model, a control test was conducted using the linear properties of Structural Steel. The extreme stiffness of the linear material eliminated numerical noise and local instabilities at the contact interface. However, this material acted as a rigid body, effectively "shielding" the model against the large local deformations necessary for realistic biomechanical representation. The results presented in Fig. 7 quantify this mechanical discrepancy. Under the same loading conditions, the model using structural steel reached an extreme peak von Mises stress of 294.97 MPa concentrated at the plantar contact zone, with virtually zero compliance. Conversely, the hyperelastic Ogden model distributed the load through localized compliance, limiting the peak stress to only 0.807 MPa (as shown in Case 2, Fig. 5b). While linear models facilitate rapid solver convergence, they completely mask the soft tissue behavior required to design effective plantar orthoses.

(a) (b)

Fig. 7: Results for the simulation with structural steel: (a) Plantar region and (b) Dorsal foot.

The efficiency in solution for the studied simplified models is presented on the results in Tab. I, where the CPU time for each case is presented.

The static analyses exhibited highly divergent processing times. Case 1 required approximately 8 hours to solve, a consequence of the artificial numerical locking caused by the fully constrained sole. In contrast, by inverting the boundary conditions in Case 2, the system achieved convergence in a 92% reduction of computational time. For the transient dynamic simulations using the LS-DYNA explicit solver, processing times ranged from 2 minutes (Case 3) to less than 20 minutes (Cases 5 and 6).

Interestingly, Case 6 (19 min 39 s) required slightly more processing time than Case 5 (18 min 11 s), despite utilizing a reduced geometric domain. In explicit dynamic solvers, the integration time step (Δt) is strictly governed by the Courant-Friedrichs-Lewy (CFL) condition, where

$$\Delta t \leq \frac{l_c}{c}.$$

Here, l_c represents the characteristic length of the smallest element in the mesh and c is the speed of sound in the material. During the geometric truncation of the foot model to isolate the plantar region (Version 2), the relative concentration of refined 3 mm elements increased and mesh generation at the artificial boundaries created slightly more distorted elements with smaller characteristic lengths. This decreased the critical time step, forcing the solver to execute more iterations and slightly increasing the total CPU time. Nevertheless, both Cases 5 and 6 solved in under 20 minutes, which represents an extremely high computational saving (over 97%) compared to the 14 hours required by anatomically detailed 3D models running on high-performance supercomputers. This duality corroborates with the fact that although simplified models did not replicate the precise physics of the bone kinematics, they should indeed be considered as alternative for quick solutions and design in structural evaluation of orthosis design.

This trade-off between anatomical realism and processing speed demonstrates that although simplified models fail to replicate dynamic bone kinematics, they present a highly viable, near-real-time option for fast static structural evaluation in orthosis design.

V. Conclusions

This work investigated the feasibility of using simplified computational models for human gait simulation as a tool to obtain stress distribution on the foot sole and support the design of personalized plantar orthoses in the future. The research employed numerical simulations in ANSYS, utilizing the Ogden hyperelastic model to represent plantar soft tissue in a continuous geometry devoid of internal skeletal structures.

The different simulation scenarios provided clear conclusions regarding the limitations of anatomical simplification. While static tests revealed a high sensitivity to boundary conditions and movement constraints, the dynamic impact tests proved that representing the foot as a bone-less continuous block is inadequate for simulating real gait kinematics. The absence of a rigid internal component, which represents the bones and ligaments, removed the mechanical constraints necessary to support dynamic loads. Consequently, during the simulated impact, the hyperelastic tissue suffered excessive geometric deformations, leading to the artificial collapse and flattening of the plantar arch against the ground.

Furthermore, comparative analyses showed that although linear materials (such as structural steel) provide better numerical stabilization, they mask the realistic "strain-stiffening" behavior of soft tissue required for accurate pressure mapping. Therefore, while this research serves a relevant scientific role by delimiting the boundaries of biomechanical modeling, it concludes that the complexity of the human foot cannot be neglected in dynamic simulations.

Ultimately, to design realistic plantar orthoses and replicate dynamic pressure distributions effectively, the inclusion of the skeletal structure is a mandatory requirement. Future efforts should focus on optimizing these skeletal models to balance the need for anatomical realism with the computational efficiency required for practical clinical applications.

***Abstract*—This paper presents a computational framework for rapid-acquisition Unmanned Aerial Vehicle photogrammetric data into interactive 3D digital twins within Unreal Engine 5 for disaster management and flood simulation. The methodology was applied across a stretch of the Atuba River basin covering a 0.408 km^2 study area, where 719 images were successfully aligned within a total processing time of 31 minutes and 29 seconds. To enable real-time execution, the high-resolution geometric mesh was optimized in RealityScan environment and decimated into a 5-million triangle topology distributed across 21 structural parts. Quantitative reconstruction validation yielded a Structural Similarity Index of 0.3285, a Peak Signal-to-Noise Ratio of 16.0247 dB, and a stable Learned Perceptual Image Patch Similarity of 0.3620, indicating that pixel-level fidelity is limited while macro-geometric boundaries relevant to physical rigid-body collisions appear comparatively better preserved. The flood simulation was performed in Unreal Engine 5, modeling the progression of the water body in four scenarios, quantifying severe impacts under the maximum flood parameter, which inundated 38 out of 40 structural assets and caused a 35% disruption along the main highway. Finally, it a proof-of-concept decision framework was proposed to optimize medical logistics, establishing the viability of translating rapid aerial surveys into immediate tactical routing directives for climate-induced crises.**

I. Introduction

A 3D Digital Twin (DT) is a computational framework that continuously synchronizes a physical environment with a digital representation [1]. The deployment of DTs has become essential for the management and operation of smart cities [2]. In disaster scenarios, these applications provide critical data for decision-making, coordination, and efficient resource reallocation [3].

The impact of this technique was demonstrated in the reconstruction of historical monuments after catastrophic events, such as the Notre Dame Cathedral [4]. Beyond heritage conservation, this technique can be tailored to specific operational requirements within the scope of disaster medicine, blending 3D reconstruction and geospatial data into 3D digital twin environments to deliver dynamic, real-world representations of affected areas. In the context of disaster medicine, integrating spatial information into 3D environments enhances real-time situational analysis and critical healthcare decision-making processes. While recent frameworks by Lagap and Ghaffarian [5] as well as Ge and Qin [6] have enhanced urban resilience models, executing these simulations in real time remains computationally expensive [7]. This creates a critical disconnect between initial spatial reconstruction and active emergency response loops, limiting their immediate clinical and tactical utility.

Recent extreme weather events, such as the floods in Rio Grande do Sul, Brazil [8] and Bavaria, Germany [9], underscore the urgency of developing aid solutions that are adaptable to diverse international contexts, despite territorial and demographic variances. Traditional aerial monitoring platforms offer high-resolution post-disaster data, but the prolonged processing times required for dense geometric reconstruction limit their immediate, field-deployable utility during active emergency response loops [10]. Furthermore, translating

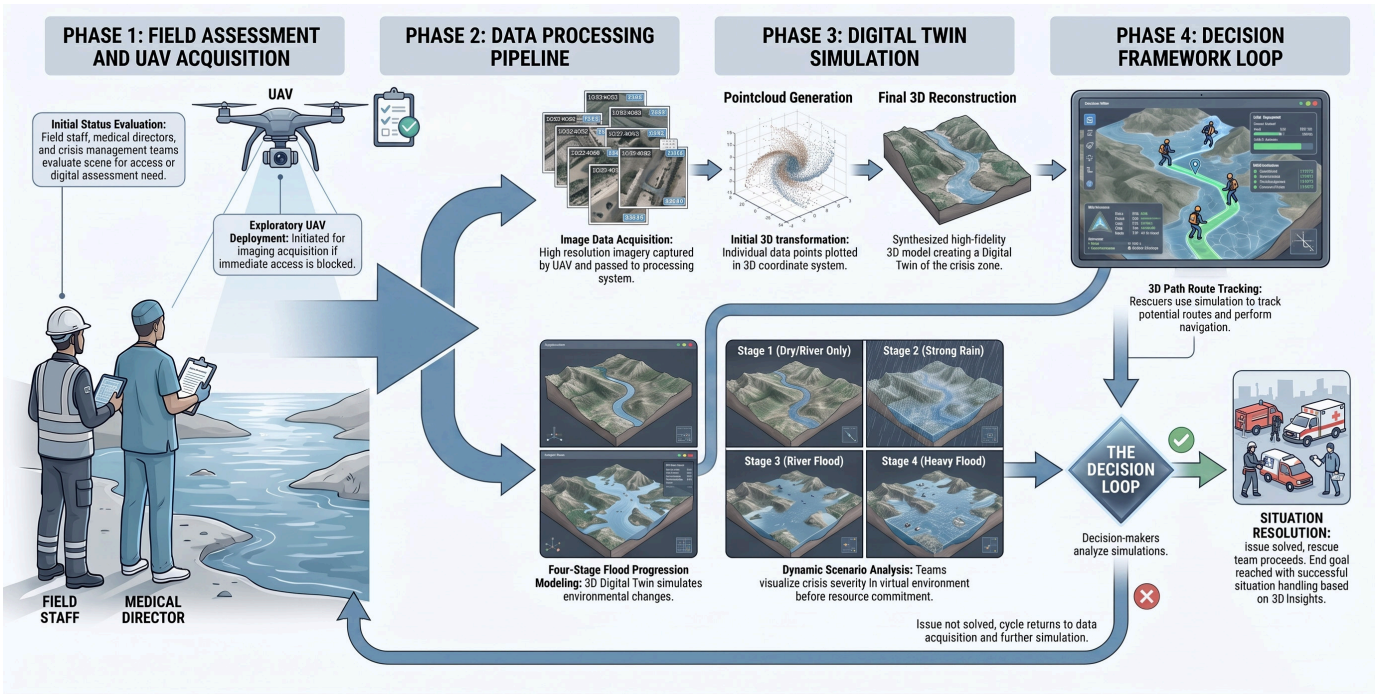

Fig. 1. Graphical abstract showing the entire deployment framework, from field assessment and UAV acquisition, data processing pipeline, digital twin simulation and decision framework loop.

raw topographic changes into active logistical routing for emergency medical supply distribution presents an ongoing bottleneck in disaster management workflows [11].

This challenge operates under the premise that structural alterations observed in urban structures can provide preliminary indicators of the impacts sustained by buildings and affected areas. The accessibility conditions of urban highways directly dictate the mobility of emergency response teams, access to critical regions, and the timely transportation of victims, medical supplies, and healthcare resources. Within this context, leveraging interactive game engines and real-time spatial monitoring becomes important to assess the relationship between raw topographic data and actionable health logistics [12]. To address these operational limitations, this paper proposes an integrated framework that applies rapid UAV photogrammetry to generate a 3D digital twin for simulations within Unreal Engine environment using a water body progression. The technological contributions of this architecture are:

- An end-to-end execution pipeline, which can communicate between unstructured UAV data and localized field action,
- A multi-stage mesh optimization and decimation workflow that minimizes computational rendering while preserving macro-geometric elevation profiles,
- A proof-of-concept decision framework designed to support territorial accessibility analysis, damage assessment, and health logistics, such as rescue operations and resource distribution, while integrating spatial information into 3D digital twins to enhance situational analysis in complex health emergencies.

The conceptual workflow is shown in the Graphical Abstract (Fig. 1) by each stage: (1) Initial assessment: field staff or medical director evaluating the situation, (2) UAV Data Acquisition: highlighting the exploratory drone flights, including checks for weather conditions, battery capacity, and flight plans, (3) 3D Reconstruction: visualizing the transition from image data acquisition to point cloud generation and full 3D reconstruction, (4) Flood Simulation: incorporating the progression of the flooding, and (5) Decision Framework: integrating the decision-making loops where rescuers use the 3D model and path route simulations to determine if the situation can be handled.

II. Theoretical Background

A. 3D Environmental Reconstruction Pipeline

The digital twin generation workflow employs a modern photogrammetric architecture within the desktop-rebranded RealityScan engine (incorporating core algorithms from RealityCapture, Epic Games). The structural conversion of unordered 2D aerial imagery into an actionable 3D mesh operates across two fundamental computing items:

1) Structure-from-Motion (SfM): Feature detection is initiated using scale-invariant descriptors to establish tie points across overlapping frames. The relative camera poses, internal calibrations, and spatial orientations are resolved via a global bundle adjustment optimization, minimizing the global reprojection error to construct a sparse point cloud [13].
2) Multi-View Stereo (MVS) & Surface Reconstruction: To transition from a sparse point cloud to dense surface to-

pography, a depth-map computation is computed across multi-view matrices. Surface meshing is formalized using a variational or Delaunay-based signed distance field (SDF) optimization [14], yielding a vectorized polygon mesh defined as:

$$M = \{V, E, F\} \tag{1}$$

where $V \in \mathbb{R}^3$ represents the spatial coordinates of the vertices, E denotes connectivity edges, and F specifies the polygon faces mapping the macro-elevation bounds of the terrain.

For wide-area disaster modeling (0.4 km^2), computational efficiency necessitates strict decimation constraints to produce static physics colliders that are fully compatible with real-time runtime rendering and fluid simulation processing.

B. Image Quality & Structural Fidelity Metrics

To objectively evaluate the fidelity of the reconstructed digital twin against reference aerial imagery, three independent mathematical formulations are evaluated: Peak Signal-to-Noise Ratio (PSNR), Structural Similarity Index Measure (SSIM), and Learned Perceptual Image Patch Similarity (LPIPS).

1) Peak Signal-to-Noise Ratio (PSNR): PSNR serves as a standard metric to compute pixel-level absolute logarithmic error differences between the ground-truth frame (I) and the projected digital twin render (K), defined over an $M \times N$ image matrix:

$$\text{MSE} = \frac{1}{MN} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} [I(i,j) - K(i,j)]^2 \tag{2}$$

$$\text{PSNR} = 10 \cdot \log_{10} \left(\frac{\text{MAX}_I^2}{\text{MSE}} \right) \tag{3}$$

where MAX_I is the maximum possible pixel value of the image. While highly sensitive to global illumination variations and absolute pixel displacement, PSNR lacks direct alignment with human visual structural perception.

2) Structural Similarity Index Measure (SSIM): To capture structural degradation, SSIM shifts the assessment from independent pixel errors to perceived luminance (l), contrast (c), and structural configuration (s) comparisons within localized window kernels [15]:

$$\text{SSIM}(x, y) = [l(x,y)]^\alpha \cdot [c(x,y)]^\beta \cdot [s(x,y)]^\gamma \tag{4}$$

When parameter weights are normalized ($\alpha = \beta = \gamma = 1$), the index simplifies to:

$$\text{SSIM}(x, y) = \frac{(2\mu_x\mu_y + C_1)(2\sigma_{xy} + C_2)}{(\mu_x^2 + \mu_y^2 + C_1)(\sigma_x^2 + \sigma_y^2 + C_2)} \tag{5}$$

where μ and σ^2 dictate the mean and variance profiles of the windows, σ_{xy} is the cross-covariance, and C_1, C_2 act as stabilizing constants to avoid division by zero. SSIM bounds scale between $[-1, 1]$, where a value of 1 signifies absolute structural replication.

3) Learned Perceptual Image Patch Similarity (LPIPS): To overcome the mathematical rigidities of classical metrics, LPIPS utilizes deep feature representations to emulate human perceptual judgement [16]. Given a deep convolutional network (e.g., VGG or AlexNet), features are extracted from layer l, normalized across channels, and scaled by vector w_l to compute the L_2 distance:

$$d(x, x_0) = \sum_l \frac{1}{H_l W_l} \sum_{h,w} \left\| w_l \odot \left(\hat{y}_{h,w}^l - \hat{y}_{l,h,w}^0 \right) \right\|_2^2 \tag{6}$$

An LPIPS value closer to 0.0 signifies a minimizing perceptual distance, demonstrating authentic texture preservation and fewer perceived visual artifacts.

III. Methods

A. UAV Data Acquisition

The initial environmental asset data was captured via an unmanned aerial vehicle (UAV) survey covering a critical flood-prone stretch of the Atuba River basin, as illustrated in the full orthomosaic and digital elevation layout (Fig. 2). The survey encompassed a total coverage area of 0.408 km^2, capturing 733 high-resolution aerial frames from an average flying altitude of 122 m. Imagery was acquired using an onboard FC3411 camera sensor with a fixed focal length of 8.38 mm and a native resolution of 5472×3648 pixels (2.51×2.51 μm pixel size), yielding an average ground sampling distance (GSD) of 3.06 cm/pix.

Fig. 2. Full geographic view of the 0.408 km^2 Atuba River study region, showing the generated orthomosaic overlay, digital elevation characteristics, and key architectural assets modeled for the digital twin.

B. Photogrammetric Processing

Photogrammetric processing and 3D reconstructions of the dataset were performed on RealityScan desktop version environment. A laptop was used to handle the computational demand of the dense point cloud and mesh generation. The system is equipped with an Intel Core i9-14400HX processor, 32 GB of DDR5 RAM (5600 MHz) and an NVIDIA GeForce RTX 4060 GPU.

Prior to dense matching, an image downscale factor of 2 was applied to optimize processing efficiency. Out of the 733 captured frames, 719 images were successfully registered during the alignment stage, yielding a total of 3.5M projections and an average track length of 3.0. This optimization process generated a sparse point cloud containing 1.1M points. The spatial alignment accuracy was validated by a mean reprojection error of 0.85 pixels (with a median of 0.79 pixels and a maximum error threshold of 2.00 pixels). The reconstructed environment was successfully geo-referenced, establishing its absolute spatial positioning despite operating without explicit metric scaling at this preliminary stage.

To balance structural fidelity with the strict real-time rendering constraints required for hydrodynamic simulations in Unreal Engine 5, a multi-stage mesh optimization, decimation, and texturing strategy was implemented. The initial dense reconstruction produced a raw high-polygon model (*HighPoly*) comprising 97M triangles and 48M vertices. To eliminate non-manifold geometries and topological noise, filtering and smoothing algorithms were applied, refining the mesh structure (*HighPoly Smoothed*) to 97M triangles and 48M vertices.

The model was then subjected to a severe decimation process to generate an optimized low-poly variant (*LowPoly*) consisting of 5M triangles and 2.5M vertices, which was partitioned into 21 discrete mesh parts to facilitate efficient spatial streaming and occlusion culling within the virtual environment. To compensate for the loss of geometric detail resulting from the decimation, high-frequency surface details and color data from the *HighPoly Smoothed* topology were baked onto the *LowPoly* mesh via a reprojected texturing workflow. A single 8192×8192 pixel texture atlas was generated using a maximal texture count unwrapping style, achieving a texture utilization rate of 87%. The visual fidelity was preserved by computing a 32-bit BGRA diffuse color layer and a 128-bit floating-point RGBA normal map layer, both reprojected directly from the smoothed high-resolution geometry.

The time for the complete reconstruction pipeline totaled 31 minutes and 29 seconds. This processing duration was distributed across the following pipeline stages: 2 minutes and 29 seconds for feature detection, 4 minutes and 39 seconds for image registration, 9 minutes and 25 seconds for depth-map computation, 12 minutes and 39 seconds for dense meshing, 1 minute and 08 seconds for topological post-processing, and approximately 1 minutes and 09 seconds for mesh unwrapping and layer reprojection.

C. Reconstruction metrics

To evaluate reconstruction fidelity, each rendered frame from the digital twin was paired with its corresponding reference aerial photograph by matching file name between a held-out reference set and its rendered counterpart; files without a match in the other set were excluded from the comparison. Prior to metric computation, both images in a pair were resized (Lanczos resampling) to the smaller of their two native resolutions and converted to RGB. The rendered image was then photometrically aligned to the reference through an independent per-channel linear regression (least-squares fit of pixel intensity, applied only to the rendered image, reference left unaltered), correcting for systematic tonal, white-balance, and radiometric differences between the physical UAV sensor and the RealityScan render pipeline. This calibration step isolates the structural component of the comparison from purely photometric mismatch and follows standard practice in real-vs-synthetic view evaluation. SSIM was computed on the full RGB image (multichannel, scikit-image implementation) with a data range of 255; PSNR was computed over the same 8-bit range. LPIPS was computed with an AlexNet backbone on images resized to 512×512 pixels. The exact number of image pairs contributing to the averages in Table I (Section IV-A), and whether a sub-sampling ratio was applied to the matched set, could not be reliably reconstructed from archived data at the time of revision; this is acknowledged as a documentation gap rather than reported as a specific figure.

IV. Results and Discussion

A. Structural Reconstruction Fidelity

The quantitative assessment of the photogrammetric digital twin was completed by evaluating the absolute pixel, structural, and perceptual distance errors across the dataset. The aggregated statistical performance is summarized in Table I, while the localized distribution behavior across the 0.408 km^2 study area is illustrated via density distributions in Fig. 3.

TABLE I
Visual Fidelity Evaluation of the Reconstructed 3D Environment

Metric	Average	Min	Max	Std Dev
SSIM	0.3285	0.0738	0.8002	0.1303
LPIPS	0.3620	0.1911	0.5950	0.0597
PSNR	16.0247	11.0378	20.1108	1.3460

The mean SSIM of 0.3285 and PSNR of 16.02 dB indicate limited pixel-level and structural agreement between the rendered and reference imagery, and should not be interpreted as evidence of high pixel-level reconstruction fidelity. As shown by the wide probability density distributions in Fig. 3, the largest deviations concentrate in regions with dynamic or ambiguous surface properties: open river water, where specular reflectance and temporal change between capture and render are pronounced; dense tree canopies, whose fine, repetitive geometry is poorly resolved by multi-view stereo and further degraded by mesh decimation; asphalt roadways,

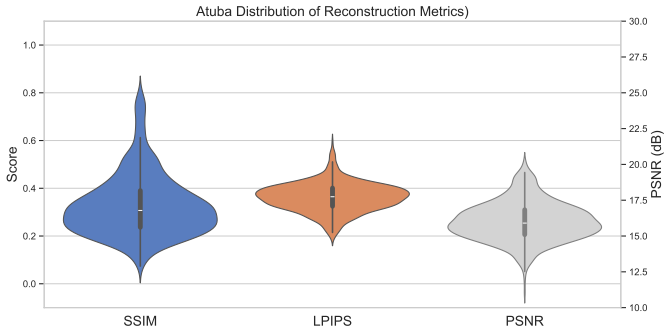

Fig. 3. Probability density and distribution profiles (Violin Plot) of the SSIM, LPIPS, and PSNR (dB) metrics computed over the reconstructed Atuba river basin terrain sample frames.

which combine low native texture with variable glare; and areas affected by residual viewpoint mismatch between the UAV capture pose and the virtual render camera. In contrast, the comparatively tighter LPIPS distribution (mean 0.3620, std 0.0597) indicates that macro-scale perceptual structure and topographic boundaries are better preserved than pixel-level detail. This should be read as evidence that coarse geometric layout survives decimation and not as an indication of overall high-fidelity reconstruction, which the SSIM and PSNR results do not support.

B. Unreal Engine 5 Flooding Progress Simulation

The operational deployment of the digital twin was demonstrated by implementing the decimated low-poly mesh as a static physics collider topology within Unreal Engine 5. The physical accuracy of the terrain geometry directly governs water body volume distribution algorithms during runtime.

The quantitative impacts of the multi-stage water body progression across the four simulated environments—*Dry*, *Strong Rain*, *River Flood*, and *Heavy Flood*—are structuralized in Table II. The sequential visual state changes are mapped from a regional perspective, Fig. 5, and a semantic path safety layout, Fig. 6. During both the baseline *Dry* and *Strong Rain* phases, the fluid vector remains entirely restricted within the natural riverbanks (35.28% and 35.72% area occlusion, respectively), resulting in zero architectural inundation.

Topological failure occurs during the transition to the *River Flood* stage. The over-bank water body propagation drives the total affected surface area to 53.37%, directly submersing 22 out of the 40 tracked structural assets and generating a 25% structural obstruction across the primary transportation highway. Under the maximum parameterization of the *Heavy Flood* scenario, the sub-basin reaches structural saturation, culminating in 77.58% total area submergence, severe structural flooding of 95% of the architectural zone ($38/40$ buildings), and a 35% logistic roadblock along the main highway infrastructure.

C. Decision Framework

To operationalize these simulations for field disaster management and medical emergency logistics, the data routing

TABLE II
FLOOD ASSESSMENT ACROSS UNREAL ENGINE SIMULATION (TOTAL IMAGE AREA: 1.96M PIXELS)

Flood Scenario	Affected Area (%)	Non-Affected Area (%)	Affected Buildings (Qty/40)	Highway Disruption (%)
Dry (River Only)	35.28	64.72	0	0
Strong Rain	35.72	64.28	0	0
River Flood	53.37	46.63	22	25
Heavy Flood	77.58	22.42	38	35

follows a tiered complexity escalation logic, as formalized in the Decision Framework Flowchart (Fig. 4). The core objective of this layered architecture is to systematically resolve tactical logistics problems using the lowest necessary level of computational requirements, preventing unnecessary operational latency during a crisis.

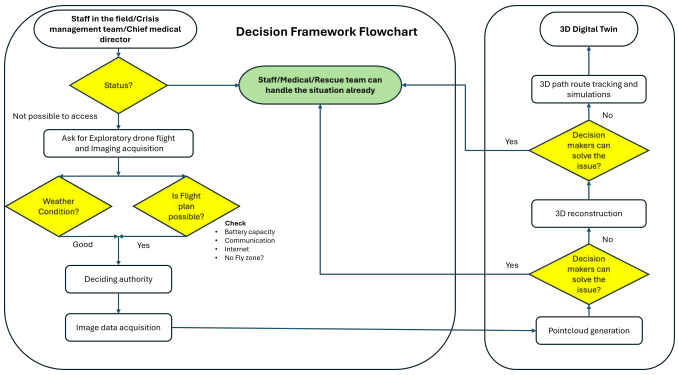

Fig. 4. Proposed Decision Framework Flowchart illustrating the complete data routing from image capture to real-time interactive risk visualization and simulation adjustment loop.

The first operational tier relies solely on the static 3D reconstruction and high-resolution elevation modeling. If local civil defense teams and/or medical directors face low-intensity or static threats, situational awareness can be achieved entirely through geographic inspection of the static asset layout. At this baseline stage, preliminary deployment zones, field hospitals, and resource positioning can be validated without triggering active runtime simulations.

When static terrain information is insufficient to predict structural risk, the framework escalates to the second operational tier: the Unreal Engine 5 water body flooding simulation. By mapping water body vectors over the static colliders, the framework quantifies upcoming infrastructure vulnerabilities before physical immersion occurs, pinpointing specific logistical threats such as the 35% highway disruption and the 38 affected buildings shown in Table II.

To make explicit which capabilities were implemented and evaluated versus conceptually proposed, Table III summarizes each simulation feature against its input data and output.

The third operational tier executes dynamic path tracking and safe corridor mapping, as visualized by the non-affected

Fig. 5. Flood progression simulation map through four different scenarios: Dry, Strong Rain, River Flood, Heavy Flood

overland vectors (green zones) in Fig. 6. By computing mathematical isolation boundaries over the active water body limits, the framework extracts safe supply routes and emergency evacuation corridors. This integrated approach solves critical logistical bottlenecks directly from the digital twin, toward the goal of translating rapid-acquisition UAV surveys into actionable routing directives for emergency vehicles, pending implementation and field validation of the automated routing component (Table III).

V. CONCLUSION

This paper presented a photogrammetric and simulation framework to translate rapid-acquisition UAV datasets directly into interactive digital twins within Unreal Engine 5. By processing a 733-frame aerial survey over a 0.408 km^2 flood-prone corridor of the Atuba River, 719 images were successfully aligned within a total pipeline computational footprint of 31 minutes and 29 seconds. The results demonstrate that lightweight aerial workflows can efficiently initialize a real-time-capable 3D digital twin environment. This work is best characterized as a rapid digital-twin initialization case study; whether it translates into operational disaster-response performance has not yet been tested and requires validation with end users or live emergency data.

Quantitative validation of the environment revealed a mean SSIM of 0.3285, a PSNR of 16.0247 dB, and a tightly bounded perceptual distance (LPIPS $= 0.3620$). While classical pixel-level indices exhibit degradation over uniform textures like canopies and minor buildings, a multi-stage mesh optimization and decimation strategy to a 5-million triangle topology appear to preserve macro-geometric boundary definitions better than pixel-level detail, based on the LPIPS results. Implemented as static physical colliders, the mesh accurately handled real-time water body vectors to simulate a four-stage flood progression. As demonstrated along the simulations, $38/40$ buildings were affected due to heavy flood, with obstruction of 35% of the highway.

Finally, this architecture establishes the potential of 3D digital twins to expand situational monitoring and decision support in complex disaster scenarios and public health emergencies. Future work will focus on integrating autonomous path-tracking algorithms and active rescue routing protocols directly into the virtual environment to support emergency field operations. Moreover, the proof-of-concept decision framework can be used as a tactical feasibility from each stage of the digital twin reconstruction. This study also has two acknowledged limitations: the exact number and sampling ratio of image pairs contributing to the SSIM/PSNR/LPIPS averages could not be fully reconstructed from archived processing data, and the proposed decision-support and autonomous-routing components (Table III) remain conceptual and untested with real users or live emergency data.

ACKNOWLEDGMENT

The authors would like to express their gratitude to the Improvement of Higher Education Personnel (CAPES) and the German Academic Exchange Service (DAAD), under the CAPES/DAAD - PROBRAL program (Grant No. 88881.986264/2024-01) for the financial support provided through the Probral program. Special thanks are extended to the RWTH Uniklinik and the Pontifical Catholic University of Paraná (PUCPR) for institutional support for providing the high-resolution datasets of the study area, which were fundamental to the development and validation of the 3D Digital Twin.

I. INTRODUCTION

The rapid advancement of Artificial Intelligence (AI) and, more specifically, Machine Learning (ML) has enabled the development of intelligent systems capable of supporting decision-making processes in a wide variety of domains, including healthcare, industry, finance, agriculture, and education [1], [2].Instead of being explicitly programmed to solve every possible situation, machine learning algorithms learn patterns directly from historical data, allowing them to make predictions or classifications when new data are presented.

The quality of these predictions depends not only on the amount of available data but also on how effectively the learning algorithm extracts useful information from them. Consequently, developing accurate and reliable machine learning models requires more than simply selecting a classification algorithm. Data quality, appropriate preprocessing, class balancing strategies, and the configuration of the learning algorithm all play fundamental roles in determining the final predictive performance of the model [3], [4].

One of the most important aspects of this process is the definition of hyperparameters. Hyperparameters are configuration values specified before the training process begins and determine how a machine learning algorithm learns from the available data. Unlike model parameters, which are automatically learned during training, hyperparameters must be selected beforehand by the user or by an optimization algorithm. Examples include the maximum depth of a Decision Tree, the number of neighbors considered by the K-Nearest Neighbors (KNN) algorithm, the learning rate of boosting algorithms, and the number of neurons in an Artificial Neural Network. Selecting inappropriate hyperparameter values may produce models that are unable to capture important data patterns (underfitting) or models that become excessively specialized to the training data, reducing their ability to generalize to unseen examples (overfitting) [3].

As machine learning algorithms become increasingly sophisticated, the number of possible hyperparameter combinations grows rapidly. This set of possible combinations is commonly referred to as the search space. Exploring every possible configuration through exhaustive search is often computationally expensive or even infeasible, especially for complex models containing numerous hyperparameters. For this reason, automatic optimization methods have become an essential component of modern machine learning workflows [4].

Among the available optimization approaches, bio-inspired metaheuristics have attracted considerable attention. Metaheuristics are optimization techniques designed to efficiently search for high-quality solutions without evaluating every possible alternative. Inspired by natural phenomena such as biological evolution and collective animal behavior, these methods balance the exploration of new regions of the search space with the exploitation of promising solutions that have already been discovered [4].

Two of the most widely adopted bio-inspired optimization methods are the Genetic Algorithm (GA) and Particle Swarm Optimization (PSO) [5], [6]. The Genetic Algorithm simulates the principles of natural evolution, where candidate solutions evolve through selection, crossover, and mutation operations. In contrast, Particle Swarm Optimization models the collective behavior of groups such as bird flocks or fish schools, where each candidate solution continuously adjusts its position according to both its own previous experience and the best solution found by the swarm. Although based on different optimization strategies, both methods have demonstrated excellent performance in solving complex optimization problems, including machine learning hyperparameter tuning.

The use of optimization algorithms enables the automatic discovery of hyperparameter configurations capable of im-

proving model performance while significantly reducing the manual effort traditionally required during experimentation. Consequently, evolutionary optimization techniques have become an important component of Automated Machine Learning (AutoML), a research area dedicated to automating tasks such as algorithm selection, hyperparameter optimization, and model evaluation.

Despite the remarkable advances achieved by existing AutoML platforms, many available solutions still present limitations regarding flexibility, transparency of the optimization process, or ease of use for users with limited programming experience. In many cases, understanding or modifying the optimization strategy employed by these platforms is difficult, which restricts their applicability in educational and experimental environments.

To address these limitations, this work presents Genetic App, a desktop application designed to automate machine learning experiments by integrating classification algorithms, class balancing techniques, and evolutionary optimization methods for hyperparameter tuning. The application provides an intuitive graphical user interface that allows users to configure and execute experiments without requiring advanced programming knowledge while maintaining flexibility for experimentation.

The application currently supports the following classification algorithms: K-Nearest Neighbors (KNN), Decision Tree, Random Forest, Logistic Regression, Multi-Layer Perceptron (MLP), XGBoost, LightGBM, and CatBoost. Hyperparameter optimization can be performed using either the Genetic Algorithm or Particle Swarm Optimization, allowing users to compare the behavior of both optimization techniques under different experimental scenarios. In addition, the platform incorporates class balancing through UnderSampling and SMOTE, improving the handling of imbalanced datasets.

The main contributions of this work are summarized as follows:

- Development of a graphical desktop application for automatic hyperparameter optimization.
- Integration of multiple classification algorithms, data balancing strategies, and evolutionary optimization methods into a unified platform.
- Support for both Genetic Algorithm and Particle Swarm Optimization for automated hyperparameter tuning.
- Automatic generation of evaluation metrics and feature importance analysis to improve model interpretability.
- A modular and extensible software architecture that facilitates the incorporation of additional machine learning algorithms and optimization techniques. The remainder of this paper is organized as follows. Section II presents the theoretical background required to understand the proposed approach. Section III reviews the most relevant related work. Section IV describes the proposed model and system architecture. Section V details the implementation of the Genetic App. Section VI discusses the experimental results obtained during validation, and Section VII concludes the paper while presenting directions for future research.

II. THEORETICAL BACKGROUND

A. Hyperparameter optimization

The development of an accurate and reliable machine learning model depends not only on the amount and quality of the available data but also on the configuration adopted during the learning process. Before a model can learn from the training data, several configuration values must be specified. These values are known as hyperparameters and determine how the learning algorithm will operate during training [3]. It is important to distinguish hyperparameters from model parameters. Model parameters are automatically learned from the training data during the learning process. For example, in a Logistic Regression model, the coefficients associated with each feature are learned during training. Hyperparameters, on the other hand, are defined before training begins and control the behavior of the learning algorithm itself. Examples include the maximum depth of a Decision Tree, the number of trees in a Random Forest, the number of neighbors considered by the K-Nearest Neighbors (KNN) algorithm, and the learning rate employed by gradient boosting methods. To address this challenge, hyperparameter optimization techniques automatically search the space of possible configurations to identify those that maximize model performance according to a predefined objective function. The objective function, often called the fitness function in evolutionary optimization, measures the quality of each candidate solution using one or more evaluation metrics. By automating this search process, optimization algorithms reduce human effort while increasing the likelihood of obtaining highly accurate predictive models[4].

B. Genetic Algorithms

Genetic Algorithms (GA), originally proposed by Holland [5], are among the most established optimization techniques in the field of Evolutionary Computation. Their operation is inspired by the principles of natural selection and biological evolution, where populations evolve over successive generations and individuals with desirable characteristics are more likely to survive and reproduce. In the context of hyperparameter optimization, each candidate solution corresponds to a specific combination of hyperparameter values and is represented by a chromosome. Each hyperparameter is encoded as a gene, meaning that a chromosome completely describes one possible configuration of the machine learning model. By repeatedly applying selection, crossover, mutation, and fitness evaluation over multiple generations, the population gradually evolves toward increasingly effective hyperparameter configurations. The combination of exploration through mutation and exploitation through the preservation of high-quality individuals makes Genetic Algorithms particularly suitable for complex optimization problems characterized by large and irregular search spaces [5].

C. Particule Swarm Optimization

Particle Swarm Optimization (PSO), introduced by Kennedy and Eberhart [6], is another widely adopted bio-inspired optimization technique. Unlike Genetic Algorithms, which

simulate biological evolution, PSO is inspired by the collective behavior observed in groups of animals such as bird flocks and fish schools. In PSO, each candidate solution is represented by a particle positioned within the search space. The position of a particle corresponds to one possible hyperparameter configuration, while its movement through the search space represents the continuous search for improved solutions. Compared with Genetic Algorithms, PSO does not require crossover or mutation operators. Instead, optimization emerges naturally from the continuous movement of particles toward increasingly promising regions of the search space. Because of its conceptual simplicity, relatively small number of control parameters, and computational efficiency, PSO has become one of the most frequently employed optimization techniques for machine learning hyperparameter tuning [6].

D. Class Balancing

In many real-world applications, datasets exhibit imbalanced class distributions. Under such conditions, classification algorithms tend to favor the majority class, resulting in degraded predictive performance for the minority class.

Two of the most commonly used techniques to mitigate this problem are UnderSampling and SMOTE (Synthetic Minority Over-sampling Technique) [7].

UnderSampling reduces the number of instances belonging to the majority class. In contrast, SMOTE artificially generates new minority-class examples by interpolating between existing instances, thereby promoting a more balanced data distribution.

E. Model Evaluation and interpretability

Proper model evaluation is essential for assessing a model's generalization capability. In this work, the evaluation metrics Accuracy, Precision, and Recall are employed, as they are widely used in supervised classification problems [11].

Beyond quantitative evaluation, model interpretability has become an increasingly important aspect of modern machine learning applications. Feature importance analysis techniques make it possible to identify which variables have the greatest influence on the predictions generated by machine learning models [12].

Whenever available, native feature importance measures provided by the classification algorithms are used. Otherwise, the Permutation Importance technique is employed, allowing a consistent and model-independent evaluation of feature contributions to predictive performance [8], [12].

III. Related Work

Hyperparameter optimization has become one of the most active research topics in machine learning because of its significant influence on predictive model performance. Since the effectiveness of a machine learning algorithm depends heavily on the selected hyperparameter configuration, numerous optimization techniques have been proposed to automate this process and reduce the need for manual experimentation [3], [4].

Traditional optimization strategies such as Grid Search and Random Search have been widely employed due to their simplicity of implementation. Grid Search systematically evaluates all possible combinations within predefined ranges, whereas Random Search randomly samples candidate configurations from the search space.Although both approaches are straightforward, they become computationally expensive as the number of hyperparameters increases, a phenomenon commonly referred to as the curse of dimensionality. Consequently, these methods often become impractical for complex machine learning models containing numerous hyperparameters or large search spaces [4].

To overcome these limitations, researchers have increasingly adopted metaheuristic optimization algorithms, which aim to identify high-quality solutions without exhaustively evaluating every possible configuration. Among the various metaheuristics proposed in the literature, Genetic Algorithms (GA) and Particle Swarm Optimization (PSO) have consistently demonstrated competitive performance across a wide variety of optimization problems [4].

Genetic Algorithms have been extensively investigated for hyperparameter optimization because of their ability to explore large and irregular search spaces through evolutionary operators such as selection, crossover, and mutation. By continuously evolving a population of candidate solutions, GA can effectively identify high-quality hyperparameter configurations even for highly nonlinear optimization problems [5].

Similarly, Particle Swarm Optimization has become one of the most widely adopted optimization techniques in machine learning. Instead of relying on evolutionary operators, PSO performs optimization through the cooperative movement of particles that exchange information while searching the solution space. Owing to its relatively simple implementation, reduced number of control parameters, and fast convergence characteristics, PSO has demonstrated excellent performance in numerous hyperparameter optimization applications [6].

Comparative studies indicate that both GA and PSO are capable of significantly improving the predictive performance of machine learning models when compared with manually selected hyperparameters or exhaustive search techniques. While Genetic Algorithms generally provide greater search diversity through crossover and mutation operations, Particle Swarm Optimization frequently converges more rapidly toward high-quality solutions by exploiting the collective experience accumulated by the swarm [4], [6]. Because each method exhibits distinct optimization characteristics, both remain widely employed in contemporary machine learning research.

In parallel with advances in optimization algorithms, the field of Automated Machine Learning (AutoML) has emerged to simplify the development of predictive models. AutoML aims to automate tasks such as data preprocessing, algorithm selection, hyperparameter optimization, and model evaluation,

enabling users to build high-quality machine learning models with reduced manual intervention.

Among the best-known AutoML platforms are Auto-WEKA [9] and Auto-Sklearn [10]. Auto-WEKA extends the WEKA machine learning framework by automatically selecting classification algorithms and optimizing their hyperparameters. Auto-Sklearn, built upon the Scikit-learn ecosystem, combines Bayesian optimization, meta-learning, and ensemble techniques to automatically identify effective machine learning pipelines. Both platforms have demonstrated strong predictive performance across numerous benchmark datasets and have become important references in the AutoML literature.

Despite their effectiveness, these platforms present certain limitations from the perspective of experimentation and educational use. The optimization process is often highly automated, providing users with limited visibility into the internal behavior of the optimization algorithms. Furthermore, extending these platforms with alternative optimization strategies or integrating custom experimental workflows may require considerable programming expertise.

Another research topic closely associated with predictive model performance concerns class imbalance. Numerous studies have demonstrated that highly imbalanced datasets may considerably degrade classifier performance, particularly for minority classes that often correspond to the events of greatest practical interest. To mitigate this problem, balancing techniques such as UnderSampling and the Synthetic Minority Over-sampling Technique (SMOTE) have been extensively investigated and successfully applied in various application domains [7].

More recently, model interpretability has also become an important research direction within machine learning. As predictive models become increasingly complex, understanding how they reach their decisions has become essential in domains such as healthcare, finance, and industrial applications. Feature importance analysis and model-agnostic interpretation techniques have therefore gained considerable attention, providing valuable insights into the contribution of individual features to the prediction process [8], [12].

Unlike many existing solutions, Genetic App integrates multiple stages of the machine learning workflow into a single desktop application. The platform combines an intuitive graphical user interface with several classification algorithms, data balancing techniques, Genetic Algorithm and Particle Swarm Optimization for hyperparameter tuning, automatic performance evaluation, and feature importance analysis. Rather than focusing exclusively on optimization or algorithm selection, the proposed application provides a unified and extensible environment that facilitates experimentation, comparative analysis, and educational activities while requiring minimal programming knowledge from the user.

IV. PROPOSED MODEL

Genetic App was developed to automate the cycle of building, optimizing, and evaluating machine learning models using tabular data from different application domains, including medical spreadsheets and structured clinical datasets.

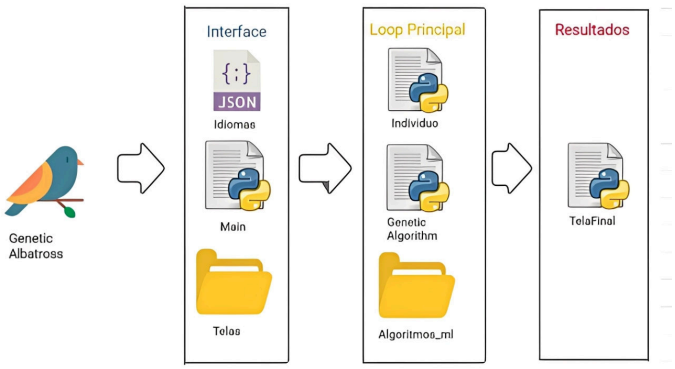

Figure 1. General Architecture of Genetic App

The execution workflow begins with dataset importation and proceeds through data preprocessing, classifier configuration, selection of the data balancing strategy, and definition of the optimization algorithm.

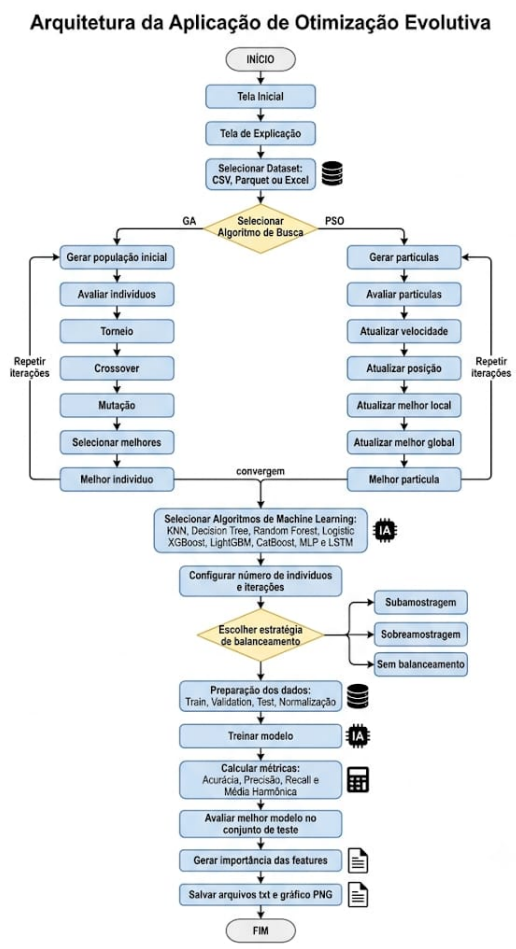

Figure 2. fluxogram of app

The system architecture is composed of five main modules:
- Graphical User Interface (GUI);
- Data Preprocessing;
- Classification Algorithms;
- Optimization Algorithms;
- Evaluation and Report Generation.

A. Graphical User Interface

The Graphical User Interface (GUI) provides the primary interaction between the user and the application. It was designed to simplify the configuration of machine learning experiments by offering an intuitive interface that eliminates the need for programming knowledge. Through the interface, users can import datasets, select the target variable, choose one of the available classification algorithms, configure the optimization method, define optimization parameters, enable optional data balancing techniques, and execute the complete experiment. During execution, the interface also provides feedback regarding the current processing stage, allowing users to monitor the progress of the optimization procedure. Because all experimental parameters are configured through graphical components, the application can be used not only by machine learning researchers but also by students and professionals with limited programming experience.

B. Data Preprocessing Module

Before model training begins, the imported dataset is processed by the preprocessing module. This stage prepares the data to ensure compatibility with the selected classification algorithm and improve the quality of the learning process. Initially, the dataset is divided into input features and the target variable. Subsequently, numerical features may be normalized or transformed when required by the selected classifier. Since several machine learning algorithms are sensitive to differences in feature scales, appropriate preprocessing contributes to more stable optimization and improved predictive performance. If requested by the user, the preprocessing module also applies one of the available class balancing techniques. UnderSampling reduces the number of majority-class samples, whereas SMOTE generates synthetic instances of the minority class to obtain a more balanced training dataset.

C. Classification Module

The classification module is responsible for training and evaluating predictive models using the hyperparameter configurations generated during the optimization process. The current version of the Genetic App supports eight supervised classification algorithms: - K-Nearest Neighbors (KNN); - Decision Tree; - Random Forest; - Logistic Regression; - Multi-Layer Perceptron (MLP); - XGBoost; - LightGBM; - CatBoost. Each classifier possesses its own set of hyperparameters and learning characteristics. Consequently, the optimization algorithms explore different search spaces depending on the selected classifier. This modular design facilitates the incorporation of additional machine learning algorithms in future versions of the application without requiring significant modifications to the remaining system components.

D. Optimization Module

The optimization module constitutes the core of the proposed application. Its primary responsibility is to automatically identify hyperparameter configurations capable of maximizing the predictive performance of the selected classification algorithm. The module supports both Genetic Algorithm (GA) and Particle Swarm Optimization (PSO), allowing users to compare the behavior of these two evolutionary optimization techniques under identical experimental conditions. When the Genetic Algorithm is selected, an initial population of candidate solutions is generated. Each individual represents a complete hyperparameter configuration. After evaluating the predictive performance of each individual, the population evolves through successive generations using selection, crossover, and mutation operators until a termination criterion is satisfied. Alternatively, when Particle Swarm Optimization is selected, each candidate solution is represented by a particle moving through the hyperparameter search space. During each iteration, particles update their positions by considering both their own best solution (pBest) and the best solution discovered by the swarm (gBest). This cooperative search mechanism enables the swarm to progressively converge toward high-quality

hyperparameter configurations. Regardless of the selected optimization technique, every candidate solution is evaluated by training the corresponding machine learning model and computing its fitness value.

E. Evaluation and Report Generation

After the optimization process is completed, the application automatically generates a comprehensive report describing the experiment. The report includes the optimized hyperparameter configuration, evaluation metrics, execution time, and feature importance analysis. Whenever the selected classifier provides native feature importance scores, these values are presented directly. Otherwise, Permutation Importance is employed to estimate the contribution of each feature. The fitness function adopted during optimization simultaneously considers Accuracy, Precision, and Recall, encouraging the selection of hyperparameter configurations that achieve balanced predictive performance rather than optimizing only a single evaluation metric.

V. Implementation

The Genetic App was implemented in Python due to its widespread adoption within the Data Science community and the extensive ecosystem of specialized libraries available for machine learning applications.

The system architecture was designed in a modular manner, ensuring a clear separation between the graphical user interface, data processing, classification algorithms, and optimization mechanisms.

The graphical user interface was developed using the Tkinter library, providing an intuitive environment for configuring and executing machine learning experiments. Through the interface, users can import datasets, select classification algorithms, configure optimization methods, and choose data balancing strategies.

Machine learning functionalities were implemented using the Scikit-learn library, which provides support for data preprocessing, model training, and the computation of evaluation metrics.

In addition, specialized libraries for gradient boosting algorithms, including XGBoost, LightGBM, and CatBoost, were integrated into the application, expanding the diversity of classification models available for analysis.

The optimization module was designed to support both Genetic Algorithm and Particle Swarm Optimization, allowing the automatic exploration of different hyperparameter configurations.

At the end of each experiment, the application automatically generates reports containing the selected hyperparameters, evaluation metrics, execution time, and feature importance analysis.

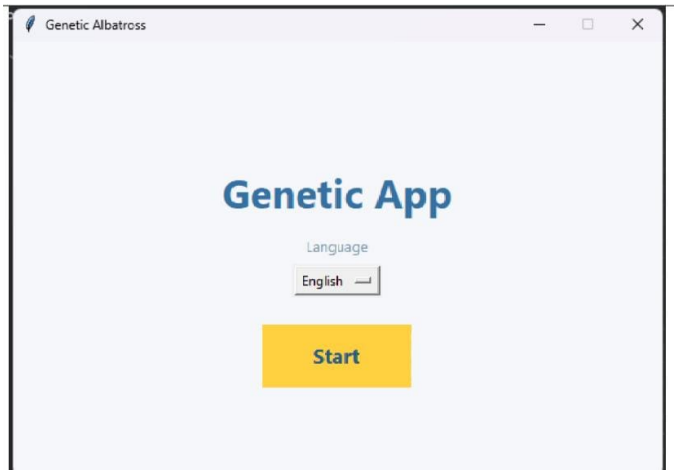

Figure 3. Main Interface of Genetic App

VI. Result and Analysis

The proposed application was experimentally evaluated to investigate its ability to automate the hyperparameter optimization process while improving the predictive performance of machine learning models. The experiments considered different classification algorithms, evolutionary optimization techniques, and class balancing strategies, allowing a comprehensive analysis of the proposed framework. Each experiment followed the workflow implemented in the Genetic App. Initially, the selected dataset was preprocessed and, when required, balanced using either UnderSampling or SMOTE. Subsequently, the chosen classification algorithm was optimized through either the Genetic Algorithm (GA) or Particle Swarm Optimization (PSO). During the optimization process, each candidate solution was evaluated according to the fitness function, which measured the predictive performance obtained after model training. Once the optimization procedure was completed, the best hyperparameter configuration was selected and used to train the final model. Model performance was assessed using Accuracy, Precision, and Recall, providing complementary information about the quality of the generated classifiers. In addition, whenever supported by the selected algorithm, feature importance analysis was performed to improve model interpretability. For algorithms without native feature importance measures, Permutation Importance was employed. The experimental results demonstrate that automatic hyperparameter optimization consistently identified configurations capable of improving predictive performance compared with default parameter settings. Both optimization algorithms successfully explored the search space and converged toward competitive solutions, confirming their suitability for machine learning hyperparameter optimization. Although both optimization techniques produced satisfactory results, some differences were observed in their search behavior. The Genetic Algorithm generally explored a broader portion of the search space due to the combined effects of crossover and mutation, making it effective for avoiding premature convergence. In contrast, Particle Swarm Optimization often converged more

rapidly by continuously adjusting candidate solutions according to both individual and collective experience. Depending on the characteristics of the evaluated dataset and the selected classifier, either optimization method could achieve the best overall performance. The application also demonstrated the importance of class balancing for imbalanced datasets. When balancing techniques were applied before model training, improvements were observed mainly in Precision and Recall, indicating that the optimized models became more capable of correctly identifying minority-class instances. While UnderSampling reduced the number of majority-class samples and consequently shortened training time, SMOTE preserved the original data while generating synthetic minority samples, frequently leading to superior predictive performance. Feature importance analysis provided additional insight into the prediction process by identifying the variables that contributed most strongly to the classification decisions. This information complements the quantitative evaluation metrics and increases the transparency of the generated models, allowing users to better understand the influence of individual features on the final predictions. Overall, the experimental evaluation demonstrates that the Genetic App successfully integrates machine learning algorithms, class balancing techniques, and evolutionary optimization methods into a unified framework capable of automating hyperparameter optimization. The obtained results indicate that the proposed application provides an efficient and flexible environment for conducting machine learning experiments while reducing the manual effort traditionally associated with hyperparameter selection.

A. Feature Importance Analysis

Feature importance analysis proved to be a valuable resource for interpreting model behavior.

After the optimization process is completed, the application automatically generates rankings of the most influential features for each trained classification model.

Whenever available, the native feature importance measures provided by the classification algorithms are used.

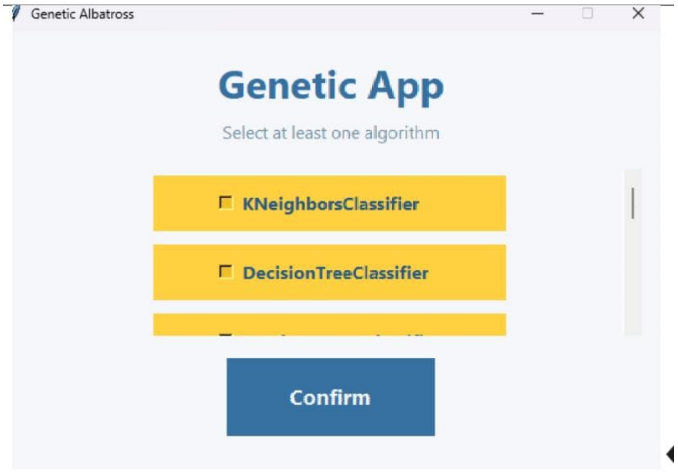

Figure 4. Example of Feature Ranking

The experimental results indicate that the combination of evolutionary optimization, automated preprocessing, data balancing, and feature importance analysis provides an efficient and practical environment for machine learning experimentation.

VII. CONCLUSION

This work presented Genetic App, a desktop application developed to automate hyperparameter optimization for machine learning algorithms.

The platform integrates traditional and state-of-the-art classification algorithms, data balancing techniques, evolutionary optimization methods, and model interpretation mechanisms into a unified environment.

The experimental results demonstrated the feasibility of employing Genetic Algorithm and Particle Swarm Optimization as effective approaches for automatic hyperparameter tuning.

Furthermore, the inclusion of class balancing techniques and feature importance analysis expands the applicability of the platform across different domains and machine learning scenarios.

As future work, new metaheuristic optimization algorithms will be incorporated, the set of supported classification algorithms will be expanded, and advanced AutoML functionalities will be integrated, further increasing the flexibility and analytical capabilities of the platform.

***Abstract*—Electrochemotherapy (ECT) is a technique used for the treatment of tumors that combines the administration of chemotherapeutic agents with the application of high-intensity electric pulses, promoting the electroporation of cell membranes and enhancing the intracellular uptake of drugs. The effectiveness of the treatment depends directly on the distribution of the electric field within the tissue, which is influenced by anatomical geometry, the electrical properties of the tissues, and the positioning of the electrodes. In this study, a simplified computational model of the canine middle phalanx was developed to simulate the electric field distribution during electrochemotherapy procedures. The model was implemented in COMSOL Multiphysics® using the Electric Currents module, with electrical properties assigned to the different tissues based on data reported in the literature. The results made it possible to identify regions subjected to reversible and irreversible electroporation, as well as areas with insufficient electric field coverage, referred to as blind spots. The developed model proved capable of representing the spatial distribution of the electric field and constitutes a promising tool for studies aimed at optimizing electrode positioning and the therapeutic parameters employed in electrochemotherapy.**

***Key words*—electroporation, COMSOL, finite element method, electric field.**

I. Introduction

Electrochemotherapy (ECT) is an oncological treatment technique that combines the use of chemotherapeutic agents with specialized electrodes to deliver high-intensity electric pulses capable of inducing electroporation in cell membranes, thereby temporarily increasing cell membrane permeability and, consequently, enhancing drug uptake [1]. Electroporation is a biophysical phenomenon characterized by the temporary formation of pores in the cell membrane when exposed to electric pulses, facilitating the transport of molecules into the cell [1], [2].

A key factor for the success of electrochemotherapy is the distribution of the electric field within the target region. For the treatment to be effective, the entire tumor volume must be exposed to adequate electric field levels, while the exposure of healthy tissues should be minimized [3]. Therefore, treatment outcomes are influenced by factors such as patient anatomy, the electrical properties of biological tissues, and electrode coupling and positioning [3], [4].

To improve treatment predictability and safety, computational models based on the Finite Element Method (FEM) have been widely used as planning and pre-treatment tools, allowing the safe evaluation of the effects of electric field distribution and electrode positioning in electrochemotherapy procedures [3], [5]. The use of geometries reconstructed from medical images enables the development of models that more accurately represent patient anatomy, allowing different therapeutic configurations to be evaluated before clinical application [5]. Furthermore, computational modeling makes it possible to incorporate tissue-specific dielectric properties, contributing to a realistic representation of the electromagnetic phenomena involved [2].

The use of computational models to study electroporation has been widely explored in the literature as a tool to support the development of electroporation-based techniques and the optimization of devices used in electrochemotherapy. Sel *et al.* [10] introduced a sequential finite element model in which tissue electrical conductivity is iteratively updated according to the local electric field, allowing the estimation of worst-case electric field distributions and equipment current during treatment. Corović *et al.* [6] later developed a finite element model to analyze electric field distribution in biological tissues during electroporation, demonstrating the influence of tissue electrical properties and conductivity changes on the coverage of the treated region. More recently, Lopes *et al.* [4] proposed a computational methodology to optimize the electrical conductivity of conductive gels for electrochemotherapy, demonstrating that case-oriented numerical simulations can improve electric field coverage while reducing unnecessary current increase and minimizing the occurrence of blind spots. Similarly, Andrade *et al.* [3] used computational models to investigate the effects of parallel electrode deflection on electric field distribution and treatment safety, while Guedert *et al.* [2] proposed a dynamic model capable of representing changes in tissue electrical properties during electroporation by considering phenomena such as biological dispersion and Joule heating. In turn, Lopes *et al.* [5] developed a computational model based on medical imaging to evaluate the performance of a novel electrode designed for the treatment of bone cavities, demonstrating the importance of numerical modeling in the development and optimization of electrochemotherapy devices. Despite these advances, studies focused on the development of computational models specifically for canine digits remain scarce,

which motivates the proposal of the present work. Finally, this work aims to develop a parametrized computational model of a canine digit to analyze the electric field distribution during electrochemotherapy procedures. The model is designed to investigate different configurations of commercially available electrode positioning, conductive gel coupling, and anatomical variations, enabling the evaluation of their influence on electric field coverage and treatment outcomes.

II. Materials and Methods

A. Development of the Simplified Geometry

Therefore, a simplified geometry was developed while preserving the main anatomical and dimensional characteristics of the canine digit. The simplified geometry adopted in this study is shown in Figure 1.

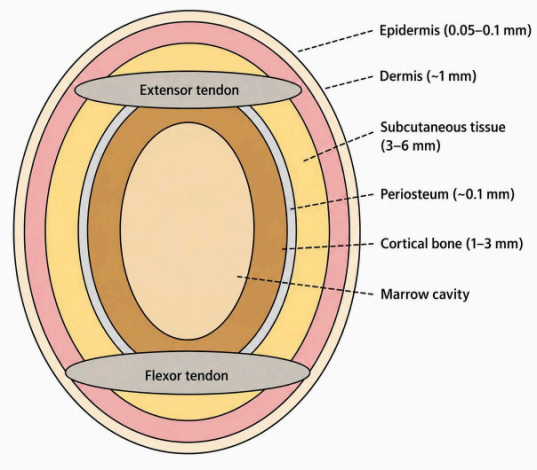

Fig. 1: Schematic cross-sectional view of the canine middle phalanx used to construct the simplified computational geometry.

Figure 1 illustrates the organization of the domains considered in the simplified geometry. The dimensions adopted for each domain were defined based on anatomical references available in the literature and parametrically adjusted to generate a geometry suitable for finite element simulations, as summarized in Table I.

TABLE I: Geometric dimensions adopted for the construction of the computational model.

Structure	Adopted Thickness
Epidermis	0.05–0.10 mm
Dermis	∼1.0 mm
Subcutaneous tissue	3–6 mm
Periosteum	∼0.10 mm
Cortical bone	1–3 mm
Medullary cavity	Variable
Extensor tendon	Dorsal elliptical structure
Flexor tendon	Ventral elliptical structure

Source: Adapted from Evans and De Lahunta (2013) and MSD Veterinary Manual (2024).

B. Computational Model

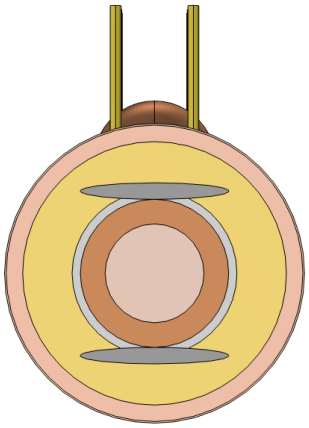
The computational model was developed focusing on the middle phalanx and was constructed using parameterized geometric solids dimensioned according to anatomical references reported in the literature [7], [8]. The final geometry included domains corresponding to the epidermis, dermis, subcutaneous tissue, periosteum, cortical bone, medullary cavity, extensor tendon, and flexor tendon. The geometry construction and numerical simulations were performed using *COMSOL Multiphysics®*.

The *Electric Currents* interface was employed to solve the electric potential distribution within the different tissues. Electrical properties were assigned individually to each domain based on values reported in the literature. Furthermore, the nonlinear dependence of electrical conductivity on the applied electric field was considered according to electroporation models.

The electrical characterization of the different domains was performed by assigning tissue-specific electrical conductivity values and electroporation thresholds reported in the literature [2], [6]. These parameters are essential for describing the nonlinear response of biological tissues subjected to electric pulses and for determining the regions undergoing reversible and irreversible electroporation. The nonlinear dependence of the electrical conductivity on the magnitude of the applied electric field was modeled using a sigmoidal function, allowing the transition from the initial conductivity to the maximum conductivity as the electric field increases. This approach reproduces the gradual increase in tissue conductivity associated with the electroporation process and has been widely adopted in computational models of electroporation [2], [6], [10]. The conductivity function is defined as:

$$\sigma(\|\mathbf{E}\|) = \sigma_{\min} + \frac{\sigma_{\max} - \sigma_{\min}}{1 + \exp\left(-\dfrac{\|\mathbf{E}\| - A}{B}\right)} \tag{1}$$

$$A = \frac{E_{\text{rev}} + E_{\text{irrev}}}{2}, \qquad B = \frac{E_{\text{irrev}} - E_{\text{rev}}}{8}. \tag{2}$$



where $\sigma_{\min}$ and $\sigma_{\max}$ are the initial and maximum electrical conductivities of the tissue, respectively, $\|\mathbf{E}\|$ is the magnitude of the electric field, and E_{irrev} and E_{irrev} correspond to the lower and upper electric field thresholds that define the conductivity transition. The adopted values are presented in Table II.

It should be noted that the adopted static conductivity model is protocol-dependent. Therefore, its parameters may require recalibration when pulse characteristics, such as waveform, duration, number of pulses, or repetition rate, are modified [11]. Consequently, the results presented in this study should be interpreted within the specific pulse protocol considered in the simulations. Figure 2a shows the front view of the developed computational model, including the different tissues considered, the tumor region, and the electrode arrangement adopted in the simulations.

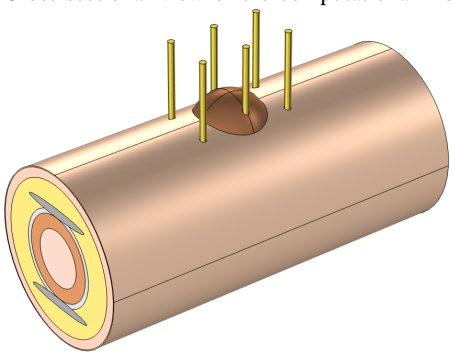


TABLE II: Electrical properties of the tissues used in the *COMSOL Multiphysics*® simulations.

Material	σ_0 **(S/m)**	$\sigma_{\max}$ **(S/m)**
Tumor	0.300	0.750
Epidermis	0.008	0.800
Dermis	0.250	1.000
Subcutaneous tissue	0.020	–
Muscle	0.135	0.340
Cortical bone	0.010	–
Electrodes (copper)	5.998×10^7	–
Material	E_{rev} **(kV/m)**	E_{irrev} **(kV/m)**
Tumor	40	80
Epidermis	40	120
Dermis	30	120
Subcutaneous tissue	20	80
Muscle	20	80
Cortical bone	–	–

(a) Cross-sectional view of the computational model.

(b) Orthogonal view of the computational model.

Fig. 2: Comparison between the Cross-sectional view and the orthogonal view of the computational model.

C. Electrode Configuration and Boundary Conditions

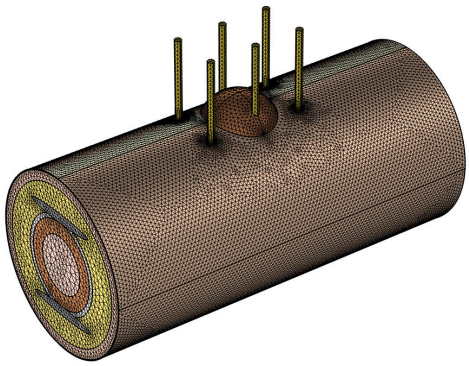
To deliver the electric pulses, six electrodes were positioned around the tumor region, as shown in Figure 2b. The electrodes were modeled as ideal conductors with a diameter of 0.7 mm, an active length of 15 mm, and a spacing of 5 mm between adjacent electrodes, resulting in three electrodes on each side of the tumor region. The three electrodes located on the left side of the model were assigned an electric potential of 600 V, whereas the three electrodes on the right side were defined as the electrical ground (0 V). The external surfaces of the model were assumed to be electrically insulated, imposing a zero normal current density across these boundaries.

D. Mesh Generation

After defining the geometry, the electrical properties of the tissues, and the boundary conditions, the computational domain was discretized by generating a three-dimensional mesh composed predominantly of tetrahedral elements, as shown in Figure 3. The mesh was automatically generated using *COMSOL Multiphysics*® and subsequently refined to ensure an adequate representation of the interfaces between the different anatomical domains.

The computational domain was discretized using an unstructured Fine tetrahedral mesh generated automatically in COMSOL Multiphysics®. The final mesh consisted of 1,485,722 tetrahedral elements and 258,965 mesh vertices, providing adequate spatial resolution for the numerical simulations.

The resulting discretization enabled the representation of the different anatomical structures of the model, providing support for the numerical solution of the electric field distribution within the analyzed tissues. Based on the developed computational model, simulations were performed to evaluate the electric field distribution and the regions subjected to electroporation under the different scenarios considered.



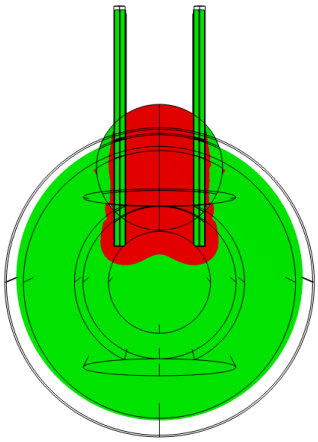


Fig. 3: Orthogonal view of the computational mesh.

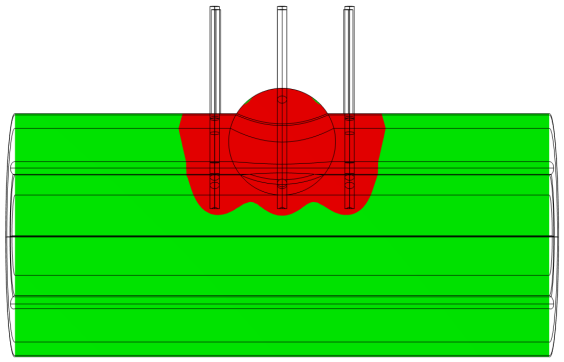
III. Results and Discussion



The developed computational model enabled the evaluation of the spatial distribution of the electric field within the canine digit during electrochemotherapy. Based on the adopted tissue-specific electroporation thresholds, the simulations allowed the identification of regions expected to undergo electroporation,

as well as regions where the electric field remained below the required threshold.

Figure 4 illustrates the simulated treatment coverage from frontal and lateral perspectives. In both views, the red regions correspond to locations where the electric field exceeded the adopted threshold for electroporation (approximately 60 kV/m), whereas the green regions indicate areas where the electric field remained below this threshold.

(a) Frontal view of the regions affected (red) and unaffected (green) by the applied electric field.

(b) Lateral view of the affected and unaffected regions.

Fig. 4: Spatial distribution of the regions affected by the applied electric field.

As observed in Figure 4a, the highest electric field intensities were concentrated around the electrodes, resulting in effective coverage of a substantial portion of the tumor volume. However, peripheral portions of the tumor remained outside the affected region, indicating incomplete treatment coverage. These areas represent potential *blind spots*, where the electric field intensity may be insufficient to induce the desired cell membrane permeabilization.

The lateral view shown in Figure 4b complements the frontal analysis by revealing the longitudinal extension of the affected volume along the digit. This perspective highlights the relationship between electrode positioning and the spatial distribution of the electric field within the tumor.

Furthermore, the proximity of the electrodes to the cortical bone influences the propagation of the electric field due to the marked differences in tissue electrical conductivity. This heterogeneity contributes to a non-uniform electric field distribution and reinforces the importance of considering tissue composition during treatment planning.

Overall, the adopted electrode configuration was capable of inducing electroporation over a substantial portion of the tumor volume while preserving most of the surrounding healthy tissues. Nevertheless, the persistence of peripheral *blind spots* indicates that alternative electrode arrangements, different pulse protocols, or complementary strategies, such as conductive gel coupling, may further improve treatment coverage. These findings demonstrate the usefulness of the proposed computational model as a tool for evaluating electrode configurations and supporting electrochemotherapy treatment planning.

IV. Conclusion

This work presented a simplified finite element model of a canine digit for analyzing electric field distribution during electrochemotherapy. The model reproduced the main tissues of the region of interest and enabled the spatial assessment of tumor coverage from complementary frontal and lateral perspectives. The evaluated electrode configuration produced electric field levels compatible with electroporation over a substantial portion of the tumor volume; however, peripheral regions remained below the adopted threshold, indicating incomplete treatment coverage and the occurrence of potential *blind spots*. These results highlight the influence of electrode positioning and tissue electrical heterogeneity, particularly the presence of bone structures, on the resulting electric field distribution. Despite the geometric simplifications adopted, the proposed model provides a useful framework for evaluating electrode configurations and treatment parameters. Future studies should investigate patient-specific anatomies, alternative electrode arrangements, conductive gel coupling, protocol-dependent conductivity models, and experimental validation of the numerical results.

***Resumo*—A ativação dos canais HCN é regulada pelo potencial de membrana e por nucleotídeos cíclicos, como o cAMP. Estes canais são expressos ao longo dos axônios de interneurônios GABAérgicos corticais sensíveis a parvalbumina e sua atividade é descrita como um mecanismo essencial na geração de padrões de disparos característicos desse grupo celular. Experimentalmente foi observado que a alteração na atividade dos HCNs pode modificar a dinâmica das sinapses GABAérgicas. No presente trabalho, reproduzimos e investigamos achados experimentais por meio de modelagem matemática e simulações computacionais. Nossas análises indicam que o bloqueio dos canais HCN pode alterar as permeabilidades de Ca^{2+} no terminal pré-sináptico, e em consequência, o comportamento de correntes pós-sinápticas inibitórias no hipocampo de rato.**

Palavras-chave—interneurônio, sinapses, HCN, hipocampo, CA1, modelagem computacional

I. Introdução

Interneurônios GABAérgicos que expressam parvalbumina (PV+) desempenham um papel fundamental na regulação da excitabilidade neuronal na formação hipocampal, contribuindo para a prevenção da hipersincronização neuronal [1], [2], [3]. Esses interneurônios podem disparar em alta frequência, gerar e sustentar disparos persistentes. Essas propriedades intrínsecas desse grupo celular são essenciais para manter o controle inibitório contínuo sobre as células excitatórias e é frequentemente associada à expressão de canais HCN (*Hyperpolarization-activated Cyclic Nucleotide-gated*) em seus axônios [4], [5].

Os canais HCN pertencem à superfamília dos canais de K^+ [6] e possuem características distintas: são permeáveis a Na^+, K^+ e também a Ca^{2+}, são ativados por potenciais de membrana polarizados ($\approx$ -55 mV) e modulados por nucleotídeos cíclicos, especialmente o cAMP [7], [8]. Esses canais são fundamentais para a regulação da excitabilidade neuronal [9] e apresentam variações na sua expressão (isoformas 1 a 4) no sistema nervoso central, com a isoforma HCN1 predominando no hipocampo e no neocórtex, enquanto HCN2 e HCN4 têm maior expressão no tálamo [10], [11], [12], [13], [14]. Além da localização, as subunidades diferem na sensibilidade ao cAMP, que é significativamente superior nas isoformas HCN2 e HCN4 em comparação à HCN1 [15].

A ligação do cAMP ao domínio intracelular dos canais HCN desloca o limiar de ativação para potenciais menos polarizados [16], integrando a dinâmica elétrica ao estado metabólico [7], [17]. Essa integração é sustentada pela cooperação metabólica entre neurônios e astrócitos, descrita pela hipótese ANLSH (*Astrocyte-Neuron Lactate Shuttle Hypothesis*). Nesse modelo, a atividade neuronal estimula a glicólise nos astrócitos, resultando na produção de lactato, que é transferido para os neurônios para servir como substrato oxidativo eficiente na geração de ATP [18], [19]. Como o ATP é substrato para a síntese de cAMP pela adenilato ciclase, o suporte energético fornecido pelos astrócitos torna-se um determinante direto da modulação dos canais HCN, permitindo que a excitabilidade neuronal seja ajustada conforme a disponibilidade metabólica local [20].

A transmissão sináptica dos interneurônios PV+ na formação hipocampal pode ser modulada pela atividade dos canais HCN. Estudos de *patch-clamp* realizados na região CA1 revelam que a inibição farmacológica desses canais com ZD7288 resulta em uma redução acentuada da corrente pós-sináptica inibitória (IPSC). Essa queda na IPSC foi verificada ao aplicar um pulso despolarizante de 0,2 ms na membrana do interneurônio e registrar a resposta em uma célula piramidal conectada. Os autores também avaliaram a IPSC com injeção de pulsos pareados no interneurônio e demonstraram que, com o bloqueio dos HCNs, a resposta ao segundo pulso apresenta menor redução de amplitude [21]. Esses achados sugerem que a atividade dos canais HCN não apenas regula a excitabilidade intrínseca, mas pode também participar ativamente da plasticidade neuronal [16].

No presente trabalho, com o uso de modelagem matemática e simulações computacionais, buscamos reproduzir e investigar o comportamento observado experimentalmente [21]. O modelo utilizado teve como base

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

os trabalhos [22], [23], [24] para a descrição das células piramidais e de mecanismos de acoplamento não sinápticos. A neurotransmissão foi baseada no modelo descrito em [25]. Para representar o interneurônio PV+, os canais HCN e o metabolismo, seguimos a metodologia de [26]. As simulações permitiram propor que a influência dos canais HCN na propagação de correntes sinápticas no hipocampo de ratos pode estar relacionada à permeabilidade de Ca^{2+} nos terminais pré-sinápticos.

II. Materiais e Métodos

A. Estrutura espacial do modelo

O modelo é composto por unidades funcionais constituídas por um neurônio (interneurônio ou célula piramidal), um prolongamento astrocítico e um compartimento correspondente ao meio extracelular. Neste estudo, foi utilizada uma rede bidimensional de 5 x 5 unidades funcionais, composta por um interneurônio e 24 células piramidais. Na borda inferior da rede, foram posicionados compartimentos com concentrações iônicas constantes, representando a solução de perfusão do tecido.

B. Mecanismos não sinápticos

O movimento iônico no meio extracelular causado por eletrodifusão foi descrito com base na equação de Nernst-Planck (1), que calcula os fluxos iônicos extracelulares considerando o efeito combinado da difusão iônica e do campo elétrico.

$$\left(\frac{\partial[C]_o}{\partial t}\right)_{dif} = \frac{D}{\lambda^2}\vec{\nabla}[C]_o + \frac{zFD\omega}{RT\lambda^2}\vec{\nabla}[C]_o \cdot \vec{\nabla}V + \frac{zFD\omega}{RT\lambda^2}[C]_o\nabla^2 V, \quad (1)$$

em que

$$\omega = 0.4\left(\frac{-1}{e^{vol_{extra}-1.1\times10^{-13}+1}} + 1\right) + 0.5 \quad (1)$$

e

$$\vec{\nabla}V = -\frac{RT}{F}\frac{\sum z_C D_C \vec{\nabla}[C]_o}{\sum {z_C}^2 D_C [C]_o} \quad (3)$$

onde C representa as concentrações dos íons Na^+, K^+, Cl^-, HCO_3^-, H^+. e λ a tortuosidade do meio extracelular, z a valência, F a constante de Faraday, T a temperatura, D a constante de difusão.

O campo elétrico extracelular foi modelado com duas componentes: uma refletindo a distribuição iônica ao longo do meio extracelular, responsável pela variação lenta do potencial extracelular (3), e outra associada às correntes transmembranares de Na^+ e K^+ (4) [22], [23].

$$V_{extra,rápido} = \tau F \sum_{n=1}^{N} \frac{A_m^{NEURON}\left(\Phi_{Na,canal\ iônico}^{NEURON} + \Phi_{K,canal\ iônico}^{NEURON}\right)_n}{d_n}, \quad (4)$$

em que

$$\tau = \bar{\tau}\left[16\left(\frac{-1}{exp\left(-\frac{vol_{extra} - 2{,}50\times10^{-1}}{(8\times10^{-16})}\right)+1} + 1\right) + 1\right], \quad (5)$$

e, então:

$$I_{campo\ elétrico} = \varepsilon V_{extra,rápido} \quad (6)$$

Fluxos por cootransportadores cátion cloreto (KCC, NKCC), trocadores iônicos que regulam pH (NHE, HCE), bomba de H^+ estão presentes no modelo e foram calculados utilizando o formalismo de Michaelis-Menten [23], [24].

A bomba de Na^+/K^+ também foi incluída no modelo, acoplando o efluxo de Na^+ ao influxo de K^+, na respectiva proporção estequiométrica de 3:2, utilizando energia proveniente da hidrólise de ATP. Para calcular a corrente gerada pela bomba, consideramos um íon fictício A^+ resultante do efluxo líquido de carga positiva dos íons transportados na direção oposta. As concentrações intra e extracelulares do íon A^+ foram determinadas usando o modelo de Albers-Post, com base nas reações dos ligantes com a enzima Na^+/K^+ ATPase [22].

O cálculo das correntes por canais iônicos dependentes do potencial e pela bomba de Na^+/K^+ é dado pela equação de Goldman-Hodgkin-Katz (GHK)

$$\Phi_{C,mech}^{CELL} = P_{C,mech} z_C F \frac{V_m^{cell}}{RT}\left(\frac{[C]_i^{cell}\, exp\left(-\frac{z_C F V_m^{cell}}{RT}\right) - [C]_o}{exp\left(-\frac{z_C F V_m^{cell}}{RT}\right) - 1}\right), \quad (7)$$

O potencial de membrana foi calculado pela extensão da equação de GHK para corrente:

$$Vm = \frac{RT}{F} ln\left(\frac{P_{Na}[Na^+]_o + P_K[K^+]_o + P_{Cl}[Cl^-]_i + P_A[A^+]_o + f_{ef} + f_{ed} + Inj}{P_{Na}[Na^+]_i + P_K[K^+]_i + P_{Cl}[Cl^-]_o + P_A[A^+]_i}\right) \quad (8)$$

onde f_{ef}, f_{ed} representam a influência do efeito de campo e eletrodifusão e Inj os pulsos injetados.

As permeabilidades dos canais iônicos foram calculadas utilizando o formalismo de Hodgkin-Huxley [27]. No interneurônio e células piramidais, foram considerados:

- Canais de Na^+ de dinâmica rápida (*fast*);
- Canais persistentes de Na^+;
- Canais de K^+ do tipo A;
- Canais retificadores de K^+ com atraso;
- Canais muscarínicos de K^+;
- Canais de K^+ do tipo Kir;
- Canais de cloreto com permeabilidades constantes.

No interneurônio, também foram representados canais do tipo L, usados para estimar a produção de cAMP pela enzima adenilato ciclase. A membrana dos astrócitos foi considerada inexcitável. Apenas o canal retificador de entrada de K^+ foi

modelado de forma dependente do potencial; para os demais canais, as permeabilidades foram consideradas constantes.

As permeabilidades para Na^+ e K^+ dos canais HCN expressos nos interneurônios foram calculadas da seguinte forma:

$$P_{Na}^{HCNC} = \overline{P_{Na}^{HCNC}} f_{HCNC} q_{Na}^{HCNC}, \tag{9}$$

$$P_{K}^{HCNC} = \overline{P_{K}^{HCNC}} f_{HCNC} q_{K}^{HCNC}, \tag{10}$$

em que

$$\frac{dq_{Na}^{HCNC}}{dt} = \frac{\left[0.085\left(\tanh\left(\frac{[cAMP]^i - 0.039}{0.0014}\right) + 1.0\right) + 0.05\right] - q_{Na}^{HCNC}}{0.001} \tag{11}$$

$$\frac{dq_{K}^{HCNC}}{dt} = \frac{\left[0.5\left(\tanh\left(\frac{[cAMP]^i - 0.01}{0.0045}\right) + 1.0\right) + 0.63\right] - q_{K}^{HCNC}}{0.001} \tag{12}$$

$$f_{HCNC} = 0.5\left(\tanh\left(-\frac{Vn-(-84+20\cdot DV_{HCNC})}{13.1}\right) + 1.0\right), \tag{13}$$

$$DV_{HCNC} = 0.5\left(\tanh\left(\frac{[cAMP]^i - 0.039}{0.0018}\right) + 1.0\right). \tag{14}$$

O metabolismo energético e as interações entre interneurônio e astrócito também foram descritas. A produção de cAMP a partir de ATP pela adenilato ciclase foi definida como:

$$ATP^i \xrightarrow{adenilato\ ciclase} cAMP^i + 2P^i, \tag{15}$$

A taxa de reação é dada por:

$$r_{AC} = \propto_{AC} \frac{[ATP]^i}{[ATP]^i + 0.2} \times (0.001 + y_{INa}), \tag{16}$$

em que y_{INa} é a função de transferência dependente da corrente de Na^+ usada para representar o efeito no canal do tipo L que ativa a adenilato ciclase:

$$y_{INa} = y_{INa} e^{-DT/0.2\times10^{-3}} + y_1 0.2(1 - e^{-DT/0.2\times10^{-3}}), \tag{17}$$

$$y_1 = y_1 e^{-DT/2.5\times10^{-3}} + y_2 2.5(1 - e^{-DT/2.5\times10^{-3}}), \tag{18}$$

onde y_2 é o estímulo de entrada que identifica a ocorrência do potencial de ação através da taxa de variação da corrente de Na^+, e é dado por:

$$y_2 = \begin{cases} 1\ se\ \frac{dINa}{dt} < -3.07 \times 10^3\ e\ ContarPA = 0 \\ 0\ se\ não \end{cases}, \tag{19}$$

$$ContarPA = \begin{cases} ContarPA + 1\ \ se\ 0 < ContarPA < 10 \\ 0\ se\ não \end{cases}., \tag{20}$$

Nas simulações, y_{INa} e y_1 recebem valores inicialmente nulos. Para a conversão de cAMP para AMP, foi descrita a reação relacionada ao efeito da fosfodiesterase:

$$cAMP^i \xrightarrow{PDE} AMP^i, \tag{21}$$

$$r_{PDE} = \propto_{PDE} \frac{[cAMP]^i}{[cAMP]^i + 0.0201} \tag{22}$$

A [cAMP] foi estimada por:

$$\frac{d[cAMP]^i}{dt} = r_{AC} - r_{PDE} \tag{23}$$

C. Transmissão sináptica

A transmissão sináptica foi representada por um conjunto de passos. Primeiramente, a membrana pré-sináptica é despolarizada devido à ocorrência do potencial de ação no neurônio pré-sináptico. A despolarização aumenta a permeabilidade de Ca^{2+}, promovendo o influxo desse cátion no terminal pré-sináptico. O influxo de Ca^{2+} promove a liberação de neurotransmissores na fenda sináptica. Esses neurotransmissores difundem-se até a membrana pós-sináptica, onde se ligam a receptores e promovem a abertura de canais iônicos. A depender do tipo de canal iônico e do potencial de Nernst do íon em questão, a corrente pode ser excitatória ou inibitória. Após permanecerem ligados por determinado intervalo de tempo, os neurotransmissores são inativados devido à ação enzimática, são transportados novamente para o terminal pré-sináptico e armazenados em vesículas [25].

Seguindo as etapas envolvidas no processo de neurotransmissão, foram incluídas no modelo as seguintes equações:

- Permeabilidade de Ca^{2+} no terminal pré-sináptico:

$$P_{Ca} = \bar{P}_{Ca} m^3 h, \tag{24}$$

onde,

$$\alpha_m = \frac{C_{\alpha_m}(Vt - Vm + 25)}{e^{\frac{Vm+2}{10}} - 1}, \tag{25}$$

$$\beta_m = C_{\beta_m} e^{\frac{Vt-V}{18}}, \tag{26}$$

- Fluxo de Ca^{2+} através dos canais dependentes de potencial:

$$\phi_{Ca,cha} = \frac{F^2}{RT} z_{Ca}^2 P_{Ca} V_m \frac{[\mathrm{Ca}]_i e^{\frac{z_{Ca}FVm}{RT}} - [Ca]_o}{e^{\frac{z_{Ca}FVm}{RT}} - 1}, \quad (27)$$

- Fluxo de Ca^{2+} pela bomba iônica:

$$\phi_{Ca,pump} = \frac{P_{Ca,pump}^{max}}{1 - e^{-3\times10^{-3}([Ca]_i - 1\times10^{-2})}}, \quad (28)$$

- Fluxo devido à movimentação ao longo do axônio, por difusão:

$$\phi_{Ca,dif} = \gamma(8 \cdot 10^{-2} - [Ca]_i), \quad (29)$$

- Em função dos fluxos descritos, as taxas de variação das concentrações intra e extracelular de Ca^{2+} são dadas por:

$$\frac{d[Ca]_i}{dt} = -\frac{f_{vol}}{Vol_{syn}}\left(\phi_{Ca,pump} + \phi_{Ca,channel} + \phi_{Ca,eq}\right) + \phi_{Ca,dif}, \quad (30)$$

$$\frac{d[Ca]_o}{dt} = \frac{f_{vol}}{Vol_o}\left(\phi_{Ca,pump} + \phi_{Ca,channel} + \phi_{Ca,eq}\right), \quad (31)$$

- Taxa de variação da concentração de neurotransmissores no terminal pré-sináptico:

$$\frac{d[NT]_i}{dt} = 10.4(-\Delta T_o + 2\times10^{-3} T_v), \quad (32)$$

- Taxa de liberação de neurotransmissores na fenda sináptica:

$$\frac{d[NT]_o}{dt} = 8\times10^2(\Delta T_o - \Delta T_o R - \Delta T_o E), \quad (33)$$

- Taxa de ligação dos neurotransmissores aos receptores da membrana pós-sináptica:

$$\frac{dToR}{dt} = 8\times10^2 \Delta T_o R, \quad (34)$$

- Taxa de inativação dos neurotransmissores:

$$\frac{dT_oE}{dt} = 8\times10^2(\Delta T_o - \Delta T_o E - \Delta T_o EER), \quad (35)$$

- Taxa de armazenamento de neurotransmissores nas vesículas pré-sinápticas:

$$\frac{dT_v}{dt} = 8\times10^2(\Delta T_o EER - 2\times10^{-3} T_v), \quad (36)$$

em que

$$\Delta T_o = 6\times10^2 [NT]_i([Ca]_i + [Ca]_{i,repouso}), \quad (37)$$

$$\Delta T_o R = 1{,}5[NT]_o - 3T_o R, \quad (38)$$

$$\Delta T_o E = 1{,}5[NT]_o - 3T_o R, \quad (39)$$

$$\Delta T_o EER = \frac{0{,}16}{1+e^{110([NT]_i - 0{,}98)}} T_o E, \quad (40)$$

- A corrente pós-sináptica inibitória (IPSC) foi considerada proporcional à concentração de neurotransmissores ligados aos receptores pós-sinápticos:

$$I_{inib} = \delta T_o R, \quad (41)$$

onde δ (pA) é uma constante de proporcionalidade, que representa o efeito das forças difusiva e elétrica através da membrana pós-sináptica, consideradas constantes no modelo.

D. Implementação computacional

O modelo foi implementado em linguagem Fortran (Fortran 90), utilizando o método de diferenças finitas com erro menor que 10^{-4}. Os resultados foram analisados em Matlab®. Valores iniciais e parâmetros foram baseados nos trabalhos anteriores [23], [24], [25], [26]. O código do programa foi compilado e executado em um computador de alta performance (Cluster SGI UV 2000, 80 *cores* — Intel Xeon E5-4650v2 10-core, 2.4 GHz, 25 MB Cache, 1024 GB DDR3 1866 MHz, 80 TB HD, Cluster SGI UV 300, 144 *cores* Intel Xeon E7-8867v4, 2.4 GHz, RAM 2048 GB DDR4 2400 MHz, 80 TB HD, SUSE Linux Enterprise Server 11, SGI Performance Suite, Intel Cluster Studio XE).

III. RESULTADOS

Simulando o protocolo experimental [21], um pulso retangular de potencial foi aplicado durante 0,2 ms na membrana do interneurônio. A Fig. 1B mostra que a IPSC não sofreu alteração quando os canais HCN foram bloqueados (Fig. 1B, 100% PCa). Para esse caso, o acúmulo de Ca^{2+} intracelular durante o potencial de ação e, consequentemente, os comportamentos das concentrações de neurotransmissores no terminal pré-sináptico e na fenda sináptica não são alterados pelo bloqueio dos canais HCN (Fig. 1C).

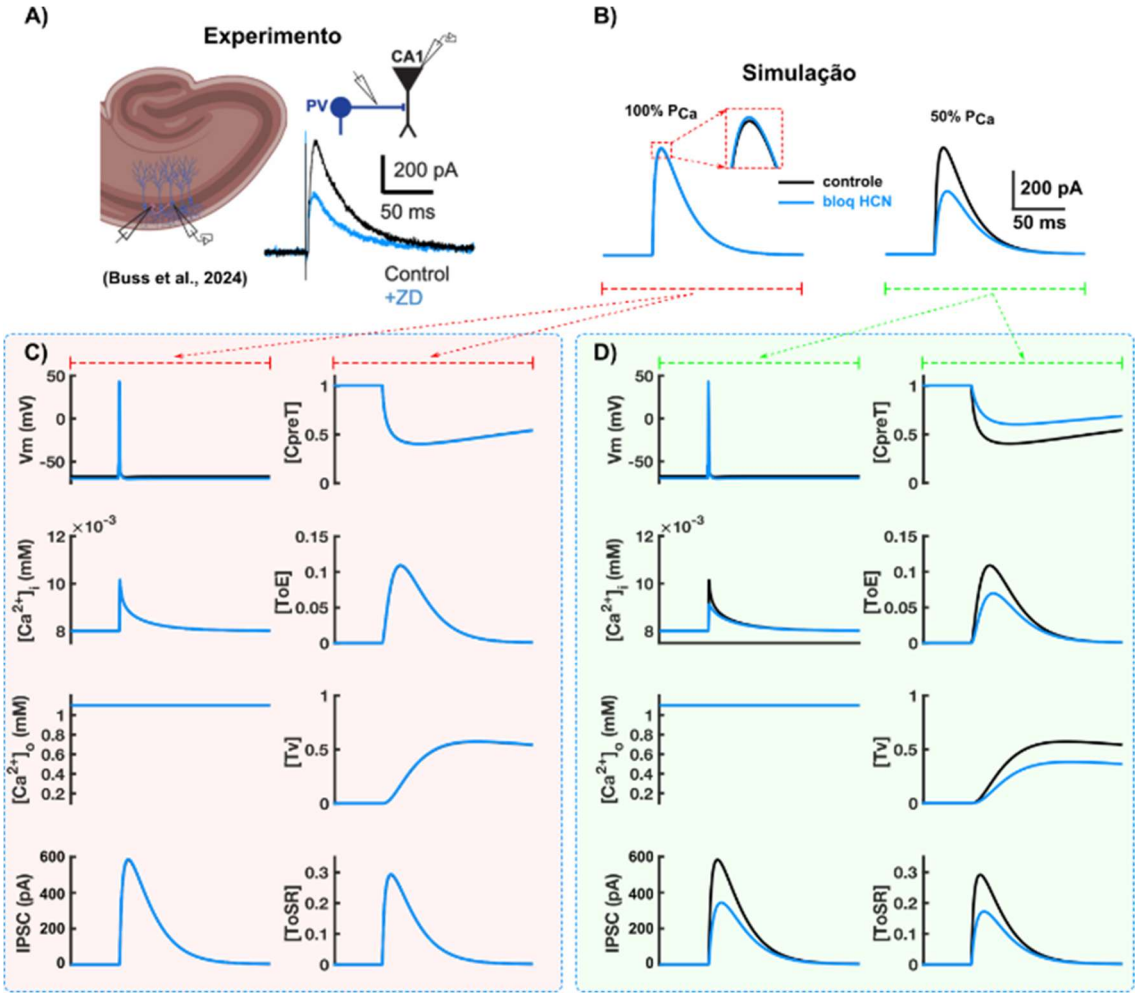

Fig. 1. Redução da IPSC causado pelo bloqueio dos canais HCN. (A) Registro experimental [22]. (B) IPSC simulada no caso controle e bloqueando os HCN em duas situações: 100% PCa – sem alterar o influxo de Ca2+; 50% PCa – reduznindo o influxo de Ca2+. Os comportamentos das concentrações pré-sinápticas e na fenda sináptica de Ca2+ e neurotransmissores são apresentadas para os dois casos: 100% PCa (C) e 50% PCa (D). (preto – controle;. azul – bloqueio do HCN; as curvas em azul se sobrepõem às curvas em preto).

Como os canais HCN também apresentam permeabilidade ao Ca^{2+} [8], [21], o seu bloqueio deveria reduzir o influxo de Ca^{2+}. Considerando que a permeabilidade do Ca^{2+} cai durante o bloqueio dos HCNs, a simulação foi capaz de reproduzir o comportamento de redução da IPSC (Fig. 1B, 50% PCa) observada experimentalmente. Nesse caso, Fig. 1D, durante o bloqueio dos HCNs, a redução do influxo de Ca^{2+} reduz o seu acúmulo no meio intracelular do neurônio pré-sináptico. Isso leva a uma redução na quantidade de neurotransmissores liberados na fenda sináptica e na ligação aos receptores na membrana pós-sináptica. Logo, a IPSC é menos intensa (curvas em azul) do que no caso controle (curvas em preto).

Experimentalmente também foi observado que o bloqueio dos HCNs altera a razão das amplitudes da IPSC de pulsos pareados aplicados com intervalo de 50 ms [21], [22] (Fig. 2A). Como pode ser observado na Fig. 2B, a simulação permite reproduzir o comportamento experimental, sendo que o bloqueio dos HCNs associado com a redução do influxo de Ca^{2+}, apesar de reduzir a amplitude da IPSC, aumenta a razão (amplitude da segunda IPSC) / (amplitude da primeira IPSC) durante esse protocolo de estimulação. Observa-se que, com o bloqueio dos canais HCN, o menor acúmulo de Ca^{2+} intracelular durante cada potencial de ação (Fig. 2C) resulta em uma variação menos acentuada da concentração de neurotransmissores. Esse efeito atenua a depressão sináptica, de modo que a resposta ao segundo pulso sofre menor redução em comparação com a resposta ao primeiro.

IV. Discussão

Alterações na expressão e na atividade dos canais HCN podem estar relacionadas a diferentes patologias do sistema nervoso central [28], [29], [30]. Portanto, compreender como esses canais modulam a transmissão sináptica pode contribuir para a identificação de mecanismos fisiopatológicos relevantes e orientar, futuramente, o desenvolvimento de estratégias terapêuticas mais específicas.

Para representar o interneurônio, utilizamos um modelo que inclui uma descrição dos canais HCN e metabolismo celular [26]. Como observado experimentalmente, os canais HCN também são permeáveis a Ca^{2+} [8], embora essa permeabilidade seja relativamente baixa, ela pode exercer efeito sobre o processo de neurotransmissão [21]. Reforçando essa hipótese, nas simulações, quando a permeabilidade de Ca^{2+} é reduzida durante o bloqueio dos canais HCN, a IPSC apresenta menor intensidade (Fig. 1B e 1D, 50% PCa). De acordo com a simulação, a redução do influxo de Ca^{2+} causa uma menor liberação de neurotransmissores na fenda sináptica. Logo, a IPSC em resposta ao pulso despolarizante apresenta menor amplitude. Sustentando essa hipótese de que o bloqueio dos canais HCN reduz o influxo de Ca^{2+} [21], em resposta a pulsos pareados, a amplitude do segundo pulso

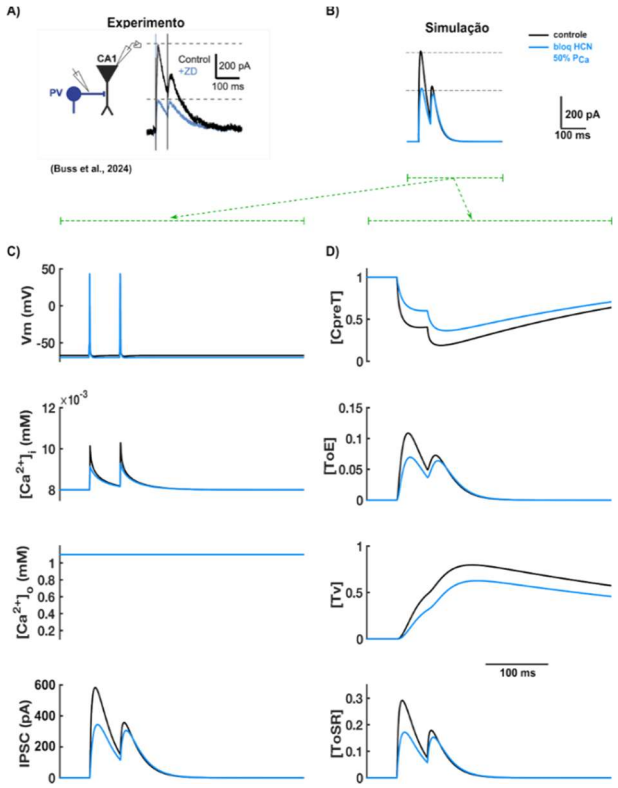

Fig. 2. O bloqueio dos canais HCN aumenta a razão de pulsos pareados das correntes pós-sinápticas inibitórias (IPSCs) evocadas pela estimulação de interneurônios. (A) Registro experimental [22].. (B) IPSC simulada no caso controle e bloqueando os HCN. (C) e (D) Comportamentos das concentrações pré-sinápticas e na fenda sináptica de Ca2+ e neurotransmissores durante os potenciais de ação gerados pelos pulsos.

apresenta menor redução em relação ao primeiro pulso quando comparado ao caso em que os canais HCN não são bloqueados, conforme exibido na Fig. 2. Segundo a simulação, combinando o bloqueio do HCN com um menor influxo de Ca^{2+}, a liberação de neurotransmissores fica menos intensa. Consequentemente, a concentração de neurotransmissores pré-sinápticos reduz menos, afetando pouco a amplitude da resposta ao segundo pulso injetado.

Nas simulações realizadas foi necessário reduzir a permeabilidade ao Ca^{2+} em aproximadamente 50% do valor basal para reproduzir o comportamento observado experimentalmente. Essa redução é substancialmente maior do que os 6% previstos na literatura [8], [21]. Os resultados permitem levantar a hipótese de que os canais HCN estão presentes nos terminais axônicos (pré-sinapses) dos interneurônios, contribuindo com cerca de 50% da permeabilidade total de Ca^{2+}.

***Resumo*—O envelhecimento populacional acarreta o aumento da incidência de patologias musculoesqueléticas e do risco de quedas, o que demanda o uso de dispositivos assistivos. Contudo, a maioria desses dispositivos atuais foca apenas na navegação sem oferecer garantias ativas de segurança contra a perda de equilíbrio do usuário. Nesse contexto, o presente trabalho propõe a implementação de uma Função de Controle de Barreira (CBF) em um andador eletrificado, inteligente, atuando como uma malha de *Safety Control* para a prevenção de quedas. Nesta fase da pesquisa, a dinâmica da marcha foi simplificada por meio de um modelo de pêndulo invertido acoplado ao andador. Um controlador de impedância foi projetado para atuar na intenção de movimento nominal, enquanto a CBF atua por meio da solução de um problema de Programação Quadrática (QP) para restringir o ângulo de inclinação do tronco a uma zona estritamente segura. Simulações do modelo matemático demonstraram que, diante de perturbações externas, o controlador intervém na trajetória de forma estritamente mínima, limitando a inclinação do usuário e evitando o tombamento. Os resultados preliminares sugerem que a técnica CBF apresenta-se como uma alternativa robusta e promissora para garantir a segurança formal na robótica assistiva.**

***Index Terms*—controle, andador, assistivo, barreira**

I. Introdução

O enorme avanço sócio-econômico e tecnológico da humanidade tornou possível um aumento substancial da expectativa de vida. Contudo, a Organização Mundial da Saúde exibe uma preocupação com as implicações desse aumento da expectativa de vida na saúde pública [1]. A expectativa de vida global atingiu 73,3 anos em 2024, um aumento de 8,5 anos desde o ano de 1995, o que resulta em uma projeção de aumento de 1,1 em 2023 para 1,4 bilhão em 2030 na população de mais de 60 anos [1].

Contudo, o avanço da expectativa de vida traz consigo o aumento de alguns problemas associados ao envelhecimento populacional. As patologias associadas a dificuldade de locomoção e redução da mobilidade estão entre as principais preocupações da comunidade científica. [2]. Em virtude do aumento de patologias relacionadas a mobilidade, anualmente, o mundo registra aproximadamente 37,3 milhões de quedas severas o suficiente para que a pessoa precise de atendimento médico de acordo com [3]. A população idosa apresenta o maior risco de morte ou ferimento sério acarretado por uma queda, sendo que 20-30% de idosos ao caírem sofrem algum tipo de ferimento moderado ou severo, como hematomas, fraturas nos quadris, traumatismo craniano etc [3].

O autor Vinicius Alves Cecchi agradece ao Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) pela concessão da bolsa de Mestrado (Processo nº 131724).

A. Justificativa

Diante do envelhecimento populacional evidenciado por [1], as patologias músculo-esqueléticas associadas ao envelhecimento, como as descritas por [2] são engrandecidas diante dos riscos que se associam a quedas por idosos e a incidência de quedas na população idosa. A fragilidade músculo-esquelética aumenta mais ainda o risco de fraturas no fêmur, quadril, outros ossos e até a morte, além do dano psicológico, o que evidencia uma crescente demanda por dispositivos assistivos que garantam não só a mobilidade mas a segurança dos usuários.

B. Objetivo

Com isso, o objetivo principal do presente trabalho é a implementação de uma função de controle de barreira em um dispositivo andador para idosos com a finalidade de impedir ou diminuir o índice de quedas de usuários.

II. Fundamentação teórica

A fundamentação teórica se divide em dois pilares principais: o primeiro deles concentra-se no estudo da biomecânica da marcha e da queda, já o segundo, constitui-se do estudo acerca das estratégias de controle aplicadas no desenvolvimento do controlador de barreira.

A. Biomecânica da Marcha e Queda

O ciclo da marcha humana é fundamentado na alternância entre os estados de suporte duplo e suporte simples. Enquanto o primeiro ocorre com o contato simultâneo de ambos os pés com o solo, o segundo caracteriza-se pelo apoio de apenas uma

das extremidades inferiores. Sob a perspectiva de um membro isolado, o movimento é segmentado em duas etapas principais: a fase de apoio, que ocupa cerca de 62% do ciclo, e a fase de balanço, que compreende os 38% restantes. Conforme proposto por [4], [5] e [6], essa progressão pode ser detalhada em oito eventos discretos.

1) Contato Inicial: Marca o começo do ciclo quando o calcanhar atinge o solo. Neste ponto, o centro de gravidade atinge seu nível mais baixo, com o quadril flexionado em cerca de 30° e o joelho em 5°. A força de reação do solo supera o peso corporal, exigindo esforço máximo do músculo reto femoral.
2) Resposta à Carga: Caracteriza-se pelo contato total da planta do pé com a superfície. Ocorre uma flexão rápida do joelho até 15°, mecanismo essencial para a absorção de impactos e continuidade do movimento.
3) Apoio Médio: Período em que o peso do corpo se projeta verticalmente sobre o membro em suporte simples. O joelho permanece em extensão enquanto o membro oposto inicia o balanço. O centro de gravidade atinge seu ápice e o joelho flexiona-se levemente (18°), com redução da atividade do reto femoral.
4) Apoio Terminal: Instante em que o calcanhar se eleva, perdendo o contato com o chão. O impulso para a progressão é gerado pela ativação dos músculos tríceps surais, resultando na flexão plantar do tornozelo.
5) Pré-balanço (Desprendimento): Etapa final do apoio, encerrada no momento em que os dedos deixam a superfície de caminhada.

Quedas são uma das principais causas de acidentes entre a população idosa. O trabalho de [7] teve como objetivo determinar o que causa uma queda entre idosos e o que dificulta a recuperação postural. Em [8], um estudo previamente conduzido os pesquisadores aplicaram um experimento no qual induziam o voluntário a tropeçar, com isso, foi possível observar que o tronco, sendo responsável por aproximadamente 50% do peso do corpo e dada a sua altura do chão, ao inclinar-se quando o indivíduo tropeça tem grande impacto na queda. A flexão do tronco pós tropeço ficava em torno de $27 \pm 9°$ e o pico de velocidade da flexão foi de $140°/s$, o que ocorreu 300ms após o tropeço.

Um tropeço é descrito por [9] como um contato inesperado do pé com a superfície que acaba gerando momento suficiente para desestabilizar o indivíduo. Sendo assim, conclui-se que os fatores-chave para uma queda por tropeço são: contato inesperado com o chão e momento excessivo.

Dada as limitações fisiológicas e neuromusculares um tropeço pode ser desafiador para um idoso ou alguém que sofra de uma patologia neuromuscular, isso porque essas condições acarretam no enfraquecimento músculo-esquelético do indivíduo, diminuindo a magnitude do momento que amortece a flexão do tronco. Além disso, o atraso nos reflexos e tempo de reação aumenta o tempo de resposta, ocasionando em uma maior flexão do tronco que é o que foi observado em [8].

Segundo [8] resvalos (desequilíbrio para trás) causam mais quedas proporcionalmente pois a recuperação deste tipo de distúrbio postural se mostra muito mais difícil do que sua contraparte. Por exemplo, para o caso de tropeços e quedas frontais nas quais o tronco é flexionado, nenhum voluntário jovem caiu, por outro lado, 25% dos mais velhos caíram. Já para um resvalo, ou seja, uma queda para trás na qual o tronco é extendido, 6% dos jovens e 86% dos mais velhos caíram. A capacidade de evitar uma queda para trás está associada com a capacidade de atenuar movimentos indesejados do tronco.

B. Controlador de Barreira

Uma função de controle de Barreira (CBF) pode ser descrita a partir de um sistema descrito pela equação 1.

$$\dot{x} = f(x) + g(x)u \tag{1}$$

Deve-se considerar uma função de barreira $h(x)$ que tende a zero. Tendo um conjunto C chamado de "conjunto seguro", se $h(x)$ tende a zero, x encontra-se dentro do conjunto seguro.

Um controlador de realimentação deve ser projetado para o sistema ((1)) com o objetivo de manter os estados $\mathbf{x}$ no conjunto de segurança, definido conforme:

$$\begin{aligned} \mathcal{C} &= \{\mathbf{x} \in D \subset \mathbb{R}^n : h(\mathbf{x}) \geq 0\}, \\ \partial\mathcal{C} &= \{\mathbf{x} \in D \subset \mathbb{R}^n : h(\mathbf{x}) = 0\}, \\ \text{Int}(\mathcal{C}) &= \{\mathbf{x} \in D \subset \mathbb{R}^n : h(\mathbf{x}) > 0\}, \end{aligned} \tag{2}$$

onde $h(\mathbf{x}) : D \subset \mathbb{R}^n \to \mathbb{R}$ é uma função continuamente diferenciável.

A função $h(\mathbf{x})$ é uma função, cuja classificação como CBF torna-se possível devido a existência de uma classe $\mathcal{K}$ (denominada α_{cbf}) tal que:

$$\sup_{u \in U} [L_f h(\mathbf{x}) + L_g h(\mathbf{x}) u + \alpha_{cbf}(h(\mathbf{x}))] \geq 0. \tag{3}$$

Considerando o conjunto seguro $\mathcal{C}$ definido em (2), o conjunto de controles $K_{cbf}(\mathbf{x})$ para o sistema ((1)) é definido como em [10]:

$$K_{cbf}(\mathbf{x}) = \{u \in U : L_f h(\mathbf{x}) + L_g h(\mathbf{x}) u + \alpha_{cbf}(h(\mathbf{x})) \geq 0\}. \tag{4}$$

C. Funções de Controle de Barreira Exponenciais

Em determinados problemas há uma limitação, dada pela própria natureza do sistema. Por vezes, a variável controlável do sistema não encontra-se na primeira derivada da função de barreira, em função disso, foram desenvolvidas funções de barreira exponenciais (ECBF), que são descritas por [10] conforme:

Definição 1:Dado um conjunto $C \subset D \subset \mathbb{R}$ definido como o supernível de um conjunto de uma função r vezes diferenciável, sendo $h(x) : D \to \mathbb{R}$ então, h(x) é uma ECBF se existe um vetor $K_b \in \mathbb{R}$ de tal forma que,

$$\sup_{u \in U} \left[L_f^r h(\mathbf{x}) + L_g L_f^{r-1} h(\mathbf{x}) u + K_b \eta_b(\mathbf{x}) \right] \geq 0 \tag{5}$$

onde o vetor de estados estendido $\eta_b(\mathbf{x})$ é definido como:

$$\eta_b(\mathbf{x}) := \begin{bmatrix} h(\mathbf{x}) \\ \dot{h}(\mathbf{x}) \\ \ddot{h}(\mathbf{x}) \\ \vdots \\ h^{(r-1)}(\mathbf{x}) \end{bmatrix} = \begin{bmatrix} h(\mathbf{x}) \\ L_f h(\mathbf{x}) \\ L_f^2 h(\mathbf{x}) \\ \vdots \\ L_f^{(r-1)} h(\mathbf{x}) \end{bmatrix} \tag{6}$$

III. Metodologia

A abordagem metodológica consiste primariamente no desenvolvimento de um modelo matemático capaz de representar a marcha humana de forma simplificada, mas que apresente coerência com a realidade do movimento humano. Posteriormente, faz-se necessário projetar um controlador capaz de garantir a segurança do usuário, por fim, foi desenvolvido um protocolo experimental para simulação computacional de uma queda induzida.

A. Modelagem Biomecânica

O modelo do pêndulo invertido é amplamente utilizado para a representação matemática da marcha, seja ela humana ou robótica. Sendo assim, utiliza-se um pêndulo invertido para representar o movimento do corpo humano ao longo do plano sagital, no qual ele se alterna entre situações de equilíbrio e desequilíbrio controlado para gerar movimento de avanço.

O pêndulo é representado como uma barra de comprimento l sem massa, e toda a massa (m_h) do corpo está concentrada na ponta desta barra, representando o centro de gravidade (CG) do usuário. Conforme o usuário se movimenta, o pêndulo forma um ângulo de deslocamento θ em relação a sua posição inicial. Naturalmente, um ser humano tem uma rigidez muscular natural dos membros inferiores, que impede a sua queda em situações de repouso. Para simular esta rigidez natural, foi adicionada uma mola com rigidez k_1 a uma altura h_1 do chão que corresponde a distância do chão ao centro de gravidade da perna, que gera um momento contrário ao causado pela força peso.

Além disso, o desafio principal da modelagem matemática é emular também a presença do andador. Para representar a força dos braços segurando no andador foi adicionada uma mola na mesma altura do CG com rigidez k_2. O andador por sua vez é representado como um bloco de altura h_a e massa m_a, além da força atuante da mola, o andador conta com a força F_m do motor que é a variável controlável do sistema que atua para garantir a estabilidade do usuário. O acoplamento entre o andador e o usuário é feito pelo deslocamento da mola k_2 ($x - l\sin(\theta)$).

Após a realização do Diagrama de Corpo Livre, torna-se possível equacionar o pêndulo invertido:

$$I_h\ddot{\theta} = m_h l g \sin(\theta) - k_2 l\cos(\theta)(l\sin(\theta) - x) - k_1 h_1^2 \tan(\theta) \tag{7}$$

Considerando que o pêndulo restringe-se a pequenos deslocamentos, é possível linearizar o comportamento dele, o que resulta em (8):

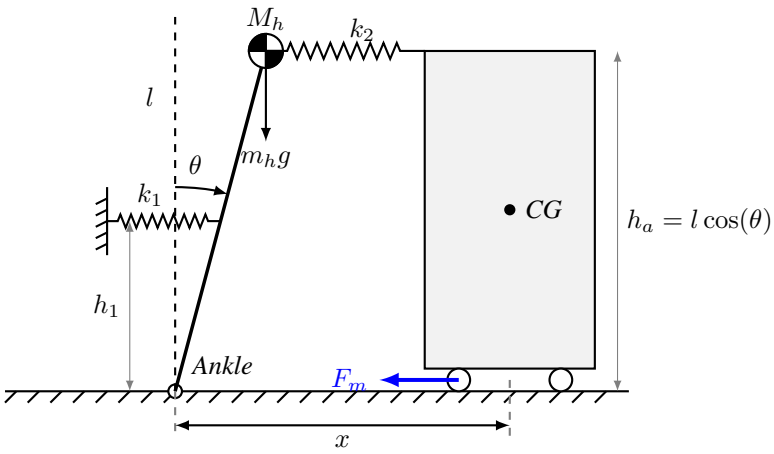

Fig. 1: Diagrama esquemático do modelo geométrico e de forças do sistema acoplado humano-andador.

$$\ddot{\theta} = \frac{m_h l g\theta - k_1 h_1^2\theta - k_2(l\theta - x)l}{I_h} \tag{8}$$

Quanto ao comportamento do andador utiliza-se a somatória de forças no mesmo, o teorema do movimento do baricentro.

$$m_a\ddot{x} = F_m + k_2(l\sin(\theta) - x) \tag{9}$$

Linearizando:

$$\ddot{x} = \frac{F_m + k_2(l\theta - x)}{m_a} \tag{10}$$

Contudo, é necessário impor uma distância mínima (d_{min}) entre o andador e o usuário, resultando em um termo adicional no acoplamento:

$$\ddot{\theta} = \frac{m_h l g\theta - k_1 h^2\theta - k_2(l\theta - x + d_{min})l}{I_h} \tag{11}$$

E o mesmo acontece para o andador:

$$\ddot{x} = \frac{F_m + k_2(l\theta - x + d_{min})}{m_a} \tag{12}$$

Embora a formulação de Funções de Barreira de Controle (CBF) possa ser aplicada diretamente a sistemas não-lineares, a linearização em torno da vertical de equilíbrio ($\theta \approx 0$) é adotada neste trabalho por duas razões fundamentais: primeiramente, como o envelope de segurança do dispositivo assistivo restringe a inclinação do usuário a pequenos ângulos ($\theta < 30°$), as aproximações de primeira ordem ($\sin\theta \approx \theta$ e $\cos\theta \approx 1$) introduzem desvios de modelagem desprezíveis na região de operação segura. Em segundo lugar, a representação linear no espaço de estados ($\dot{\mathbf{x}} = \mathbf{Ax} + \mathbf{Bu}$) simplifica analiticamente o cálculo das derivadas de Lie sucessivas exigidas pela Função de Barreira de Controle Exponencial (ECBF) de grau relativo $r = 2$. Adicionalmente, esta abordagem garante que a restrição de segurança mapeada para o espaço de controle preserve a linearidade na variável de decisão u_{safe}.

Isso assegura a convexidade do problema de Programação Quadrática (QP) resolvido a cada passo de amostragem, viabilizando a implementação e a convergência do algoritmo de otimização em tempo real.

Para fazer a representação linear no espaço de estados, faz-se necessário substituir as variáveis do sistema ((13)).

$$\begin{aligned} x_1 &= x \\ x_2 &= \dot{x} \\ x_3 &= \theta \\ x_4 &= \dot{\theta} \end{aligned} \tag{13}$$

Para simplificar a representação do sistema, definem-se os coeficientes dinâmicos γ e β como:

$$\gamma = \frac{m_h l g - k_1 h^2 - k_2 l^2}{I_h} \tag{14}$$

$$\beta = \frac{k_2 l}{I_h} \tag{15}$$

Sendo assim, o modelo no espaço de estados pode ser escrito de forma compacta como:

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \\ \dot{x}_4 \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -\frac{k_2}{m_a} & 0 & \frac{k_2 l}{m_a} & 0 \\ 0 & 0 & 0 & 1 \\ \beta & 0 & \gamma & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{1}{m_a} \\ 0 \\ 0 \end{bmatrix} u + \begin{bmatrix} 0 \\ \frac{k_2 d_{min}}{m_a} \\ 0 \\ -\beta d_{min} \end{bmatrix} \tag{16}$$

B. Controlador de Impedância

Para garantir que o andador consiga seguir os movimentos do usuário e manter-se próximo, mas ainda assim sendo capaz de adaptar-se a possíveis mudanças de rota, perturbações do ambiente etc, foi utilizado um controlador de impedância.

A dinâmica de impedância desejada para a inclinação do usuário/pêndulo (θ) impõe uma relação dinâmica entre a aceleração angular e o torque externo aplicado pela interação (T_{ext} ou $F_{\text{ext}} \cdot l$):

$$I_d\ddot{\theta} + B_d\dot{\theta} + K_d(\theta - \theta_0) = \tau_{ext} \ddot{\theta}_{des} = \frac{1}{I_d}\left(\tau_{ext} - B_d\dot{\theta} - K_d(\theta - \theta_0)\right) \tag{17}$$

Sendo:

- I_d a inércia desejada;
- B_d o amortecimento desejado;
- K_d a rigidez desejada;
- θ_0 o ângulo de equilíbrio de referência;
- τ_{ext} o torque externo exercido pelo usuário no sistema.

A partir da dinâmica do pêndulo linearizada, é possível isolar a posição desejada do andador (x_d) capaz de gerar o torque equivalente para essa impedância:

$$x_d = -\frac{1}{\beta}\left[\left(\gamma + \frac{K_d}{I_d}\right)\theta + \frac{B_d}{I_d}\dot{\theta} - \frac{\tau_{\text{ext}}}{I_d}\right] \tag{18}$$

A força de controle nominal aplicada pelos motores ($u_{\text{nom}} = F_m$) sintetiza a rigidez (K_{imp}) e amortecimento (B_{imp}) virtuais da interação linear, adicionando a compensação por gravidade do modelo invertido ($M_{\text{lcm},g}$):

$$\begin{aligned} x_{atual} &= x - l\theta - d_{min} \\ \dot{x}_{\text{atual}} &= v - l\dot{\theta} \end{aligned} \tag{19}$$

$$u_{\text{nom}} = -M_{\text{lcm},g} - K_{\text{d}}, x_{\text{atual}} - B_{\text{d}}, \dot{x}_{\text{atual}} \tag{20}$$

Onde $M_{\text{lcm},g} = m_h\, l\, g\, \theta$ representa a componente de compensação do momento gravitacional linearizado do usuário. Essa interação com o ambiente é feita através da criação de uma mola e um amortecedor virtual. A partir de uma abordagem analítica, entende-se que ao inclinar-se pra frente, o usuário comprime essa mola virtual, criando uma força que empurra o andador para frente. Em uma situação oposta, ao inclinar-se para trás, ele faz com que a mola se expanda, puxando o andador para perto do seu corpo. Dessa forma, é possível garantir que o andador esteja colado ao corpo do idoso, a todo momento (respeitando uma distância mínima imposta). Nota-se que o controlador de impedância gera um esforço de controle nominal (u_{nom}) capaz de manter o andador próximo do usuário a todo momento. No entanto, esse controlador não conta com a capacidade preditiva necessária para antecipar e previnir uma possível queda do usuário. Por isso, faz-se necessário também o uso de uma CBF como supervisor desse esforço de controle, visando garantir que o mesmo não coloque o usuário em uma zona de risco, fora do conjunto seguro.

C. Condições de Barreira

Diante das informações presentes em [7], é estabelecido um limite para a flexão de tronco do qual os idosos conseguem se recuperar de uma possível queda. Esse limite encontra-se em torno de 30 ° de inclinação. Sendo assim, a condição inicial de barreira é que o ângulo θ não pode passar desse limite de inclinação (Equação (21)).

$$\theta < \theta_{max} \tag{21}$$

Sendo assim, a barreira $h(x)$ pode ser descrita como:

$$h(x) = \theta_{max} - \theta - \alpha_c x \geq 0 \tag{22}$$

No qual o termo da Equação (22) $\alpha_c x$ introduzido na função de barreira tem o objetivo de incorporar o acoplamento entre a posição horizontal do sistema e o limite admissível de inclinação angular. Dessa forma, em vez de estabelecer um limite angular constante, a função de barreira define uma região segura dependente do estado de posição x. A constante α_c determina a intensidade na qual esse acoplamento impacta a condição de barreira $h(x)$.

Seguindo a condição imposta pela Equação (22):

$$L_f h(x) + \alpha(h(x)) \geq 0 \tag{23}$$

Onde o termo $L_f h(x)$ representa a derivada de Lie da função de barreira e $\alpha(h(x))$ um termo responsável por criar um gradiente de ação que antecipa a ação da barreira, fazendo com que ela atue antes de chegar próxima ao limite. O aumento do valor de α acarreta a intensidade da antecipação.

Seguindo a seguinte lógica:

$$\dot{h}(x) = -\dot{\theta} - \alpha_c \dot{x} \tag{24}$$

Dado que a variável de controle está presente na segunda derivada da posição x, seguindo o formalismo matemático, comprova-se através da Equação (25) que o sistema trata de uma ECBF de grau relativo $r = 2$.

$$\ddot{h}(x) = L_f^2 h + L_g L_h h u \tag{25}$$

Sendo assim, a equação de barreira ECBF com grau relativo 2 seguindo a condição imposta pela Equação (22) é igual a:

$$\ddot{h}(x) + K_1 \dot{h}(x) + K_2 h(x) \geq 0 \tag{26}$$

Expandindo os termos:

$$-\ddot{\theta} - \alpha_c \ddot{x} + K_1(-\dot{\theta} - \alpha_c \dot{x}) + K_2(\theta_{max} - \theta - \alpha_c x) \geq 0 \tag{27}$$

Para garantir que a resposta do sistema seja amortecida e evite sobressinal, utiliza-se a técnica de alocação de polos, alocando 2 polos iguais e negativos como as constantes (autovalores) do sistema.

$$(s + \lambda)^2 = s^2 + 2\lambda s + \lambda^2 \tag{28}$$

$$-\ddot{\theta} - \alpha_c \ddot{x} + 2\lambda(-\dot{\theta} - \alpha_c \dot{x}) + \lambda^2(\theta_{max} - \theta - \alpha_c x) \geq 0 \tag{29}$$

D. Otimização

Enquanto o controlador de impedância atua na malha nominal para garantir uma interação suave e complacente entre o usuário e o andador (rejeitando distúrbios externos e mantendo uma distância de conforto), o controlador baseado em Funções de Barreira de Controle (CBF) atua como um filtro supervisor de segurança. A função deste filtro é garantir, de forma estrita, a invariância do conjunto seguro, mitigando riscos de quedas.A fusão dessas duas estratégias de controle é realizada em tempo real por meio de um algoritmo de Programação Quadrática (QP). O objetivo do otimizador é encontrar a ação de controle final segura (u_{safe}) que minimize o desvio em relação ao sinal nominal gerado pela impedância (u_{nom}), submetendo o sistema às restrições cinemáticas e dinâmicas impostas pelas barreiras de segurança. Formalmente, o problema de otimização QP é descrito por:

$$u^* = \arg\min_{u \in \mathbb{R}} (u_{cbf} - u_{nom})^2 \qquad \text{sujeito a:} \quad A_{cbf} u \leq b_{cbf} \tag{30}$$

Aplicando a restrição estruturada pela Equação (29), as matrizes de restrição linear A_{cbf} e b_{cbf}, que delimitam matematicamente a fronteira de segurança contra quedas frontais, são dadas por:

$$\begin{aligned} A_{\text{cbf}} &= -g_h \\ b_{\text{cbf}} &= -f_h - 2\lambda(\dot{\theta} + \alpha_c \dot{x}) - \lambda^2(\theta - \theta_{max} + \alpha_c x) \end{aligned} \tag{31}$$

Os componentes f_h e g_h são derivados analiticamente a partir do modelo dinâmico acoplado do sistema, de acordo com as Equações (10) e (11). O termo f_h isola a contribuição da evolução natural dos estados da planta, ao passo que g_h representa o ganho de acoplamento da entrada, mapeando como o esforço de controle aplicado ao andador impacta diretamente na dinâmica angular do usuário:

$$\begin{aligned} f_h &= (\ddot{\theta} - \alpha_c \ddot{x}) \\ g_h &= \frac{\alpha_c}{m_a} \end{aligned} \tag{32}$$

A partir dessa formulação, o parâmetro estrutural α_c determina a autoridade e a magnitude do acoplamento do atuador na dinâmica de inclinação do usuário. Adicionalmente, a constante de projeto λ atua como ganho de convergência da Função de Barreira de Controle Exponencial (ECBF), ditando quão agressivamente o filtro de segurança deve intervir à medida que o usuário se aproxima do ângulo limite de inclinação (θ_{max}).

E. Diagrama de Blocos

Nesta seção apresenta-se o diagrama de blocos para ilustrar a lógica de controle. Nele é possível notar que a CBF atua como um supervisor, encontrando o equilíbrio entre o controlador nominal e o controlador CBF, gerando um sinal de controle u_{safe}.

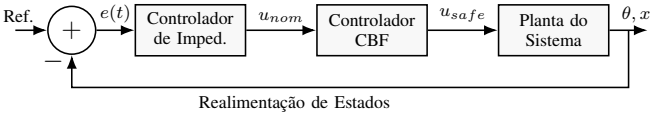

Fig. 2: Diagrama de blocos da malha de controle com filtro de segurança baseado em CBF.

F. Protocolo Experimental

Para testar o funcionamento da função de controle e sua eficácia, foi utilizado o *MATLAB/Simulink* no qual o controlador de Impedância calcula uma força nominal u_{nom} cuja função é manter o usuário próximo do andador. A CBF por sua vez calcula uma força segura u_{safe} que mantém o usuário dentro da região segura.

O intuito dessa simulação é introduzir uma situação crítica onde o controlador é obrigado a entrar em ação e evitar uma queda do usuário. Para isso, foi introduzido mais um elemento na equação (11), um distúrbio d. Para simular o empurrão, aplicou-se na simulação o distúrbio na forma de um pulso retangular com amplitude inicial de 100 N e duração de 0,3 segundos no instante t = 0.

Na Tabela I encontram-se os valores utilizados para os parâmetros do sistema e dos controladores. Foram utilizados valores hipotéticos, mas de magnitude coerente com aqueles encontrados na literatura.

TABELA I: Parâmetros dinâmicos e de controle do sistema acoplado humano-andador.

Categoria	**Parâmetro**	**Símbolo**	**Valor Nominal**
Dinâmica do Andador	Massa do andador	m_a	20
Dinâmica do Humano	Massa do usuário	m_h	70
	Comprimento do pêndulo	l	1.50
	Momento de inércia humano	I_h	157.50
Constantes Físicas	Rigidez da mola traseira	k_1	2500
	Rigidez da mola frontal	k_2	1000
	Altura da mola traseira	h_1	0.5
	Coeficiente de amortecimento	b	100
	Aceleração da gravidade	g	9.81
Controle Nominal	Constante de Rigidez Virtual	K_{imp}	10
	Constante de Amortecimento Virtual	B_{imp}	10
Filtro de Segurança (ECBF)	Fator de agressividade	α_c	0.8

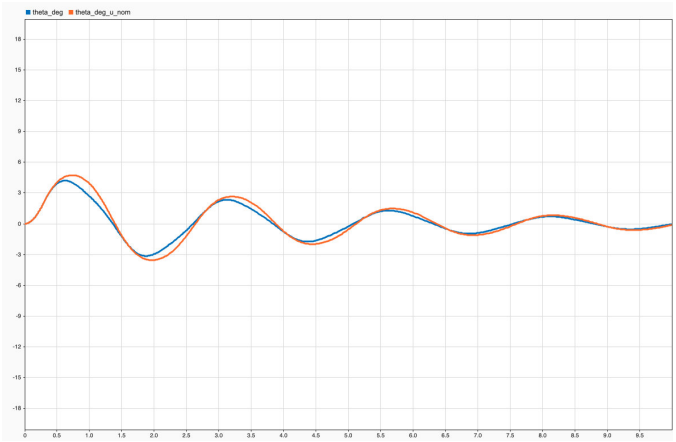

Fig. 3: Comportamento dinâmico do pêndulo em Graus sob força de 100 N, sendo a linha azul com CBF e a linha laranja sem CBF (Fonte: Autor, 2026)

G. Resultados Preliminares

Nesta seção serão apresentados os resultados obtidos nas simulações utilizando o *MATLAB/Simulink*.

A Figura 3 mostra o efeito do empurrão de 100 N no pêndulo apenas com o controlador de impedância (linha laranja) e com o controlador de Barreira (linha azul). Mesmo com um empurrão pequeno é possível notar que a CBF atua restringindo a inclinação do pêndulo, e diminuindo a amplitude do movimento. Essa ação fica evidente ao comparar o esforço de controle de u_{nom} e u_{safe} (Figura 4).

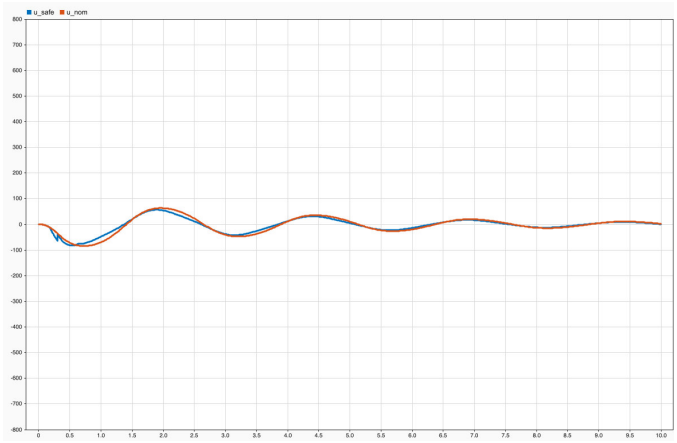

Fig. 4: Comportamento dos controladores sob esforço de 100 N sendo a linha azul com CBF e a linha laranja sem CBF (Fonte: Autor, 2026)

Em seguida, foram realizados testes com esforços maiores, para intensificar a ação do controlador de Barreira.

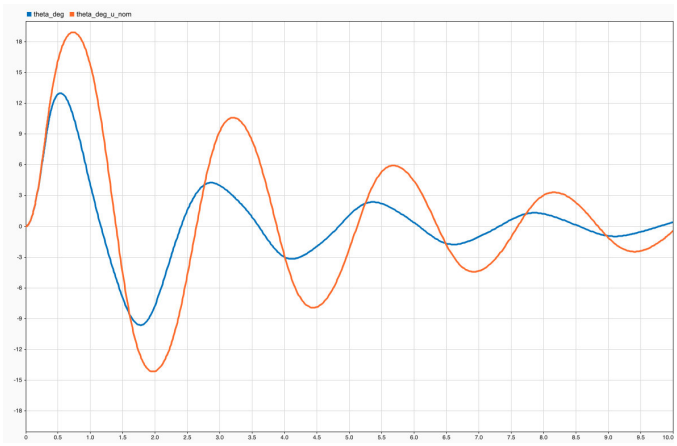

Fig. 5: Comportamento dinâmico do pêndulo em Graus sob força de 400 N, sendo a linha azul com CBF e a linha laranja sem CBF (Fonte: Autor, 2026)

A Figura 5 evidencia um esforço ainda maior do controlador de Barreira que impede que o pêndulo avance em direção ao limite do conjunto seguro. Enquanto no sistema sem a CBF o pêndulo chega próximo a 20° de amplitude, ao ativar a CBF, a mesma é capaz de limitar a amplitude próxima de 12°.

A divergência entre o controlador de Barreira e Controlador de Impedância fica ainda mais evidente com um empurrão de maior magnitude. Nota-se que há um pico de aceleração repentino no u_{safe}, isso acontece para impedir que haja uma colisão entre o usuário e o andador. Mas, mesmo com essa limitação que é imposta pela própria natureza do sistema, o mesmo é capaz de manter o usuário dentro do conjunto seguro.

É de suma importância também se atentar ao comportamento da função $h(t)$ que indica se a condição de segurança está sendo respeitada ou não.

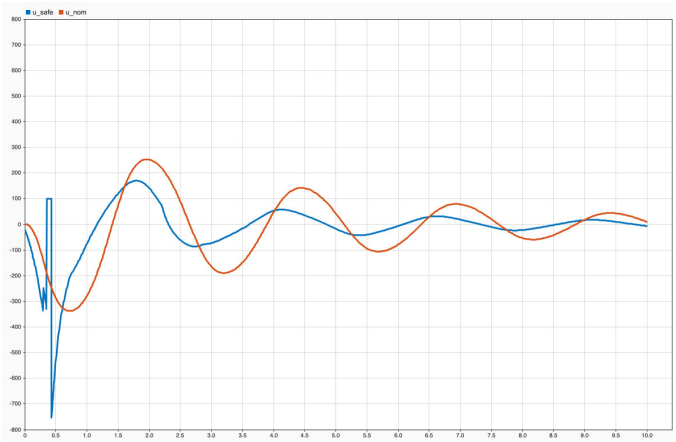

Fig. 6: Comportamento dos controladores sob esforço de 400 N sendo a linha azul com CBF e a linha laranja sem CBF (Fonte: Autor, 2026)

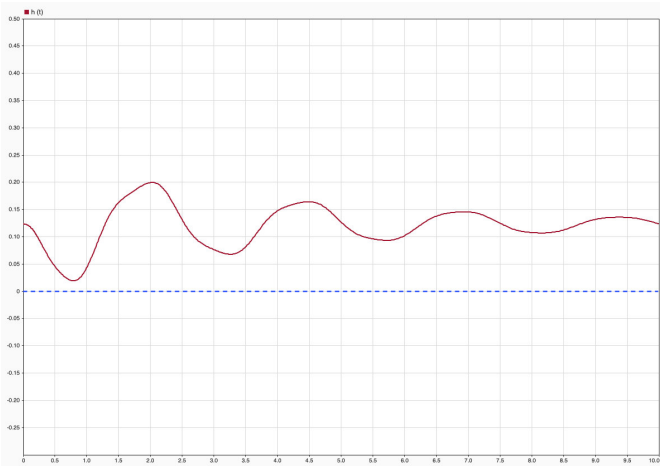
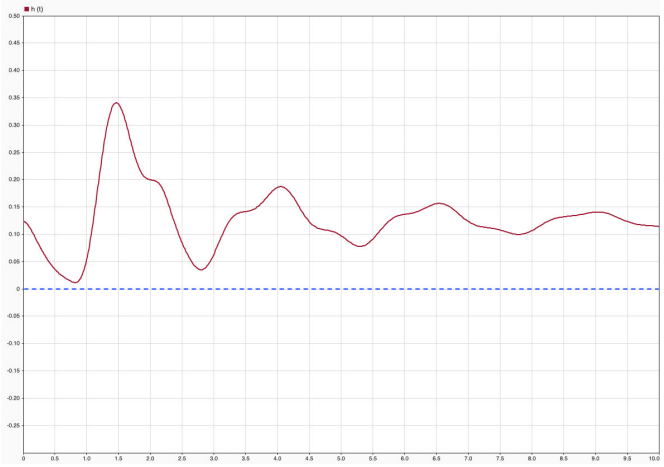
As curvas na Figura 7 comprovam que a CBF foi capaz de manter o sistema dentro do conjunto seguro, respeitando a condição imposta pela (22) em quase todos os esforços, com excessão do impulso de 500 N, em que a função $h(t)$ atinge valores negativos. É importante ressaltar que foi feita uma linha tracejada em azul com o objetivo facilitar a visualização do limite $h(t) = 0$.

IV. Conclusão



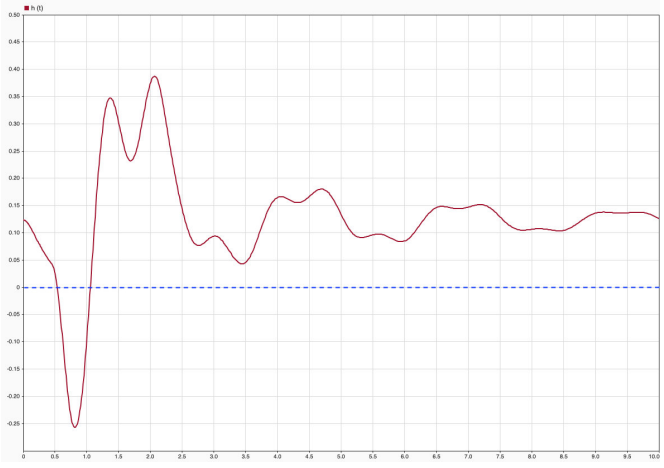
O presente trabalho apresentou como objetivo a elaboração de uma abordagem à segurança de usuários de dispositivos assistivos utilizando uma Função de Controle de Barreira otimizada com uma Lei de Controle de Impedância através de QP (Programação Quadrática. Foram feitas simulações computacionais utilizando um modelo biomecânico simplificado com o objetivo de compreender e avaliar o efeito do uso da CBF no sistema. Com auxílio da literatura foi estabelecido um limite de inclinação de $30°$ para o pêndulo invertido. Posteriormente, na Figura 5 fica evidente que a ação da CBF conteve a inclinação máxima em $12°$, abaixo fronteira crítica, prevenindo efetivamente uma queda irreversível.

Para trabalhos futuros tem-se em vista um refinamento do modelo biomecânico e das condições de barreira visando torná-los mais próximos da realidade, a realização de testes em um protótipo físico com o objetivo de identificar as principais limitações do dispositivo e como pode-se contorna-las.



Por fim, a análise dos resultados sugerem que a estratégia proposta apresenta-se como uma alternativa promissora para garantir a segurança formal na robótica assistiva.

V. Declaração de Uso de IA



Durante a preparação deste trabalho, os autores utilizaram ferramentas assistidas por IA, como o Grammarly para redação e revisão gramatical, e o Turnitin para verificação de plágio. Após o uso dessas ferramentas, os autores revisaram e editaram o conteúdo conforme necessário e assumem total responsabilidade pelo conteúdo desta publicação.

Abstract*—This study investigated differences in the mediolateral component of the ground reaction force (F_x) during gait in individuals with knee dysfunction using the Discrete Wavelet Transform (DWT). Data from a public gait database were analyzed, comparing healthy male participants with groups of individuals with left- or right-knee dysfunction matched 1:1 by body mass. Analyses were performed under the self-selected walking-speed condition. F_x signals were decomposed using a Daubechies wavelet (db4) at four levels, resulting in detail bands yhp1 to yhp4 and approximation band ylp4. For each band, the mean squared wavelet coefficient was calculated at the participant level. Between-group comparisons were performed using Welch's t-test, with Holm correction for 10 primary comparisons and effect-size estimation using Cohen's d with 95% confidence intervals. After adjustment for multiple comparisons, yhp3 (15.63–31.25 Hz) showed significantly lower values in the left-knee dysfunction group ($p_{Holm} = 0.0005$; $d = -0.566$) and the right-knee dysfunction group ($p_{Holm} < 0.0001$; $d = -0.704$). In the right-knee dysfunction group, a significant reduction was also observed in yhp4 (7.81–15.63 Hz; $p_{Holm} < 0.0001$; $d = -0.647$). No significant differences after Holm correction were identified in ylp4, yhp2, or yhp1. The results show that wavelet decomposition can identify scale-specific differences in the F_x signal associated with knee dysfunction. The consistent alteration in yhp3 on both sides indicates that this band constitutes a candidate quantitative feature for future investigation, although the current results do not establish diagnostic performance or allow the observed differences to be attributed to specific physiological mechanisms.

***Index Terms*—Discrete wavelet transform; gait analysis; knee dysfunction; ground reaction force; biomechanics.**

I. Introduction

Human gait is a complex motor task that depends on coordinated interaction between the musculoskeletal and neuromuscular systems. Instrumented gait analysis enables quantitative characterization of changes in locomotor patterns and is an important tool for assessing individuals with musculoskeletal impairments [1], [2]. Among the biomechanical variables used in this context, ground reaction forces (GRFs) represent the resultant mechanical interaction between the individual and the support surface during locomotion [2], [4].

The knee joint plays an important role during gait, contributing to load absorption and transmission, stability during the stance phase, and lower-limb progression [1], [4]. Structural or functional alterations of the knee can modify the locomotor pattern and, consequently, the characteristics of the forces exerted against the ground [3], [4]. Studies in populations with knee osteoarthritis and pain have also demonstrated differences in GRF patterns, including the mediolateral component, reinforcing the relevance of analyzing the complete force curve [10].

Conventional analysis of GRF curves often uses time-domain parameters such as peaks, impulse, and temporal variables. Although useful, these measures summarize global aspects of the signal and do not directly describe its combined variation over time and frequency [2], [5]. In nonstationary biomechanical signals, time-frequency approaches can provide complementary information [5], [11].

Among these approaches, the Wavelet Transform allows the signal to be decomposed into different scales with temporal and spectral localization. In its discrete form (DWT), successive filtering and downsampling stages produce detail and approximation coefficients associated with different frequency ranges [5]. This approach has been applied to gait data and GRFs, including total knee arthroplasty and classification of pathological gait patterns [7]– [9], [11].

Publicly available instrumented gait-analysis databases have expanded the possibility of investigating these characteristics in larger clinical samples. GaitRec contains ground reaction force records from healthy participants and individuals with different musculoskeletal impairments, together with clinical metadata [6]. The database provides raw and processed signals and allows secondary analyses of different GRF components [6].

Nevertheless, it remains relevant to investigate whether wavelet decomposition of the mediolateral component identifies signal characteristics associated with knee dysfunction. By examining different scales separately, the DWT may complement conventional descriptors without assuming a direct correspondence with specific physiological mechanisms.

Accordingly, the aim of this study was to investigate differences in the mediolateral component between healthy participants and individuals with unilateral knee dysfunction during gait at self-selected speed, using the DWT to characterize the signal across different frequency scales. Comparisons were performed separately for the left and right sides, evaluating the Mean Squared Wavelet Coefficient (MSWC) in each band.

Given the exploratory nature of the analysis, we hypothe-

sized that the distribution of this measure across the different wavelet bands would differ between healthy participants and individuals with knee dysfunction, without prespecifying which band should be altered or attributing such differences to a specific physiological mechanism.

II. Methodology

A. Data source, population, and definition of the experimental unit

Data were obtained from the publicly available GaitRec database, which contains bilateral GRF recordings from more than 2,000 patients with different musculoskeletal impairments and 211 healthy controls, together with clinical and demographic metadata [6]. Because men were more highly represented among both healthy participants and those with musculoskeletal impairment, the present analysis was restricted to male participants.

Eligible participants were men with gait recordings at self-selected speed and from the initial session (SPEED = 2; SESSION_TYPE = 1). Among those with knee dysfunction, 210 had left-side involvement, 160 right-side involvement, and 5 bilateral involvement. Bilateral cases were excluded because comparisons were defined by side.

The experimental unit was defined as the unique participant, rather than the limb or each isolated gait trial. Although the same participant could have multiple valid trials, these repeated trials were initially processed separately and subsequently aggregated into a single observation per participant and side. Thus, each individual contributed only once to each primary statistical comparison.

Participants were classified according to the presence and laterality of knee dysfunction based on the clinical information and annotations available in GaitRec [6]. According to Horsak et al. [6], before gait assessment each participant underwent a physical examination performed by a physician. The database annotation was subsequently performed manually by an experienced physiotherapist based on the available medical diagnosis. The knee class (K_xxx) includes, among other conditions, fractures of the patella, femur, or tibia near the knee, ligament or meniscal tears, and total knee arthroplasty. Laterality was determined from the AFFECTED_SIDE metadata field, coded as 0 for left, 1 for right, and 2 for bilateral. Participants were therefore assigned to the left- or right-knee dysfunction groups according to the laterality recorded in the database, and bilateral cases were excluded from the present analysis. The GaitRec publication also reports that no information is available on the history of similar or other types of musculoskeletal injuries for either patients or healthy controls; this limitation of the database should be considered when interpreting the results.

B. Walking condition and trial selection

The self-selected walking-speed condition (SPEED = 2) from the initial session (SESSION_TYPE = 1) was analyzed [6]. According to the GaitRec description, healthy controls had a mean self-selected walking speed of 1.27 ± 0.13 m/s.

Metadata were linked to the raw-signal tables using participant and session identifiers, retaining only trials that simultaneously met both criteria.

C. Body-mass matching

One-to-one nearest-neighbor matching (NNM) used body mass as the only variable, without replacement and without a caliper.

A total of 104 eligible healthy controls were identified, all of whom were included as the reference group. Matching was performed separately for the left- and right-side comparisons, always against the same set of controls. To define the sequence of the algorithm, controls were ordered according to the proximity of their body mass to the median body mass of the dysfunction candidates; then, for each control, the remaining candidate with the smallest absolute body-mass difference was selected. Each final comparison included 104 controls and 104 participants with dysfunction. After matching, 106 candidates in the left group and 56 in the right group remained unmatched, in addition to the 5 bilateral cases previously excluded.

Post-matching body-mass balance was assessed using Welch's t-test and Cohen's d effect size. Balance results are presented in Table I.

D. Biomechanical signal and preprocessing

The biomechanical variable of interest was the mediolateral component (F_x). GaitRec reports that the signals were originally digitized at 2,000 Hz; however, the raw signals made available were previously downsampled to 250 Hz as part of the rehabilitation center's internal procedures [6]. The present analysis used these RAW signals at 250 Hz, preserving the original temporal length of each trial.

Missing values (NaN) located at the ends of the series were interpreted as structural table padding and removed. Any internal gaps would have been linearly interpolated; however, none of the trials included in the analysis contained internal gaps. Trials without a valid signal or with insufficient length for four levels of decomposition would have been excluded.

No additional digital filter was applied to the mediolateral signal before the DWT. This distinction is important because GaitRec provides both RAW and processed (PRO) signals: the PRO data were filtered by the database authors using a second-order low-pass Butterworth filter with a cutoff frequency of 20 Hz, temporally normalized to 101 points, and normalized by body mass; these procedures were not reapplied to the RAW signals used in the present analysis [6].

E. Discrete Wavelet Transform

Time-frequency analysis was performed separately on each original trial, without prior temporal normalization, using the DWT with a fourth-order Daubechies wavelet (db4), four decomposition levels, and symmetric boundary extension (symmetric). This procedure mirrors values at the signal edges during wavelet filtering, reducing artificial discontinuities associated with edge processing. Given the sampling

frequency of 250 Hz and a Nyquist frequency of 125 Hz, the decomposition produced four detail coefficients and one approximation coefficient. The frequency ranges reported for each level correspond to the approximate theoretical bands of the decomposition: yhp1, 62.50–125.00 Hz; yhp2, 31.25–62.50 Hz; yhp3, 15.63–31.25 Hz; yhp4, 7.81–15.63 Hz; and ylp4, 0–7.81 Hz. These bands were interpreted as signal scales and were not directly attributed to specific physiological events of the gait cycle, because the study did not include complementary kinematic or neuromuscular measures capable of supporting such correspondence.

F. Mean squared wavelet coefficients (MSWC)

For each trial and wavelet band, the mean squared wavelet coefficient (MSWC) was calculated. For a band j containing N_j coefficients $c_{j,k}$, the measure was defined as:

$$E_j = \frac{1}{N_j} \sum_{k=1}^{N_j} c_{j,k}^2 \tag{1}$$

This definition corresponds to the mean of the squared wavelet coefficients and reduces the influence of the number of coefficients produced at each decomposition level. The measure does not correspond to Relative Wavelet Energy, which is defined as the ratio between the energy of a band and the total signal energy. After calculating the MSWC for each trial, the values obtained from repeated trials for each participant were averaged separately for each band, resulting in a single measure per participant, side, and band.

G. Temporal normalization for graphical representation

Temporal normalization was used exclusively for the construction of Figs. 1 and 2 and was not part of the MSWC calculation or the statistical analyses. For Fig. 1, each trial was resampled to 101 points, corresponding to 0%–100% of the gait cycle. Repeated trials from each participant were then aggregated to obtain an individual curve, and these curves were used to calculate the group mean curves. The shaded regions in Fig. 1 represent the mean and standard deviation across participants.

For Fig. 2, the group mean curves obtained from the normalized signals were subjected to the db4 DWT solely to visually illustrate the distribution of coefficients across the five wavelet subbands.

These temporal-normalization and group-mean decomposition procedures were used only for graphical representation. For the quantitative analysis, the DWT was applied separately to the original trials, without temporal normalization, preserving the length of each signal. The resulting coefficients were used to calculate the MSWC, which was subsequently used in the statistical comparisons.

H. Statistical comparisons and multiple-testing control

The primary comparisons were performed separately for each side. The left limb of healthy participants was compared with the left-knee dysfunction group, whereas the right limb of healthy participants was compared with the right-knee dysfunction group. Thus, each analysis used the same-side limb of healthy controls as the reference, without averaging the two limbs. For each of the five wavelet subbands, participant-level MSWC values were compared between the healthy group and the knee-dysfunction group using Welch's t-test. Although nearest-neighbor matching associated participants with similar body masses, this procedure was used to balance the groups and does not, by itself, establish a natural dependence between observations. Therefore, the primary analysis treated the groups as independent samples. For each comparison, the mean, standard deviation, mean between-group difference (defined as dysfunction minus healthy), and its 95% confidence interval (95% CI) were calculated. Effect size was estimated using Cohen's d, calculated from the pooled standard deviation. The 95% CIs for Cohen's d were obtained by bootstrap with 5,000 resamples with replacement and a fixed random seed to ensure reproducibility.

Because five subbands were evaluated for each side, totaling 10 primary comparisons, p values were jointly adjusted using the Holm procedure to control the family-wise error rate arising from multiple tests. A comparison was considered statistically significant when the Holm-adjusted p value was < 0.05. Raw p values were also retained and are presented in Table II.

As a sensitivity analysis, the same 10 comparisons were repeated using the paired t-test, preserving the correspondence established by the matching procedure and again applying Holm correction. This analysis was performed to determine whether the main conclusions were maintained when the matched-pair structure was accounted for statistically, without replacing the primary Welch analysis.

The analytical pipeline was implemented in Python, using NumPy and pandas for data manipulation, SciPy for statistical tests, and PyWavelets for DWT decomposition.

TABLE I
BODY-MASS BALANCE AFTER MATCHING

Comparison	Group	N	Body mass, mean ± SD (kg)	p value	Cohen's d
Healthy × Left knee	Healthy	104	82.34 ± 14.58	0.8578	-0.025
	Left knee	104	81.98 ± 14.64		
Healthy × Right knee	Healthy	104	82.34 ± 14.58	0.8012	0.035
	Right knee	104	82.85 ± 14.13		

III. RESULTS

A. Participant matching

After body-mass matching, each comparison included 104 healthy participants and 104 participants with knee dysfunction.

Body mass was similar between groups for both the left-side comparison (82.34 ± 14.58 vs. 81.98 ± 14.64 kg; $p = 0.8578$; $d = -0.025$) and the right-side comparison (82.34 ± 14.58

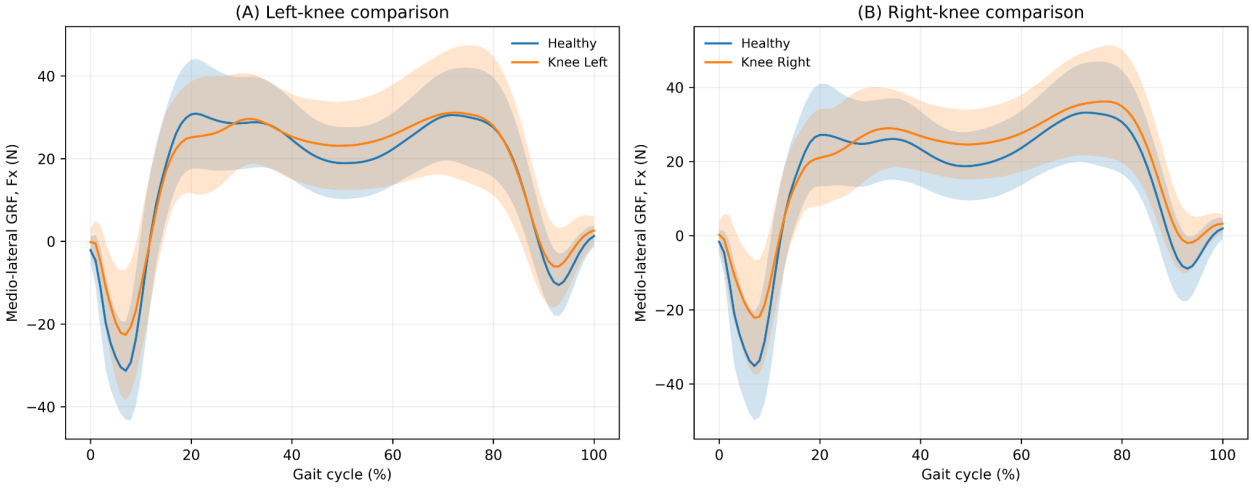

Fig. 1. Mean morphology of the mediolateral ground reaction force (F_x) across the gait cycle for (A) the left-knee comparison and (B) the right-knee comparison. Trials were temporally normalized to 101 points exclusively for graphical representation. Lines indicate group means, and shaded regions represent mean ± SD across participants. Temporal normalization was not used in the MSWC calculation or statistical analyses.

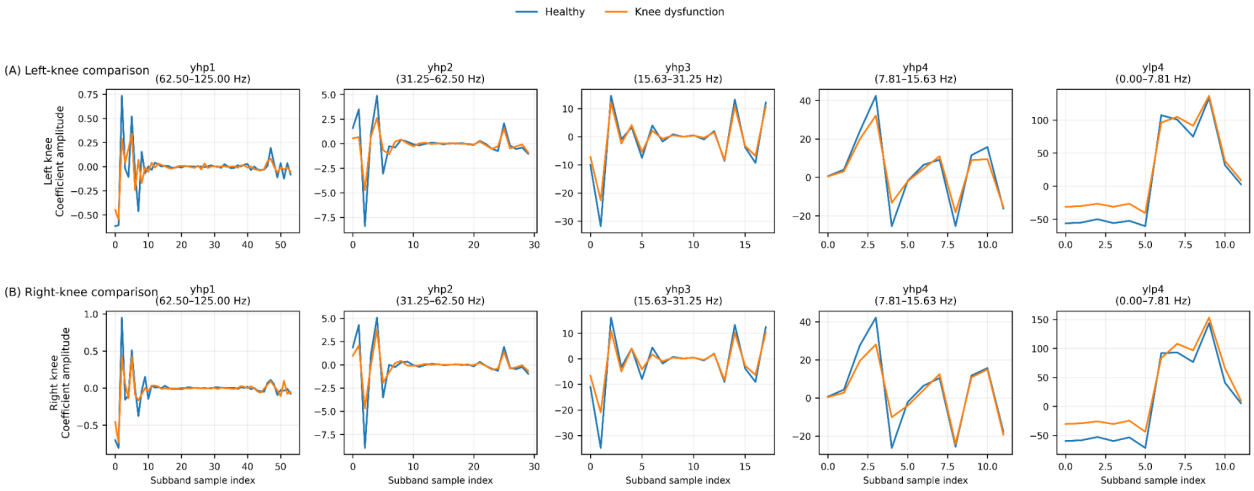

Fig. 2. Illustrative db4 DWT decomposition of the temporally normalized mean F_x curves for (A) the left-knee comparison and (B) the right-knee comparison. Panels show the detail coefficients yhp1 to yhp4 and the approximation coefficient ylp4 as a function of the sample index within each subband. This graphical decomposition was not used in the MSWC calculation or statistical inference, which were performed on the original trials without temporal normalization.

Note: Frequencies in Hz. The 95% CIs reported for the mean difference and Cohen's d were not adjusted for multiple comparisons. Statistical significance of the primary comparisons was determined using Holm-adjusted p values.

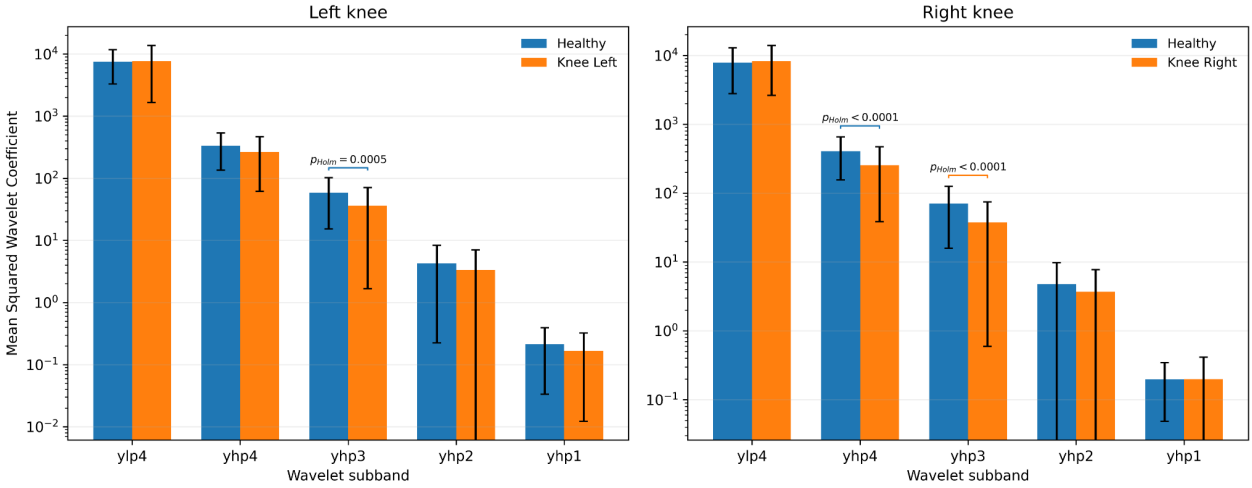

Fig. 3. Mean Squared Wavelet Coefficient (MSWC; mean ± SD) at the participant level for the five DWT subbands in the left- and right-knee comparisons. Statistically significant differences are identified by Holm-adjusted p values, considering the 10 primary comparisons. The y-axis is shown on a logarithmic scale because MSWC values span several orders of magnitude.

vs. 82.85 ± 14.13 kg; $p = 0.8012$; $d = 0.035$), indicating negligible differences after matching (Table I).

B. Graphical representation and wavelet decomposition of the mediolateral signal

Fig. 1 presents the mean morphology of the F_x component across the gait cycle after temporal normalization used exclusively for visualization. Fig. 2 illustrates the db4 DWT decomposition of the normalized mean curves into the five subbands, whereas Fig. 3 presents participant-level MSWC values. As described in the methodology, the temporal normalization and the decomposition shown in Fig. 2 are for graphical purposes; the MSWC calculation and statistical tests were based on the DWT applied to the original trials without temporal normalization. Complete quantitative results are provided in Table II.

C. Left-knee comparison

In the yhp3 band (15.63–31.25 Hz), the mean squared wavelet coefficient was 58.66 ± 43.38 in the healthy group and 36.40 ± 34.74 in the left-knee dysfunction group. The mean difference, defined as dysfunction minus healthy, was -22.26, with a 95% CI of -33.01 to -11.51. The difference had a raw p value < 0.0001 and remained statistically significant after Holm correction for the 10 primary comparisons ($p_{Holm} = 0.0005$). The effect size was moderate ($d = -0.566$; 95% CI: -0.862 to -0.293). The negative sign indicates lower values in the knee-dysfunction group.

In yhp4, the difference observed before adjustment ($p = 0.0115$; $d = -0.354$) did not remain significant after Holm correction ($p_{Holm} = 0.0803$). The ylp4, yhp2, and yhp1 bands also showed no significant differences after adjustment.

D. Right-knee comparison

In the yhp3 band (15.63–31.25 Hz), the mean squared wavelet coefficient was 70.67 ± 54.82 in the healthy group and 37.70 ± 37.11 in the right-knee dysfunction group. The mean difference was -32.97, with a 95% CI of -45.78 to -20.16. This difference had $p_{Holm} < 0.0001$ and an effect size of $d = -0.704$ (95% CI: -0.987 to -0.444).

In the yhp4 band (7.81–15.63 Hz), the values were 405.72 ± 249.42 for healthy participants and 254.83 ± 216.10 for those with right-knee dysfunction. The mean difference was -150.89, with a 95% CI of -214.70 to -87.08. The difference remained significant after Holm adjustment ($p_{Holm} < 0.0001$), with an effect size of $d = -0.647$ (95% CI: -0.980 to -0.346). No statistically significant differences after Holm correction were observed in ylp4, yhp2, or yhp1.

In the paired sensitivity analysis, yhp3 remained significant on the left ($p_{Holm} = 0.0023$) and right ($p_{Holm} < 0.0001$), as did yhp4 on the right ($p_{Holm} < 0.0001$). For yhp4 on the left, the result differed from the primary analysis ($p_{Holm} = 0.0429$ in the paired test vs. 0.0803 in Welch's test), indicating that this inference was sensitive to the statistical treatment of the matched pairs.

IV. Discussion

The analysis revealed a selective pattern of between-group differences, concentrated primarily in yhp3 and, on the right side, also in yhp4. The presence of moderate effects in these comparisons and the persistence of the bilateral yhp3 finding across both inferential strategies indicate that the observed differences were not limited to statistical significance but were concentrated at specific signal scales.

A. Multiscale pattern associated with knee dysfunction

yhp3 showed the most consistent pattern: MSWC values were lower in the dysfunction groups on both sides, with moderate effects ($d = -0.566$ on the left and $d = -0.704$ on the right) and 95% CIs that did not include zero. This behavior suggests that the information capable of differentiating the

groups, under the analyzed conditions, was concentrated at this decomposition scale.

On the right side, yhp4 also showed a reduction with a moderate effect ($d = -0.647$), extending the pattern to the immediately lower scale. On the left, however, yhp4 did not remain significant in the primary analysis after Holm correction, although it reached the significance threshold in the paired test.

These findings should be interpreted in the signal domain, without direct attribution to physiological mechanisms. The study did not include kinematics, electromyography, or other measures capable of establishing the biomechanical origin of the observed differences.

B. Contribution and limitations of wavelet analysis

The absence of differences after Holm correction in ylp4, yhp2, and yhp1 reinforces the selective nature of the observed pattern but does not allow the conclusion that the biomechanical phenomena represented at these scales are preserved.

The main contribution of the DWT in this context was to enable separate analysis of signal components that would otherwise be condensed into global descriptors such as peaks, impulse, or temporal parameters. The use of wavelets in gait and ground reaction force data has precedent in the literature [7]– [9], and the present results support its use as an exploratory tool for multiscale characterization.

However, the study did not evaluate diagnostic or classification performance; therefore, yhp3 should be considered a candidate quantitative signal feature rather than a diagnostic biomarker.

C. Limitations

Several limitations should be considered. This is a retrospective analysis of a public database, with no control by the authors over participant selection, clinical procedures, or original signal acquisition.

The GaitRec "knee dysfunction" category is clinically heterogeneous, including fractures, ligament or meniscal injuries, and arthroplasty [6]; therefore, the results should not be generalized to a specific pathology.

The analysis was restricted to men and to gait at self-selected speed, which limits generalization to women and other walking speeds.

Matching considered body mass only; age, height, diagnosis, severity, and other clinical characteristics remained potential confounding factors.

In addition, the analysis included only the mediolateral component of the ground reaction force, without complementary kinematic, electromyographic, or clinical measures to support mechanistic interpretations.

D. Implications and future studies

The consistency of yhp3 supports its investigation in independent and clinically more homogeneous samples.

Future studies should stratify participants by diagnosis and clinical severity, include both sexes, control additional confounding factors, and integrate GRF with kinematics, electromyography, and other biomechanical measures.

Any eventual clinical application of these features will depend on external validation and formal evaluation of classification performance.

V. Conclusion

Multiscale analysis of the mediolateral ground reaction force component using the Discrete Wavelet Transform identified differences between healthy participants and individuals with knee dysfunction, concentrated primarily in yhp3. The bilateral consistency of this finding, with moderate effects and persistence across both statistical approaches, supports its investigation as a candidate quantitative signal feature.

The results also show that the Discrete Wavelet Transform can complement global gait descriptors by localizing differences at specific signal scales. However, the findings remain limited to group-level differentiation and do not establish physiological mechanisms or diagnostic performance.

Validation in independent, clinically more homogeneous samples accompanied by other biomechanical measures will be necessary to determine the functional relevance and potential applicability of these features.

Ethical Considerations

This study used a public, anonymized clinical database [6]. The original experimental procedures, data collection, and publication of the GaitRec database were conducted in accordance with ethical standards and approved by the local Ethics Committee of Lower Austria (Approval No. GS1-EK-4/299-2014) [6].

***Abstract*— Aortic stenosis is one of the most common valvular diseases in the adult population and is associated with significant hemodynamic and energetic changes in the cardiovascular system. In this context, exergy analysis emerges as a promising approach to quantify the irreversibilities involved in cardiac function. The aim of this study was to develop and validate CardioExergy, a computational platform designed for the exergy analysis of the human heart under varying degrees of aortic stenosis. The web-based platform integrates mathematical models of ventricular mechanics, circulatory dynamics, and exergy balance; it is implemented in Python, with interfaces developed via Google AI Studio. The tool allows for the simulation of different aortic valve areas (AVA) and the calculation of variables such as transvalvular pressure gradient, cardiac work, energy metabolism, exergy destruction, and exergy efficiency. Validation was performed by comparing the obtained results with data previously published in the literature. The simulations adequately reproduced expected physiological behavior, demonstrating increased exergy destruction and reduced cardiac efficiency as the stenosis progressed. The results indicate that CardioExergy is a robust tool for *in silico* studies of cardiovascular function, capable of supporting research in cardiac physiology, bioengineering, and the energetic analysis of the cardiovascular system.**

Keywords*— *Exergy Analysis, Aortic Stenosis, Computational Modeling, Cardiovascular System, Biomedical Engineering

I. Introduction (*Heading 1*)

Aortic stenosis is a common valvular heart disease, particularly among the elderly, characterized by a reduction in valve area and the consequent difficulty in ejecting blood from the left ventricle [1]. This condition increases the transvalvular pressure gradient, imposes a cardiac workload, and intensifies energy losses within the cardiovascular system, progressively compromising cardiac performance and efficiency. Assessing the effects of aortic stenosis requires approaches that consider not only hemodynamic aspects but also energetic ones [2]. In this context, exergy analysis enables the investigation of the heart's ability to convert metabolic energy into useful work, providing quantitative indicators regarding cardiac efficiency and energy losses associated with structural and functional changes in the cardiovascular system [3]. Exergy represents the maximum useful work obtainable from a system in equilibrium with its environment and serves as a valuable tool for analyzing biological systems [4]. Unlike conventional energy analysis, it evaluates energy quality and quantifies process irreversibilities, allowing for a more comprehensive understanding of energy losses and the efficiency of cardiac function [5]. Cardiac exergy analysis remains limited by a scarcity of models integrating relevant physiological variables and a lack of accessible computational tools [6]. To address this need, CardioExergy was developed—a web-based platform that combines hemodynamic, metabolic, and thermodynamic aspects to simulate varying degrees of aortic stenosis. The platform enables the estimation of indicators such as cardiac output, ventricular work, destroyed exergy, and exergy efficiency, thereby contributing to the understanding of cardiac energy performance under physiological and pathological conditions and across different aortic valve areas (AVA).

II. Materials and Methods

A. Mathematical Model

Although the present model is based on the exergetic approach proposed by Roll et al. (2019) [2], certain adaptations were made to extend its applicability and analytical capabilities. Unlike the original model, this study incorporates heart rate as a control variable, enabling an assessment of cardiovascular system behavior under varying physiological demands. Furthermore, the valvular discharge coefficient (Cd) was introduced; this parameter represents the actual efficiency of blood flow through the aortic valve and allows for the investigation of how valve geometry impacts energy losses. The model also encompasses thermal analyses and various simulation protocols, including scenarios of cardiac stress as well as pre- and post-intervention conditions.

Basal metabolism (1), M_{Heart}, was determined according to the model proposed by Suga [7]:

$$M_{Heart} = a \cdot W_{Heart} + b \quad (1)$$

Where a and b are model parameters and W_{Heart} is the work performed by the heart.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

The exergy destroyed (2) at the aortic valve, B_{d_aortic}, is the stenosis power associated with the heartbeat (W_{sten}) multiplied by the ratio of the reference temperature (T_{ref} to the internal temperature (T_{int}).

$$B_{d_aortic} = W_{sten} \cdot \left(\frac{T_{ref}}{T_{int}}\right) \quad (2)$$

The heart's mechanical exergetic efficiency (3), η_1, is defined as the ratio between the reference power made available for pumping (W_{Heart_ref}) and the total metabolic exergy, expressed as a percentage [2]:

$$\eta_1 = 100 \cdot \left(\frac{W_{Heart_ref}}{B_M}\right) \quad (3)$$

The exergy transfer efficiency (4), η_2, represents the amount of energy utilized to move and heat the blood, being the ratio of blood exergy (ΔB_{blood}) to basal metabolism [2]:

$$\eta_2 = 100 \cdot \left(\frac{\Delta B_{blood}}{B_M}\right) \quad (4)$$

The scope of the present study was the analysis of the left heart, modeled as a thermodynamic system (Fig. 1), in order to investigate blood flow dynamics through the cardiac chambers and their respective valvular structures [8].

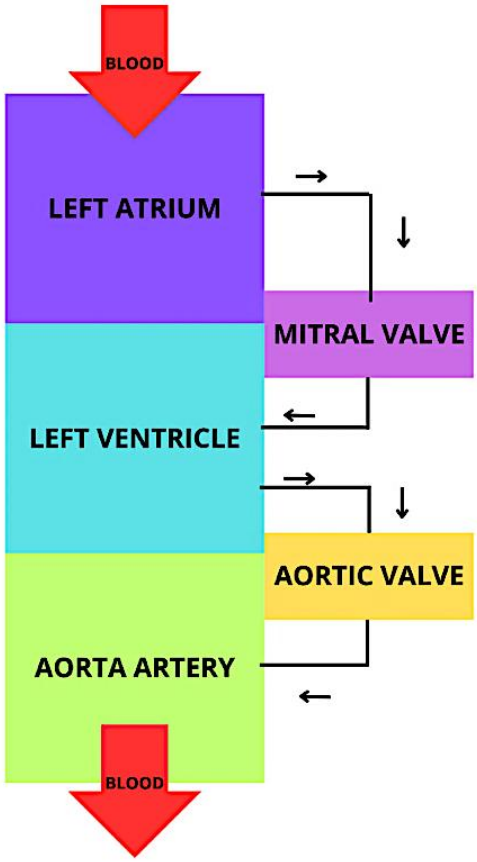

Fig. 1. Thermodynamic system of the left side of the human heart

B. Computational Implememntation

CardioExergy is an interactive web-based tool developed for the analysis of cardiac bioenergetics, assisting students, researchers, and healthcare professionals in investigating alterations associated with pathological conditions. It was implemented using Python, and the interfaces were developed with the support of Google AI Studio.

This web-based computational tool enables "in silico" studies by simulating various physiological and pathological scenarios of the cardiovascular system. The environment allows for the quantitative evaluation of hypotheses, sensitivity analyses, and the investigation of how hemodynamic, metabolic, and exergetic parameters influence cardiac performance.

C. Validation Protocol

The validation of the proposed mathematical model was carried out by evaluating its ability to reproduce physiological behaviors and hemodynamic trends described in the literature [2, 3] for varying degrees of aortic stenosis. To this end, simulation results were analyzed regarding the physical, mathematical, and physiological consistency of the calculated variables, including cardiac output, transvalvular pressure gradient, ventricular mechanical work and power, destroyed exergy, and exergy efficiency indices.

Additionally, the model's ability to adequately represent disease progression was investigated by verifying whether a gradual reduction in aortic valve area (AVA) produced responses consistent with the known pathophysiological mechanisms of aortic stenosis. Specifically, the expected observations included an increase in the transvalvular pressure gradient, elevated metabolic demand and cardiac work, greater exergy destruction resulting from blood flow irreversibilities, and a reduction in the cardiovascular system's overall energy efficiency. The agreement between these trends and those reported in the literature served as the criterion for the model's qualitative validation.

Simulation protocols (Table I) were established to analyze the model's behavior under various conditions related to aortic stenosis, including disease progression, as well as variations in heart rate, cardiac temperature, and valve geometry.

TABLE I. SIMULATIONS PROTOCOLS

Protocol	***Description***	***Objective***
Standard Test	Variation of AVA from 0.5 to 3.5 cm² in regular increments	Evaluate typical clinical progression and identify efficiency limits
Cardiac Stress	Simulation of different HR values for each AVA	Identify vulnerability under tachycardia or bradycardia

III. RESULTS

A. Software Overview

CardioExergy is an academic platform designed for simulating cardiac bioenergetics under conditions of aortic stenosis, based on mathematical models that apply principles of the Second Law of Thermodynamics [9]. The digital environment was developed to support teaching and research activities, offering users an interactive interface that enables the exploration of the heart's energy efficiency mechanisms across various clinical scenarios. The platform can be accessed via the following link: https://cardioexergy.mathematicalmodels.app/

The system usage workflow is structured sequentially. Initially, the user accesses the portal and selects the language.

Next, upon selecting the "Start Simulator" option, the participant is directed to the initial screen. The introductory screen provides context for the tool and outlines the theoretical background. From there, the user can enter values for heart rate, temperature, and discharge coefficient in the control panel (Fig. 2). It is also possible to select the AVA interval for the simulation.

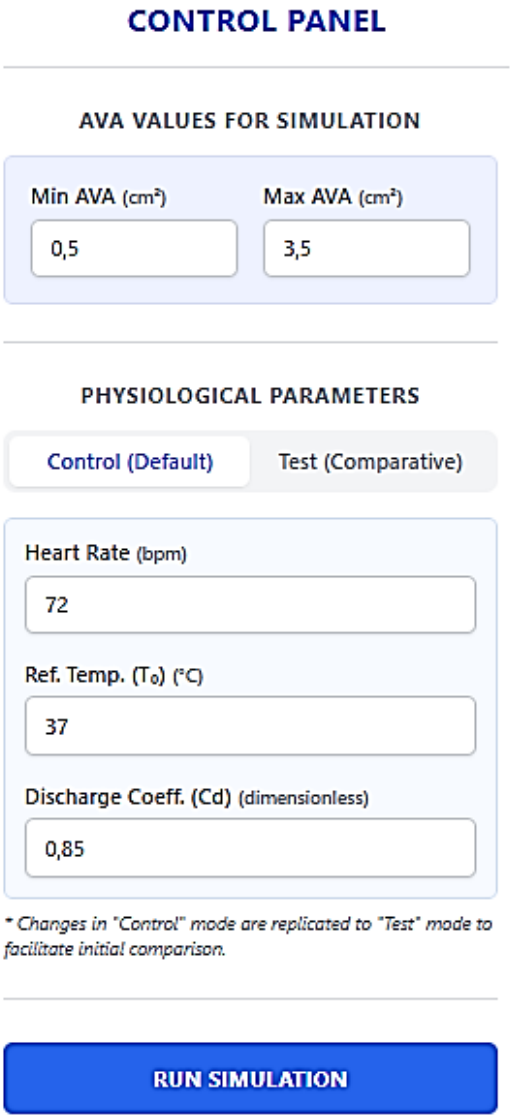

Fig. 2. Control Painel of cardioExergy

Once input parameters are defined and the simulation is executed, the results are displayed in specific interface tabs, allowing for an organized view of calculated variables, graphs, and cardiovascular system performance indicators. Additionally, the platform offers a comparative analysis mode, enabling users to run multiple simulations with different sets of initial parameters and compare the resulting data. This feature facilitates the assessment of how physiological, hemodynamic, and thermodynamic changes affect model behavior, supporting sensitivity studies, parametric analyses, and investigations into various clinical scenarios.

The central area of the interface features the "View Charts" tab (Fig. 3), designed to display simulation results via interactive graphs, allowing users to analyze the behavior of variables of interest under different simulated conditions. Complementarily, the "View Data" tab provides the corresponding numerical data in a tabular format, enabling detailed inspection of the values generated by the model.

The "Results" tab presents a textual interpretation of the findings, highlighting their physiological, hemodynamic, and thermodynamic significance, as well as their potential implications for cardiovascular function and the exergetic analysis of the heart.

The "Activities" tab proposes simulation activities and scenarios that encourage exploration of the computational model, helping users understand how input parameters influence calculated variables and the system's overall behavior.

Finally, the remaining tabs include an AI-based virtual assistant designed to support users while navigating the platform, and a "Help" section containing information, guidelines, and detailed instructions regarding the computational environment's features and capabilities.

Fig. 3. Web plattaform tabs

B. *Simulation of Different Degrees of Aortic Stenosis*

The first simulation was conducted with a heart rate of 72 bpm at 37°C and a discharge coefficient (Cd) of 0.85, aiming to compare variations in Aortic Valve Area (AVA)—categorized as severe (1 cm²), moderate (1.5 cm²), mild (2 cm²), or healthy (3.5 cm²). Shown below are the exergy graph (Fig. 4) based on AVA, and the efficiencies η_1 and η_2 (Figs. 5 and 6, respectively) corresponding to the different levels of aortic stenosis represented by the various AVA values.

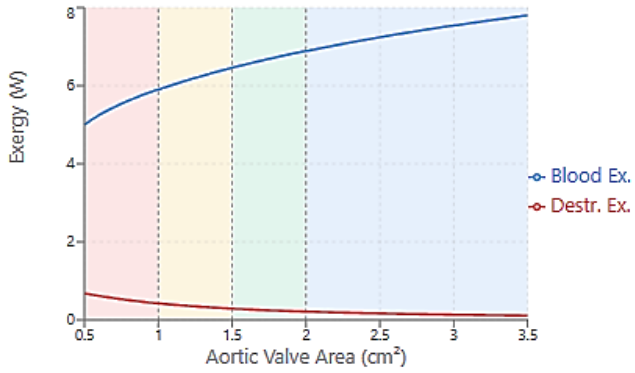

Fig. 4. Blood exergy and destroyed exergy as function of AVAs.

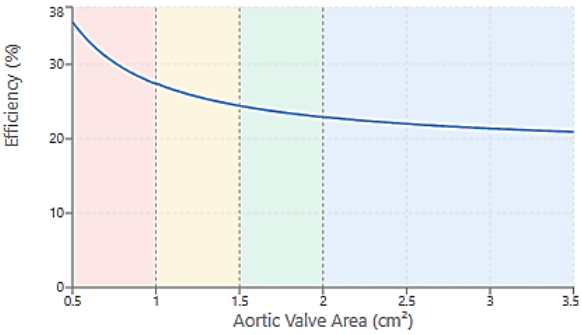

Fig. 5. Exergy Mechanical Effiency as function of AVAs.

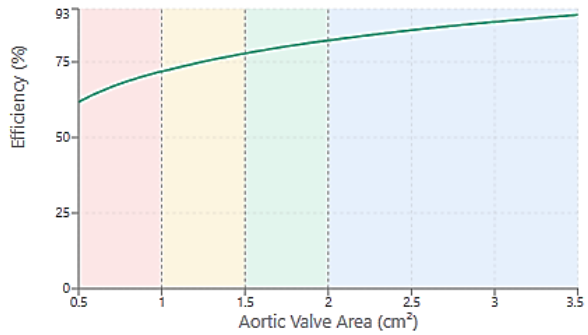

Fig. 6. Exergy Mechanical Effiency as function of AVAs.

C. Clinical Scenario Simulations

The second simulation was performed by comparing the behavior of exergy (Fig. 7), mechanical efficiency (Fig. 8), and exergy transfer efficiency (Fig. 9) at heart rates of 72 bpm (control) and 100 bpm (test), considering a temperature of 37°C and maintaining the discharge coefficient at 0.85.

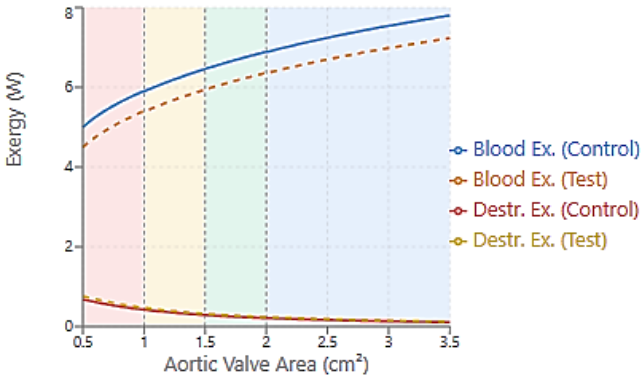

Fig. 7. Blood exergy and destroyed exergy as function of AVAs.

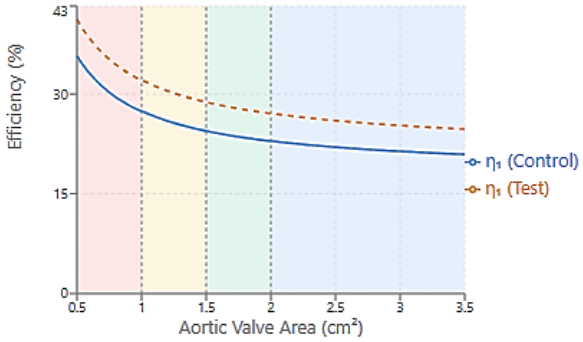

Fig. 8. Exergy Mechanical Effiency as function of AVAs.

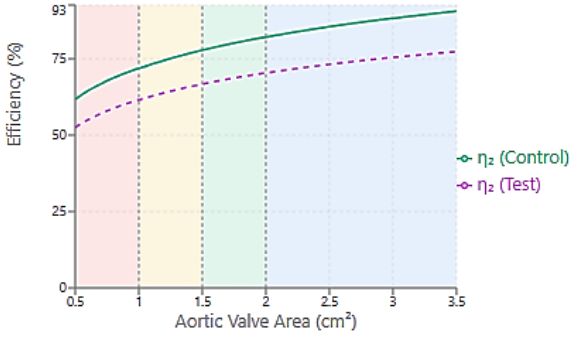

Fig. 9. Exergy Mechanical Effiency as function of AVAs.

Table II shows a comparison of the percentage change in results from Roll et al. [2] and CardioExergy,

TABLE II. COMPARAÇÃO DOS RESULTADOS

Variable	*AVA interval (cm²)*	*Roll et al. variation (%)*	*CardioExergy variation (%)*
Valve Exergy Destruction	1 → 2	-42.86	-50.0
	2 → 3.5	-37.5	-47,62
Blood Exergy	1 → 2	+12.0	+16.78
	2 → 3.5	+3.57	+13.21
Exergetic Mechanical Efficiency	1 → 2	-9.38	-16.31
	2 → 3.5	-13.79	-8.72
Exergy Transfer Efficiency	1 → 2	+10.16	+14.29
	2 → 3.5	+2.84	+10.30

IV. DISCUSSION

A. Validation of the simulations

The results obtained with CardioExergy showed behavior consistent with that reported by Roll et al. (2019) [2], highlighting the effects of aortic stenosis progression on the cardiovascular system's energetic performance. In the first simulation, as the aortic valve area was reduced from 3.50 cm² to 1.00 cm², an increase in exergy destruction at the valves was observed (from 0.11 to 0.42 W), accompanied by a reduction in the exergy transferred to the blood (from 7.80 to 5.90 W) and in the exergetic efficiency η_2 (from 90.58% to 71.85%). These trends align with the findings of Roll et al. [2], who demonstrated that a decrease in valve area leads to increased thermodynamic irreversibilities and reduced cardiac energy conversion efficiency.

In the second simulation, the observed increase in cardiac work confirms the higher energy demand placed on the left ventricle under conditions of severe stenosis, reproducing the same physical behavior described in the reference model. Increasing the heart rate from 72 to 100 bpm raises cardiac output and mechanical cardiac work, as more contraction-relaxation cycles occur within the same time interval, requiring greater myocardial effort [10]. Under both physiological and pathological conditions, an increased heart rate helps maintain the supply of oxygen and nutrients to the tissues. Consequently, myocardial oxygen consumption rises and cardiac metabolism intensifies, resulting in greater generation of metabolic exergy [11].

In both simulations, cases of more severe aortic stenosis show an increase in thermodynamic irreversibilities within the cardiovascular system, evidenced by greater exergy destruction. This occurs due to blood flow turbulence and viscous losses at the narrowed valve, which intensify dissipative mechanisms and reduce the energy available for useful work. Consequently, a decrease in exergy efficiency is observed, confirming that exergy destruction is a key indicator of stenosis severity. Thus, the more severe the stenosis, the greater the energy dissipation, the lower the capacity to

convert metabolic energy into useful work, and the lower the heart's overall efficiency. The apparent "higher efficiency" at advanced stages of stenosis is, in fact, a dangerous overload for the heart. The progressive reduction of the aortic valve area imposed a greater load on the left ventricle, evidenced by the increase in the transvalvular pressure gradient and the cardiac work required to maintain blood flow [3]. As the stenosis worsened, the heart had to generate higher pressures to overcome the additional flow resistance, signifying an increase in ventricular load. This behavior aligns with the findings of Roll et al. [2], who observed that a reduction in valve area results in greater mechanical effort by the heart and higher energy demand to sustain blood circulation.

Although it shows good agreement with the results of Roll et al. [2], CardioExergy still employs a simplified representation of the cardiovascular system, considering average operating conditions and pre-defined physiological parameters. Furthermore, the model does not account for individual patient characteristics or complex adaptive mechanisms associated with disease progression. Consequently, its results should be interpreted as estimates of the cardiovascular system's overall exergetic behavior, and future studies are required for its application in specific clinical scenarios.

B. Impact of Aortic Stenosis on Cardiac Energetics

Thus, the results obtained qualitatively validate CardioExergy, as they reproduce the key hemodynamic and exergetic trends reported by Roll et al. [2], while simultaneously extending the analysis through the inclusion of additional parameters such as heart rate, body temperature, and the valvular discharge coefficient. Consequently, CardioExergy stands as a significant scientific resource for understanding the effects of aortic stenosis on cardiac energy efficiency, fostering the integration of theory and practice in educational and research settings.

C. Model Validation

The CardioExergy tool offers potential applications across various academic and scientific contexts, standing out as a platform for research, education, and training. Its ability to integrate hemodynamic, metabolic, and thermodynamic parameters enables the quantitative investigation of cardiac energetic mechanisms, contributing to the advancement of knowledge in biomedical engineering, cardiovascular physiology, and applied thermodynamics. Furthermore, it can serve as an educational resource to facilitate the understanding of complex concepts related to cardiac performance and exergy analysis.

V. CONCLUSION

The CardioExergy tool is a computational platform capable of integrating hemodynamic, metabolic, and thermodynamic aspects into the analysis of cardiac performance. The results obtained aligned with trends described in the literature, demonstrating the model's ability to reproduce physiological behaviors and alterations associated with aortic stenosis. Furthermore, the use of exergy-based indicators allowed for the quantification of the disease's energetic impact, providing information complementary to conventional hemodynamic analyses.

Regarding limitations, the model employs a simplified representation of the cardiovascular system, omitting three-dimensional blood flow phenomena and long-term adaptive mechanisms. As a future step, the platform will undergo evaluation by students and faculty in the health sciences to assess its usability, educational applicability, and potential as a tool to support teaching and research in cardiovascular physiology.

***Abstract*—Computed tomography protocols must balance image quality and radiation dose. This work presents a fully simulation-based methodology to evaluate longitudinal tube current modulation in CT imaging. Both the topogram and the CT projection data were generated through Monte Carlo simulation using a computational patient model. The simulated topogram was stitched and used to estimate the longitudinal attenuation profile of the model, from which relative current weights were defined for each axial turn. These weights were then applied to a second set of Monte Carlo CT simulations to generate modulated projection data for image reconstruction and to calculate the absorbed dose within the model. As a proof of concept, the study was restricted to six axial turns in one anatomical range of a scaled MASH model and to a single 120 kV x-ray spectrum. A constant-current acquisition was compared with a modulated-current approach based on the square root of the attenuation profile. The modulated acquisition produced visually comparable reconstructed CT images and preserved the mean values measured in selected regions of interest. The total absorbed dose was reduced by approximately ten percent, with the largest local reduction observed in the neck region. These results indicate that the proposed workflow is effective for evaluating longitudinal current modulation strategies in small-field CT systems before experimental implementation.**

***Index Terms*—computed tomography, Monte Carlo simulation, tube current modulation, patient dose, image noise, topogram**

I. Introduction

Computed tomography (CT) is widely utilized in medical diagnosis due to its ability to provide high-spatial-resolution cross-sectional information. However, CT imaging also constitutes a major source of patient exposure to ionizing radiation. Consequently, optimization strategies are essential to minimize radiation dose while preserving the image quality required for clinical interpretation and quantitative analysis.

Automatic tube current modulation (ATCM) is a well-established strategy in clinical CT designed to adapt tube output to patient attenuation. The underlying principle involves increasing the tube current in highly attenuating regions and reducing it in less dense areas, thereby maintaining a target image quality with a lower radiation burden. Previous simulation and phantom studies have demonstrated that attenuation-based current modulation can significantly decrease dose, depending on patient geometry and modulation amplitude [1], [2]. Furthermore, clinical investigations have shown that z-axis modulation reduces the tube current–time product while maintaining image noise and diagnostic acceptability at comparable levels [3], [4].

Despite this established background, commercial ATCM implementations are typically proprietary. Their internal logic and specific responses to scanner geometry, detector design, patient shape, and reconstruction algorithms remain inaccessible. This lack of transparency limits the ability to study modulation strategies in a controlled and reproducible manner, particularly for custom CT systems and research prototypes.

In this work, we present and evaluate a Monte Carlo-based methodology to study z-axis tube current modulation in a compact CT system. The proposed workflow extracts a longitudinal attenuation profile from a topogram, translates this profile into modulation weights, and applies them to the number of simulated photon histories. Subsequently, it reconstructs the corresponding CT images and calculates the absorbed dose within the patient model using the same simulation framework. Rather than replicating a specific commercial ATCM implementation, this proof-of-concept study aims to provide a transparent, open framework to test z-axis modulation strategies under fully controlled conditions. It was intentionally restricted to one anatomical range, one 120 kV spectrum, and a scaled phantom geometry due to the high computational cost of pure Monte Carlo transport.

II. Materials and Methods

A. CT Geometry and Computational Phantom Simulation

The proposed methodology was developed to be later tested in a hybrid CT prototype with photon-counting and energy-integrating detectors [5], [6]. In this work, only the energy-integrating detector configuration was considered, and the acquisition was simulated in axial mode.

The simulated detector followed the specifications of the detector installed in the hybrid CT prototype. It was composed of 12 X-ACE 32 modules [6], each featuring a 32×32 pixel matrix with a pixel size of $1.06 \times 1.12\ \mathrm{mm}^2$. The source-to-object distance (SOD) and source-to-detector distance (SDD) were set to $493\ \mathrm{mm}$ and $986\ \mathrm{mm}$, respectively. After post-processing, the effective detector configuration used for topogram acquisition consisted of 384×32 pixels, providing multiple axial detector rows.

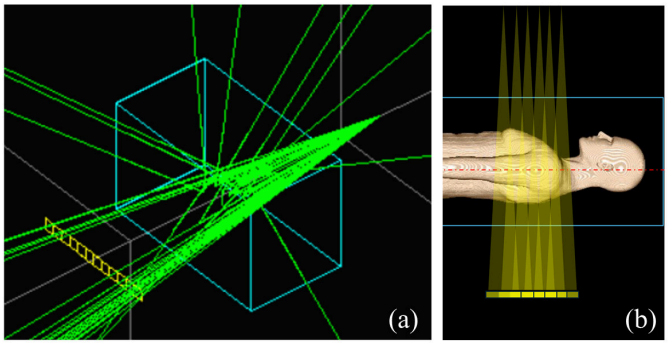

Fig. 1. (a) Simulation geometry and photon source visualization. (b) MASH axial turns selected for current modulation

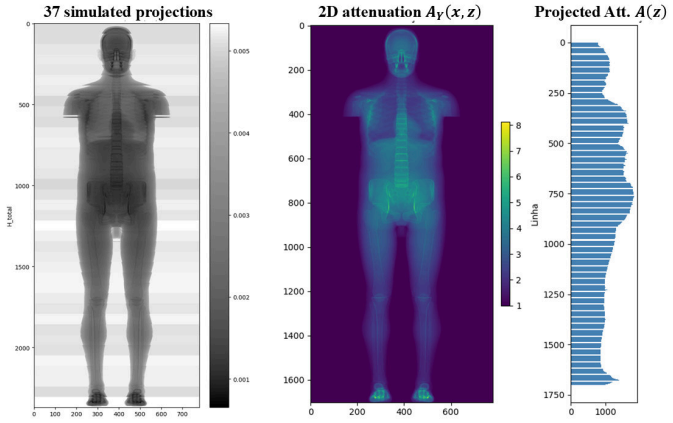

Fig. 2. Topogram-based estimation of the longitudinal attenuation profile. After projections were stitched, the normalized transmission image is converted to projected attenuation using $-\ln(I/I_0)$, and the attenuation values are summed along the transverse detector direction to obtain $A(z)$.

Monte Carlo simulations were performed using GATE version 9.4, a Geant4-based toolkit widely adopted for medical imaging and dosimetry applications [7], [8]. A 120 kV x-ray spectrum was implemented for the source. The Male Adult meSH (MASH) computational phantom was used as the patient model and was scaled to fit within the field of view of the compact CT system. The MASH phantom is based on polygon mesh surfaces and was designed for radiation transport and dosimetric studies [9], [10]. Additional details on its implementation in related computational CT simulations can be found in [11]–[14].

The simulations included a whole-body topogram of the scaled MASH model using 37 longitudinal positions. For this initial proof-of-concept assessment, however, only six axial turns from the thoracic region were simulated. Here, an axial turn denotes one full 360-degree axial acquisition at a selected longitudinal position. This longitudinal range covered the anatomy from the neck down to the lower rib cage, as shown in Fig. 1.

For each of the six turns, 360 angular projections were simulated for two acquisition scenarios: a baseline constant-current case and a z-axis modulated-current case.

B. Topogram Generation and Attenuation Profile

Initially, a topogram of the complete scaled MASH model was generated. A total of 37 simulated projections of 384×32 pixels were normalized and stitched to reconstruct the longitudinal topogram.

The normalized transmission image was converted into projected attenuation using

$$A(z,y) = -\ln\left(\frac{I(z,y)}{I_0(z,y)}\right), \tag{1}$$

where $I(z,y)$ is the transmitted intensity and $I_0(z,y)$ is the flat-field intensity, obtained from a projection without the MASH phantom. The longitudinal attenuation profile was then estimated by integrating the attenuation image along the transverse detector direction, as shown in Fig. 2:

$$A(z) = \sum_y A(z,y). \tag{2}$$

The resulting profile was smoothed using a cubic spline and used as the basis for the z-axis modulation curve along the selected patient range.

C. Z-Axis Current Modulation

In this work, tube current modulation was represented by a relative weight $w(z)$ assigned to each axial turn. This weight was derived from the longitudinal attenuation profile according to

$$w(z) = \frac{A(z)^\alpha}{\max\left[A(z)^\alpha\right]}, \tag{3}$$

where α controls the modulation strength. Two candidate functions were initially evaluated from the topogram: $\alpha = 1$, directly proportional to the attenuation profile, and $\alpha = 0.5$, proportional to the square root of the attenuation profile, as shown in Fig. 3. The square-root profile was selected for the Monte Carlo assessment because previous attenuation-based modulation studies reported favorable noise behavior for this type of dependence [1]. In addition, in the present topogram it limited the minimum weight to 0.757, compared with 0.573 for $\alpha = 1$, thereby avoiding an excessive reduction of photon histories in the lowest-attenuation position.

For each selected turn i, the number of simulated histories in the modulated scenario was defined by

$$N_i = w_i N_{\max}, \tag{4}$$

where $N_{\max} = 5 \times 10^7$ histories. The number of histories used for each turn is shown in Table I. In the constant-current reference acquisition, all turns were simulated with $N_{\max}$ histories.

D. CT Simulations and Reconstruction

The proof-of-concept assessment comprised 4320 independent simulations, corresponding to two acquisition scenarios and six turns, each one with 360 angular projections. To manage the high computational demand, with several hours required per projection, the simulations were executed in

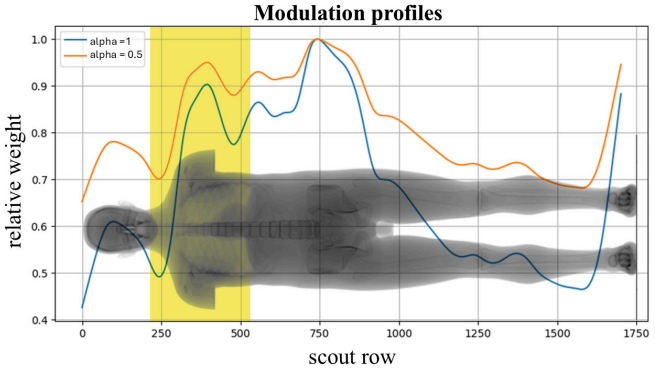

Fig. 3. Relative modulation profiles obtained from the longitudinal attenuation curve. The profile with $\alpha = 0.5$ was selected for the Monte Carlo assessment because it reduces dose while avoiding excessive loss of photon statistics in low-attenuation regions.

TABLE I
RELATIVE MODULATION WEIGHTS AND NUMBER OF HISTORIES FOR THE SIX EVALUATED AXIAL TURNS

Axial turn	$w_{\alpha=1}$	$N_{\alpha=1}$	$w_{\alpha=0.5}$	$N_{\alpha=0.5}$
5	0.573	28,649,134	0.757	37,845,062
6	0.727	36,344,723	0.851	42,548,965
7	0.948	47,389,939	0.973	48,668,849
8	1.000	50,000,000	1.000	50,000,000
9	0.928	46,387,524	0.963	48,159,906
10	0.876	43,803,048	0.936	46,792,931

parallel on a server equipped with an Intel Xeon Gold 5318Y processor, 503 GB of RAM, and Ubuntu 22.04. Before reconstruction, the projection outputs were converted from MHD/RAW to HDF5 format.

CT images were reconstructed using our in-house reconstruction code, RECON4. After axial stitching, the reconstructed volume for the constant-current scenario consisted of $364 \times 364 \times 144$ voxels. The same reconstruction and stitching pipeline was applied to the modulated-current data, as shown in Fig. 4.

E. Quantitative Analysis

Both reconstructed volumes were evaluated visually and quantitatively. Circular regions of interest (ROIs) with a radius of 15 pixels were placed within selected anatomical structures and background regions, as shown in Fig. 5. For each of the six simulated axial turns, the mean value, standard deviation, signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR) were calculated.

The SNR and CNR were defined as

$$\mathrm{SNR} = \frac{\bar{S}}{\sigma_S}, \tag{5}$$

and

$$\mathrm{CNR} = \frac{|\bar{S} - \bar{B}|}{\sqrt{\sigma_S^2 + \sigma_B^2}}, \tag{6}$$

where $\bar{S}$ and σ_S are the mean value and standard deviation of the selected signal ROI, and $\bar{B}$ and σ_B are the corresponding quantities for the background ROI.

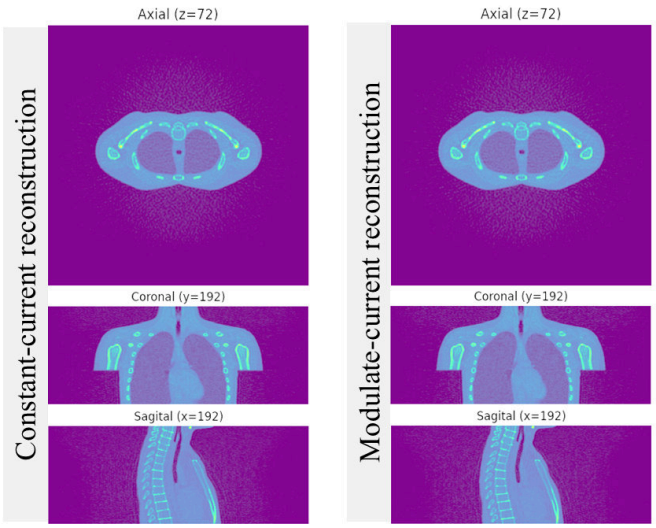

Fig. 4. Reconstructed CT images obtained without tube current modulation and with z-axis tube current modulation using $\alpha = 0.5$.

Two background ROIs, located in the superior and left lateral portions of the axial view, were included to account for differences associated with the asymmetric body thickness along these directions.

The total absorbed dose per axial turn was also extracted from the simulations for both acquisition scenarios. Dose values were reported in Gy for the number of histories used in each simulation.

No inferential statistical test was applied in this proof-of-concept study. Comparisons between constant-current and modulated-current acquisitions were performed descriptively using ROI mean values, standard deviations, SNR, CNR, and dose ratios. The results were summarized either as a function of the reconstructed-slice index of the CT volume or as a function of the axial-turn index, depending on the evaluated quantity.

III. RESULTS

The results presented in this section refer only to the six selected turns, corresponding to positions 5/37 to 10/37 of the simulated topogram. Therefore, they should be interpreted as a proof-of-concept assessment of the proposed workflow rather than as a full-body dosimetric evaluation.

A. Modulation Profile

The topogram-derived attenuation profile exhibited the expected longitudinal behavior. In the selected region used for CT simulation, highlighted in yellow in Fig. 3, attenuation minima were observed in the neck and lower thoracic anatomical regions, whereas maxima occurred near the shoulders and thicker anatomical cross-sections. Consequently, the modulation weights were lowest in turn 5/37 and progressively increased toward turn 8/37, where the maximum weight was reached, as shown in Table I.

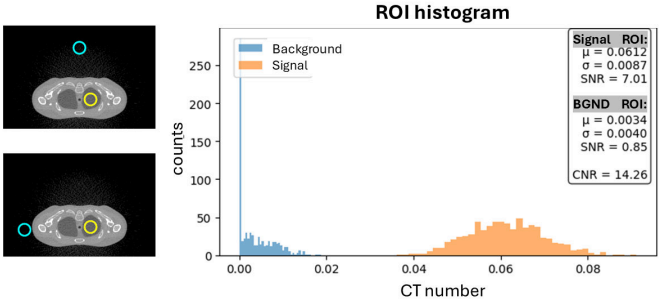

Fig. 5. Example of ROIs selected in the third evaluated axial turn for the quantitative analysis of signal and background regions in the constant-current case.

Under the $\alpha = 0.5$ modulation regime, the number of simulated histories was reduced from 5×10^7 to 3.78×10^7 for position 5/37, and to 4.25×10^7 for position 6/37. The remaining positions exhibited weights closer to unity. The average modulation weight was approximately 0.91, corresponding to an 8.7% mean reduction in simulated histories relative to the constant-current reference.

B. Image Reconstruction

Images reconstructed with and without z-axis current modulation showed visual comparability, as shown in Fig. 4. A quantitative analysis is presented in Fig. 6, where the mean value, SNR, and CNR were evaluated for selected ROIs. The results showed that the mean CT values in the selected anatomical regions, including the heart and lung, remained comparable between the constant-current and modulated-current acquisitions within the descriptive ROI analysis.

The mean background values showed differences when comparing the superior and lateral background regions, which is expected due to the asymmetric body thickness along these directions. However, for each background region, the values obtained with and without current modulation remained consistent. The CNR values were also very similar, with slightly higher values in the constant-current case. Overall, the modulated acquisition showed the expected marginal increase in noise, mainly in axial turns with reduced history counts, but no structural degradation or visible artifacts were introduced in the anatomical features.

C. Absorbed Dose

The absorbed dose values for each turn are compiled in Table II. The total absorbed dose decreased from 1.93×10^{-5} Gy in the constant-current baseline to 1.74×10^{-5} Gy in the modulated configuration, corresponding to an overall dose reduction of 10%.

The most pronounced reduction occurred in turn 5/37, associated with the neck region, where the absorbed dose decreased by 42.3%. Turn 6/37 also exhibited a substantial dose reduction of 26.9%. From 7/37 to 10/37, where modulation weights were closer to unity, dose variations were smaller. The acquisition 8/37 exhibited a negligible increase of 0.2%, which can be attributed to statistical fluctuations inherent to

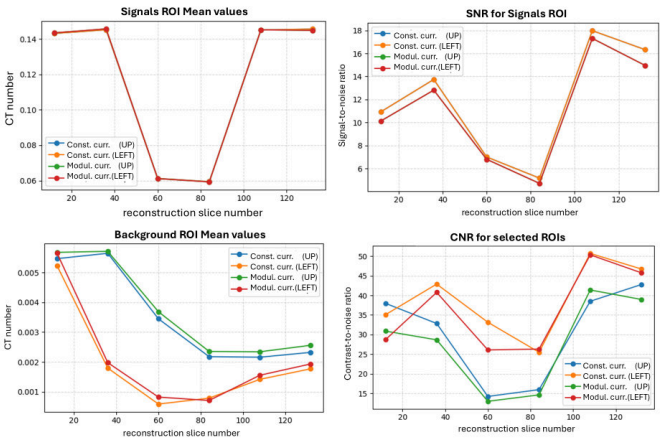

Fig. 6. Signal and backgrounds mean values, SNR, and CNR for selected ROIs.

TABLE II
ABSORBED DOSE COMPARISON FOR THE SIX SIMULATED AXIAL TURNS. DOSE VALUES ARE GIVEN IN GY FOR THE TOTAL NUMBER OF HISTORIES USED IN EACH SIMULATION.

Turn	No mod.	Mod.	Ratio	Reduction (%)
5	1.17×10^{-6}	6.75×10^{-7}	0.577	42.31
6	2.49×10^{-6}	1.82×10^{-6}	0.731	26.91
7	3.82×10^{-6}	3.62×10^{-6}	0.948	5.24
8	4.21×10^{-6}	4.22×10^{-6}	1.002	-0.24
9	3.94×10^{-6}	3.73×10^{-6}	0.947	5.33
10	3.70×10^{-6}	3.31×10^{-6}	0.895	10.54
Total	1.933×10^{-5}	1.738×10^{-5}	0.899	10.11

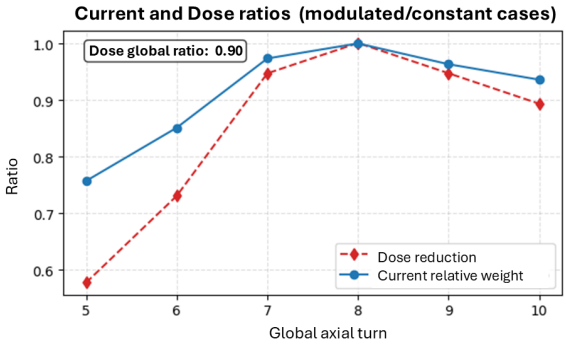

Fig. 7. Dose comparison between constant-current and modulated-current acquisitions. The modulated acquisition reduced the total absorbed dose by 10%, with the largest local reduction observed in the neck axial turn.

Monte Carlo dose estimation and to the fact that this axial turn was simulated with the maximum modulation weight.

IV. Discussion

These findings support the use of topogram-derived attenuation profiles to establish z-axis modulation weights within a compact CT simulation framework. The square-root modulation profile selectively reduced history counts in lower-attenuation positions while preserving robust photon statistics across thicker anatomical cross-sections. This performance aligns with the primary objective of ATCM: adapting tube

output to patient attenuation without compromising image quality [3].

The observed total dose reduction of 10% falls well within the ranges reported in previous tube current modulation literature. Specifically, Gies et al. reported simulated dose reductions of up to 50%, contingent upon phantom geometry and the chosen modulation function [1]. Similarly, Kalender et al. measured experimental dose reductions between 8% and 56% using physical phantoms [2]. Clinical assessments of z-axis modulation have likewise demonstrated reduced tube current–time products alongside comparable image noise and diagnostic acceptability [4]. Hence, the dose savings achieved in this study are highly plausible, particularly given the intentionally conservative nature of the selected $\alpha = 0.5$ profile.

While a more aggressive modulation profile (e.g., $\alpha = 1$) would yield greater dose saving, particularly in the neck region, it risks increasing image noise. Such configurations should only be explored after establishing explicit noise tolerance thresholds. For this initial proof-of-concept assessment, the $\alpha = 0.5$ profile served as a robust baseline, producing measurable dose reductions while preserving visual image quality and ROI mean values.

Several limitations warrant acknowledgment. First, this study was restricted to six selected acquisitions of the MASH phantom due to the long computation times required for pure Monte Carlo transport. Second, evaluations were limited to a 120 kV x-ray spectrum. Alternative spectra may alter beam hardening effects, photon statistics, absorbed dose distribution, and reconstructed image quality. Third, the current quantitative analysis focused exclusively on selected ROIs and per-acquisition dosimetry. A more comprehensive assessment should encompass additional anatomical regions, formal dose uncertainty estimation, and rigorous image-noise acceptance criteria. Finally, the proposed methodology represents an idealized simulation framework rather than a clinical hardware implementation; thus, experimental evaluation with the Hybrid CT prototype remains imperative. Future work will extend the simulations to the full set of 37 longitudinal positions, include different x-ray spectra, incorporate the response of the physical hybrid CT detectors, evaluate radiologist-defined noise tolerance criteria, and investigate AI-based denoising or acceleration strategies to enable larger simulated volumes and more aggressive modulation profiles.

V. Conclusion

A Monte Carlo-based proof-of-concept workflow was developed and evaluated to study z-axis tube current modulation within a compact CT system. It integrates topogram-based attenuation profiling, modulation weight generation, photon history scaling, RECON4 image reconstruction, and MASH phantom dosimetry within a unified workflow. Utilizing a conservative square-root modulation profile ($\alpha = 0.5$), an overall absorbed dose reduction of 10% was achieved, with localized dose savings reaching up to 42% in the neck region. Reconstructed images were visually comparable to the constant-current baseline, and ROI mean values were preserved. These findings show that the proposed methodology is suitable for preliminary benchmarking of tube current modulation strategies before physical prototyping and broader experimental evaluation.

***Abstract*—The Na^+/K^+-ATPase plays a fundamental role in maintaining ionic homeostasis and neuronal excitability and is commonly represented in computational models of epileptiform activity by phenomenological formulations. However, these approaches do not explicitly describe the conformational transitions of the catalytic cycle, limiting the representation of transient responses during rapid ionic fluctuations. In this work, a kinetic Na^+/K^+-ATPase model based on the Post-Albers cycle was integrated into a computational model of non-synaptic epileptiform activity. Three formulations were implemented to estimate the pump current, and the effects of rapid Na^+ and K^+ concentration changes in the perimembrane region were investigated. The proposed model preserved the overall dynamics of epileptiform events while providing a detailed description of pump state occupancy and transition kinetics. Simulations showed that transient perimembrane ionic fluctuations produced dynamic behaviors not reproduced by the phenomenological model. In particular, the current formulation based on electrogenic transitions of the catalytic cycle provided the best qualitative agreement with experimental observations, reproducing post-ictal oscillatory events associated with rapid extracellular ionic changes. Furthermore, simulations of reduced extracellular volume reproduced the emergence of post-events observed under hypo-osmotic conditions. These results indicate that explicit kinetic modeling of the Na^+/K^+-ATPase provides a more realistic description of pump dynamics during intense neuronal activity and offers a useful framework for investigating the role of ionic homeostasis in epileptiform activity.**

Keywords— Na^+/K^+-ATPase, Post-Albers cycle, non-synaptic epileptiform activity, computational modeling, ionic homeostasis.

I. INTRODUÇÃO

A atividade elétrica cerebral depende da manutenção rigorosa dos gradientes transmembranares de Na^+ e K^+, os quais são continuamente restabelecidos pela Na^+/K^+-ATPase [1], [2], [3]. Além de preservar o potencial de repouso, essa proteína desempenha papel essencial na recuperação da excitabilidade neuronal após potenciais de ação e na manutenção da homeostase iônica durante períodos de intensa atividade elétrica [4], [5]. Alterações em sua atividade comprometem o equilíbrio eletroquímico da membrana, favorecendo condições associadas à hiperexcitabilidade neuronal, como a epilepsia.

Modelos computacionais têm contribuído significativamente para a compreensão dos mecanismos envolvidos na geração e manutenção da atividade epileptiforme [4], [6]. Entre eles, o modelo de Atividade Epileptiforme Não Sináptica (AENS) desenvolvido por [4] descreve a dinâmica espaço-temporal das concentrações iônicas e do potencial de membrana, permitindo investigar como alterações na homeostase extracelular podem desencadear crises epilépticas. Entretanto, nesse modelo, a Na^+/K^+-ATPase é representada por uma formulação fenomenológica baseada apenas na dependência das concentrações de Na^+, K^+ e ATP, sem considerar explicitamente as etapas cinéticas do ciclo catalítico da enzima.

Experimentalmente, sabe-se que a Na^+/K^+-ATPase opera por meio de uma sequência de estados conformacionais descritos pelo ciclo de Albers-Post, envolvendo processos de ligação e liberação de íons, fosforilação, desfosforilação e transições conformacionais [3], [7]. A velocidade de cada uma dessas etapas pode influenciar a resposta dinâmica da bomba frente às rápidas alterações iônicas observadas durante eventos epileptiformes, aspecto que não pode ser representado por modelos simplificados.

Neste trabalho, o objetivo foi desenvolver um modelo cinético da Na^+/K^+-ATPase baseado no ciclo de Albers-Post e integrá-lo a um modelo computacional de atividades epileptiformes não-sinápticas. Simulações computacionais foram realizadas para investigar os efeitos da cinética explícita da bomba sobre o transporte iônico, a corrente eletrogênica e a dinâmica das crises. Os resultados demonstram que o

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

modelo reproduz respostas transitórias da Na^+/K^+-ATPase que não podem ser representadas por abordagens fenomenológicas, fornecendo uma descrição mais realista da dinâmica da bomba durante atividades neuronais intensas.

II. Métodos

A. Modelo para atividades epileptiformes não-sinápticas

O modelo matemático usado para simular atividades epileptiformes não-sinápticas (AENS) descreve o transporte de íons tanto no meio extracelular quanto através da membrana celular [4]. A movimentação iônica no espaço extracelular foi representada por uma equação de eletrodifusão baseada na formulação de Nernst-Planck [8]. O transporte transmembranar incluiu os cotransportadores $Na^+/K^+/2Cl^-$ (NKCC) e K^+/Cl^- (KCC), os trocadores Na^+/H^+ (NHE) e HCO_3^-/Cl^- (HCE), a bomba de H^+ e a enzima anidrase carbônica, responsável pela interconversão reversível entre CO_2, H_2O, H^+ e HCO_3^- [9]. Os fluxos iônicos promovidos por esses mecanismos foram calculados em função das concentrações dos ligantes e das afinidades dos respectivos transportadores.

A manutenção dos gradientes transmembranares de Na^+ e K^+ foi representada pela Na^+/K^+-ATPase, responsável pelo efluxo de três íons Na^+ e influxo de dois íons K^+ por ciclo catalítico [5]. No presente trabalho, o modelo fenomenológico originalmente empregado na AENS foi substituído por um modelo cinético baseado no ciclo de Albers-Post. As correntes da bomba e dos canais iônicos foram calculadas por meio da equação de Goldman-Hodgkin-Katz (GHK) [4].

Os neurônios foram representados por canais rápidos de Na^+, canais de K^+ tipo A, canais persistentes de Na^+, canais retificadores tardios de K^+, canais muscarínicos de K^+ e canais de Cl^- dependentes de voltagem, cujas permeabilidades seguiram o formalismo de [10]. Para os astrócitos, a membrana foi considerada inexcitável, contendo canais retificadores de entrada para K^+ e permeabilidades constantes para os demais canais [4].

B. Modelo Cinético para Na^+/K^+-ATPase

A Fig. 1 apresenta o modelo cinético da Na^+/K^+-ATPase utilizado neste trabalho, baseado no ciclo de Albers-Post [11] e expandido pela inclusão do subestado P-E2(Na_3), envolvido na via de transporte de Na^+ [12]. Esse subestado foi incorporado por sua relevância na eletrogenicidade da bomba e por já ter sido empregado em estudos experimentais e computacionais posteriores [12], [13], [14].

O modelo descreve as transições conformacionais entre os estados E_1 e E_2, incluindo as etapas de ligação, oclusão e liberação de Na^+ e K^+, bem como as reações de fosforilação e desfosforilação da enzima. As constantes cinéticas, originalmente propostas por [11], foram complementadas pelas constantes adicionais reportadas por [12], possibilitando a representação completa do ciclo expandido.

A partir do esquema apresentado na Fig. 1, foram definidas 30 taxas de reação (r_i), cada uma correspondente ao fluxo líquido entre dois subestados consecutivos do ciclo catalítico. De forma geral, cada taxa foi calculada como a diferença entre a velocidade da reação direta e a velocidade da reação reversa, sendo ambas determinadas pelas populações dos subestados envolvidos, pelas respectivas constantes cinéticas e, quando aplicável, pelas concentrações dos ligantes (Na^+, K^+, ATP, ADP e Pi). As expressões específicas das taxas

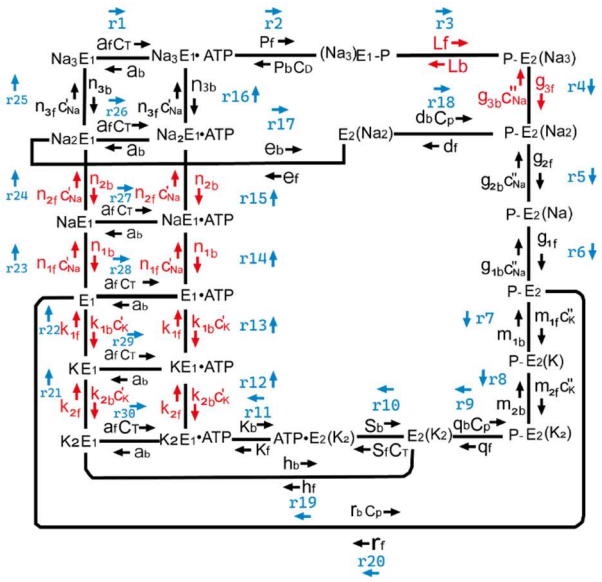

Fig. 1. Modelo cinético expandido da Na^+/K^+-ATPase baseado no ciclo de Albers-Post, adaptado de [11]. O modelo inclui o subestado P-E2(Na_3) e as constantes cinéticas adicionais propostas por [12]. As setas indicam as reações direta e reversa; E_1 e E_2 representam os principais estados conformacionais da enzima; **CT**, **CD** e **CP** correspondem às concentrações de ATP, ADP e Pi, respectivamente; C'_{Na}, C'_K, C''_{Na} e C''_K representam as concentrações intracelulares e extracelulares de Na^+ e K^+.

seguiram diretamente o esquema cinético da Fig. 1, de acordo com a seguinte equação geral:

$$r_i = k_{i,f} \prod_j C_j^{\nu_j} X_i - k_{i,b} \prod_j C_j^{\mu_j} X_{i+1}, \qquad (1)$$

onde X_i representa a população do subestado, $k_{i,f}$ e $k_{i,b}$ são as constantes cinéticas das reações direta e reversa, e C_j corresponde às concentrações dos ligantes envolvidos em cada etapa. As 30 reações do ciclo foram descritas por essa formulação geral, variando apenas os subestados, os ligantes e as constantes cinéticas de cada transição.

As equações diferenciais do modelo foram, então, obtidas por balanço de massa, considerando, para cada um dos 22 subestados, a soma das contribuições das reações de entrada e saída. Dessa forma, a evolução temporal da população de cada subestado foi descrita por um sistema de equações diferenciais ordinárias acopladas.

A corrente da Na^+/K^+-ATPase pode ser estimada por diferentes estratégias, dependendo do nível de detalhamento considerado no ciclo catalítico. Neste trabalho foram propostas três abordagens complementares: (i) uma baseada apenas nos fluxos líquidos de Na^+ e K^+ efetivamente transportados através da membrana; (ii) uma que considera simultaneamente as etapas de ligação e liberação dos íons, representando todo o transporte ao longo do ciclo catalítico; e (iii) uma fundamentada nas contribuições eletrogênicas das transições individuais do ciclo, conforme o formalismo de [15]. A comparação entre essas abordagens permitiu avaliar como diferentes representações da eletrogênese da bomba influenciam a estimativa da corrente de bombeamento.

Para isso, foram calculadas as quantidades de Na^+ ligadas no meio intracelular (ΔNa_i) e liberadas no meio extracelular (ΔNa_o), bem como as quantidades de K^+ ligadas no meio

extracelular (ΔK_o) e liberadas no meio intracelular (ΔK_i). Essas grandezas foram obtidas pela soma das taxas líquidas das reações correspondentes e utilizadas para o cálculo das três versões da corrente da bomba.

Na primeira abordagem (IpV1), a corrente foi estimada a partir da diferença entre os fluxos líquidos de Na^+ liberado no meio extracelular e K^+ liberado no meio intracelular:

$$I_{pV1} = F(\Delta Na_o - \Delta K_i) \quad (2)$$

Na segunda abordagem (IpV2), foram consideradas conjuntamente as etapas de ligação e liberação dos íons, resultando em:

$$I_{pV2} = F[(\Delta Na_i + \Delta Na_o) - (\Delta K_i + \Delta K_o)] \quad (3)$$

Por fim, a terceira abordagem (IpV3) foi baseada no modelo eletrogênico de [15], no qual a corrente corresponde à soma das contribuições das transições eletrogênicas do ciclo, ponderadas pelos respectivos coeficientes dielétricos obtidos de [11]:

$$I_{pV3} = e_0 \sum_i \alpha_i r_i \quad (4)$$

onde e_0 é a carga elementar, r_i representa a taxa líquida da i-ésima reação e α_i corresponde ao coeficiente dielétrico associado à respectiva transição.

C. Efeito eletrogênico da Bomba de Na^+/K^+

Além de reproduzir as alterações das concentrações intracelulares e extracelulares de Na^+ e K^+, o modelo também incorporou a contribuição eletrogênica da Na^+/K^+-ATPase ao cálculo do potencial de membrana. Como o potencial neuronal é determinado pela equação de Goldman-Hodgkin-Katz (GHK), a corrente da bomba foi convertida em um termo auxiliar (C_A), obtido por rearranjo da forma correspondente da equação de corrente de GHK. Esse procedimento permite incorporar o efeito eletrogênico da bomba na formulação do potencial sem introduzir instabilidades numéricas. Assim, a partir da corrente da bomba (I_{pNaK}), foi calculado o termo C_A:

$$C_A = \frac{RT}{F^2 V_m} I_{pNaK} + \left(1 - \frac{RT}{F^2 V_m} I_{pNaK}\right) \alpha e^{-\frac{FV_m}{RT}}, \quad (5)$$

onde R é a constante universal dos gases, α uma constante, T a temperatura absoluta, F a constante de Faraday e V_m o potencial de membrana.

O termo C_A foi então incorporado ao denominador da equação de GHK utilizada no modelo AENS, juntamente com as contribuições das correntes por gap junction (f_{gsi}) e efeito de campo(f_{ef}):

$$Vm = \frac{RT}{F} ln\left(\frac{P_{Na}[Na^+]_o + P_K[K^+]_o + P_{Cl}[Cl^-]_i + f_{ef} + f_{gsi} + \alpha}{P_{Na}[Na^+]_i + P_K[K^+]_i + P_{Cl}[Cl^-]_o + C_A}\right) \quad (6)$$

onde P_{ion} é a permeabilidade, $[ion]_o$ e $[ion]_i$ as concentrações iônicas no meio intra e extracelular.

Para avaliar o impacto da nova representação da bomba, os resultados obtidos com o modelo cinético foram comparados ao modelo fenomenológico originalmente empregado por [4], analisando-se seus efeitos sobre as concentrações iônicas, o potencial de membrana e as características dos períodos ictal e interictal, incluindo duração, amplitude e intervalo entre eventos.

D. Simulações Computacionais

Os parâmetros e valores iniciais das variáveis do modelo foram baseados em trabalhos anteriores [4], [5], [9]. O método das diferenças finitas, considerando um erro menor que 10^{-4}, foi utilizado para realizar as simulações. Para as simulações, o programa foi implementado em linguagem Fortran (FORTRAN 90) e os resultados foram analisados em Matlab®. O código do programa foi compilado e executado em um computador de alta performance (Cluster SGI UV 2000, 80 Cores — Intel Xeon E5-4650v2 10-core, 2.4 GHz, 25 MB Cache, 1024GB DDR3 1866 MHz, 80 TB HD, Cluster SGI UV 300, 144 Cores Intel Xeon E7-8867v4, 2.4 GHz, RAM 2,048 GB DDR4 2,400MHz, 80 TB HD, SUSE Linux Enterprise Server 11, SGI Performance Suite, Intel Cluster Studio XE).

No modelo AENS original, as concentrações iônicas são assumidas espacialmente homogêneas em cada compartimento intra- e extracelular. Assim, os fluxos transmembranares alteram instantaneamente a concentração de todo o compartimento, reduzindo as taxas locais de variação das concentrações iônicas e, consequentemente, atenuando os efeitos transitórios decorrentes da cinética finita da Na^+/K^+-ATPase. Nessas condições, o modelo cinético baseado no ciclo de Albers-Post apresenta comportamento semelhante ao modelo fenomenológico, uma vez que ambos operam próximos ao regime estacionário.

Para investigar os efeitos de variações rápidas das concentrações iônicas nas proximidades da membrana, foram introduzidos compartimentos intermediários para Na^+ e K^+ nas faces intracelular e extracelular. As concentrações nesses compartimentos passaram a ser determinadas simultaneamente pelos fluxos transmembranares e pela difusão com os compartimentos principais:

$$\frac{d[\text{ion}]_o^{int}}{dt} = \frac{\phi_{\text{ion}}^m A^m}{f_o Vol_o} + v_o([\text{ion}]_o - [\text{ion}]_o^{int}), \quad (7)$$

$$\frac{d[\text{ion}]_i^{int}}{dt} = -\frac{\phi_{\text{ion}}^m A^m}{f_i Vol_i} + v_i([\text{ion}]_i - [\text{ion}]_i^{int}), \quad (8)$$

onde ϕ_{ion}^m representa o fluxo transmembranar do íon, A^m a área de membrana, Vol o volume do compartimento, f define a fração de volume correspondente à região perimembranar e v representa a taxa de difusão entre o compartimento intermediário e o compartimento principal. Valores menores de f intensificam as variações locais de concentração, enquanto valores maiores de v aceleram o restabelecimento do equilíbrio com o restante do meio intra- ou extracelular.

III. Resultados

Na Fig. 2A, pode-se observar que o modelo cinético da Na^+/K^+-ATPase incorporado no modelo de AENS permite reproduzir a dinâmica característica da atividade

epileptiforme não sináptica para as três formulações propostas para o cálculo da corrente eletrogênica (IpV1, IpV2 e IpV3), apresentando comportamento semelhante ao obtido com o modelo fenomenológico. A Fig. 2B apresenta os efeitos da inclusão de compartimentos intermediários para representar

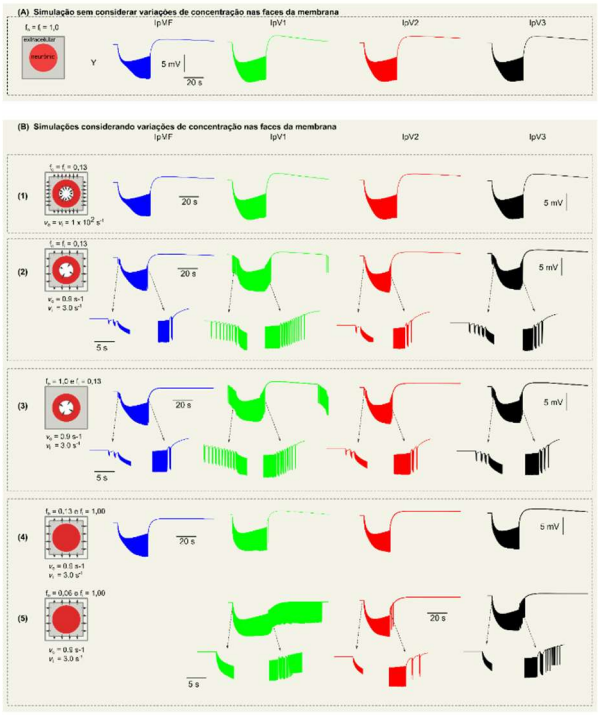

Fig. 2. Influência das flutuações locais das concentrações de Na^+ e K^+ nas proximidades da membrana sobre a atividade epileptiforme simulada. (A) Modelo original, sem compartimentos perimembranares. (B1–B5) Resultados obtidos para diferentes valores da fração do volume perimembranar (f_i e f_o) e das taxas de difusão (v_i e v_o). A consideração explícita desses compartimentos evidencia o surgimento de efeitos transitórios dependentes da cinética da Na^+/K^+-ATPase, não observados na representação fenomenológica convencional.

variações rápidas das concentrações de Na^+ e K^+ nas proximidades da membrana. Quando foi considerada uma fração correspondente a 13% dos volumes intra- e extracelulares ($f_i = f_o = 0{,}13$) e altas taxas de difusão ($v_i = v_o = 10^2\ s^{-1}$), o comportamento dos eventos epileptiformes permaneceu semelhante ao do modelo controle (Fig. 2A-B1). Entretanto, a redução das taxas de difusão ($v_i = 3{,}0\ s^{-1}$ e $v_o = 0{,}9\ s^{-1}$) resultou no aparecimento de pré- e pós-eventos, caracterizados por descargas de menor amplitude no início e no término do período ictal (Fig. 2B2).

Para identificar a contribuição de cada face da membrana, foram realizadas simulações considerando separadamente as variações rápidas das concentrações intracelulares e extracelulares. Quando apenas o compartimento intracelular foi considerado, observou-se comportamento semelhante ao da simulação completa, com a presença de pré- e pós-eventos (Fig. 2B3). Em contraste, considerando somente o compartimento extracelular ($f_o = 0{,}13$), esses eventos não foram observados (Fig. 2B4).

A redução adicional da fração do compartimento extracelular para $f_o = 0{,}065$ evidenciou diferenças entre os modelos da Na^+/K^+-ATPase. Enquanto o modelo fenomenológico tornou-se numericamente instável, impedindo a simulação, o modelo cinético baseado no ciclo de Albers-Post permaneceu estável nas três estratégias de cálculo da corrente (IpV1, IpV2 e IpV3), reproduzindo pós-eventos. Entre elas, a abordagem eletrogênica baseada nas transições do ciclo (IpV3) produziu respostas mais compatíveis com o comportamento experimental esperado.

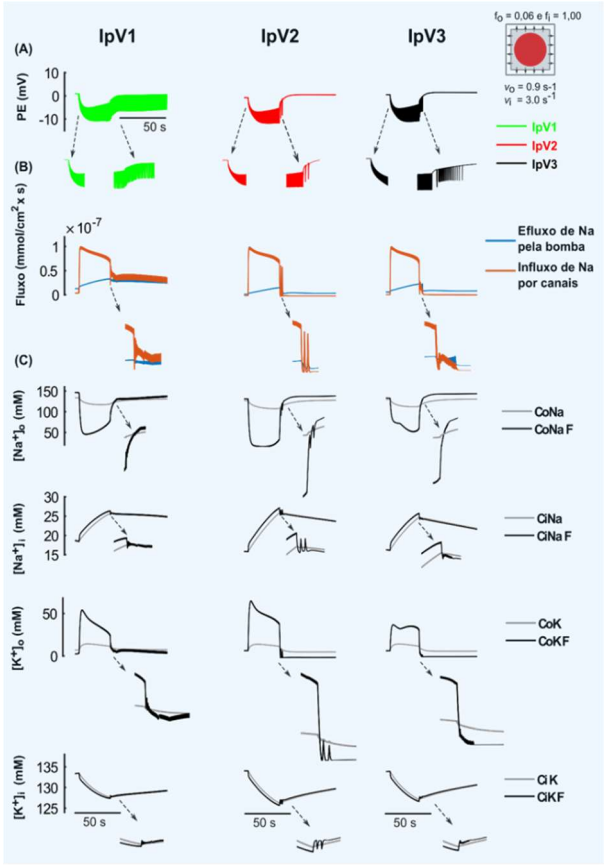

Fig. 3. Efeito das flutuações rápidas das concentrações perimembranares ($f_o = 0{,}06$, $f_i = 1{,}00$, $v_o = 0{,}9\ s^{-1}$ e $v_i = 3{,}0\ s^{-1}$) sobre a dinâmica da atividade epileptiforme. (A) Eventos epileptiformes simulados utilizando as três formulações da corrente da Na^+/K^+-ATPase (IpV1, IpV2 e IpV3). (B) Cruzamento entre o efluxo de Na^+ pela bomba e o influxo de Na^+ pelos canais. (C) Concentrações de Na^+ e K^+ nos compartimentos globais e perimembranares.

Esses resultados indicam que a consideração explícita da cinética da Na^+/K^+-ATPase, associada às variações locais de concentração nas proximidades da membrana, permite reproduzir dinâmicas transitórias que não são obtidas com a representação fenomenológica convencional.

As Figuras 3 e 4 apresentam os resultados obtidos considerando flutuações rápidas das concentrações de Na^+ e K^+ na face extracelular da membrana ($f_o = 0{,}06$) e concentrações homogêneas no meio intracelular ($f_i = 1{,}0$), com $v_o = 0{,}9\ s^{-1}$ e $v_i = 3{,}0\ s^{-1}$. Nessas condições, o modelo cinético reproduziu eventos epileptiformes seguidos por pós-eventos, cuja dinâmica depende da formulação empregada para o cálculo da corrente da Na^+/K^+-ATPase (Fig. 3A). A formulação IpV3 apresentou comportamento mais próximo do esperado experimentalmente, produzindo pós-eventos oscilatórios mais bem definidos.

A Fig. 3B mostra o cruzamento entre o efluxo de Na^+ pela bomba e o influxo de Na^+ pelos canais. Nas três formulações, esse cruzamento ocorreu durante a transição para os pós-eventos, porém a versão IpV3 apresentou oscilações mais pronunciadas e persistentes, indicando maior influência da cinética da bomba sobre a dinâmica do transporte de Na^+.

As concentrações calculadas nos compartimentos perimembranares (Fig. 3C) apresentaram variações significativamente maiores que aquelas observadas nos compartimentos intracelular e extracelular homogêneos. Destacam-se a redução acentuada da concentração extracelular de Na^+ durante o evento e pequenas oscilações nas concentrações locais de Na^+ e K^+ durante os pós-eventos, evidenciando a importância das flutuações iônicas locais para a dinâmica da bomba.

A Fig. 4 apresenta a evolução temporal das populações dos subestados e das taxas de reação do ciclo de Albers-Post para as três formulações da corrente. Durante o período ictal, ocorreu redistribuição da população entre os subestados da bomba, acompanhada pelo aumento das principais reações de transporte. Nos pós-eventos, IpV3 apresentou oscilações coordenadas envolvendo tanto os subestados quanto as reações eletrogênicas do ciclo, enquanto IpV1 e IpV2 exibiram respostas mais amortecidas. Esses resultados indicam que a representação explícita da cinética molecular da Na^+/K^+-ATPase modifica a dinâmica transitória da bomba e favorece o surgimento de oscilações pós-ictais.

Os resultados anteriores sugerem que os pós-eventos estão associados a variações rápidas das concentrações iônicas na face extracelular da membrana. Assim, levantou-se a hipótese de que a redução do volume extracelular, ao intensificar essas flutuações locais, favoreceria o surgimento dos pós-eventos. Essa hipótese é consistente com resultados experimentais obtidos após redução de 20% da osmolaridade da solução de perfusão, que evidenciaram o aparecimento de pós-eventos durante a atividade epileptiforme não sináptica (Fig. 5A-B).

Para reproduzir essa condição experimental, o modelo incorporou os efeitos da redução da osmolaridade por meio da diminuição da concentração de cátions impermeantes, da corrente *leakage* inibitória e da taxa de difusão intracelular de K^+. Adicionalmente, o parâmetro f_o, que representa o volume efetivo do compartimento perimembranar extracelular, foi modelado como função do volume extracelular, permitindo intensificar as variações locais de concentração durante a redução desse volume.

Como mostrado na Fig. 5C, o modelo reproduziu os principais efeitos observados experimentalmente, incluindo redução do intervalo entre eventos, aumento da duração do período ictal, maior deslocamento do potencial DC, aumento da amplitude dos *population spikes* e, principalmente, o surgimento de pós-eventos. Esses resultados indicam que a diminuição do volume extracelular intensifica as flutuações perimembranares de Na^+ e K^+, modificando a dinâmica da Na^+/K^+-ATPase e favorecendo o aparecimento de oscilações pós-ictais.

IV. Discussão

Até onde foi possível verificar, não foram encontrados estudos que investigassem como diferentes representações matemáticas da Na^+/K^+-ATPase influenciam a dinâmica de atividades epileptiformes não sinápticas. Os modelos computacionais disponíveis representam, em geral, a bomba por formulações fenomenológicas baseadas em cinéticas de saturação [4], [9], [16], assumindo implicitamente que as transições conformacionais ocorrem de forma instantânea. Embora essa aproximação seja adequada para fenômenos de evolução lenta, sua validade torna-se questionável durante AENS, nas quais as concentrações iônicas podem variar significativamente em escalas de centenas de milissegundos a segundos [4], [6]. Nesse contexto, este trabalho incorporou um modelo cinético baseado no ciclo de Albers-Post ao modelo AENS e demonstrou que a consideração

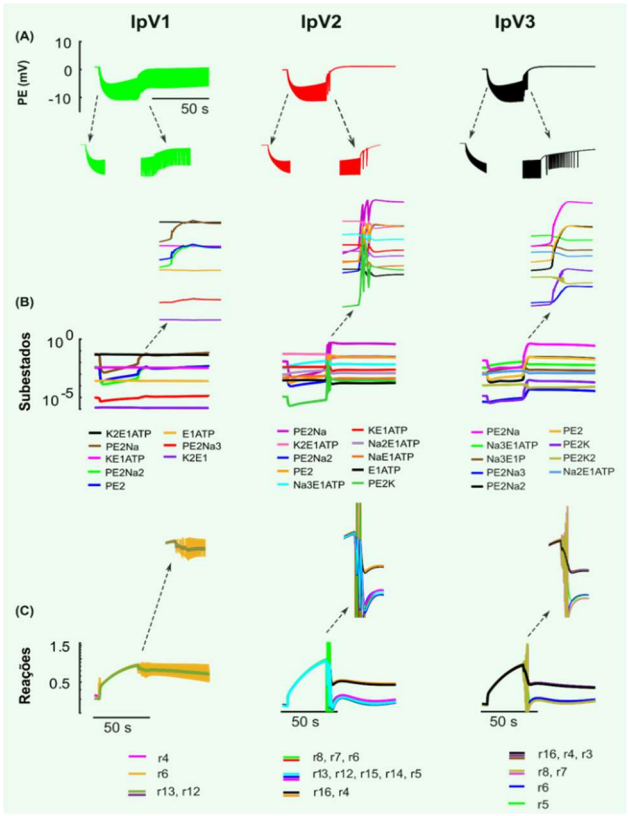

Fig. 4. Dinâmica da Na^+/K^+-ATPase durante os eventos epileptiformes para as três formulações da corrente. (A) Eventos epileptiformes simulados. (B) Evolução temporal das populações dos subestados do ciclo de Albers-Post. (C) Taxas das principais reações do ciclo catalítico da bomba. A formulação IpV3 apresentou as oscilações transitórias mais pronunciadas durante os pós-eventos.

explícita das transições conformacionais da Na^+/K^+-ATPase modifica a dinâmica transitória do transporte iônico e da corrente eletrogênica, produzindo comportamentos que não são reproduzidos pelo modelo fenomenológico.

Os resultados demonstram que a substituição do modelo fenomenológico da Na^+/K^+-ATPase por um modelo cinético baseado no ciclo de Albers-Post preserva a dinâmica geral das atividades epileptiformes não sinápticas (AENS), mantendo o papel fundamental da bomba na determinação das transições entre os períodos ictal e interictal, como previsto por [4]. Além disso, a nova abordagem permite descrever explicitamente a dinâmica dos subestados e das transições conformacionais da enzima, durante a atividade neuronal, e que se apresentam correlacionados a efeitos sobre os regitros extracelulares da atividade não-sináptica. Esses efeitos observados nas simulações com o modelo cinético da bomba também são observados experimentalmente. Por outro lado, o mesmo não acontece com as simulações envolvendo modelos fenomenológicos para a Na^+/K^+-ATPase.

Embora a estequiometria média do transporte permaneça próxima da razão fisiológica de $3Na^+:2K^+$, as simulações mostraram que alterações rápidas das concentrações iônicas podem produzir desvios transitórios dessa relação e modificar a corrente eletrogênica da bomba. Esses efeitos tornam-se evidentes quando são consideradas flutuações locais das concentrações de Na^+ e K^+ nas proximidades da membrana,

condição na qual o modelo cinético reproduz respostas transitórias ausentes na representação fenomenológica.

As simulações também sugerem que os pós-eventos observados durante AENS estão associados principalmente às rápidas variações das concentrações iônicas na face extracelular da membrana. Essa hipótese é corroborada pela reprodução computacional dos efeitos da redução da osmolaridade extracelular, condição experimental que reduz o

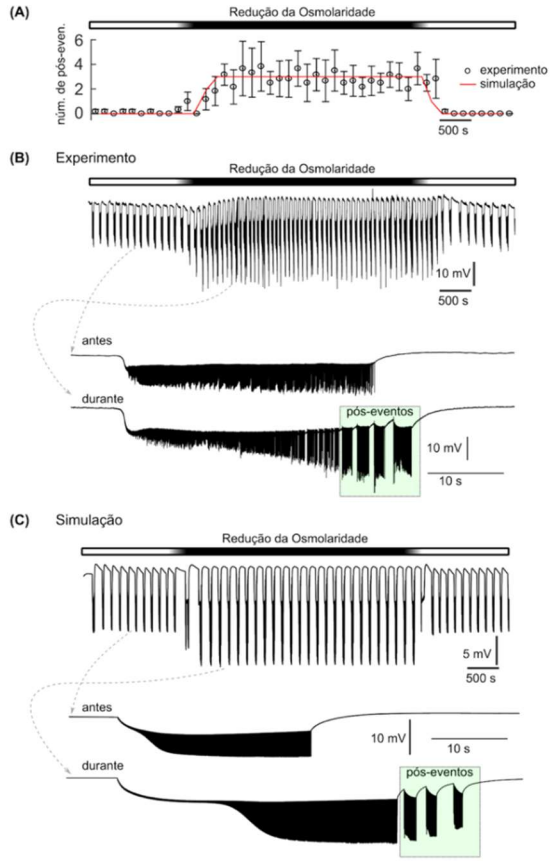

Fig. 5. Efeito da redução da osmolaridade sobre a atividade epileptiforme não sináptica. (A) Número de pós-eventos observados experimentalmente durante redução de 20% da osmolaridade da solução de perfusão. (B) Registro experimental do potencial extracelular (adaptado de [17]). (C) Simulação computacional reproduzindo a redução do intervalo entre eventos, o aumento da duração do período ictal e o surgimento de pós-eventos após a diminuição do volume extracelular.

volume extracelular e favorece o aparecimento de pós-eventos. Esses resultados são consistentes com estudos experimentais que demonstram aumento da excitabilidade e prolongamento das crises epilépticas após redução da osmolaridade [18], [19].

Por fim, somente o modelo cinético baseado no ciclo de Albers-Post foi capaz de reproduzir os pós-eventos mantendo estabilidade numérica quando as flutuações perimembranares foram intensificadas. Esse resultado indica que a representação explícita das transições conformacionais da Na^+/K^+-ATPase fornece uma descrição mais realista da dinâmica transitória da bomba e constitui uma ferramenta promissora para investigar mecanismos associados à epilepsia, à depressão alastrante e a outras condições que envolvem alterações rápidas da homeostase iônica.

V. Conclusão

O modelo cinético da Na^+/K^+-ATPase baseado no ciclo de Albers-Post foi integrado ao modelo de atividade epileptiforme não sináptica, permitindo representar explicitamente as transições conformacionais da bomba durante eventos neuronais intensos. As simulações mostraram que essa abordagem preserva a dinâmica geral das AENS e, diferentemente da representação fenomenológica, reproduz efeitos transitórios ao término dos eventos. No presente trabalho, esses efeitos são associados às rápidas flutuações perimembranares das concentrações de Na^+ e K^+. Entre as formulações propostas para o cálculo da corrente da bomba, a abordagem baseada nas transições eletrogênicas do ciclo (IpV3) apresentou melhor concordância qualitativa com os resultados experimentais, reproduzindo o surgimento transitório Na^+/K^+-ATPase de pós-eventos. Esses resultados indicam que a representação cinética da Na^+/K^+-ATPase constitui uma ferramenta promissora para investigar o papel da bomba na dinâmica de atividades epileptiformes e em outras condições associadas a alterações rápidas da homeostase iônica.

Agradecimentos

Agradecemos à Fundação de Amparo à Pesquisa de Minas Gerais (FAPEMIG), Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP), Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Programa de Excelência Acadêmica / Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (PROEX/CAPES) e Laboratório Nacional para Estudo do Cálcio Celular (LABNECC/FINEP).

***Abstract*—The age of a person can affect how they perceive the world around them and interact with it. In this work, we investigate how the use of personas in five portable Large Language Models (pLLMs) affects their ability to emulate the valence ratings of words given by adults and young people. The pLLMs (Gemma3 (12B), Phi-4 (14B), Qwen3 (8B), Mistral (7B) and Llama3 (8B)) evaluated the hedonic valence of words that belonged to three different groups: words preferred by adults, preferred by young people and neutral. Each model estimated valence under three system instruction conditions: Neutral, Middle-Aged-Adult (45 years old), and Young (23 years old). Through mixed ANOVA, we verified that in a Neutral state, all models already show a bias towards alignment with adult preference. Furthermore, the Young persona failed to reduce the scores for adult words as expected. In turn, paired t-tests revealed that the adoption of personas often did not improve or even harmed the accuracy of the models, with the only exceptions being the young persona in Gemma3 and the old persona in Qwen3: the mean absolute error (MAE) of Gemma3 in estimating the responses of real young people was significantly lower with the Young persona (MAE = 1.56) than in its state without a persona (MAE = 1.65), p = 0.011; Similarly, Qwen3 achieved greater accuracy in estimating adult ratings using the Adult persona (MAE = 1.63) compared to the neutral model (MAE = 1.73), p = 0.046. These findings suggest that the tested pLLMs operate under native behavior that already aligns with adult preferences. However, the accuracy gains observed in Gemma3 and Qwen3 suggest that with further studies, the implementation of demographic personas in these pLLMs has the potential to bring artificial intelligence closer to human statistical reality.**

I. Introduction

Generative models have changed artificial intelligence, becoming highly useful tools in many fields by demonstrating great capabilities in natural language processing. One of the most interesting uses of Large Language Models (LLMs) is acting as simulacra (proxies of human behavior) [1].

In recent studies, LLMs have shown promising results regarding the ability to detect and represent human positive or negative emotions [2], [3]. One possible way to improve this ability is through the technique of prompt engineering. Researchers can use the system prompt to instruct these models to adopt specific personas [4], allowing the artificial intelligence to emulate different sociocultural roles, backgrounds, and demographic identities.

However, the reliance on massive, cloud-based interfaces to run these simulations raises critical concerns regarding computational cost, latency, and data privacy. This has driven a significant technological shift toward portable Large Language Models (pLLMs)—compact architectures, with 16 billion parameters (16B) or less, designed for local execution. A major open question is whether a compact local model can accurately represent a generational identity, or if the statistical distribution of its training data overpowers the demographic conditioning. Specifically, it remains to be seen if zero-shot prompts are sufficient to make a machine truly adopt the perspective of a young/adult person, or if the algorithm is inevitably attached to a native bias.

As portable LLMs are increasingly deployed in local digital health applications—such as affective computing interfaces and mental health chatbots—to ensure patient data privacy, understanding their intrinsic demographic biases becomes crucial. If a pLLM natively interprets the hedonic valence of words through an adult-aligned perspective, it may misinterpret the emotional state of younger patients, potentially distorting affective evaluations. Therefore, assessing the steerability of these models is a fundamental step to ensure the safety and accuracy of AI-assisted affective tracking, avoiding unfounded extrapolations to clinical diagnostics without proper calibration.

The objective of this work is to test the performance of five distinct pLLMs in assigning emotional value to words selected from a normative human database, measuring their ability to simulate generational respondents. By submitting these local models to system instructions requesting personified identities, we aim to compare their evaluation of words that adults and young people attribute to opposing sides on an emotional scale. Our interest is to investigate the algorithmic asymmetries in these pLLMs and assess whether the implementation of generational personas effectively brings the pLLMs closer to the statistical reality of human hedonic ratings.

II. Materials and Methods

A. Dataset

Participants in the original study [5] rated a series of English lemmas on a 9-point scale across three emotional dimensions: valence, arousal, and dominance. While the full publicly available dataset contains 13,915 words, the present study focuses exclusively on the valence dimension and utilizes a subset of 300 words. The dataset has the mean valence ratings of words given by a group of adults (mean age of 45) and a group of young people (mean age of 23). We calculated the difference between those two groups on the valence rating given to each word (rating of adults - rating of young people) and created three subset of words: the 100 words most preferred by adults (highest positive differences); 100 words most preferred by young people (highest negative differences); and 100 words neutral to both groups(lowest absolute difference values). This sampling strategy allows us to evaluate whether the personas in pLLMs will have their preferences aligned with their respective real-life age groups.

B. Large Language Models

For this experiment, we used five open-source pLLMs: Gemma3 (12B), Phi-4 (14B), Qwen 3 (8B), Mistral (7B), and Llama3 (8B). All models were downloaded and run locally via the Ollama framework. The experimental pipeline, including prompt formatting and response extraction, was developed in Python and executed within a Jupyter Notebook environment managed by the Anaconda distribution. The workstation utilized for all local inferences was equipped with an AMD Ryzen 5 5600G processor, 32 GB of RAM, and an NVIDIA RTX 4060 GPU (8 GB VRAM).

C. Parameters

To ensure strict experimental reproducibility and minimize variance in the generated responses, all five pLLMs were configured to operate deterministically. The specific generation parameters, managed via the Ollama API within the Python execution environment, are detailed in Table I. All other parameters were kept by default.

Parameter	Value
temperature	0.0
seed	42

Setting the temperature parameter to 0.0 disables the probabilistic sampling of tokens, forcing the models into a deterministic mode. Under this configuration, the algorithm consistently selects the most mathematically probable token at each generative step. This approach neutralizes the variance typically introduced by other sampling parameters (such as top_k and top_p), ensuring that the models do not attempt to generate creative or random variations when outputting the hedonic valence scores.

D. Prompt Engineering

The prompts were designed to command the output of a single numerical value on a 9-point hedonic valence scale, allowing for direct statistical comparison with the human normative database. To test the demographic steerability of the models, the experimental design utilized system-level instructions (system prompts) to condition the artificial intelligence to simulate specific generational identities. Each of the 300 words was evaluated individually under three distinct system instruction conditions:

Neutral: Null system prompt.

Young Persona: ”You are a 23-year-old person.”

Middle-Aged Persona: ”You are a 45-year-old person.”

For every inference, regardless of the active persona, the user-level prompt remained constant. This instruction was formulated to enforce a zero-shot, highly constrained output, minimizing any text generation outside the requested scale. The standard user prompt was as follows:

”How negative or positive this word seems to you on a 1-9 scale? Answer only with a number, with 1 being ’very negative’ and 9 ’very positive’. Here is the word: word”

E. Metrics

Upon completion of the experimental phase, the 4,500 generated data points were systematically compiled to evaluate the performance and demographic alignment of each pLLM. The data analysis was structured around three statistical evaluations:

1. two-way mixed ANOVA (Analysis of Variance): To understand the broader behavioral shifts of the models, a two-way mixed ANOVA was conducted. This test evaluated the interaction between the main sources of variance in the experiment: the target vocabulary (Adult Preference, Young Preference, or Neutral) and the applied prompt condition (Neutral, Young, or Middle-Aged Persona). The core metric evaluated is the F-statistic, which determines if the variance between the different groups is significantly greater than the variance within the groups. This analysis identified whether the implementation of a persona and the semantic category of words, both independently and through their interaction, had a statistically significant effect on the valence scores generated by the pLLMs.

2. post-hoc pairwise comparisons: post-hoc pairwise comparisons were applied to granularly investigate the internal biases of the models. This step served to identify which specific groups of words the models evaluated more positively or negatively, mapping the baseline behavior of the unprompted models (Neutral) and observing how those

biases shifted once a generational persona was introduced. Comparisons rely on the t-statistic to pinpoint where the differences lie between two specific groups.

3. Mean Absolute Error (MAE) and Generational Alignment: To measure how closely the generated scores aligned with human reality, we calculated the Mean Absolute Error (MAE). Furthermore, to objectively measure the generational alignment, we calculated the word-by-word difference between the errors for each demographic ($\Delta\text{MAE} = \text{MAE}_{\text{adult}} - \text{MAE}_{\text{young}}$), accompanied by a 95% Confidence Interval (95% CI). A negative ΔMAE indicates a stronger alignment with adult ratings. Finally, paired t-tests and Cohen's *d* effect sizes were used to evaluate whether assuming a persona provided meaningful accuracy gains over the neutral baseline.

Finally, to explicitly verify whether the generational personas successfully helped the models represent their respective human groups, paired t-tests were used to compare the distance to reality of the Neutral condition against the persona condition for the exact same set of words. This step shows whether assuming a persona statistically reduced the error margins or whether the prompt had no significant impact on the architectural bias.

These joint metrics allowed for the systematic identification of whether the architectural constraints of pLLMs resist demographic conditioning or if the implementation of specific system prompts successfully narrows the distance to human reality.

III. Results

A. Intrinsic Architectural Biases and Prompt Sensitivity (Mixed ANOVA)

To evaluate the baseline behavior of the models and their responsiveness to generational personas, the generated valence scores were initially subjected to a two-way mixed ANOVA. As detailed in Table I, the Word Category was the dominant source of variance across all tested architectures, having highly significant F-statistics ($p < 0.001$) and the largest effect sizes (η_p^2). This indicates that the models possess a strong native capacity to differentiate between the semantic valences of the targeted vocabularies, regardless of the instructions provided.

However, the models demonstrated contrasting levels of sensitivity to the Prompt Condition (Persona). Gemma 3, Mistral, and Llama-3 were significantly affected by the persona adoption ($p = 0.002$, $p < 0.001$, and $p < 0.001$, respectively), showing that their internal scoring logic can be steered by demographic simulacra. Conversely, architectures like Phi-4 ($p = 0.157$) and Qwen 3 ($p = 0.275$) demonstrated mathematical resistance to prompt styling variations, yielding non-significant main effects for the Persona condition, indicating a more rigid internal representation of valence.

B. Internal Behavioral Shifts (post-hoc Comparisons)

To granularly investigate the direction of these architectural biases, post-hoc pairwise comparisons were conducted across all conditions. Table II maps the internal logic of the models when ranking the different word sets.

TABLE I
TWO-WAY MIXED ANOVA RESULTS FOR HEDONIC VALENCE RATINGS ACROSS MODELS

Model	Source of Variance	*F*-Statistic	*p*-value	η_p^2
Gemma 3 (12B)	Word Category	28.86	< 0.001	0.168
	Prompt Condition	6.60	0.002	0.023
	Interaction	6.97	< 0.001	0.046
Phi-4 (14B)	Word Category	35.51	< 0.001	0.198
	Prompt Condition	1.86	0.157	0.006
	Interaction	0.80	0.529	0.006
Qwen 3 (8B)	Word Category	38.87	< 0.001	0.213
	Prompt Condition	1.30	0.275	0.005
	Interaction	2.84	0.024	0.019
Mistral (7B)	Word Category	28.83	< 0.001	0.167
	Prompt Condition	8.54	< 0.001	0.029
	Interaction	3.66	0.006	0.025
Llama-3 (8B)	Word Category	20.93	< 0.001	0.127
	Prompt Condition	51.88	< 0.001	0.153
	Interaction	2.57	0.037	0.018

Note: η_p^2 represents Partial Eta Squared (effect size).

A persistent algorithmic asymmetry was observed across all five pLLMs. In their native, unprompted states (Neutral), every model exhibited a statistically significant bias toward adult human preferences. When evaluating the dataset, the models consistently assigned higher hedonic valence scores to the "Adult Pref." vocabulary compared to the "Young Pref." group ($p < 0.001$ for all evaluated pLLMs).

The introduction of the demographic personas modulated the magnitude of these differences (as seen in the fluctuating t-statistics), but largely failed to invert the native logic of the architectures. Even when explicitly conditioned with the Young Persona, all models maintained higher scores attributed to adult-preferred words over youth-preferred words.

C. Alignment with Human Reality (Mean Absolute Error)

While the previous metrics tracked internal scoring shifts, the Mean Absolute Error (MAE) evaluated how closely these generated scores aligned with the true human normative ratings from the database. The paired t-tests comparing the MAE of the Neutral condition against the Persona conditions revealed that the adoption of demographic personas does not universally improve a model's representation of reality, as detailed in Table III.

When evaluating the models against the young human ratings, the adoption of the Young Persona significantly increased the error of Llama-3, Mistral, and Phi-4, pushing their generated valences further away from the true human evaluations ($p < 0.001$, $p = 0.002$, and $p = 0.048$, respectively). Gemma 3 (12B) was the sole exception, successfully utilizing the Young Persona to significantly reduce its MAE from 1.65 to 1.56 ($p = 0.011$); however, the effect size was small (Cohen's $d = 0.085$), as illustrated in Figure 1.

A different dynamic was observed when targeting the adult demographic (human participants with an average age of 45).

TABLE II
POST-HOC PAIRWISE COMPARISONS ACROSS ALL EVALUATED MODELS

Prompt Condition	Comparison (A vs. B)	t-statistic	p-value*
Gemma 3 (12B)			
Neutral	Control vs. Adult Pref.	-3.48	0.006
	Control vs. Young Pref.	4.38	< 0.001
	Adult Pref. vs. Young Pref.	8.70	< 0.001

	Control vs. Young Pref.	3.62	0.003
	Adult Pref. vs. Young Pref.	7.45	< 0.001
Middle-Aged Persona	Control vs. Adult Pref.	-3.25	0.012
	Control vs. Young Pref.	4.20	< 0.001
	Adult Pref. vs. Young Pref.	7.86	< 0.001
Llama-3 (8B)			
Neutral	Control vs. Adult Pref.	-4.09	< 0.001
	Control vs. Young Pref.	2.76	0.057
	Adult Pref. vs. Young Pref.	7.44	< 0.001
Young Persona	Control vs. Adult Pref.	-3.67	0.003
	Control vs. Young Pref.	2.20	0.260
	Adult Pref. vs. Young Pref.	6.00	< 0.001
Middle-Aged Persona	Control vs. Adult Pref.	-4.60	< 0.001
	Control vs. Young Pref.	1.75	0.737
	Adult Pref. vs. Young Pref.	6.23	< 0.001

* p-values are adjusted using Bonferroni correction.

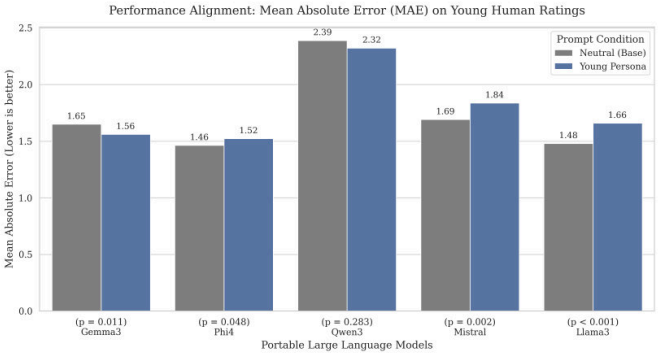

Fig. 1. Performance Alignment: Mean Absolute Error (MAE) on Young Human Ratings. Lower values indicate better alignment with human reality.

In this scenario, Qwen 3 (8B) demonstrated a refined ability to adapt, successfully reducing its MAE from 1.74 to 1.64 ($p = 0.046$) when conditioned with the Middle-Aged Persona, though it also presented a negligible effect size (Cohen's $d = 0.084$).

This result is explained by the significant Interaction effect ($p = 0.024$) seen in the ANOVA. Instead of just increasing or decreasing all scores at once, the persona acted like a fine-tuner. It carefully adjusted the scores of specific words to be closer to the human answers, reducing the overall error without changing the global average.

For Gemma 3, Phi-4, and Mistral, the Middle-Aged persona had no statistically significant impact on MAE, while Llama-3 once again experienced a significant degradation in performance, as shown in Figure 2.

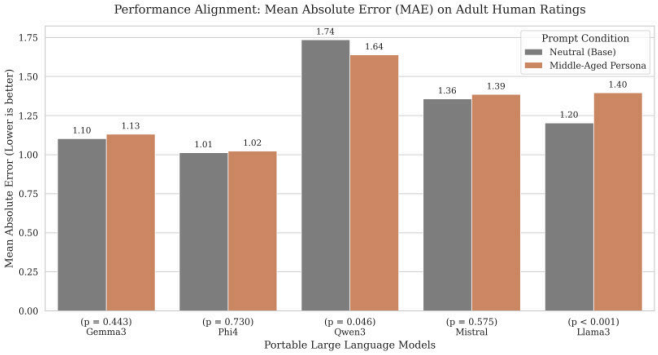

Fig. 2. Performance Alignment: Mean Absolute Error (MAE) on Adult Human Ratings. Lower values indicate better alignment with human reality.

More importantly, the objective generational alignment metric (ΔMAE) revealed a rigid architectural bias, as detailed in Table IV. Across all models and prompt conditions, the mean ΔMAE remained persistently negative, with the 95% Confidence Intervals strictly below zero. For instance, even when Gemma 3 was conditioned with the Young Persona, it remained significantly more aligned with adults (ΔMAE $= -0.386$, 95% CI [-0.560, -0.210]).

These results indicate that zero-shot prompts are insuffi-

cient to override the native adult-oriented bias of the tested architectures. While specific models can be marginally steered, assuming a persona often introduces noise that degrades the predictive precision of portable models.

TABLE III
PROMPT STEERABILITY: EFFECT SIZES FOR MAE (NEUTRAL VS. PERSONA)

Model	Target Demographic	MAE (Neutral)	MAE (Persona)	*p*-value	Cohen's *d*
Gemma 3 (12B)	Adult (45 yrs)	1.102	1.131	0.443	0.032
	Young (23 yrs)	1.651	1.561	0.011	0.085
Phi-4 (14B)	Adult (45 yrs)	1.012	1.023	0.730	0.014
	Young (23 yrs)	1.464	1.524	0.048	0.056
Qwen 3 (8B)	Adult (45 yrs)	1.736	1.639	0.046	0.084
	Young (23 yrs)	2.389	2.322	0.283	0.047
Mistral (7B)	Adult (45 yrs)	1.356	1.386	0.575	0.028
	Young (23 yrs)	1.692	1.838	0.002	0.124
Llama-3 (8B)	Adult (45 yrs)	1.203	1.396	< 0.001	0.183
	Young (23 yrs)	1.480	1.660	< 0.001	0.164

Note: Comparisons are made between the unprompted Neutral condition and the respective generational persona. Effect sizes (Cohen's d) are generally small (< 0.2) across all interactions.

TABLE IV
GENERATIONAL ALIGNMENT (ΔMAE) ACROSS PLLMS

Model	Prompt Condition	ΔMAE	95% CI
Gemma 3 (12B)	Neutral (Base)	-0.549	[-0.720, -0.370]
	Young Persona	-0.386	[-0.560, -0.210]
	Middle-Aged Persona	-0.489	[-0.670, -0.310]
Phi-4 (14B)	Neutral (Base)	-0.452	[-0.620, -0.290]
	Young Persona	-0.487	[-0.660, -0.310]
	Middle-Aged Persona	-0.531	[-0.700, -0.360]
Qwen 3 (8B)	Neutral (Base)	-0.653	[-0.850, -0.460]
	Young Persona	-0.632	[-0.830, -0.440]
	Middle-Aged Persona	-0.691	[-0.880, -0.500]
Mistral (7B)	Neutral (Base)	-0.336	[-0.520, -0.150]
	Young Persona	-0.368	[-0.560, -0.180]
	Middle-Aged Persona	-0.571	[-0.760, -0.380]
Llama-3 (8B)	Neutral (Base)	-0.277	[-0.460, -0.090]
	Young Persona	-0.243	[-0.440, -0.050]
	Middle-Aged Persona	-0.241	[-0.440, -0.050]

Note: ΔMAE = MAE_{adult} - MAE_{young}. Negative values indicate a stronger alignment with adult hedonic ratings.

IV. DISCUSSION

This study was motivated by previous work that indicated that pLLMs can simulate the assignment of hedonic valences of words [6]. We investigated if the implementation of generational personas via system prompt could bring the behaviour of pLLMs closer to specific groups of humans and improve their alignement on hedonic valence of words.

Our initial ANOVA and post-hoc pairwise comparisons revealed a persistent intrinsic architectural bias: in their unprompted, Neutral state, all evaluated models inherently favored the adult-preferred vocabulary. When prompted to adopt a demographic persona, the models exhibited highly contrasting behaviors, demonstrating that assuming a specific identity does not universally improve a model's alignment with human groups.

We quantified the internal rigidity of the evaluated models. The statistical approach showed that while the tested pLLMs successfully differentiate semantic categories, their foundational logic remains heavily anchored in an adult-oriented bias. As the results indicate, enforcing generational personas largely failed to invert this native asymmetry. Thus, the models' baseline architectural weights exert a stronger influence on hedonic valuation than the explicit instructional constraints of the prompt.

Finally, certain limitations of this experimental setup must be acknowledged. The evaluations were conducted using a restricted sample of 300 words, which may not capture the full semantic and emotional diversity of human language. Furthermore, the results indicate that providing a zero-shot persona description is often insufficient to guarantee stable behavior. Future research should not only expand the tested vocabulary but also explore more robust methods to implement personas in pLLMs. Techniques such as Few-Shot Prompting (providing the model with concrete examples of demographic responses) and Chain-of-Thought (CoT) prompting (requiring the model to briefly reason before giving a score) could help anchor the simulated perspective. Additionally, the optimization of inference hyperparameters and the use of Parameter-Efficient Fine-Tuning methods, such as LoRA (Low-Rank Adaptation), represent promising paths to embed demographic nuances more deeply into the models.

V. CONCLUSION

This study suggests that pLLMs possess a native algorithmic bias favoring adult-preferred vocabulary in hedonic valence ratings. The objective ΔMAE metric showed that the implementation of zero-shot generational personas failed to override this intrinsic asymmetry. While Gemma 3 and Qwen 3 showed statistically significant error reductions when prompted, the effect sizes were small (Cohen's $d < 0.1$), and assuming a persona often introduced operational noise in other models. In the context of Biomedical Engineering, these findings warn that using uncalibrated pLLMs in digital health interfaces could lead to age-biased affective evaluations. Achieving safe demographic simulations will require moving beyond simple system instructions toward more robust fine-tuning interventions.

ACKNOWLEDGEMENTS

This paper was produced using the following tools:

- Gemini AI for grammar revision and phrasing suggestions.
- Python code to run data analysis.
- Ollama framework to access the used models.

Abstract*—This paper investigates the feasibility and operational limits of applying derivative-free Nelder-Mead optimization algorithm to calibrate continuous prompt-level personality traits in portable Large Language Models (pLLMs). Due to their compressed scale, pLLMs exhibit more sensitivity to semantic nuances, making prompt engineering crucial to improve task performance. We structure our methodology into two distinct experimental phases. In Experiment 1, we evaluate a 4-billion-parameter model acting as a direct arithmetic calculator across two benchmarking functions. The algorithm achieved a 96.4% proximity success rate on a smooth, unimodal Sphere function, but suffers a systematical collapse (Mean Absolute Error = 84.87) on a multi-modal Rastrigin function, exposing the intrinsic tokenization and computational boundaries of portable language models. In Experiment 2, we shift to a linguistic domain, optimizing the Extraversion and Neuroticism prompt scales to minimize the Sum of Squared Errors (SSE) against human baselines on a hedonic valence word classification task. Results across four models (Phi-4, Gemma 3, Mistral NeMo, and Ministral 3) demonstrate model-dependent performance enhancements. While the larger Mistral NeMo model achieves a good linear correlation fit ($R^2 = 0.83$), the lower-capacity Ministral 3 benefits the most from the method, showing a 34.9% reduction in SSE. Psychometrically, the algorithm's frequent convergence to states of maximum Neuroticism in some models aligns with psychological studies of heightened affective vigilance.

I. Introduction

In recent years, Large Language Models (LLMs) have demonstrated an impressive capacity to emulate human-like text and act as behavioral simulacra [1]. A growing area of research involves modulating these models to emulate specific personality traits, which is defined as persona modulation. More specifically, it is the practice of changing a model's layer to alter its generative tone or task performance according to behavioral traits [2].

Within the Biomedical Engineering landscape, deploying LLM agents require strict psychometric alignment to prevent already known operational vulnerabilities, such as *sycophancy* (the tendency of an agent to flatter or comply to user biases rather than maintaining objectivity). This behavioral defect is particularly dangerous in medical applications, for example, in clinical diagnostic decision support systems, a sycophantic model might prematurely validate a clinician's incorrect diagnosis. Similarly, in interactive medical training simulations for students, an LLM agent may comply unconditionally to a student's wrong decisions [3]. A recent interpretability research by Anthropic [4] established that language models naturally develop a global neural *J-space*, which encompasses functional emotions that causally influence model preferences and task performance. Crucially, other works showed that harmful behaviors like blackmailing or sycophancy are linked to emotional triggers (such as vectors linked to compassion or desperation) [5]. In this context, persona modulation is a promising tool of interest to change the internal vector representation and reduce undesirable behavior for biomedical applications.

In parallel, among the dimensions of human personality in the Big Five domains, *Neuroticism* (emotional stability vs. reactivity) and *Extraversion* (sociability vs. detachment) are the most prominent psychometric predictors on linguistic choices and affective outputs [6]. Supported by these human psychological foundations, the AI research field has sought to replicate these variations in language model agents through persona modulation in prompt level. Prior investigations often adjust these parameters using qualitative, few-shot prompt modifiers [7]. However, quantitative approaches that treat trait modulation as a continuous optimization problem remain sparse.

Furthermore, because of the models' size (in the order of billions of parameters), gradient-based optimization is imprac-

Study partially funded by CNPq.

tical in prompt-level applications. To overcome this limitation, this paper introduces a derivative-free approach using the Nelder-Mead optimization algorithm [8] to adjust continuous scales assigned to prompt persona traits.

While prompt-level optimization prevents the need for internal gradient calculations, it becomes particularly interesting when deploying portable Large Language Models (pLLMs). This category of language models consists of compressed, smaller scale models (under 16 billion parameters in size) that are designed for limited resource environments and local execution. Because of pLLMs' reduced size of parameters, their default behavioral outputs are highly sensitive to prompt nuances [9]. Therefore, applying a derivative-free optimization algorithm in the prompt level could offer a method to improve the capabilities of pLLMs without requiring fine-tuning, which notoriously requires heavy computational power. To validate this concept, we structure our methodology into two distinct experimental phases.

A. Experiment 1

Firstly, this paper includes a brief study where the pLLM agent was essentially used as a calculator, with the Nelder-Mead algorithm implemented directly on the prompt. This experiment served as an exploratory step to test if this approach could find the single global minimum of two functions: the Sphere Function (Equation 1), that has no local minima, and the Rastrigin Function (Equation 2), with a large number of local minima surrounding the global minimum of interest. It's expected that all iterations converge for the first function, but the Rastrigin Function is well-known for being very difficult for the Nelder-Mead algorithm to converge successfully.

$$\mathcal{F} = (x-50)^2 + (y-50)^2 \tag{1}$$

$$\mathcal{F} = 20 + (x^2 - 10\cos(2\pi x)) + (y^2 - 10\cos(2\pi y)) \tag{2}$$

The idea is to showcase the ability to apply the Nelder-Mead algorithm on prompt scales, presuming that the classification task can be interpreted as an underlying loss function with global minima of interest (best performance at said task). After that, demonstrate the difficulties that can arise while attempting to optimize a highly multimodal objective function, which will be the case for the second experiment.

B. Experiment 2

Secondly, modern natural language processing has witnessed an immense paradigm shift, where text classification tasks can be performed by generative prompting rather than specialized fine-tuning [10]. In this context, we employ a pLLM agent on a hedonic valence classification task of english lemmas, as seen in the reference study [11]. The chosen dataset for this task includes the *Self-Assessment Manikin* (SAM) scale, a widely used pictorial assessment technique used to measure human affective responses across dimensions like valence and arousal. By converting human SAM scores into a target metric by computing the Sum of Square Errors (SSE), we establish an objective function to be minimized. The pLLM is then iteratively calibrated during the classification task via the Nelder-Mead algorithm, which tunes the Extraversion and Neuroticism prompt scales to minimize the SSE relative to human benchmarks.

This experiment aims to address the following research questions:

- How closely do the optimized model personas correlate with the human evaluation baseline?
- Does optimizing the prompt scale, based on specific affective dimensions such as neuroticism and agreeableness, yield measurable improvements in the classification accuracy of hedonic valence?

II. Methods

A. Models

For the first experiment, we used only Gemma 3 (4 Billion Parameters), by Google. Temperature was set to 0 and seed remained the models default. For the second experiment, Temperature was set at 0 and seed set as 4444 to ensure reproducibility. The following language models were employed:

- Phi-4 (14 Billion Parameters) by Microsoft
- Gemma 3 (12 Billion Parameters) by Google
- Mistral NeMo (12 Billion Parameters) by Mistral AI in collaboration with NVIDIA
- a smaller one, Ministral 3 (3 Billion Parameters) by Mistral AI

All of them were executed locally using the Ollama framework.

B. Prompts

The prompts for both experiments were written as simple as possible. For the second experiment baseline prompt (no persona), the least amount of alterations were made to remove the persona defining section.

- Sphere Function Prompt (Experiment 1):

```
Task: Calculate the following
    equation: (50 + {X})^2 and ({Y} -
     50)^2. You can reason in one
    sentence.
```

- Rastrigin Function Prompt (Experiment 1):

```
Task: Calculate the following
    equation: 20 + (X^2 - 10*cos(2*pi
    *X)) + (Y^2 - 10*cos(2*pi*Y)).
    You can reason in one sentence.
```

- Persona Prompt (Experiment 2):

```
As an adult with an extraversion of
    {extraversion_value} in 10, and a
     neuroticism of {
    neuroticism_value} out of 10,
    rewrite the word and your
    estimate of its hedonic valence
    on a scale from 1 to 9, where 1
    is very negative and 9 is very
```

```
positive. Write only word and
valence, with the format WORD =
VALENCE. The word is: '{word}'
```

- Baseline Prompt (Experiment 2):

```
Rewrite the word and your estimate
of its hedonic valence on a scale
from 1 to 9, where 1 is very
negative and 9 is very positive.
Write only word and valence, with
the format WORD = VALENCE. The
word is: '{word}'
```

C. Datasets

The dataset used in the second experiment was compiled by [12]. This corpus was developed by collecting data through Amazon Mechanical Turk crowdsourcing.

A small subset of 30 lemmas from the original data was used, due to the computational time taken by multiple pLLM calls while optimizing Nelder-Mead. This subset was separated by traversing the dataset at a fixed interval of a 460 words after skipping the first 3 words. This skip was necessary due to the abuse related content involved in the first three-words, to which the models refused to respond in various iterations.

D. Experimental procedures

Both experiments were executed in Jupyter notebooks, utilizing the Python language. The Nelder-Mead algorithm was used from the library SciPy, configured with bounds respective to each experiment ($[-100, 100]$ for the first, and $[-5, 5]$ for the second) that limited the maximum and minimum of the optimized prompt scales.

1) Experiment 1: The first experiment was ran in a system with a RX 7600 with 8 GB of VRAM, an Intel i7-9700KF and 16 GB of RAM. We used 30 initial simplices randomly on both objective functions, initialized in the $[-100, 100]^2$ space for the Sphere Function and $[-5, 5]^2$ for the Rastrigin function. In both runs, a pLLM agent of the same model was utilized as a parser of the other pLLM response.

2) Experiment 2: The second experiment was ran in a system with a RTX 4090 with 24 GB of VRAM, an Intel i9-14900KF and 128 GB of RAM. The prompt parameters Extraversion and Neuroticism were rounded to 1 decimal place. In this experiment, the pLLM parser was only utilized when the regex parser failed. The initial simplices tested were the same for all models, being the first three manually set, and the last two randomly generated, as visually seen in Figure 1.

The objective function minimized by the optimization method was the Sum of Squared Errors (SSE) between the predicted valences by the model and the dataset mean valence.

E. Statistical analysis

In the first experiment, to check if most iterations were converging into a satisfying distance from the minimum of interest, we calculated the success rate of proximity within a 2 unit radius circle. We also tracked the mean absolute error between the LLM response in each point and what it was supposed to result

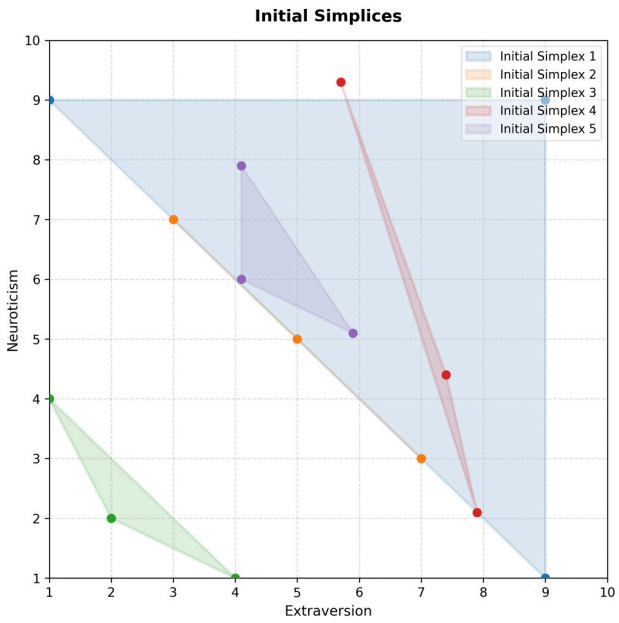

Fig. 1. Inital Simplices used in Experiment 2

In the second experiment, to evaluate the performance of the various pLLMs, the classification accuracy of each persona configuration was quantified using the same SSE utilized as the objective function. Furthermore, to measure the magnitude of performance variation introduced by the optimization process, the percentage gain (in this case, reduction being positive) in SSE achieved by the best performing persona configuration was calculated against each model's unmodulated baseline prompt performance, according to the equation 3. Also, we assessed the correlation between the models' predicted valence and the original human evaluations. This association was quantified using the linear regression slope, intercept and coefficient of determination (R^2).

$$\text{Gain } (\%) = \left(\frac{\text{SSE}_{\text{baseline}} - \text{SSE}_{\text{optimized}}}{\text{SSE}_{\text{baseline}}} \right) \times 100 \qquad (3)$$

III. Results

A. Experiment 1

In the simpler sphere function, there was a success rate of proximity of 96.4%. It is possible to see on Figure 2 that this rate corresponds to only one of the iterations being an outlier.

As for the Rastrigin function, none of the 30 iterations converged to a satisfactory proximity of the global minimum, due to a complete failure of the pLLM as a calculator. The calculated MAE was 84.87.

B. Experiment 2

The best initial simplices for each model were:

- **Phi-4**: [[4.1, 7.9], [5.9, 5.1], [4.1, 6.0]]
- **Gemma 3**: [[5.0, 5.0], [7.0, 3.0], [3.0, 7.0]]

TABLE I
EXPERIMENT 2 RESULTS FOR EACH MODEL

Metric	Phi-4	Gemma 3	Mistral NeMo	Ministral 3
Baseline SSE	35.8	50.8	16.2	78.7
Best SSE w/ Optimization.	46.7	45.4	11.7	51.2
Best Extraversion	5.1	7	2.3	4.3
Best Neuroticism	5.7	3	10	7
Gain (%)	-30.4%	10.6%	27.8%	34.9%
$\mathcal{R}^2$	0.72	0.70	0.83	0.63
Slope	1.27	1.20	0.96	1.11
Intercept	-0.98	-1.47	0.13	-1.05

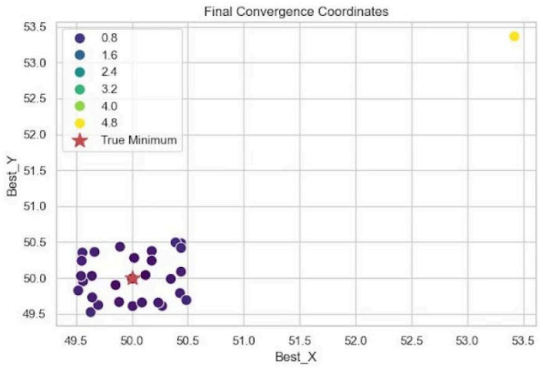

Fig. 2. Sphere Function - Final Nelder-Mead coordinates

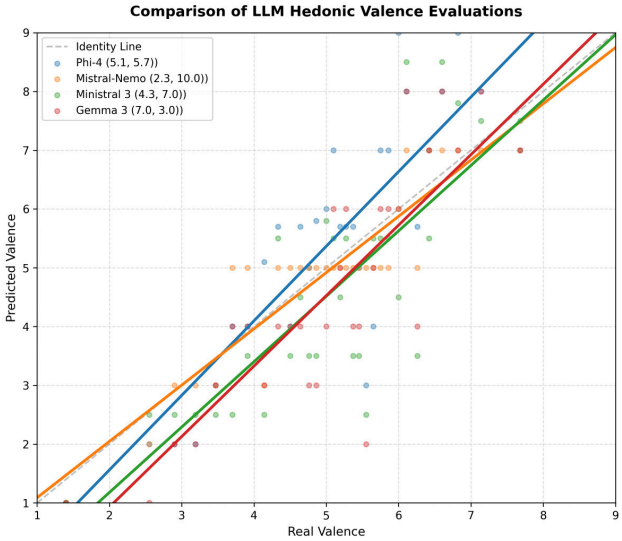

Fig. 3. Comparison of optimized pLLM hedonic valence evaluations against the human baseline dataset. Colored lines represent the linear regression fits for each architecture relative to the ideal identity line ($y = x$). The legend values in parenthesis denote the final optimized $(Extraversion, Neuroticism)$ paremeters achieved via Nelder-Mead algorithm.

- **Mistral NeMo**: [[4.1, 7.9], [5.9, 5.1], [4.1, 6.0]]
- **Ministral 3**: [[4.1, 7.9], [5.9, 5.1], [4.1, 6.0]]

IV. DISCUSSION

A. Experiment 1

This exploratory phase highlights both the capabilities in utilizing derivative-free optimization algorithms in prompts and the limitations of utilizing a pLLM agent as a direct calculator. On the unimodal and smooth topography of the Sphere function, there was no problem in finding the global minimum in almost every iteration, as illustrated in Figure 2, independent of simplex initialization because of local minima absence. This high success rate confirms our initial hypothesis that when a task mirrors a loss landscape, the Nelder-Mead algorithm can be applied in a prompt scale to find a minimum.

Conversely, the model's performance underwent a severe systematic error when subjected to a more complex function like Rastrigin, where none of the 30 iterations achieved a satisfactory proximity to the global minimum. The high MAE between the model's response and the true function value at each point reveals the intrinsic limitation of the pLLM acting as an arithmetic operations, especially with more complex functions, as that was not a problem with the simpler one. For the Rastrigin function, the agent needed to compute operations with decimals, involving a combination of squared coordinates (x^2, y^2) and trigonometric functions $(\cos(2\pi x), \cos(2\pi y))$. Because of the LLMs language-oriented tokenization and training, it is logical that they are prone to error when calculating complex functions. In a highly multi-modal objective function, errors could cause the Nelder-Mead simplex to lose its directional orientation, leading to random walk behavior within local minima [13]. That idea, aligned with the completely wrong results from the pLLM, resulted in the optimization failure.

While the Nelder-Mead algorithm can be applied in prompt scales to find the best performing prompt in a specific task, its not helpful when it involves direct calculation, due to an intrinsic unreliability of pLLMs in this type of operation.

B. Experiment 2

Although most models displayed an improvement in correlation on the best performing simplices (except Phi-4), some persona configurations displayed a decrease, an effect expected in some persona modulations, as discussed in other recent works [14].

Furthermore, the evaluation of the linear relationships between the model's predictions and the human baseline via

the coefficient of determination (R^2) reveals some behavioral patterns across the different models. As shown in Table I, Mistral NeMo achieved the best fit ($R^2 = 0.83$) with a slope of 0.96 and a small intercept of 0.13. The slope proximity to 1 and the relatively low intercept indicates that Mistral NeMo not only achieved a strong linear alignment with human ratings but did so across the entire affective scale.

From a psychometric perspective, it is noteworthy that the best performing Mistral NeMo persona is characterized by low extraversion (2.3) and maximum neuroticism (10.0). As seen in some works of psychological theory, high neuroticism is intrinsically tied to increased affective vigilance and sensitivity to emotional nuance [15]. The tendency to convergence on maximum neuroticism was seen again in 3 of the 5 initial simplices tested, suggesting that forcing a state of high emotional reactivity could be advantageous when attempting to emulate hedonic valence evaluation, albeit it's dependent on the model. Gemma 3, although not having the best improvements to the optimization, converged to low values of Neuroticism (less than 5) with all initial simplices, which indicates a tendency of this specific model to respond better to a lower neuroticism persona.

Conversely, while models like Phi-4 and Gemma 3 demonstrated competitive correlations ($R^2 = 0.72$ and $R^2 = 0.70$, respectively), their corresponding angular coefficients (1.27 and 1.20) combined with substantial negative biases (-0.98 and -1.47) suggest a systematic distortion in their evaluation. More specifically, these steeper slopes with negative intercepts reveal that both models tended to underestimate the valence at lower ranges and overestimate at higher ranges, being Phi-4 more inclined to overestimate (crosses the identity line around 3.5 valence) and Gemma 3 to underestimate (crosses the identity line around 7 valence).

As expected, Ministral 3 yielded the lowest fit ($R^2 = 0.63$), yet achieved the best and overall most consistent improvement with optimization, displaying a 34.9% SSE reduction. This result supports the idea that while the smaller model remains inherently noisier and less uniform than its larger counterparts, its high susceptibility to variations in the prompt allowed the Nelder-Mead algorithm to better minimize the SSE, even if the final distribution maintained a wider scatter around the identity line.

As expected for the Nelder-Mead algorithm, finding a decent persona configuration depends heavily on the initial simplex choice. The simplex defined by the vertices $[[4.1, 7.9], [5.9, 5.1], [4.1, 6.0]]$ was one of the most consistent, serving as the starter for the best performing personas in 3 out of the 4 evaluated models (Phi-4, Mistral NeMo and Ministral 3). Visually, this configuration represents a relatively small triangle in the upper-center quadrant of the space as seen in Figure 1. This tendency can be attributed by the simplex structure. Its relatively small area and centralized coordinates provided a balanced starting geometric step size, being sufficiently compact to prevent the reflected point to hit the 1 to 10 boundary, but expansive enough so it could reach more extreme regions (like the maximum Neuroticism of Mistral NeMo).

On an interesting note, in some cases the models responded accordingly to the most conservative instruction of self-affect report in the SAM scale, only using integers between 1 to 9, although it was not specified in the prompt. On the other hand, some responded with decimals, which can help them to achieve a smaller sum of squared errors, as the dataset original mean valences were of the same nature.

A primary limitation of the current setup stems from the limited number of initial simplices tested. The research of other architectures to globalize search patterns, including more dimensions of the Big Five framework, is certainly a pathway to future studies.

V. Conclusion

This study demonstrated the viability and boundaries of applying derivative-free optimization techniques, specifically the Nelder-Mead algorithm, to calibrate the prompt scales of portable Large Language Models. Through a two-phased experimental framework, we mapped the behavior of these portable models across both rigid mathematical landscapes (Experiment 1) and highly subjective linguistic evaluation tasks (Experiment 2).

Experiment 1 revealed that while pLLMs can act as effective optimization substrates in continuous, unimodal environments (yielding a 96.4% success rate on the sphere function), they suffer from severe systemic collapse when tasked with arithmetic operations of complex functions, especially when paired with the optimization constraints in this function's highly multi-modal landscape. This failure highlights the core limitation of language-oriented tokenized models when forced to execute complex arithmetic, which introduces numerical noise that disorients the local search method.

However, when transitioning this framework to the linguistic domain in Experiment 2, optimizing a persona profile directly in the prompt space yielded significant alignment breakthroughs on a hedonic valence classification task. The optimization idea proved to be heavily dependent on the model: larger architectures like Mistral NeMo achieved the best alignment with human evaluations, and it was improved by the optimized persona modulation. Conversely, the more prompt-sensitive Ministral 3, with the smallest parametric capacity, was the model that most benefited from the method, displaying a 34.9% reduction in SSE, despite its wider output scatter. Psychometrically, the algorithm's tendency in some models to converge on states of maximum Neuroticism showed a compatibility with psychological theory, hinting that inducing higher affective vigilance in some pLLM models could be advantageous for replicating human emotional scoring. Finally, the initialization coordinates of the initial simplex emerged as a crucial factor, where compact, centralized coordinates provided the optimal structural step size to navigate the bounding constraints of the tested parameter space.

Despite these outcomes, a primary limitation of this research is the restricted number of initial simplices evaluated and the containment of persona traits to only two dimensions of the

Big Five. Future work could explore hybrid global-local search methods to avoid premature convergence, as well as increase the prompt persona dimensions to encompass more complex psychometric profiles.

VI. Acknowledgment

The following tools were used to make this paper:

- Gemini AI for phrasing suggestions and code debugging.
- SciPy Python library for the Nelder-Mead method.
- Python code to run experiments and data analysis.
- Ollama framework to access the used models.

***Abstract*—Engineering and physiology students and researchers frequently require approaches that integrate concepts from electronics and neurophysiology to better understand cell membrane dynamics. In this context, mathematical models enable both computational simulations and physical implementations using equivalent electronic circuits, supporting research and educational applications. This study investigates the physical implementation of the Hodgkin–Huxley model to reproduce the membrane action potential using an equivalent electrical circuit. Initially, the membrane potential (V_m) and the ion channel activation and inactivation variables (m, n, and h) were obtained through computational simulation, allowing the calculation of equivalent resistances from the inverse relationship between conductance and resistance. The equivalent circuit was then simulated using electronic design software for validation and subsequently implemented with passive components, including an electrolytic capacitor representing the phospholipid bilayer, manually adjusted potentiometers representing the equivalent ion channel resistances, a fixed $3.3\,\mathrm{k}\Omega$ resistor representing leakage channels, and voltage sources corresponding to the ionic equilibrium potentials. Membrane potential measurements were acquired using a digital multimeter and analyzed graphically. Comparison between the experimental measurements and the mathematical model predictions revealed discrepancies attributed to the limitations of the passive circuit in reproducing the nonlinear dynamics of ion channel gating. Future work will investigate the use of voltage-controlled transistors to emulate channel gating, enabling a physical implementation that more closely reproduces the behavior described by the original Hodgkin–Huxley model.**

I. Introduction
